- The inorganic salts that can be decomposed in the crude oil heat exchangers and heaters. Salts that are most frequently present in crude oil are NaCl, $MgCl_2$ and $CaCl_2$. Formation of hydrogen chloride from chlorides by heat and hydrolysis can oc-

cur downstream. Hydrogen chloride gas condenses to aqueous hydrochloric acid at the overhead of distillation columns, causing serious corrosion of equipment. Hence, maintaining the ADU overhead temperature above the dew point of water vapor is important practice in distillation. Hydrogen chloride in gaseous form is not corrosive, which will be treated in the subsequent refining units.

- Sodium and calcium naphthenate compounds, which induce corrosion.
- Nickel, vanadium, iron, arsenic, and other metals in the crude, which can poison and deactivate catalysts.

At the refinery, many of these impurities are removed with hot water in one or more desalters. Two processes are used: dewatering and desalting. Dewatering removes water and constituents of brine that accompany the crude oil. Desalting is a water-washing operation that removes water-soluble minerals and entrained solids.

Desalters employ either chemical or electrostatic precipitators to expedite removal of dissolved salts and remaining solids. In chemical desalting, water and surfactants are added to the crude, heated to dissolve salts and other impurities, then sent to a settling tank, where the water and oil separate. In electrostatic desalting, chemicals are replaced with a strong electrostatic field at 12–35 kV, which drives the separation of water from oil. Coalescence is aided by passage through a tower packed with sand, gravel, and the like. Emulsion can be broken by adding chemicals, such as demulsifiers. Almost all refineries today use electrostatic desalters.

Figure 16.14 shows a flow diagram of a typical desalting unit. The blended crude is mixed with 3–10 vol.% water at 95–150 °C (200–300 °F) to dissolve salts and reduce viscosity and surface tension for easier mixing and subsequent separation of the water. The oil/water mixture is homogeneously emulsified.

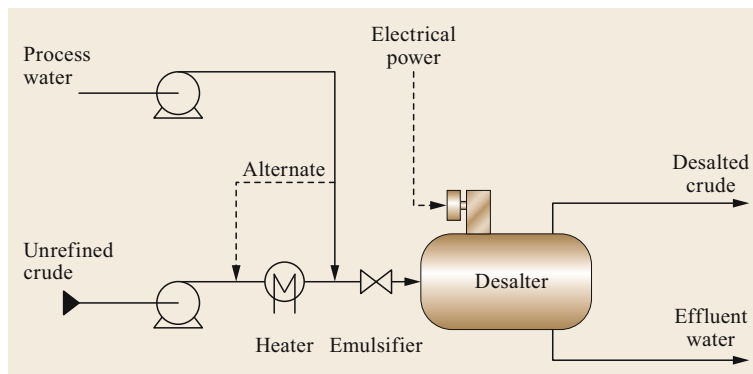

Fig. 16.14 Flow diagram of desalting involving an electrostatic desalter (after [16.15])

Fig. 16.15 Cross-section view of a desalter (after [16.16])

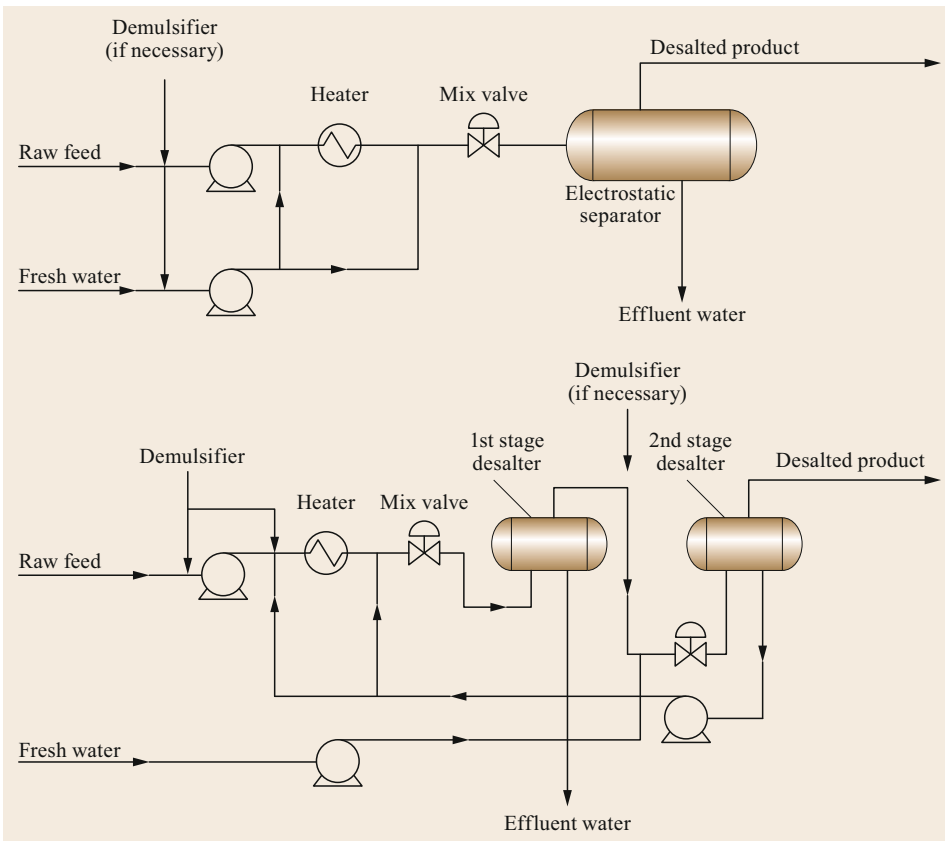

Fig. 16.16 Single- and two-stage electrostatic desalting systems (after [16.17])

The emulsion enters the desalter between a pair of electrodes of opposite polarity across which a high-potential electrostatic field (typically 12–35 kV) is imposed, where it separates into oil and water phases under the influence of electrostatic coalescence, shown in Fig. 16.15. The electrostatic field promotes coalescence with polarization of the droplets near the electrodes. Polarization of water droplets pulls them out from the oil/water emulsion phase. The droplets of opposite charges coalesce to form larger water droplets (globules) along with water-soluble salts, and settle to the bottom of the desalter to be withdrawn. Sediment is also settled at the bottom of desalter and withdrawn as sludge intermittently to prevent its blocking of the brine-water withdrawal outlet. Desalted crude oil exits at the top of desalter.

An emulsion between oil and water can be broken by adding chemicals or treating agents, such as soaps, fatty acids, sulfonates, long-chain alcohols or other demulsifiers.

A desalting unit can be designed with single stage or two stages, shown in Fig. 16.16. Refineries normally apply the two-stage desalting system with two electrostatic coalescers. Part of the brine water from the second stage can be recycled for use as wash water to the first

stage. For resid processing, three-stage desalting is used for some crudes. The two- or three-stage desalting can also be designed in a single vessel with multiple electrostatic coalescers.

16.3.3 Crude Distillation Overview

Crude oils contain numerous components with different boiling points. Continuous distillation is the simplest way to separate the components into fractions (cuts) with different boiling ranges. At atmospheric pressure, most, if not all, heavy molecules in crude oils decompose above 650 °F (≈ 350 °C).

To achieve additional separation of heavy fractions, the bottom cut from an atmospheric distillation unit (ADU) goes to a vacuum distillation unit (VDU), where additional distillates are recovered. The pressure in a VDU is typically 40 mmHg (5.3 kPa). Components that boil between 343 °C (650 °F) and 566 °C (1050 °F) at atmospheric pressure can be vaporized at less than 343 °C (650 °F) under 40 mmHg (5.3 kPa) vacuum without severe decomposition.

An important concept is the atmospheric equivalent boiling point (AEBP). The AEBP of a compound that boils at 260 °C (500 °F) at 40 mmHg

Fig. 16.17 Relationship between boiling points under atmospheric pressure (*y-axis*) and under 40 mmHg (5.3 kPa) vacuum (*x-axis*)

(5.3 kPa) vacuum is $\approx 400^\circ\text{C}$ (750°F). Similarly, the AEBP of a compound that boils at 343°C (650°F) at 40 mmHg (5.3 kPa) is $\approx 482^\circ\text{C}$ ($\approx 900^\circ\text{F}$). Figure 16.17 shows the relationship between boiling points under atmospheric pressure and under 40 mmHg (5.3 kPa) vacuum.

16.3.4 Atmospheric Distillation

A simplified diagram for atmospheric crude oil distillation is shown in Fig. 16.18. Desalted oil goes through a network of heat exchangers to a fired heater, which brings the temperature up to $347\text{--}385^\circ\text{C}$ ($657\text{--}725^\circ\text{F}$). If the oil gets much hotter than this, it starts to crack, generating coke. The coke would deposit inside the pipes and equipment through which the oil flows, increasing pressure drop and/or decreasing feed rate.

The hot crude enters the tower just above the bottom. Steam is added at the bottom to enhance separation; it does so largely by providing additional heat while decreasing the partial pressure of hydrocarbons in the column. When it enters the tower, most of the oil vaporizes. The steam flows upward with vaporized crude while the condensed liquid flows downward in a coun-

tercurrent fashion. The hottest trays are in the bottom section with the coolest at the top section. Unvaporized oil drops to the bottom of the tower, where it is drawn off.

Products are collected from the top, bottom and side of the column. Side-draw products are taken from trays where the temperature corresponds to the cut-points for desired products – naphtha, kerosene, light gas oil (diesel) and heavy gas oil. Some of the side-draws can be returned to the tower as pump-around or pump-back streams to control tower temperatures and improve separation efficiency. Side-cut strippers for naphtha and gas oil are shown in Fig. 16.18. There can be additional side-cut strippers for other distillates.

An atmospheric distillation tower usually contains 30–50 fractionation trays, and 5–8 trays for each product stream. Each stripper also has 5–8 trays to strip out the entrained light components and send them back to the distillation tower.

The boiling ranges of the distillation fractions are listed in Table 16.1. These numbers are only used as references. The actual cutpoints may vary at various refineries, depending on the season and market demands.

The distillation cuts obtained in refineries are not sharp. There are always overlaps between adjacent cuts.

Fig. 16.18 Flow diagram of an atmospheric distillation tower (side cut strippers for kerosene and diesel between naphtha and gas oil are not shown). EXG: heat exchanger, CW: cold water, LPG: liquefied petroleum gas, LSR: light straight run, STM: steam (after [16.17])

Table 16.1 Boiling ranges of distillation fractions

Fraction	Boiling range ^a	
	(°C)	(°F)
Light naphtha	–1–150	30–300
Gasoline	–1–180	30–355
Heavy naphtha	150–205	300–400
Kerosene	205–260	400–500
Light gas oil	260–315	400–600
Heavy gas oil	315–425	600–800
Lubricating oil	> 400	> 750
Vacuum gas oil	425–600	800–1100
Residuum	> 510	> 950

^a For convenience boiling range are converted to the nearest 5°

The overlap between cuts can be *sharp* or *sloppy*, depending on several factors, especially oil flow rates, steam flow rate, and heat balance. Often nothing can be done to decrease overlap at maximum flow rate without making hardware changes.

Figure 16.19 shows distillation curves for the products from a 47 000 barrel/day commercial hydrocracking unit. The desired cutpoints for light naphtha, heavy naphtha, kerosene, and heavy diesel were 90 °F (32 °C), 190 °F (88 °C), 300 °F (149 °C), and 525 °F (274 °C) respectively. Due to operational constraints, the observed effective cutpoints were 99 °F (37 °C), 188 °F (87 °C), 302 °F (150 °C), and 523 °F (273 °C) respectively. The overlap between kerosene and heavy diesel is considerable. Instead of having an initial boil-

ing point (IBP) of 525 °F (274 °C), the IBP for the heavy diesel is 360 °F (182 °C). This indicated considerable entrainment of valuable kerosene into the far-less-valuable bottom product. Guided by a modeling project, operators learned how to lift an additional 2000 barrel/day of kerosene. This increased profit by \$20 000 per day at very low cost – about 80 h of an engineer's time.

16.3.5 Vacuum Distillation

Figure 16.20 shows a flow diagram of a vacuum distillation unit (VDU). The bottom stream from the main fractionator (atmospheric distillation tower) is called atmospheric bottoms, reduced crude, atmospheric residue (AR), or long resid. It goes to a second fired heater, where the typical outlet temperature is about 750–775 °F (400–413 °C). From the second heater, the AR goes to a vacuum distillation tower. Steam ejectors reduce the absolute pressure to 25–50 mmHg (3.3–6.6 kPa) vacuum, or about 7.0 psi (0.5 bar). As discussed, under vacuum, hydrocarbons vaporize at temperatures lower than their atmospheric boiling points (normal boiling point).

There are fewer trays in the VDU tower than in the ADU tower. Products from the VDU are light vacuum gas oil, heavy vacuum gas oil, and vacuum residuum (VR). Some gas and light components entrained or decomposed during heating in a furnace are carried out at the top of the tower.

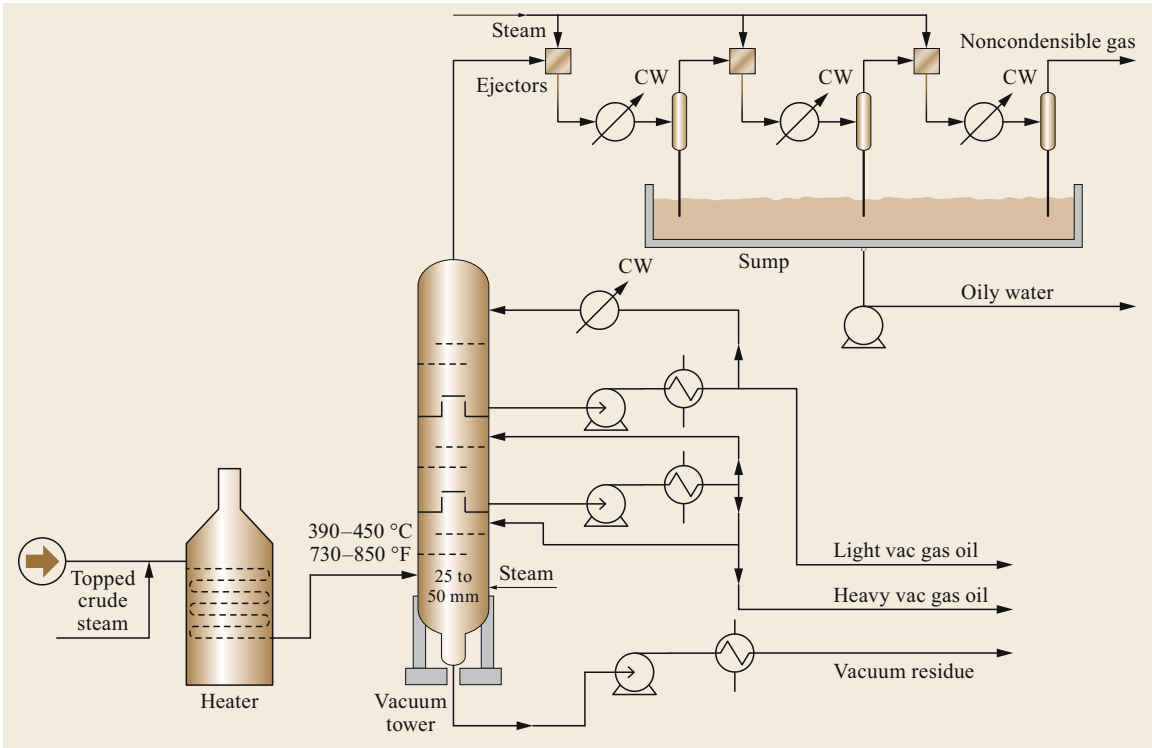

Fig. 16.20 Flow diagram of a vacuum distillation unit (after [16.17])

Fig. 16.21 Comparison of kerosene yields from light and heavy crude oils (after [16.8])

Table 16.2 Typical straight-run yields from various crudes

Source field Country	Brent Norway	Bonny Lt. Nigeria	Green Canyon USA	Ratawi Mid East
API gravity	38.3	35.4	30.1	24.6
Specific gravity	0.8333	0.8478	0.8752	0.9065
Sulfur (wt%)	0.37	0.14	2.00	3.90
Yields (wt% feed)				
Light ends	2.3	1.5	1.5	1.1
Light naphtha	6.3	3.9	2.8	2.8
Medium naphtha	14.4	14.4	8.5	8.0
Heavy naphtha	9.4	9.4	5.6	5.0
Kerosene	9.9	12.5	8.5	7.4
Atmospheric gas oil	15.1	21.6	14.1	10.6
Light VGO	17.6	20.7	18.3	17.2
Heavy VGO	12.7	10.5	14.6	15.0
Vacuum residue	12.3	5.5	26.1	32.9
Total naphtha	30.1	27.7	16.9	15.8
Total middle distillate	25.0	34.1	22.6	18.0

16.3.6 Straight-Run Distillation Yields

The products from the ADU and VDU directly are called straight-run products, such as straight-run naphtha or gas oil. The yields of different fractions depend on the crude oil being processed. Figure 16.21 shows the TBP distillation for a light and a heavy crude, comparing yields of kerosene with cutpoints between 157 and 232 °C (315 and 450 °F). The light crude yields more kerosene than the heavy crude, and hence has a higher value.

Table 16.3 Average US consumption of petroleum products, 1991–2003

Product	Consumption (barrel/day)	Percent of total
Gasoline	8032	43.6
Jet fuel	1576	8.6
Total distillates	3440	18.7
Residual fuel oil	687	4.8
Other oils	4501	24.4
Total consumption	18 416	100.0
Sum of gasoline, jet, distillates	13 048	70.8

Table 16.4 Destinations for straight-run distillates. Resid is an abbreviation for residua, and 340+ etc. means everything that boils above 340 °C etc.

Fraction	Approx. boiling range		Next destination	Ultimate product(s) or subsequent destination
	(°C)	(°F)		
LPG	−40–0	−40–31	Sweetener	Propane fuel
Light naphtha	39–85	80–185	Hydrotreater	Gasoline
Heavy naphtha	85–200	185–390	Catalytic reformer	Gasoline, aromatics
Kerosene	170–270	340–515	Hydrotreater	Jet fuel, No. 1 diesel
Gas oil	180–340	350–650	Hydrotreater	Heating oil, No. 2 diesel
Atmos. Resid	340+	650+	Visbreaker	FCC ^b or hydrocracker feed, low-viscosity resid
			Resid hydrotreater	Resid FCC ^b
			Ebullated bed hydrocracker	Naphtha, gas oils, FCC ^b
Vacuum gas oil	340–566	650–1050	FCC ^b	Gasoline, LCO ^a , gases including C ₃ /C ₄ olefins
			Hydrotreater	Fuel oil, FCC ^b , lubes
			Hydrocracker	Naphtha, jet, diesel, FCC ^b , olefins, lubes
			Solvent refining	De-asphalted oil (DAO), asphalt
Vacuum resid	540+	1000+	Coker	Coke, coker gas oil, coker naphtha, gases
			Solvent refining	DAO, asphalt
			Slurry-phase hydrocracker	Traditional hydrotreater or hydrocracker

^a Light cycle oil

^b Fluidized catalytic cracking

Table 16.2 lists a few crude oils and their typical straight-run yields. Total naphtha includes light, medium and heavy naphtha, and the middle distillates include kerosene and atmospheric gas oil. Naphtha is used for making gasoline and aromatics, kerosene for jet fuel and atmospheric gas oil for diesel. Table 16.3 shows that the demand for transportation fuels exceeds the straight-run yields for the crudes in Table 16.2.

The higher value crude oils have higher API gravity and tend to have less sulfur. The sulfur must be removed, so high sulfur content increases processing costs. Hence, the oil has lower value. Since sulfur is not removed during distillation, the straight-run products have to be treated for sulfur removal.

Products from the crude distillation unit i.e., the straight-run distillates, go to other process units, as shown in Table 16.4. The lightest cuts are gas and light naphtha. The gas goes to a gas processing plant or is liquefied into liquefied petroleum gas (LPG). The light

naphtha can be hydrotreated and sent to the motor gasoline blending pool. Heavy naphtha is a feed for catalytic reforming units. Kerosene can be used for lighting and for making jet fuel. In either case, it must first undergo hydrotreating. Light gas oil can go to diesel fuel (distillate fuel) blending. Heavy gas oil is a feed for fluid catalytic cracking (FCC), which converts it into olefin-containing gas, FCC gasoline, and cycle oil; sometimes the FCC gasoline must undergo mild desulfurization; the cycle oil is hydrotreated or hydrocracked to make diesel. The bottom stream (decant oil) boils in the atmospheric residue range. It can be processed as such in a delayed coker, or sent to a vacuum distillation tower for further fractionation. It contains large quantities of catalyst fines, which are difficult to remove.

Vacuum gas oil (VGO) and vacuum residue (VR) are of low value. They are normally converted into higher-value products through various upgrading processes, such as coking, FCC, hydrocracking or lube processing.

16.4 Summary

Crude oils are complex mixtures of numerous molecules with different boiling points. Virtually all refineries use continuous fractional distillation as the primary method to separate the molecules into fractions (cuts). Prior to distillation, a desalter is normally used to remove impurities that are harmful to the distillation unit. A crude distillation unit includes an atmospheric dis-

tillation tower, a vacuum distillation tower, and associated equipment. The cuts are processed in downstream units – hydrotreaters, catalytic reformers, fluid catalytic cracking units etc. The products of upgrading units often require further separation, usually by distillation.

Distillation is at the heart of a petroleum refinery as the most common separation technology.

Gasoline Pro

17. Gasoline Production and Blending

Chang Samuel Hsu, Paul R. Robinson

Gasoline is a volatile, flammable mixture of liquid hydrocarbons primarily obtained from refining petroleum. Most gasoline is consumed as a fuel in spark-ignition engines, primarily those which power automobiles and certain airplanes. For engine performance, important gasoline properties include volatility (Reid vapor pressure), octane number and heat content. Reid vapor pressure (RVP) is one of the gasoline specifications for performance in engine. Reformulated gasoline laws now protect the environment by limiting smog precursors, banning tetraethyl lead (TEL) and regulating concentrations of sulfur, olefins, benzene and oxygenates in gasoline. Refineries produce gasoline from blendstocks derived from various processes – crude oil distillation, catalytic reforming, fluid catalytic cracking (FCC), thermal cracking, hydrocracking, alkylation, isomerization and catalytic polymerization. Finished products sold in the market include additives, which inhibit oxidation, inhibit corrosion, passivate trace metals, reduce deposition of carbon on intake valves and combustion chambers, and minimize the formation of ice in cold weather. Relative gasoline demand is highest in North America, while automotive diesel is preferred in most of the rest of the world.

Gasoline is a volatile, flammable mixture of liquid hydrocarbons obtained primarily from petroleum refining. Outside North America, *petrol* and *benzin* are synonyms for gasoline.

Historically, four events were particularly significant for gasoline production. The first was the drilling of the first oil well in the United States by Edwin L. Drake near Titusville, Pennsylvania in 1859. The well wasn't the first in the world and it was only 70 ft deep, but it triggered the Pennsylvania oil boom, the first great event in the American oil industry.

At that time, the most desired product from crude oil was kerosene for lamp lighting. For the most part, gasoline was discarded as a byproduct that in the 1870s was sold as a solvent by Carless, Capel and Leonard, a British wholesaling company. Carless et al. got much of the petrol from coal oil [17.1].

The second major event was the development of the four-stroke internal combustion engine in 1876 by Nikolaus Otto, a German engineer. Otto's compressed-charge engine burned gasoline, which became essential to the automobile industry.

The third event was the development of the light bulb by Thomas Edison. Over time, invention and the widespread use of light bulbs decreased the demand for kerosene as an illuminant. The first commercially viable bulbs worked with carbon filaments. These appeared on the market in 1882. In 1904, bulbs with tungsten filaments displaced those with carbon filaments.

The fourth event occurred in 1913, when Henry Ford rolled out the first moving assembly line to mass manufacture Model T automobiles. Before the Model T, automobiles were luxuries. Due to its lower cost, people of ordinary means could afford a Model T. In 1914, Ford began paying his workers US\$ 5.00 per day, more than twice the average wage for auto workers. In the 1926 book, *Today and Tomorrow*, Ford [17.2] said:

The owner, the employees and the buying public are all one and the same and unless an industry can so manage itself as to keep wages high and prices low it destroys itself, for otherwise it limits the number of its customers. One's own employees ought to be one's own best customers.

Against conventional wisdom, Ford was fond of saying that doubling workers' wages was the best cost-cutting move he ever made. The need for fueling automobiles shifted the market demand from kerosene to gasoline.

Since the birth of modern automobile, the demand for gasoline to fuel automobiles with internal combustion engines has increased dramatically. It is estimated the number of automobiles in the world exceeded one billion around 2010.

The development of modern refinery processes was driven by rapid growth in demand for transportation

fuels. Gasoline blendstocks come from a variety of refining processes, including straight-run distillation, catalytic reforming, catalytic cracking (FCC), thermal cracking, hydrocracking, isomerization, alkylation and polymerization. While cracking processes break large molecules into smaller molecules, alkylation and polymerization do the opposite. They were developed specifically to transform C_3 and C_4 molecules into C_6 to C_9 molecules suitable for gasoline. Blendstocks are mixed with each other and with additives to produce finished gasoline that meets volatility, octane rating and other requirements.

Ninety percent of the gasoline produced in the US is automobile fuel, with a very small percentage used to power agricultural equipment and aircraft. Gasoline for piston-engine powered aircraft is called aviation gasoline or avgas, which has a high octane number and low flash point to improve ignition characteristics. In the United States, automotive gasoline is specified by ASTM D4814. In Europe and urban China, automotive gasoline must meet EN 228 and China V respectively. Avgas is defined by specifications Jet B or JP-4.

US refineries are designed to maximize gasoline production, especially during the summer. Asian and European refineries emphasize diesel production. Due to tax incentives and superior vehicle performance, diesel demand in Europe has grown. As a result, Europe is importing diesel and exporting gasoline. US diesel demand is driven by heavy-duty applications (truck, train, ship and industry). Heavy-duty demand grows as economies grow.

Many other chapters in this book can serve as references for this chapter. A separate book (*Song, Hsu and Mochida*) discusses diesel in great detail [17.3].

17.1 Gasoline Engines

Motor vehicles are powered by internal combustion engines. Gasoline is the most common fuel for a spark-ignition engine. Figure 17.1 illustrates the route by which gasoline moves from a fuel to the engine. In modern automobiles, the entire process, including fuel pressure, fuel flow, air supply, air-fuel injection, piston timing and ignition is computer controlled. Typically, there is a great excess of air flow. Engine speed is controlled by fuel flow, which ultimately is controlled by the extent to which a driver presses the accelerator pedal.

Modern engines employ electronically timed fuel injection, also known as electronic fuel injection (EFI). An EFI system can be subdivided into the following:

- Fuel delivery system
- Air induction system
- Air/fuel mixing system
- Sensor/computer system
- Ignition control system.

17.1.1 Fuel Delivery System

The fuel delivery system includes an electric fuel pump, a fuel filter, a pressure regulator, the injector valves and the connecting lines and hoses. The fuel pump sends fuel from the tank to the pressure regulator. The pressure regulator controls fuel flow to the injector and valves. Pressure control is achieved with spill-back through the fuel-return line. The injector valves (and

Fig. 17.1 Fuel system for a spark-ignition engine with electronically timed fuel injection, also known as electronic fuel injection (EFI)

exhaust valves as well) are controlled with solenoids. When a solenoid isn't energized, spring pressure keeps the valve closed. When energized, the solenoids open the valves.

17.1.2 Air Induction System

The air induction system includes a throttle valve, sensors, an air filter and connecting ducts. The throttle valve regulates air flow. Like the air-fuel mixing (carburetor) system, the air induction system is connected to the gas pedal. When the pedal is depressed, the throttle valve opens to allow more air into the engine.

17.1.3 Air-Fuel Mixing System

Prior to computer-controlled fuel injection, air was mixed with gasoline in carburetors. These devices followed Bernoulli's principle:

- Faster-moving air
- Lowers static pressure
- Increases dynamic pressure.

Controlling the throttle (accelerator) didn't directly control fuel flow. Instead, it controlled the carburetor, which changed the flow of air into the engine. Changing the air speed changed the air pressure, which changed the amount of fuel that was drawn into the airstream.

The *air/fuel ratio* (AFR) is the ratio between the mass of air and the mass of fuel in a combustible mix-

ture. The respective masses include all constituents, even those that do not react. For example, the air-mass calculation includes both oxygen and inerts – nitrogen, argon, CO₂ and water vapor.

For pure octane, the reaction stoichiometry is

The stoichiometric air/fuel ratio is about 14.7 wt/wt, depending on the exact composition of the air.

The *air/fuel equivalence ratio*, called λ (lambda), is the ratio of the actual AFR to the stoichiometric AFR. For stoichiometric mixtures, $\lambda = 1.0$. For rich mixtures, $\lambda < 1.0$ and for lean mixtures $\lambda > 1.0$. Naturally aspirated gasoline engines achieve maximum power at AFRs ranging from 12.5–13.3 ($\lambda = 0.850$ –0.9). The AFR for maximum fuel economy is about 16 ($\lambda = 1.09$). The composition of fuels changes, especially seasonally, so for many purposes, such as engine tuning, the industry prefers to use λ instead of AFR.

The *fuel/air equivalence ratio*, called ϕ , is defined as the ratio of the actual fuel-to-oxidizer ratio to the stoichiometric fuel-to-oxidizer ratio

$$\begin{aligned} \phi &= \frac{\text{fuel-to-oxidizer ratio}}{(\text{fuel-to-oxidizer ratio})_{\text{st}}} = \frac{m_{\text{fuel}}/m_{\text{ox}}}{(m_{\text{fuel}}/m_{\text{ox}})_{\text{st}}} \\ &= \frac{n_{\text{fuel}}/n_{\text{ox}}}{(n_{\text{fuel}}/n_{\text{ox}})_{\text{st}}}, \end{aligned}$$

where m represents the mass, n represents number of moles and st indicates stoichiometric. With ϕ , one can account both for mass and moles.

Most AFR sensors measure the amount of residual oxygen (for lean mixtures) or unburnt hydrocarbons (for rich mixtures) in the exhaust gas.

17.1.4 Sensor-Computer System

The sensor system monitors engine operating conditions and reports this information to the computer. Sensors include the following:

- Exhaust gas sensors
- Fuel oxygen sensor
- Manifold pressure sensor
- Throttle position sensor
- Engine temperature sensor
- Air flow sensor
- Inlet air temperature sensor
- Crankshaft position sensor.

Based on sensor readings, the computer optimizes fuel injection and the timing of spark-plug firing.

17.1.5 Ignition Control System

There is no need for manual tune-up for modern gasoline cars. Ignition timing in today's vehicles is controlled by computer, which measures the degree of crankcase rotation for the point at which the spark plug fires. Because it takes a fraction of a second to fire, the spark plug must fire a few degrees (such as 5°) when the engine is at idle speed) before the piston reaches the top dead center (TDC). Otherwise, the ignition of the mixture will not be complete when the piston reaches TDC and full power of explosion will not be utilized by the engine. The ignition timing is adjusted through electric signals from various sensors so that spark plugs ignite sooner when the engine speed increases. If the ignition is too far advanced, explosion will occur to push the piston down while it is still traveling up. If the ignition is too far retarded, the piston will be pushed down for only a portion of its travel, resulting in poor engine performance. However, the computer-controlled ignition is set in the factory and is not adjustable.

17.1.6 Piston Design

Figure 17.2 illustrates a typical piston assembly, including intake and exhaust valves, the spark plug and the cylinder. The piston itself is connected to the piston rod, crank shaft and wheel. The wheel is connected to the

Fig. 17.2 Typical piston assembly

drive train, which transfers power from the engine to the wheels of a vehicle, a power generator, or other device.

17.1.7 Four-Stroke Piston Engine

The four-stroke Otto-cycle engine, invented by Nikolaus Otto in 1876, is still the most widely employed spark-ignition engine. Figure 17.3 illustrates the action of an Otto-cycle engine.

Intake stroke (Fig. 17.3a): The piston begins at the top of the cylinder. The intake valve is open. The exhaust valve is closed. As the piston moves down, the air-fuel mixture is injected into the cylinder. The stroke ends with the piston at the bottom of the cylinder – bottom dead center (BDC).

Compression stroke (Fig. 17.3b): The piston is at the bottom of the cylinder – just where it was at the end of the compression stroke. The intake valve closes. The exhaust valve remains closed. The piston rises, compressing the air-fuel mixture, until it reaches the top of the cylinder – top dead center (TDC).

Power stroke (Fig. 17.3c): The piston begins at the top of the cylinder – just where it was at the end of the compression stroke. Both the intake valve and the exhaust valve remain closed. The spark plug fires, igniting the compressed air-fuel mixture. The resulting explosion drives the piston to the bottom of the cylinder, providing power, via the crankshaft, to the wheel.

In a four-stroke engine, the crankshaft turns twice for each power stroke. In contrast, in a two-stroke engine (below) the crankshaft turns once for each power stroke.

The main combustion reactions include:

- Hydrocarbons + $O_2 \rightarrow CO_2 + CO +$ water
- Sulfur in hydrocarbons + $O_2 \rightarrow$ sulfur oxides
- $N_2 + O_2 \rightarrow$ nitrogen oxides.

Fig. 17.3a–d Strokes of a four-stroke spark-ignition engine

Exhaust stroke (Fig. 17.3d): The piston is at the bottom of the cylinder – just where it was at the end of the power stroke. The intake valve remains closed. The exhaust valve opens. The piston returns to the top, expelling combustion products through the exhaust valve.

17.1.8 Lubrication

Compared to most of the designs mentioned below, in-line piston-driven engines have a significant advantage: only one side of a piston is exposed to fuel, so the cylinders can be lubricated with an independent system. For two-stroke, rotary, radial and Wankel engines, lubricating oil must be added to the fuel.

17.1.9 Engine Exhaust

Engine exhausts contain pollutants – sulfur oxides, nitrogen oxides, carbon monoxide, unburned hydrocar-

bons and volatile toxic compounds. These can be abated with reformulated fuels, catalytic converters and tighter engine design; issues which are discussed in a later section.

17.1.10 Other Gasoline Engines

Other gasoline engines include two-stroke, rotary, radial, Wankel and gasoline-powered turbine engines.

Two-Stroke Engine

The first practical two-stroke engine (Fig. 17.4) is attributed to A.A. Scott, who started making twin-cylinder water-cooled motorcycles in 1908 [17.4]. Two-stroke engines can be powered either by gasoline or diesel fuel. Gasoline-powered two-strokes require spark plugs, but in diesel-powered engines, the fuel-air mixture is ignited by the heat produced from adiabatic compression.

Fig. 17.4 Two-stroke engine cycle

The fundamental differences between two-stroke and four-stroke engines are lubrication and gas exchange – the removal of exhaust and the introduction of the fuel-air mixture. In the two-stroke engine, there is a power stroke in each cylinder during each revolution of the crankshaft. Exhaust and fuel introduction occur at the same time – when the piston is at the bottom of the cylinder.

In two-stroke engines, lubrication is supplied by the fuel. The lubricity of diesel fuel satisfies this need, but when gasoline is the fuel, it must be mixed with a small amount of lubricating oil. Compared to gasoline, lubricants are heavier and less likely to combust, so when they are burned in a two-stroke engine, they tend to generate smoke, an indication of incomplete combustion.

Two-stroke engines have fewer moving parts, are more compact and can be significantly lighter and more compact than four-stroke engines with equivalent power. Within a narrow range of engine speeds – the so-called *power band* – a two-stroke engine can have a relatively high power-to-weight ratio. This is because for each power stroke in a two-stroke engine, the crankshaft turns once, while for each power stroke in a four-stroke engine, the crankshaft turns twice.

Gasoline-powered two-stroke engines are common in lawn mowers and chain saws. In many countries, they are still common in motorcycles and *tuk-tuks*, the small, three-wheeled open-air carts found in India, Indonesia, Mexico, Thailand and other always-warm (tropical) countries. Due to air pollution caused by incomplete combustion of the lube oil that must be mixed with the gasoline, transportation vehicles powered by gasoline-burning two-stroke engines are almost impossible to find in Canada, the EU, the UK and the United States – countries with tight environmental regulations.

Rotary Engine

A rotary engine (Fig. 17.5) includes an odd number of cylinders arrayed radially around crankshaft inside a spinning crankcase. Some engines have multiple cylinder arrays. In aircraft, the crankshaft is bolted to the airframe and the propeller is bolted to the front of the crankcase. Piston firing alternates around the array. For most rotaries, fuel is mixed with air before entering a cylinder, as is the case in Otto engines.

Félix Millet built one of the first rotary engines, a five-cylinder affair, which he incorporated into a bicycle. He patented the engine in 1888 and displayed the bicycle at the Exposition Universelle in Paris in 1889 [17.5]. During World War I, rotary engines were preferred for high-speed aircraft, such as fighter planes, due to their high power-to-weight ratios. Rotaries ran smoothly because there are no reciprocating parts. Due

Fig. 17.5 Arrangement of cylinders in a seven-cylinder rotary engine

to their combined weight, the spinning crankcase and cylinders acted as a flywheel, decreasing the likelihood that the engine would stall. They were self-cooled, even when the airplane wasn't moving, which reduced their weight. On the other hand, fuel consumption was high. As with two-stroke engines, oil had to be mixed with the fuel, so oil consumption was high too. A major problem was the angular momentum of the heavy rotating crank case. It behaved like a gyroscope, causing problems with aircraft control.

Radial Engine

In a radial engine, the cylinders *radiate* outward from a central crankcase like the spokes of a wheel. Before the advent of jet engines near the end of World War II, air-cooled radials were commonly used for aircraft. At first glance, radial engines look like rotary engines, because in both cases cylinders are arranged in a circular array. But in radial engines, the crankcases don't rotate. They employ conventional rotating crankshafts in a fixed engine block. Compared to rotary engines, radial engines could achieve much higher engine speeds. The amount of rotating mass was reduced, so the gyroscopic effect and related control problems were significantly reduced.

Wankel Engine

The Wankel engine [17.6] is a pistonless internal combustion device, in which power is transferred by a rotor that resembles a Reuleaux triangle (Fig. 17.6). The concept was developed by Felix Wankel, who received the first patent for this kind of engine in 1929.

Fig. 17.6 Wankel engine cycles

In a Wankel, the four strokes of an Otto cycle occur in the spaces between the rotor and housing. The shape of the rotor is determined by a compromise between minimization of combustion chamber volume and maximization of compression ratio. The central drive shaft, called the *eccentric shaft* or *E-shaft*, passes through the center of the rotor and is supported by fixed bearings. One full orbit of the rotor equates to three turns of the E-shaft.

In theory, the Wankel engine has several advantages compared to engines with reciprocating pistons. The advantages are similar to those mentioned for rotary and radial engines, such as:

- Compact design
- Relative simplicity
- Smoother operation due to the lack of reciprocating parts
- Higher revolutions per minute
- A power-to-weight ratio that is two-thirds lower
- Less prone to engine knock
- Wider speed range.

Disadvantages include:

- Vastly different temperatures in the chambers. Metals expand when heated and the extent of expansion depends strongly on temperature. The thermal expansion phenomenon causes problems with sealing.
- Lubricating oil must be mixed into the fuel.
- Slower combustion due to the long, thin dimensions of the combustion chamber.

- Poor fuel economy due to seal leaks.
- Relatively high emissions.

Over the years, attracted by the Wankel's high theoretical power-to-weight ratios, General Motors, Mercedes-Benz, Mazda and other companies have conducted research and development on Wankel engines. Mazda has gone farther than most, achieving some success with its 12A engine at the Le Mans race in 1974. Mazda is the only company ever to win Le Mans with a nonpiston engine. At present, the emissions problems appear to be insurmountable. Until they are solved, Wankel-powered automobiles will not be approved for use on public highways.

Meanwhile, small Wankel engines continue to be sold for model airplanes, go-karts, personal motor boats and auxiliary power units.

Turbine Engine

Turbine engines, also known as gas turbines or combustion turbines, are pistonless internal combustion engines powered by kerosene-like jet fuel (avjet) or aviation gasoline (avgas). They include an upstream rotating compressor coupled to a downstream turbine, with a hot combustion chamber in between (Fig. 17.7).

Turbine engines provide power for aircraft, trains, ships, tanks and electricity generators. In a jet airplane, fresh air flows through the compressor, which brings it to high pressure. Fuel is sprayed into the air as it flows into the combustion chamber. Combustion produces tremendous heat and increases the system pressure.

Fig. 17.7 Turbine engine

The high-temperature, high-pressure gas enters a turbine, expanding as it turns the turbine, which drives the compressor and other devices, including an electricity generator. The exhaust gases exit the turbine at high velocity, driving the airplane forward.

When a jet engine is started, the engine is *spun* until air is flowing at a desired speed. Fuel is added and igniters – similar to spark plugs – initiate combustion. From that point on, engine combustion is self-sustaining and igniters are then used only in unusual circumstances, such as:

- After a flame-out
- During heavy rain
- When air speed is very slow.

Turboprop engines often burn avgas. In this application, the turbine drives a propeller. The engine exhaust does not contain enough energy to provide much thrust. The propeller is coupled to the turbine with a gear that converts the high-RPM (RPM), low-torque output of the turbine into low-RPM, high-torque power for the propeller.

17.2 Otto Engine Thermodynamic Cycle

Figure 17.8 illustrates the thermodynamic cycle for a four-stroke Otto engine. Pressure and volume are exhibited on the two-dimensional plot [17.7]. Temperature is not shown. Note that automobile engines are not closed systems. External cooling is required and the heat capacity of the engine block is high. In combination, these factors keep the engine nearly isothermal.

At the intake stroke, the intake valve is open and the exhaust valve is closed. As the piston moves to the bottom of the cylinder, the fuel-air mixture expands in an isobaric fashion, shown by the green line from left to right at the bottom of the figure. At the compression stroke, both valves are closed. As the piston rises, it causes adiabatic compression with decreasing volume and increasing pressure and temperature (not shown). At the power stroke, both valves are still closed. The fuel is ignited and combusted. Initially, the system is isochoric. The product of heat and combustion products increases pressure for power. As the cylinder is driven downwards, the gases undergo adiabatic expansion with increasing volume and decreasing pressure and temperature (not shown). At the start of the final stroke, the exhaust stroke, both valves are closed. The pressure starts to fall isochorically. When the exhaust valve

opens, the exhaust gases expand isobarically. When the piston reaches the top of the cylinder, the exhaust valve closes as the intake valve opens and the cycle is repeated, starting with the intake stroke of the following cycle.

Fig. 17.8 Otto Cycle thermodynamics

17.3 Key Gasoline Properties

Petroleum products must meet certain specifications. For engine performance, key properties include octane number, volatility, sulfur and storage stability.

17.3.1 Octane Number

In the combustion chamber, vapor heats up during compression. Ideally, the mixture of gasoline vapor and air is ignited with a spark when the piston reaches a predetermined position near the top in the cylinder. However, some compounds tend to ignite before the spark plug fires at the end of the compression stroke. This is called self-ignition or premature ignition. It causes engine knock, which stops the ascent of the piston and pushes it in the opposite direction. Knocking reduces the power, increases engine wear and can cause serious damage.

Different gasoline components have different tendencies to knock. The compression ratio (V_1/V_2), shown in Fig. 17.9, is a factor related to knock behavior. Octane rating, or octane number, is related to the smallest compression ratio at which an engine starts to knock with a given fuel. It is based on a scale in which the octane number of *n*-heptane is designated as zero and the octane number of isooctane (2,2,4-trimethylpentane) is 100. When a fuel is tested in a standard single-cylinder engine, mixtures of isooctane and *n*-heptane of various percentages are used as reference standards for correlating the knocking of the test fuel with the percentage of isooctane in the mixture.

Thus, a gasoline with the same knocking characteristics as a mixture of 94% 2,2,4-trimethylpentane and 6% *n*-heptane has an octane rating of 94. A rating of 94 does not mean that the gasoline contains just isooctane and *n*-heptane in these proportions, but that it has the

Fig. 17.9 Compression ratio V_1/V_2

same tendency to knock as this mixture. The blends of known octane ratings can also be used as references as shown in Fig. 17.10. The higher the number, the less likely is a fuel to pre-ignite.

A gasoline containing a high proportion of straight-chain alkanes has a greater tendency to knock. However, branched-chain alkanes, cycloalkanes and aromatic hydrocarbons are much more resistant to knocking. Straight-chain alkanes are converted into isoalkanes in several processes in the refinery. The gasolines available for octane rating of cars usually contain a mixture of alkanes (straight-chain, branched and cyclic) with aromatic hydrocarbons.

ASTM D2699 and ASTM D2700 describe respective methods for measuring research octane number (RON) at 600 rpm, which is most relevant to low-speed city driving with load conditions; and motor octane number (MON) at 900 rpm, which is most relevant to high-speed highway driving conditions.

In North America, the posted octane of gasoline is the arithmetic average of RON and MON: $(R + M)/2$. This is the number displayed on pumps at filling stations. Typical grades are *regular* with a posted octane of 87, *midgrade or medium* with a posted octane of 89 and *premium* with a posted octane of 91–93. In some locales, customers can dial in any octane they want between 87 and 93.

Table 17.1 provides data for 32 pure compounds that boil in the gasoline distillation range. Aromatics, olefins and branched paraffins have higher octane numbers than naphthenes and normal paraffins with similar carbon numbers. The trend is apparent especially for the C_6 and C_7 compounds shown:

Fig. 17.10 Octane rating (octane number) is determined by comparing compression ratio causing knock using reference blends

^a Net liquid heat of combustion at 77 °F (25 °C)^b This compound is also known as tetralin

- MON values for *n*-hexane, 2-methylpentane and 2,3-dimethylbutane, are 26, 73.5 and 94.3 respectively. Of the three paraffins, the MON for 2,3-dimethylbutane is highest because it is the most highly branched. MONs for the two C₆ naphthenes (methylcyclopentane and cyclohexane) are lower than the MON for the olefin (2-methyl-2-pentene) and the aromatic compound (benzene).
- In the C₇ series, the MON for *n*-heptane is, by definition, equal to zero. MONs for the other paraffins increase with branching as they did for the C₆ series. Toluene has the highest value (MON = 100.3).

Octane does not blend linearly. The RON for pure 4-methyl-2-pentene is 99, but its blended RON can be as high as 130. Ethanol and MTBE show similar behavior. Blended octanes for ethanol can be 10–20 numbers higher than the octanes for pure ethanol. Table 17.2 compares measured pure-compound octanes with blended octanes. Values were selected from a compilation prepared by Texas A&M University [17.9]. Blended octane data for ethanol and MTBE come from the EIA-AFM website [17.10]. The blended values for olefins are exceptionally high, almost too high to be believed. Values may be skewed by the method(s) used to obtain such values, such as extrapolation, explained later.

Table 17.2 Comparison of pure-compound octane numbers with blending octane numbers. For olefins, blending octane numbers are exceptionally high, but this may be an artifact of the method used to obtain such values (after [17.8])

Determining Octane Numbers Above 100

In Tables 17.1 and 17.2, several octane values exceed 100. To measure such numbers, one can extend the reference scale with standards that contain tetraethyl lead (TEL). Adding 3 ml of TEL per gallon of 2,2,4-trimethylpentane gives a reference with an octane of 125 [17.11]. This high-octane reference, which is toxic, can be purchased from the *Chevron Phillips Chemical Company* [17.12].

For octane numbers above 125, an experimenter must extrapolate. This method entails adding successively higher amounts of the sample to 100% isooctane and using the results to generate a plot.

Extrapolation is fraught with uncertainty. Results based on straight lines differ from results based on curves. This can explain the wide variation be-

tween published blending octane numbers for *i*-butane, toluene, xylenes and oxygenates.

So-called *performance numbers* provide an alternative to extrapolation. These are obtained by determining the instantaneous mean effective cylinder pressure (IMEP) for the fuel being tested at the highest boost that does not cause the engine to knock. The result is multiplied by 100 and divided by the IMEP for pure 2,2,4-trimethylpentane.

17.3.2 Reid Vapor Pressure (RVP)

Another important property of gasoline is Reid vapor pressure (RVP), which indicates the ease of starting a spark-ignition engine with the fuel.

RVP relates to vapor lock, which occurs when gasoline vaporizes while still in the fuel delivery system, resulting in too much vapor in the combustion chamber prior to ignition. A vapor-locked vehicle fails to start if a driver tries to restart a hot engine or if the outside temperature is too high. The engine won't run because vapor flow can't be controlled by injectors and pressure regulators designed to handle liquids. RVP is proportional to flash point, which indicates how likely it is for a fuel to explode spontaneously in open air.

Finally, regulations control RVP to limit evaporation of gasoline into the air, where the vapors react with ground-level ozone and nitrogen oxides to form photochemical smog.

RVP is defined as the vapor pressure measured at 100 °F (38 °C) in a volume of air four times the liquid volume. The parameter can be calculated from the composition of a fuel

$$M_t(\text{RVP})_t = \sum_{i=1}^n M_i(\text{RVP})_i ,$$

where M_t = total moles of blended product; $(\text{RVP})_t$ = specification RVP for product, psi or kPa; M_i = moles of component i ; and $(\text{RVP})_i$ = RVP of component i , psi or kPa.

Metal-Containing Octane Additives: TEL and MMT

Starting in the 1920s, adding tetraethyl lead (TEL) to gasoline substantially improved octane numbers and hence engine performance. It allowed engines to operate at higher compression. In addition to boosting power, TEL increased fuel economy.

But TEL causes cumulative neurotoxicity. Children are especially susceptible. TEL also deactivates the active metals in catalytic converters that convert unburned hydrocarbons and poisonous carbon monoxide in engine exhaust into carbon dioxide.

In the United States, the phase-out of TEL began in 1973. Except for a few low-volume specialty products, such as high-octane avgas for piston-engine aircraft, automotive gasoline was lead-free by 1986 in Japan, 1988 in Germany, 1992 in California, 1993 in Canada, 1996 in the rest of the United States, 2000 in the EU, China and India and 2002 in Australia and Russia. TEL was legal in Algeria and Iraq as recently as 2014 and illegal usage persists.

A less toxic alternative to TEL is MMT (methylcyclopentadienyl manganese tricarbonyl). MMT was common in Canadian gasoline starting in 1976. It is still permitted in small amounts in many regions, including China and the EU. Australia started using MMT in 2000. MMT is not allowed in the United States, due to concerns about as-yet-unquantified health risks.

17.3.3 Sulfur Content

Other than hydrocarbons, there are many heteroatom-containing hydrocarbons present in crude oils. The main heteroatom compounds include sulfur, nitrogen and oxygen, for which concentrations can reach 5 wt%; typically, the sulfur content is 5–10 times higher than nitrogen and oxygen. Trace metals, such as Fe, Ni, V, As and Hg are present at ppm levels. These contaminants are of concern to refining processes because they deactivate catalysts. Oxygen-containing hydrocarbons, such as naphthenic acids, can cause corrosion. Concentrations of heteroatom-containing compounds are highest in high-boiling fractions, but sulfur and nitrogen can be present in gasoline fractions.

Upon combustion, sulfur compounds form sulfur oxides (SO_x). When SO_x are released to the atmosphere, they form particulates and react with moisture to form acid rain. Hence sulfur-containing streams must be hydrotreated to remove sulfur and meet product sulfur limits. By 2017, the limit on sulfur in gasoline and diesel fuel in much of the world will be 10 ppmw.

17.3.4 Storage Stability

During storage in a fuel tank or other containers, gasoline can undergo oxidative degradation to form sticky gums, which can precipitate out of gasoline. These can cause fouling in the fuel system and engine components, reducing engine performance. Small amounts of antioxidants in gasoline additives can improve the storage stability and inhibit gum formation.

Reformulated gasolines in the United States contain ethanol, which is water soluble. At temperatures of 40 to 60 °F (4 to 16 °C), phase separation into a gasoline phase and an aqueous ethanol phase can occur when gasoline contains 10 vol.% ethanol and only 0.4 to 0.5 vol.% water. Thus, limiting water content in US reformulated gasolines can allow ethanol contents of more than 10 vol.% without phase separation.

17.4 Gasoline Specifications

Gasoline properties are specified by law or government agencies. Standard measurements for most properties are developed and published by organizations such as the American Society for Testing and Materials (ASTM) and the International Organization for Standardization (ISO). ASTM and ISO specifications incorporate information from suppliers, users, government agencies and equipment manufacturers. Except for sulfur and oxygen content, inter-

national gasolines specifications are similar in most respects for urban areas. Many countries follow ASTM D4814: Standard specification for automotive spark-ignition engine fuel. In Europe, the present specification is EN 228:2012. The Chinese specification is Gasoline V and Japanese specification is JIS K-2202.

Table 17.3 shows modern specifications for China, the EU and the United States.

^c US reformulated gasoline specifications vary regionally based on local situations. Values marked with (°) are averages from a 2005 national survey. Compliance is based on complex-model estimates of VOCs (VOCs), toxic compounds and NO_x emissions. The Clean Air Act (CAA) limits aromatics in RFG to 25 vol.%

^d US laws passed in 2005 and 2007 do not specify ethanol percentage. Instead, they specify a national target for consumption of ethanol as a gasoline blendstock, regardless of percentages. In 2016, discussions were being held on whether the ethanol percentage should exceed 15 vol.%

17.5 Gasoline Production

17.5.1 Refining Strategy

The typical gasoline boiling range is from 100 °F (≈ 40 °C) to 400 °F (≈ 200 °C) for adequate RVP. The components have carbon numbers ranging from C₅ to C₁₂.

The most straightforward gasoline blendstock is light straight-run naphtha from atmospheric pressure distillation. Heavier straight-run naphthas do not have high octane ratings. Without further processing to in-

crease octane rating, heavy naphtha can only be used as a solvent, diluent, or steam cracking feed.

As shown in Tables 17.1 and 17.2, octane numbers vary with hydrocarbon compound types. Linear normal paraffins have the lowest octane rating; for *n*-heptane as mentioned above, the octane number is 0. Isoparaffins, such as 2,2,4-trimethylpentane, have high octane numbers close to 100. Aromatic hydrocarbons, such as benzene and toluene, have octane numbers greater than 100. Cycloparaffins also have higher octane

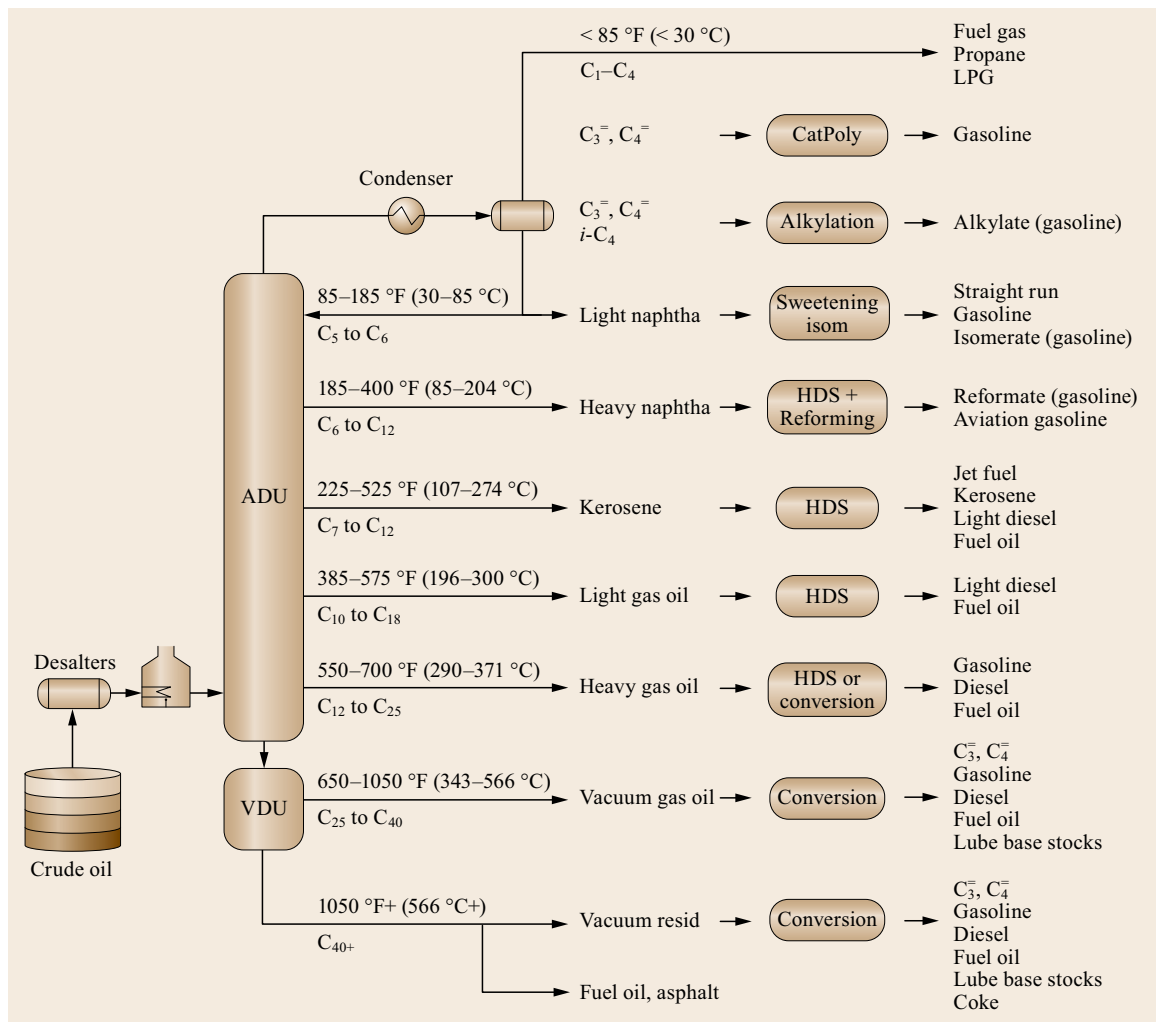

Fig. 17.11 Production of gasoline blendstocks in refineries. Fuel gas is mostly C₁C₂ compounds. All conversion processes produce at least small amounts of C₁C₂. LPG = liquefied petroleum gas, which is mostly C₃ and C₄ paraffins. Sweetening can involve mercaptan oxidation. Conversion processes include FCC, hydrocracking, delayed coking and other resid upgrading processes. C₃= and C₄= are propylene and butylenes respectively; these are converted into gasoline by catalytic polymerization. They also react with isobutane to make alkylate

Shaded cells indicate high sulfur content or comparatively low heat content. Data source include the following: API data compiled by Texas A&M University [17.9], Gary and Handwerk [17.14], Jechura [17.15], the Oak Ridge National Laboratory [17.16], the NIST Chemistry WebBook [17.17], Lengyel et al. [17.18], Virid et al. [17.19]

numbers than normal paraffins, as with isoparaffins. Normal hexane has an octane number of 25. When it is cyclized to cyclohexane, the octane number will be improved to 83. Further dehydrogenation into benzene will increase the octane rating to 115. However, due to health concerns, refineries avoid or minimize the production of benzene in gasoline. Olefins also have high octane numbers. Hence, in hydroprocessing units designed to remove gasoline sulfur, conditions are optimized for minimizing hydrogenation of olefins to form corresponding paraffins of lower octane rating.

To increase gasoline yield in a crude oil, several refining processes have been developed to either increase the molecules in the lighter fractions or decrease the molecules in the heavier fractions. Alkylation and polymerization are developed to convert molecules of carbon number less than 5 to the range of 6–12. On the other hand, cracking and coking are developed to break down larger molecules into the gasoline range. Without changing carbon numbers, isomerization and reforming are developed to convert low-octane components into high-octane constituents. These processes will be discussed further in the following sections.

Catalytic cracking without hydrogen, such as occurs in FCC, yields gasoline and middle distillate cycle oils with high aromatic contents. Such middle distillates perform poorly in compression ignition (diesel) engines. On the other hand, hydrocracking provides high yields of the easily cracked components desirable in diesel engines. Hydrocracking also yields light and heavy naphtha, which can be transformed into gasoline components.

17.5.2 Gasoline Blending Stocks

Gasoline is blended from several refinery streams including straight-run light naphtha and products from upgrading processes – isomerization (isomerate), alkylation (alkylate), catalytic reforming (reformate), catalytic polymerization (cat poly gasoline), catalytic cracking (FCC gasoline), hydrocracking (hydrocrackate, see Chap. 22) and coking. Regardless of source, heavy naphthas go through a catalytic reformer, which increases octane by converting paraffins and naph-

thenes into aromatics. Figure 17.11 depicts the refinery streams that comprise modern gasoline.

Properties of typical blendstocks are shown in Table 17.4.

A representative summer gasoline blend in the United States might contain 40 to 50% FCC gasoline, 15 to 20% straight-run gasoline, 10 to 15% alkylate, 15 to 20% reformate, up to 2% butane, 10% ethanol and up to 10% other – isomerate and polymer gasoline. The RVP of the blend depends on the relative concentration of each component. *n*-butane is a relatively inexpensive ingredient, but it has the highest vapor pressure by far at around 52 psi (≈ 360 kPa) [17.20].

Table 17.4 shows RVP, octane and API gravity for common blendstocks. Blending changes the octane and RVP of individual stocks. An extreme case is ethanol, which has a pure-compound RVP of 2 psi (≈ 14 kPa) and blended RVP of 10 for gasoline containing 10 vol.% ethanol.

For octane, the best blendstocks are alkylate, reformate, FCC gasoline, polymer gasoline, *i*-butane, *i*-pentane and aromatics concentrate (i. e., raffinate from extraction of aromatics). Other high-octane blendstocks are ethanol and methyl-*t*-butyl ether (MTBE), with blended RONs of 130 and 118 respectively. MTBE is banned in the United States but remains a desired blend component in Europe. Much of the MTBE consumed in Europe is manufactured along the US Gulf Coast.

RVP restrictions range from 7.8–9.0 psi (≈ 53 –62 kPa). Depending on location, there can be a 1 psi (6.9 kPa) allowance when the ethanol content is 9–10 vol.% [17.21]. One can see from the table that for RVP, the most favorable blendstocks are reformate, alkylate, hydrocrackate and hydrogenated heavy FCC gasoline; untreated FCC gasoline contains excess sulfur, so it isn't suitable for direct blending. For RVP, the least desired blendstocks are butanes, pentanes and C₅C₆ fractions from straight-run distillation, FCC and hydrocracking. Present RVP regulations permit little if any butane content. In some urban areas during the summer, pentane content also is limited. Adding 10 vol.% ethanol increases blended RVP by 1.1–1.25 [17.22], further reducing the practical content of butanes and pentanes.

17.6 Production of Gasoline Blendstocks

17.6.1 Distillation – Straight-Run Naphtha

Crude oil introduced to refinery processing contains many undesirable impurities, such as sand, inorganic

salts, drilling mud, polymer, corrosion byproduct, etc. These undesirable impurities, especially salts and water, need to be removed by dewatering and desalting prior to distillation. Dewatering removes water and

constituents of brine that accompany the crude oil. Desalting is a water-washing operation that can be performed at the production field or at the refinery to remove water-soluble minerals and entrained solids.

Crude oils are made of numerous components of different boiling points. The simplest way to separate them is with continuous distillation into different fractions (distillates or cuts) of different boiling ranges. At atmospheric pressure, heavy molecules can decompose above $\approx 650^\circ\text{F}$ ($\approx 343^\circ\text{C}$). To achieve additional separation of heavy fractions, continuous distillation is carried out under *vacuum* – strictly speaking, at reduced pressure – in a vacuum distillation unit (VDU). The typical operating pressure for a VDU is 40 mmHg (≈ 5.3 kPa). In the VDU, additional components vaporize. Vacuum gas oil (VGO) goes either to conversion units or lubricant production plants.

Full-range naphtha, including light and heavy naphtha, boils in the same boiling range as gasoline, between $30\text{--}205^\circ\text{C}$. Carbon numbers range between 5–12. Light naphtha boils between $85\text{--}185^\circ\text{F}$ ($30\text{--}85^\circ\text{C}$) and consists of molecules with 5–6 carbon atoms. Some light naphthas, such as those from hydrocracking units, can be used as-is for gasoline blending. Light naphtha from an atmospheric distillation unit (ADU) with adequate octane rating can be blended into gasoline pool as *straight run gasoline* after sweetening to remove sulfur and other impurities. Others are sent to isomerization units. Heavy naphthas boil between $185\text{--}400^\circ\text{F}$ ($85\text{--}204^\circ\text{C}$) and consist of molecules with 6–12 carbons. Most heavy naphthas containing seven or more carbons are feeds for catalytic reforming. Naphtha from atmospheric distillation should contain no olefins that are not present in crude oil; however, if temperatures in the CDU are too high, light olefins can be formed. Most refinery olefins come from thermal processes, such as steam cracking, FCC and coking. Naphtha from catalytic hydrocracking does not contain olefins.

Naphtha boiling range products, including reformates, isomerates and alkylates, are used in high-octane gasoline. Straight-run naphtha with low octane ratings is used as a diluent in the bitumen mining industry, as feedstock for producing olefins via steam cracking and as solvents for paints (as diluents), dry cleaning, cut-back asphalt, industrial extraction processes and in the rubber industry.

17.6.2 Isomerization

Other than straight-run naphtha, a gasoline pool comes from various processes, including isomerization [17.24], polymerization, reforming, alkylation, catalytic cracking, hydrocracking and coking.

Normal paraffins of the lighter naphtha fraction, butanes, pentanes and hexanes, have poor octane ratings for gasoline engines. Isomers of normal paraffins have high octane ratings. Isomerization units convert *n*-paraffins into isoparaffins and straight-chain olefins into *iso*-olefins. Butane isomerization provides isobutane as the major feed for subsequent alkylation. Pentane/hexane isomerization improves the octane number of light naphtha for gasoline blending. During World War II, there was a demand for high-octane aviation gasoline (avgas) for propeller fighter planes and isomerization became an important process.

AlCl_3 was originally used as a catalyst in the isomerization of normal butane. Butane isomerization provides isobutane as the major feed for subsequent alkylation. Subsequently, *n*-pentane and *n*-hexane isomerization processes were developed, using supported acid catalysts that can stand high temperature ($370\text{--}480^\circ\text{C}$) and high pressure (300–750 psi; 2070–5170 kPa). A liquid-phase process employs a dissolved catalyst for C_5/C_6 isomerization. Pentane/hexane isomerization improves the octane number of light naphtha for gasoline blending. Carbon number is not supposed to change in the isomerization process.

In butane isomerization, *n*-butane is converted to isobutane normally in a two-stage process. The feed contains *n*-butane, typically mixed with other butanes. As shown in Fig. 17.12, mixed butane feed enters a deisobutanizer to separate isobutane followed by a debutanizer to separate butanes from C_5+ impurities. The purified butanes are mixed with hydrogen and heated to 230° to 340°F ($110\text{--}170^\circ\text{C}$) under a pressure of 200–300 psi (1380–2070 kPa). The catalyst is highly sensitive to water, so the feed must be thoroughly dried. In the low-temperature first stage, the catalyst comprises aluminum chloride promoted by HCl. Hydrogen gas is added to inhibit olefin formation and to control side reactions, such as disproportionation and cracking. In the high-temperature second stage, the catalyst contains a noble metal such as platinum. The reactor effluent goes to a flash drum, from which hydrogen is recovered and recycled. Make up gas is added to compensate for the loss, which is low because the isomerization reaction itself does not consume hydrogen. HCl is removed in a stripper column. The liquids go to a stabilizer that separates C_4 gases, which can be used as a fuel gas inside the refinery, from isobutene and unconverted *n*-butane. The C_4 compounds are recycled and mixed with fresh feed. Produced isobutane is collected at the top of the deisobutanizer. Isobutane is the key feedstock for alkylation units, which produce high-octane alkylates. The Butamer process developed by UOP specifically for the isomerization of *n*-butane to isobutane uses a platinum-containing catalyst [17.25].

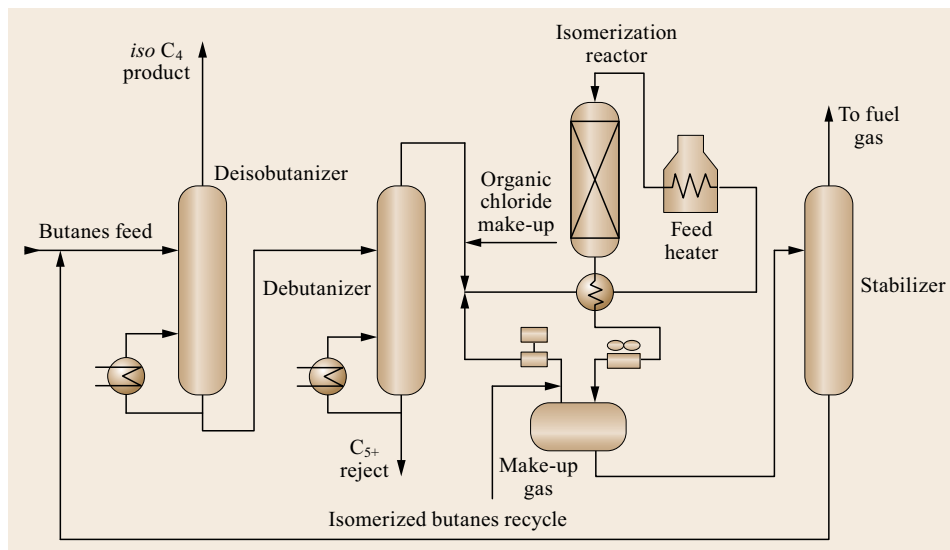

Fig. 17.12 Butane isomerization (after [17.23])

Fig. 17.13 C₅/C₆ isomerization

The C₅/C₆ isomerization process is shown in Fig. 17.13. The mixed C₅/C₆ feed enters a fractionator to separate *n*-C₅/C₆ from *iso*-C₅/C₆, which are the desired isomerization products. The purified *n*-C₅/C₆ is then mixed with hydrogen and hydrogen chloride and heated to 240–500 °C under 300–1000 psi (2070–6900 kPa) pressure before entering the reactor, which is packed with HCl-promoted AlCl₃ catalyst or a Pt-containing catalyst. The residence time is 10–40 min. Again, hydrogen is used to control side reactions (disproportionation and cracking). The product stream goes through a flash tank to recover hydrogen for reuse, then enters a stabilizer to separate C₄ and lighter impurities before entering a C₅ and C₆ splitter. The C₅ components are recycled back to the feed fractionator to recover *i*-C₅ into isomerate.

Another two-stage reactor scheme is shown in Fig. 17.14. The first reactor, using a Pt-catalyst, serves

as a hydrogenation reactor to convert organic chloride into HCl. The second reactor is packed with AlCl₃, which is promoted by HCl to perform isomerization.

Figure 17.15 shows the UOP Penex continuous isomerization unit with a similar design, first commercialized in 1958 [17.26]. Penex uses a dual-function platinum-alumina catalyst with 34 000 bbl per stream day of 85% *n*-pentane feed to produce 16 000 bbl per day of 95% isopentane. The UOP Penex process improves octane ratings from 50–60 to 82–86 or higher. The Penex-Platforming was introduced to convert unreacted *n*-pentane and *n*-hexane from platforming (a reforming process discussed later) into corresponding high-octane isoparaffins [17.25].

In the Shell Hysomer process for pentane-hexane isomerization [17.27], the feed is combined with hydrogen-rich gas, heated to 445–545 °F (230–285 °C) and routed to the Hysomer reactor at

Fig. 17.14 C₅/C₆ isomerization with two reactors and once-through hydrogen

Fig. 17.15 UOP Penex isomerization unit

190–440 psi (1300–3030 kPa). As with fixed-bed hydrotreating and hydrocracking, the process fluids flow down through the catalyst bed, where a part of the *n*-paraffins are converted into branched paraffins. The catalyst is comprised of a noble metal on a zeolite-containing support. The reactions are exothermic and temperature rise is controlled by injecting relatively cold quench gas. The reactor effluent is cooled and sent to a flash drum, which separates hydrogen from the liquid product. The hydrogen is recycled. The liquid is fractionated and the *n*-paraffins are recycled. The net

conversion of *n*-paraffins into branched products can be as high as 97% and the octane can be boosted by 8–10 numbers.

The Iso-Kel process, developed by M.W. Kellogg (now KBR), is specifically for the isomerization of *n*-pentane and *n*-hexane, employing a nonplatinum precious metal catalyst operated at 700–850 °F (370–450 °C) and under 100–750 psi (690–5200 kPa) pressure [17.25]. Often, the heat-exchanger and fractionation systems of isomerization units are integrated with those of other process units, such as catalytic

reformers. In the Union Carbide total isomerization process (TIP) [17.28], C₅/C₆ isomerization was integrated with molecular sieve separation, which provided complete conversion to *n*-paraffins.

The CDTech Isomplus process achieves near-equilibrium conversion of *n*-butenes into isobutylene and *n*-pentenes into isoamylene over a highly selective zeolite catalyst [17.29]. It was developed when methyl *t*-butylether (MTBE) was in high demand for reformulated gasolines. Isobutylene is also an important feedstock for polyisobutylenes.

Olefin isomerization converts straight-chain C₄–C₆ olefins into corresponding *iso*-olefins, which can be used as alkylation feeds with an excess amount of isobutane for producing high-octane gasoline.

17.6.3 Catalytic Reforming

Straight-run gasoline (naphtha) from distillation has a very low octane number, i. e., high tendency to knock. Thermal reforming was initially developed from thermal cracking processes with naphtha as the feed. The feed with an end point of 400 °F (≈ 200 °C) is heated to 950–1100 °F (510–595 °C) under 400–1000 psi (2700–6900 kPa) pressure. The higher octane number is due to the cracking of long-chain paraffins into high-octane (65–80) olefins. Gases, residual oil or tar can be formed. Thermal reforming is less effective and less economical than catalytic reforming (Chap. 18). Catalytic reforming was commercialized during the 1950s to produce reformate with research octane numbers on the order of 90–95 [17.30]. Catalytic reforming now furnishes approximately 30–40% of US gasoline requirements.

Catalytic reforming is conducted in the presence of hydrogen over hydrogenation-dehydrogenation catalysts supported on alumina or silica-alumina. The first reforming catalysts were based on molybdena-alumina or chromia-alumina, but since the commercialization of the platforming process in 1949, noble metal catalysts have been used, either with supported platinum alone or with supported platinum-rhenium, platinum-rhenium-tin, or other trimetallics [17.31, 32]. Hydrogen chloride is a cocatalyst.

The noble metals catalyze reversible dehydrogenation reactions. Bimetallic catalysts bring the following advantages versus platinum-only catalysts:

- Better yield stability
- Lower temperature requirement
- Less hydrocracking at a given temperature
- Higher activity recovering after regeneration
- Longer ultimate life.

Table 17.5 Typical feed and product distributions in reforming

Component	Feed	Product
Paraffins	30–70%	30–50%
Olefins	0–2%	0–25%
Naphthenes	20–60%	0–3%
Aromatics	7–20%	45–60%

Fresh catalyst is chlorided (chlorinated) prior to use. Chlorinating the alumina support provides the acid sites needed for isomerization and cyclization. Acid sites also catalyze unwanted hydrocracking. Excessive chlorination depresses overall catalyst activity. Significantly, chlorination maintains dispersion of the active metals by inhibiting reductive agglomeration.

The operation conditions for modern catalytic reforming are: temperature at 840–965 °F (≈ 450–520 °C), pressure at 100–600 psi (690–4100 kPa). Continuous catalyst regeneration (CCR) reformers operate at the low end of the pressure range 100–150 psig (690–1030 kPa), where production of aromatics is more favored by thermodynamics.

Naphtha containing seven or more carbons is used as a reformer feed. There are four main hydrocarbon types in naphtha:

1. Paraffins
2. Olefins (rarely)
3. Naphthenes
4. Aromatics.

Organic sulfur and olefins must be removed by prior hydrotreating; the sulfur content must be < 1 ppmw. During the process, paraffins are cyclized into naphthenes and naphthenes undergo dehydrogenation to form aromatics. Aromatics left essentially unchanged. The preferred conditions for dehydrogenation are:

- High temperature
- Low pressure
- Low space velocity
- Low H₂/hydrocarbons ratio.

The dehydrogenation reaction in reforming is endothermic. Heat is required. Table 17.5 lists typical feed and product compositions in a reforming process.

Figure 17.16 summarizes the reactions of catalytic reforming, the purpose of which is to transform C₆ to C₁₁ naphthenes and paraffins into aromatic compounds. The aromatics can go to chemical plants or be used as high-octane gasoline blendstocks. For the paraffins in the feed, the acidic sites of the catalyst isomerize *n*-paraffins to isoparaffins. This is a key step for cyclization. It is followed by dehydrogenation to form

Fig. 17.16 Catalytic reforming reactions

Fig. 17.17 Representative semiregenerative catalytic reforming process flow

aromatic compounds. The process yields considerable amounts of hydrogen; in Fig. 17.10, 4 mol of hydrogen are produced from 1 mol of hexane. The hydrogen is used in hydrotreaters, hydrocrackers, isomerization units and others.

In contrast to hydrocracking, which operates at high pressure, catalytic reforming operates at low pressure and high temperature, which favors production of aromatics by losing hydrogen. The isomerization of alkylcyclopentanes into cyclohexanes is a key step in the production of benzene and alkylbenzenes.

The three major process flows for catalytic reforming are:

1. Semiregenerative
2. Cyclic
3. Continuous catalyst regeneration (CCR).

Semiregenerative and Cyclic Catalytic Reforming

Figure 17.17 shows a process flow scheme for a semiregenerative catalytic reformer. Units can employ either traditional fixed-bed trickle-flow reactors (Fig. 17.18)

Fig. 17.18 Fixed-bed trickle-flow reactor with one bed. Not to scale

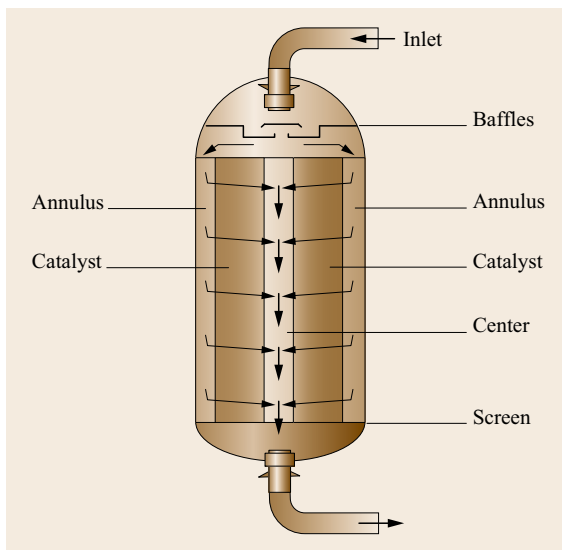

Fig. 17.19 Radial flow reactor. Not to scale. The direction of flow is shown in *black arrows*

or radial-flow reactors (Fig. 17.19). They are comprised of three cylinders. The catalyst is loaded between the two inner cylinders, both of which are slotted. The feed flows downward through the outer annular space, then inward through the catalyst to the center, where reaction products flow downward to the bottom of the reactor. Radial flow reactors are nearly isothermal. Compared to fixed-bed reactors, for a given average reactor temperature the peak temperature is lower. Undesired cracking is faster at higher temperatures, so in theory, radial reactors should make less gas and more liquid product. In practice, however, the difference in yields is low, and due to their complex design radial reactors are more difficult to operate and signifi-

cantly more expensive. They are still being used in older units [17.33], but almost all new catalytic reformers are CCR units, which are described below.

Catalyst cycles last from 6–12 months. A cycle ends when the unit is unable to meet its process objectives – typically octane number and overall C₅-plus yields. At the end of a cycle, the entire unit is brought down and coke is burned off the catalyst. Pentane and hexane are removed from desulfurized naphtha to be used as isomerization feeds, as discussed earlier. The depentanized/dehexanized naphtha is mixed with hydrogen and heated to > 900 °F (> 480 °C) and passed through a series of fixed-bed reactors. The feed is spiked with an organic chloride, which converts to hydrogen chloride in the reactors. This provides the required catalyst acidity and helps minimize catalyst coking. There are three reactors shown. One of them can be shut down in turn for catalyst regeneration, leaving the other two to continue the reforming operations.

The major chemical reactions – dehydrogenation and dehydrocyclization – are endothermic and the reactors are adiabatic. Consequently, the temperature drops as reactants flow through a reactor. Between reactors, fired heaters bring the process fluids back to desired reactor inlet temperatures (RIT). The product stream is cooled down by a heat exchanger and enters a high-pressure gas separator at 38 °C to collect hydrogen. A portion of hydrogen is recycled and other portions are used as hydrogen product. The liquid is then sent to a stabilizer to separate out gas from the final reformate product of octane number of 90–95. Like the distillation tower, both reflux and reboiler are used.

A cyclic reformer has more reactors and catalyst cycles are shorter – 20–40 h. Shutdowns are staggered so that only one reactor is down at a given time.

Fig. 17.20 CCR catalytic reforming process flow

Fig. 17.21 Mechanism for alkylation of butenes in the presence of excess isobutane, where X = HSO₄ for sulfuric acid or F for hydrofluoric acid and ASO is acid-soluble oil

CCR Catalytic Reforming

While semiregenerative platforming employing regenerable platinum catalysts was commercialized by UOP in 1949 [17.29], the CCR platforming process (Fig. 17.20) was commercialized by UOP in 1971 (Chap. 18). CCR catalytic reforming also is licensed by IFP (now Axens). Hydrotreated feed mixes with recycle hydrogen and goes to a series of adiabatic, radial-flow reactors arranged in a vertical stack. Cat-

alyst flows down the stack, while the reaction fluids flow radially through the catalyst beds. Heaters are used between reactors to reheat the reaction fluids to the required temperature. Flue gas from the fired heaters is typically used to generate steam. A CCR can operate at very low pressure (100 psi; 791 kPa). This improves yields of aromatics and hydrogen, but it accelerates catalyst deactivation by increasing the rate of coke formation. However, faster coke forma-

Fig. 17.22 Overall reactions for butylene and propylene alkylation

tion is acceptable in a CCR reformer because the catalyst is continuously being regenerated. The hydrogen recovery is superior to that for semiregenerative platforming and correspondingly product aromatics are higher.

Other catalytic reforming processes based on platinum catalysts include the following:

- Magnaforming, developed by Engelhard and Atlantic Richfield (now a part of BP). Magnaforming employs a manganese-containing catalyst for sulfur removal along with a platinum-containing catalyst for reforming [17.34].
- Powerforming, developed by Esso (now Exxon-Mobil). Powerforming uses a highly selective dual-function catalyst with atomically dispersed platinum to provide high activity for reversible dehydrogenation and chlorine on the alumina base to promote acidity for acid-catalyzed reactions [17.35].

- Ultraforming, developed by Standard Oil Indiana (Amoco, now a part of BP) in 1954. Ultraforming is a cyclic semiregenerative process [17.36].
- Rheniforming, developed by Chevron [17.25]. Rheniforming employs platinum-rhenium bimetallic catalysts where rhenium is combined with platinum to form more stable catalysts operated at low pressures [17.37]. The amounts of metal are very low, about 0.6 wt%, but they are highly dispersed. Acidity is provided by the support and dispersion is maintained by HCl.

Due to the high expense of the metals, such as platinum and rhenium, complete recovery of catalysts is emphasized, including dust and fines.

17.6.4 Alkylation

In alkylation [17.38], isobutane reacts with C_3 to C_5 olefins in the presence of strong acids to produce branched-chain hydrocarbons. The olefins come mainly from cracking units. Propylene and butylenes are gases. Alkylation with isobutane increases their carbon numbers to the gasoline range. The product hydrocarbons, often referred to as alkylate, have high octane values (motor octane number from 88–95 and research octane number from 90–98), with low Reid vapor pressures, no sulfur/aromatics/olefins and limited heavy ends, making them an excellent contributor to the gasoline blending pool.

Figure 17.21 shows the mechanism for the alkylation reaction of butenes with isobutane [17.39]. The process uses an excess of isobutane to control heat and minimize olefin polymerization. In reaction 1, butene is protonated by the acid catalyst, either hydrofluoric acid (HF) or sulfuric acid (H_2SO_4), to form a stable *t*-butyl

Fig. 17.23 HF alkylation process flow

Fig. 17.24 Phillips HF alkylation reactor

cation as an initiation step. The *t*-butyl ion reacts with different butenes in the feed via reactions 2–4. The reaction with isobutylene forms a stable 2,2,4-trimethyl pentyl cation. The reaction with 2-butene forms a 2,2,3-trimethyl pentyl cation, which can undergo isomerization to form a more stable 2,2,4-trimethyl pentyl cation via methyl shift. Similarly, the reaction with 1-butene produces a 2,2-dimethyl hexyl cation, which can isomerize to a 2,2,4-trimethyl pentyl cation as well. The isomerization reaction will not reach completion due to thermodynamic equilibrium of reversible reactions, which is also evidenced by the presence of 2,2,3-trimethyl pentane and 2,2-dimethyl hexane in the final product (alkylate). The various C_8 cations are neutralized by extracting hydrogen (hydride transfer) from isobutane to yield *t*-butyl ion and propagate the alkylation reaction. The excess amount of isobutane is used to prevent polymerization of the olefins in great extent. However, some C_8 cations can proceed to react with olefins to form C_{12} cations, which could continue the polymerization and eventually produce sludge and

acid-soluble oil (ASO). Hence, temperature and space velocity control are important for limiting the extent of the reaction, ensuring maximum production of products in the gasoline range (C_5 to C_{12}).

Figure 17.22 summarizes the overall alkylation reaction. 2,2,4-trimethylpentane has been mistakenly called isooctane as a reference compound for which the gasoline octane rating is defined as 100.

Isobutane feed comes from a hydrocracker, an FCC unit, or a butane isomerization unit, as discussed earlier. Olefins are not present in crude oils, hence, they cannot come from distillation directly. There are many conversion units in the refinery, such as thermal cracking, catalytic cracking, hydrocracking, coking, etc. Except for hydrocracking, all these processes make olefins.

The alkylation reaction is highly exothermic, so the mixed feed of isobutene and cracked gas containing olefins need to be chilled to a low temperature before entering the reactor. The low temperature also decreases polymerization of the olefins. Alkylation is catalyzed by either hydrofluoric acid, as in a hydrofluoric acid alkylation unit (HFAU), or sulfuric acid, as in a sulfuric acid alkylation unit (SAAU). Temperatures for HF-catalyzed reactions are 70–100 °F (21–38 °C). For sulfuric acid they are 35–50 °F (2–10 °C), hence, it needs to be refrigerated.

After the reaction, the acid is recovered and recycled. The product is caustic-washed to remove the residual acid from the product. Then the product stream goes through the depropanizer to separate propane, to the deisobutanizer to recover isobutane for reuse, and to the debutanizer to separate butane from the desired product, alkylate.

Alkylate is an ideal gasoline component. It has high octane numbers in the 90s. It has zero sulfur, so it does not contribute to acid rain; zero benzene, so it does not contribute to air toxics; and zero olefins, so it does not contribute to gum formation. Its low Reid vapor pressure (RVP) reduces hydrocarbon emissions.

Hydrofluoric Acid Alkylation

Figure 17.23 describes a HF alkylation unit [17.40] (HFAU). HF is dangerous and extra precautions are taken to ensure that it is always contained. The feed is mixed with recycled isobutene to give an isobutene/olefin ratio of 15 : 1. The combination is introduced into the reactor at a temperature of 70–100 °F (\approx 20–38 °C). There it reacts in the presence of HF with purity > 88%. The product mixture is sent to a settler and an acid stripper to recover the acid, HF. The bottom of the stripper is sent to the deisobutanizer to recover isobutene. A depropanizer is used to purify the isobutene. The product stream is then enters a defluorinator for caustic wash the residual acid before entering

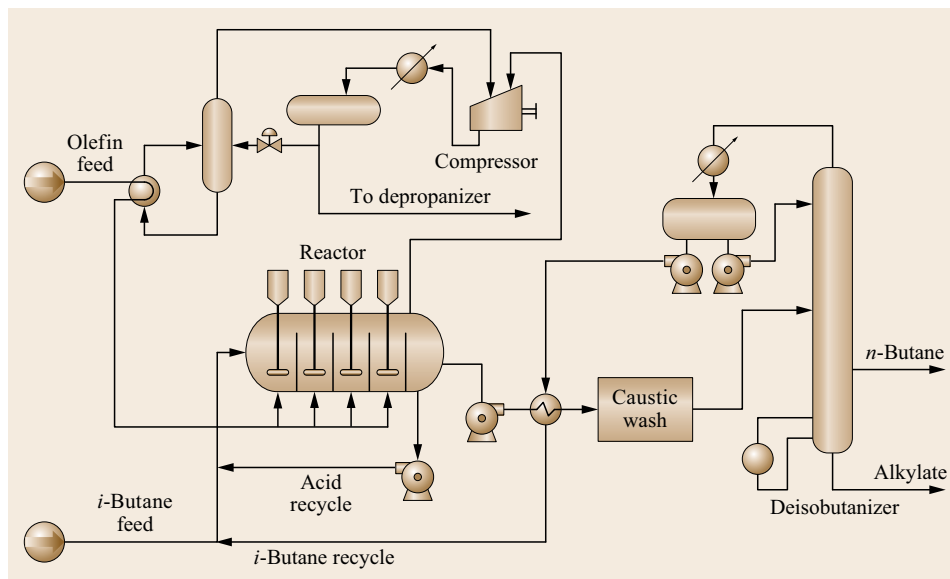

Fig. 17.25 Autorefrigeration sulfuric acid alkylation unit

a debutanizer for separating *n*-butane from the final product, alkylate.

Phillips developed a single-column HF alkylation reactor, shown in Fig. 17.24. The isobutene and olefin feed is mixed with acid in a reactor pipe at 70–80 °F ($\approx 20\text{--}25\text{ }^\circ\text{C}$), which leads to a settler to separate the product from the acid. Acid flows down a side pipe by gravity, without a pump, for returning to the reactor pipe after cooling.

A single tower can be used for fractionation of the product mixture. Propane comes off as an overhead. Isobutane recycles and is withdrawn at several trays above the feed tray. *n*-Butane is taken off as a vapor several trays below the feed tray. Alkylate flows off at the bottom.

Sulfuric Acid Alkylation

Figure 17.25 shows an autorefrigeration sulfuric acid alkylation unit [17.41]. The olefin feed is mixed with isobutane and acid and chilled to 35–45 °F ($\approx 2\text{--}7\text{ }^\circ\text{C}$) for minimizing redox reaction and preventing tar and SO_2 formation. A pressure at 5–15 psi (3–100 kPa) is applied to prevent vaporization. Propane and lighter gases are withdrawn at the top of the reactor. The gases are compressed and liquefied. A portion of this liquid is vaporized in an economizer to cool the olefin feed, as autorefrigeration, before it is sent to the reactor.

The C_4s and alkylate mixture is sent to debutanizer, after caustic wash to remove residual acid, to fractionate into isobutane for recycling with the isobutane feed, *n*-butane and alkylate.

A typical Stratco effluent refrigerated sulfuric acid alkylation unit is shown in Fig. 17.26. Stratco's effluent

refrigerated technology uses acid settler effluent as the refrigerant to provide cooling in the contactor reactor. The Stratco contactor reactor is a horizontal pressure vessel containing an inner circulation tube, a tube bundle to remove the heat of reaction and a mixing impeller. Hydrocarbon feed and recycle acid enter on the suction side of the impeller inside the circulation tube. As the feeds pass across the impeller, a fine emulsion of hydrocarbon and acid is formed by the extremely high shear forces induced by the impeller. Heat transfer from the reaction side of the tube bundle to the refrigeration side is aided by the high circulation rate, which also prevents any significant temperature differential within the contactor reactor. A portion of the circulating emulsion in the contactor reactor flows from the circulation tube, on the discharge side of the impeller, to the acid settler, where the hydrocarbon phase is separated from the circulating acid phase. Hydrocarbon leaves the settlers and is let down across a back-pressure control valve to the tube side of the contactor reactor bundle. The heat of reaction from the shell side is removed by further vaporization of the hydrocarbon effluent as it passes through the tubes.

HF Alkylation Process versus H_2SO_4 Alkylation Process

The HF alkylation process has several advantages over the sulfuric acid alkylation process:

1. Smaller and simpler reactor design
2. Less sensitive to temperature so that cooling water can be used instead of refrigeration
3. Smaller settling device for emulsions

Fig. 17.26
Stratco effluent refrigeration process

4. HF consumption is low due to essentially complete regeneration
5. Disposal of acid is not necessary
6. Flexibility of operations in temperature and isobutane-to-olefin ratio and less need for turbulence or agitation.

On the other hand, the advantages of sulfuric acid alkylation process over HF alkylation process include:

1. Additional equipment, such as HF stripper, HF regeneration tower, etc. is needed for the HF process to recover or neutralize HF in various streams on-site. In the H_2SO_4 process, the entire HC stream is neutralized offsite.
2. Drying is not required for the H_2SO_4 process, while drying down to a few ppm water is needed for the HF process. In the H_2SO_4 process, only feed coalescers are used to remove the free water that drops out of the chilled feed.
3. Additional safety equipment is required for HF process, with greater costs.
4. Capital costs for HF process are higher.
5. Self-alkylation of isobutane occurs in the HF process.
6. H_2SO_4 alkylation works better for butylene.

However, due to their strong acidity in the liquid phase, both HF and H_2SO_4 require relatively expensive corrosion-resistant equipment. Safety in handling and operations is a major concern for both, which also face disposal issues associated with spent acids and acid-soluble oils (ASO). These problems can be diminished with ionic-liquid alkylation and essentially eliminated

by solid acid-catalyzed alkylation. These recently developed breakthrough processes are discussed below.

Ionic-Liquid Alkylation

Due to their lower vapor pressures, ionic liquids are easier to handle. The catalyst can be regenerated on-site, giving it a lower environmental footprint than HF and H_2SO_4 technologies.

The world's first composite ionic liquid alkylation (CILA) commercial unit, with a capacity 120 kt/a, was commissioned at the Deyang Petrochemical Plant in Dongying, Shandong in August, 2013. This followed a successful pilot plant test run and retrofitted into an existing 65,000 t/a sulfuric acid alkylation unit as *ionikylation* at a PetroChina Lanzhou Petrochemical plant starting in 2005. The technology was developed at the China University of Petroleum [17.42, 43]. The chemistry, alkylation of isobutylene, occurs in a strongly Lewis acidic ionic liquid based on aluminum(III) chloride. The retrofit not only increased the yield of the process (compared to sulfuric acid), but increased the process unit's capacity by 40% (to 248 tonnes per day), with attractive economics. This is by far the largest commercial usage of ionic liquids reported to date [17.44].

In the US, Honeywell UOP announced in 2016 the commercialization of ISOALKY, a new alkylation technology developed by Chevron USA [17.45]. Chevron proved the technology in a small demonstration unit at its Salt Lake City refinery, where it operated for five years. Due to the success of the small unit, Chevron committed to converting its hydrofluoric acid (HF) alkylation unit in Salt Lake City to ISOALKY technology. Construction is ex-

pected to commence in 2017, pending permit approvals.

The catalyst for the process is a highly acidic ionic liquid – a nonaqueous liquid salt. The process operates at temperatures below 100 °C. The net reactions are the same as for other alkylation processes: isobutane + C₃–C₅ olefins → alkylate. The ionic liquid catalyst performs as well or better than HF and H₂SO₄, but with lower volatility. Due to the lower vapor pressure, the ionic liquid is easier to handle. HF alkylation units can be cost-effectively converted to ISOALKY technology. Other advantages include the ability to produce alkylate from a wider range of feedstocks using a lower volume of catalyst. The catalyst can be regenerated onsite, giving it a lower environmental footprint than HF and H₂SO₄ technologies.

Zeolite Catalyzed Alkylation

AlkyClean is a solid-acid gasoline alkylation process developed by CB&I, Albemarle catalysts and Neste oil [17.46]. The process employs a robust zeolite catalyst. According to the developers, the total installed cost of an AlkyClean unit is significantly lower than current HF and H₂SO₄ units. No product posttreatment or acid disposal is required. Due to the lack of corrosive acids and the relatively mild operating conditions, carbon steel can be used for construction. The catalyst is much more tolerant to water and other feed impurities, such as oxygenates, sulfur compounds and butadiene. Deactivation from these impurities can be restored via gas-phase regeneration with hydrogen at 250 °C. The product quality from AlkyClean is comparable to that of liquid acid processes, with higher yields. This is because there are no acid-soluble oils produced.

The world's first solid acid catalyst alkylation unit employing Albemarle's AlkyStar catalyst, together with CB&I's novel reactor scheme, was started up at the Shandong, China, plant of Zibo Haiyi Fine Chemical Co., a subsidiary of Shandong Wonfull Petrochemical Group Co., on 18 August 2015. Without the use of liquid acid catalysts, the solid-acid catalyzed AlkyClean technology is not only safer but also more environmental friendly due to the reduction of waste streams, such as spent acids and acid-soluble oils. The alkylates produced consistently have high octane values between 96–98 [17.47].

17.6.5 Polymerization

Olefin gases can be polymerized [17.48] to liquid products that are suitable for gasoline in the carbon number range between 5–12. Polymer gasoline exhibits high octane values due to the branchiness of the hydrocarbon backbone. A typical reaction is shown in Fig. 17.27.

Fig. 17.27 Typical polymerization reactions

The usual feedstock is propylene and butylene from cracking processes. Catalytic polymerization came into use in the 1930s and was one of the first catalytic processes to be used in the petroleum industry.

Figure 17.28 shows a flow diagram of a UOP solid phosphoric acid (SPA) polymerization unit. The SPA catalyst is a combination of Kieselguhr and phosphoric acid [17.49]. The conditions can be varied to produce maximum polymer yield at almost complete conversion of the olefins. In the polymerization of butylenes the conditions can be carefully controlled to yield largely isoocenes, which on hydrogenation will yield isoocenes having an octane rating of 90–96. Pretreatment of feed for removal of sulfur compounds is accomplished by countercurrent contact with caustic solution. Removal of nitrogen compounds is accomplished by contact with a stream of water in a countercurrent packed tower. Water must be present in the feed to maintain the required equilibrium, i. e., to prevent the catalyst from becoming dehydrated.

17.6.6 Fluid Catalytic Cracking (FCC) Process

Fluid catalytic cracking (FCC) [17.50, 51] produces more than half of the world's gasoline (Chap. 19). It generates middle distillate streams (cycle oils) for further refining or blending. It also produces a large quantity of high-quality steam.

A possible mechanism is shown in Fig. 17.29 using *n*-octane as a representative molecule. The reaction is initiated by mild thermal cracking to form heptene with loss of a methyl radical. The acidic aluminosilicate catalyst promotes a proton transfer from a water molecule to heptane, forming a heptyl carbocation. A butyl carbocation is formed upon β -cleavage, which undergoes rearrangement to form more stable *t*-butyl carbocation. Isobutane is formed from hydrogen ion transfer.

A full range of smaller molecules are formed from the breakup of large molecules. Due to deficiency of hydrogen, significant amounts of olefins are formed via proton loss from the carbon adjacent to the carbon carrying the charge in carbocations. Since the feed contains large aromatic and naphthenic molecules with long side chains attached, side chain cleavage is common. The molecules after side-chain detachment have

Fig. 17.29 Reaction mechanism for catalytic cracking

higher specific gravity, i.e., lower API gravity, with olefin formation. Coke is also formed due to there not being enough hydrogen to crack large molecules.

Coke is formed via aromatic ring growth by consecutive cyclization, polymerization and dehydrogenation. Hence, the catalyst needs to be regenerated by burning off the coke in order to restore activity. The thermo-

for catalytic cracking process (TCC) process, invented by E. Houdry, is a moving-bed catalytic cracking process [17.52]. The first TCC went on stream in 1937 at the Sun Oil refinery in Marcus Hook, Pennsylvania. The site is now a national historic monument [17.53]. Catalyst pellets were cycled between the reactor and regenerator. TCC is now obsolete, having been replaced

by more advanced fluidized bed units using greatly improved catalysts.

In fluidized catalytic cracking (FCC), finely powdered catalyst is circulated continuously between the reactor and regenerator [17.54]. The catalyst acts as a heat transfer vehicle, moving heat produced by combustion in the regenerator to the oil feed in the riser and reactor. There are two basic types of FCC units: *side-by-side*, where the reactor and the regenerator are adjacent to each other and the stacked type, in which the reactor is mounted on top of the regenerator.

A typical FCC unit (Fig. 17.30) comprises three major sections:

1. Riser-reactor
2. Regenerator
3. Disengaging vessel.

In the riser-reaction section, preheated oil is mixed with hot, regenerated catalyst. Cracking begins immediately. The mixture acts as a fluid because the catalyst particles are about the size of sifted flour. The hot catalyst vaporizes the oil and the vaporized oil carries the catalyst up the riser-reactor. The cracking reaction is very fast. It produces light gases, high-octane gasoline and heavier products called light cycle oil (LCO), heavy cycle oil (HCO), slurry oil and decant oil. It also leaves a layer of coke on the catalyst particles, rendering them inactive.

At the top of the riser, the riser outlet temperature (ROT) can reach 900–1020 °F (482–549 °C). The ROT determines conversion and affects product selectivity, so FCC operators control it as tightly as possible. Higher temperatures favor production of olefin-rich light gases, especially propylene, at the expense of gasoline; many FCC units maximize refinery-grade propylene for purification and use in nearby olefin plants. Moderate temperatures favor gasoline production. Lower temperatures decrease gasoline yields and increase heavier products – light cycle oil (LCO) and heavy cycle oil (HCO).

In the disengaging section, steam helps separate the now-deactivated catalyst from the reaction products. The spent catalyst goes to the regenerator by gravity, where the coke is burned away by fluidized combustion in the presence of air or oxygen-enriched air. The regenerated catalyst is hot, with temperatures up to 1350 °F (732 °C). It returns to the riser-reactor, where the cycle begins again.

In a 60 000 bbl/day unit processing a typical mixture of vacuum gas oils, the total catalyst in the unit (the *inventory*) is 400–500 t. To maintain activity, about 0.5–1 wt% of the inventory is replaced each day. If the feed to the unit contains significant amounts of residue, the replacement rate is higher. The discharged catalyst

Fig. 17.30 FCC process flow

is cooled and shipped either to a landfill for disposal or to another refiner, which might need a *conditioned* FCC catalyst.

FCC Pretreating and FCC Gasoline Posttreating

Conventional hydrotreating does a good job of removing sulfur from FCC feed. This leads to lower sulfur in FCC products. Once-through mild hydrocracking does a much better job. During the run-up to ULSD, more than 100 hydrocrackers for pretreating FCC feed were commissioned worldwide. Collectively known as hydroprocessing, hydrotreaters and hydrocrackers also remove nitrogen and aromatics, improving FCC operation and greatly increasing gasoline yields [17.55, 56].

Unfortunately, despite feed pretreatment, FCC gasoline can still contain up to 150 ppmw sulfur – far more than the specification of 10–15 ppmw. Additional hydrotreating of the FCC gasoline removes additional sulfur, but if not conducted with care it also reduces octane by saturating C₆–C₁₀ olefins.

In processes such as Prime-G+ [17.57], offered for license by Axens, full-range naphtha is split into light and heavy fractions. The light fraction contains most of the high-octane olefins but not much of the sulfur. After diolefins are removed via selective hydrogenation, the light cut is ready for gasoline blending. The heavy fraction contains most of the sulfur but not much of the olefins. It is then hydrotreated conventionally.

The S-Zorb process [17.58], invented by ConocoPhillips, uses selective adsorption to remove sulfur from FCC gasoline. The feed is combined with a small amount of hydrogen, heated and injected into an expanded fluid-bed reactor, where a proprietary sorbent removes sulfur from the feed. A disengaging zone in the reactor removes suspended sorbent from the vapor, which exits the reactor as a low-sulfur stock suitable for gasoline blending. The sorbent is withdrawn continuously from the reactor and sent to the regenerator section, where the sulfur is removed as SO₂ and sent to a sulfur recovery unit. The clean sorbent is reconditioned and returned to the reactor. The rate of sorbent circulation is controlled to help maintain the desired sulfur concentration in the product.

Residue FCC

Some FCC units process significant amounts of residue. These units use catalyst coolers (e.g., steam coils) in the regenerator or a second regeneration zone to remove excess heat from the unit. This is because residue generates substantially more coke than conventional FCC feeds and excess heat is generated when the extra coke is burned off the catalyst. The trace-metal content of residues can be very high. Trace metals destroy FCC catalysts, so removing them – usually with hydrotreating – is essential (Chap. 21).

Residue FCC (RFCC) units, also known as heavy oil crackers, can process atmospheric residue (650 °F+, 340 °C+) and vacuum residue to produce gasoline and lighter components [17.59]. It generates substantially more coke than conventional FCC feeds. Excess heat

is generated when the extra coke is burned in the regenerator and residues contain high amounts of trace metals, particularly nickel and vanadium. Those metals destroy FCC catalysts. Residue FCC units must handle both challenges. The metals are removed in upstream hydrodemetalation (HDM) units. Catalyst coolers and supplemental regenerators recover the excess heat. The UOP two-stage stacked regenerator with catalyst cooler is an external vertical shell-and-tube heat exchanger [17.60]. Catalyst flows across the tube bundle in the dense phase. UOP's air lance distribution system ensures uniform air distribution within the tube bundle and a uniform heat transfer coefficient. The generation of steam (up to 850 psig; 5800 kPa) from the circulating water is used to remove heat from the regenerated catalyst. Three different styles of catalyst coolers – flowthrough, back-mix and hybrid – have been designed and commercialized to accommodate a wide range of heat removal duties as well as physical and plot-space constraints.

17.6.7 Other Processes

The above processes are specifically designed to increase gasoline yield. Other refining processes produce naphtha with low or high sulfur and/or low octane rating. For example, the light naphtha fraction from a hydrocracker can be blended directly into the gasoline pool, but the heavy naphtha must first go to a catalytic reformer for production of high-octane reformate. High-sulfur coker naphtha must be hydrotreated and maybe reformed before it can be blended.

17.7 Synthetic Gasoline

Gasoline can be synthesized from synthetic gas (syngas), a mixture of carbon monoxide and hydrogen, via conversion into methanol (17.1) followed by a methanol-to-gasoline (MTG) process. The overall process is also known as syngas-to-gasoline (STG+) or syngas-to-gasoline plus (STG+).

The source of carbon monoxide can be from steam reforming of natural gas to convert to syngas (17.2) or partial oxidation of heavy petroleum fractions, coal and biomass.

Syngas can also be converted into jet fuel, diesel and heavier linear alkanes through Fischer–Tropsch synthe-

sis. With proper selection of boiling range, these linear alkanes can be isomerized into gasoline or lubricant base oils.

Hydrogen can also be generated from carbon monoxide through water shift reaction (17.3).

Methanol-to-gasoline (MTG) technology was developed at Mobil (now ExxonMobil) in the early 1970s. In the process, methanol is first dehydrated to give dimethyl ether (DME) (17.4)

DME is then further dehydrated over a zeolite catalyst, ZSM-5, to yield a gasoline range of hydrocarbons,

including alkanes (paraffins), aromatics, naphthenes (cycloparaffins) and small amount of alkenes (olefins) of mostly C₆ to C₁₀. Over 80 wt% of the hydrocarbon products are C₅+

In converting methanol to gasoline, ZSM-5 is deactivated over time by a carbon buildup forming coke on the surface. The catalyst can be reactivated by burning off the coke in a stream of hot (500 °C; 930 °F)

air. However, the number of reactivation cycles is limited.

In the MTG+ process, the DME product is further treated by transalkylation and hydrogenation to reduce durene (1,2,4,5-tetramethylbenzene) and isodurene, which have high freezing points, leaving synthetic gasoline with high octane and desirable viscometric properties.

17.8 Reformulated Gasoline (RFG) in the United States

Gasoline blending used to be much simpler. As mentioned, deficiencies in octane could be compensated with TEL, sulfur wasn't regulated and other concepts – photochemical smog, volatile organic compounds (VOC) and air toxics – were ignored or not yet defined. But in the 1970s, smog had become a major problem in Los Angeles, the effects of acid rain had become unacceptable and the toxicity of TEL was verified and the carcinogenicity of benzene was recognized.

Gasoline blending became more complex in 1970, when the US Congress created the Environmental Protection Agency (EPA) [17.61] and passed the first of three amendments to the Clean Air Act of 1963. One of the main provisions required the phase-out of TEL. The amendments, passed in 1970, 1977 and 1990, also empowered the EPA to impose emissions limits on automobiles and to require reformulated gasoline (RFG). The titles of the Clean Air Acts that impact gasoline include the following:

1. Title I – Programs and activities:
 - Part A – Air quality and emissions limits
 - Part B – Ozone protection
 - Part C – Prevention of significant deterioration of air quality
 - Part D – Plan requirements for non-attainment areas.
2. Title II – Emission standards for moving sources:
 - Part A – Motor vehicle emission and fuel standards
 - Part B – Aircraft emission standards
 - Part C – Clean fuel vehicles.
3. Title IV-A – Acid deposition control.

Title II-A deals with RFG. It was implemented in several phases. The Phase I program started in 1995 and mandated RFG for ten large metropolitan areas. Several other cities and four entire states joined the program voluntarily. Phase II, the current phase, started on 1 January 2000.

Tier 1 RFG regulations required a minimum amount (2%) of chemically bound oxygen, imposed upper limits on benzene and Reid vapor pressure (RVP) and ordered a 15% reduction in volatile organic compounds (VOCs) and air toxics. VOCs react with atmospheric NO_x to produce ground-level ozone. Air toxics include 1,3-butadiene, acetaldehyde, benzene and formaldehyde.

The regulations for Tier 2, which took force in January 2000, were based on the EPA complex model, which estimates exhaust emissions for a region based on geography, time of year, mix of vehicle types and – most important to refiners – fuel properties. As of 2006, the limit on sulfur in the gasoline produced by most refineries in the US was 30 wppm. By 2017, the limit of sulfur in gasoline will be 10 wppm.

Initially, the oxygen for RFG could be supplied as ethanol or C₅–C₇ ethers. The ethers have excellent blending octanes and low vapor pressures. Methyl-*t*-butyl ether (MTBE) can be produced at refineries in low cost and was originally used. However, MTBE is extremely soluble in water, it moves farther and more rapidly through both groundwater and surface water than gasoline. Due to leaks from filling station storage tanks, methyl-*t*-butyl ether (MTBE) was detected in ground water samples in New York City, Lake Tahoe and Santa Monica, California. In 1999, the Governor of California issued an executive order requiring the phase-out of MTBE as a gasoline component. That same year, the California Air Resources Board (CARB) adopted California Phase 3 RFG standards, which took effect in stages starting in 2002. The standards include a ban on MTBE and a tighter cap on sulfur content – 15 wppm maximum. In the United States, Tier 3 vehicle emission and fuel standards will lower the allowed sulfur content of gasoline to 10 wppm, beginning in 2017.

Alcohols are alternatives to ethers. Methanol is not as compatible with engine fuel systems as ethanol, which is now required for US RFG. However, ethanol attacks rubber and some kinds of gasket materials. It

also attracts and holds moisture, accelerating corrosion in steel fuel tanks/lines/fittings.

RFGs have lower heating values than conventional gasoline. The BTU content of ethanol is 30% lower. That means lower fuel economy. Ethanol RFG has a considerably shorter shelf life than conventional gasoline (90 days is considered the practical limit) before phase separation occurs. It has been argued that the need for oxygenated fuels is unfounded in automobiles equipped with fuel oxygen sensors. Also, 75–85% of the smog in major cities is from nonautomobile sources and tailpipe emissions of new cars are 95% lower than they were in the 1960s [17.62].

Butanol is generally used as an industrial solvent. It can also be blended with gasoline and used as a transportation fuel as a possible alternative to ethanol. Isobutanol is especially suitable. Butanol is commonly produced using fossil fuels, but it can also be produced from biomass, in which case it is called biobutanol. Biobutanol is produced from the same feedstocks as ethanol—corn, sugar beets and nonfood sources, such as corn stalk, wood, leaves and switch grass.

Butanol has slightly a lower octane rating than ethanol. The RON and MON for butanol are 96 and 78 versus 107 and 89 for ethanol [17.63]. However, it

has a higher energy density – 32 MJ/l – only slightly less than conventional gasoline (also 32 MJ/l) but far higher than ethanol (19.6 MJ/l). Hence, butanol has better fuel economy than ethanol. Due to lower water solubility, it does not damage engines like ethanol. Also, it does not separate from gasoline in the presence of water. Hence, butanol has a longer shelf life. It can be blended at the refinery rather than at blending terminals.

Butanol may be used directly as a fuel because its longer hydrocarbon chain is nonpolar; more similar to gasoline than ethanol. Butanol has been demonstrated to work in vehicles designed for use with gasoline without modification.

Biobutanol has been produced by acetone-butanol-ethanol (ABE) fermentation using a bacterium, *Clostridium acetobutylicum*, from carbohydrates such as starch and glucose, invented 100 years ago [17.64]. However, the process produces too little butanol and too many unwanted products that have to be separated out. A family of new catalysts that convert ethanol to butanol in high yield and at large scale have been developed in the lab with 95% yield demonstrated. It is estimated that it will take another 10–15 years for butanol to replace ethanol economically.

17.9 Gasoline Additives

A formulated (or finished) gasoline contains base fuel and small amounts of additives. Typical additives include metal deactivators, corrosion inhibitors, antioxidants, detergents, demulsifiers, anti-icing additives and oxygenates. Table 17.6 lists the additives used to pre-

pare finished gasoline. Additive packages vary from season to season, region to region and retailer to retailer. After-market additives contain similar types of ingredients and usually are more concentrated. They are packaged to be added by consumers to their own vehicles.

Table 17.6 Additives used in gasoline

Additive type	Function
Oxygenates	Decrease emissions
Antioxidants	Minimize oxidation and gum formation during storage
Detergents	Clean fuel injector and minimize carbon deposit
Metal passivators	Deactivate trace metals that can accelerate oxidation
Corrosion inhibitors	Minimize rust and corrosion throughout the gasoline supply chain
Demulsifiers	Prevent the formation of stable emulsion
Anti-icing additives	Minimize ice in carburetors during cold weather
IVD control (detergent)	Control deposition of carbon on intake valves
CCD control	Control deposition of carbon in combustion chambers

17.10 Blending Optimization

Refinery product blending is a daunting task. It has evolved from a guessing game into a sophisticated model-based, price-driven optimization problem involving information from the entire refinery and beyond.

A major objective of blend optimization is to reduce product quality giveaway. This can be difficult if intermediate cuts are sloppy – if they are contaminated with heavy ends. The best place to limit giveaway is to improve fractionation and/or stripping within the process units.

Essential elements of product blending include:

- The number of finished products
- Storage infrastructure
- Analysis infrastructure
- Blendstock properties
- Product flexibility
- Blending frequency
- Transportation infrastructure
- Postblending considerations
- Product quality waivers
- Product certification method
- Advanced control and real-time database infrastructure.

It has been said that preparing low-octane *regular* blends offers greater blend-optimization opportunities

than preparing high-octane *premium* blends, because only certain components can go into high-octane products. This statement is incorrect. Greater benefits accrue when all grades are considered within the same optimization problem. Even greater benefits accrue when the quality and volume of jet and diesel production are included.

Blend optimization is relatively easy in refineries with ample storage for intermediate streams. Such is not always the case. Problems arise when, due to lack storage residence time, it is difficult to analyze streams before they are on their way to the blending complex. With modern instruments, the analysis problem can be minimized. Near-infrared (NIR), Raman or other spectroscopic techniques can serve as the basis for estimating RON, MON, distillation, benzene, olefins, aromatics and specific gravity. Online sulfur analyzers also are available.

The best place to start is with an organized library of successful recipes. With database software and a good regression program, the library can be quickly searched for the recipe that most closely matches available streams. Back-casting – comparing actual blend properties with ideal properties – can predict how small adjustments can improve profit. It is crucial to ensure that all analyses, including spectra, are correctly associated with individual blendstocks and the final blend.

Catalytic Reforming

Pierre-Yves le Goff, William Kostka, Joseph Ross

Since the early 1940s, dual function catalysts have been converting lower octane, naphtha-range hydrocarbons into aromatics and higher octane blend stock for petrochemical and gasoline production while producing valuable hydrogen as a by-product. Early on, the associated technology became known as *catalytic naphtha reforming* to acknowledge that the desired products resulted from molecular rearrangement, reforming, of the reactants without alteration of their carbon number. Numerous improvements in catalyst and process technology have been commercialized over the past seven plus decades. Catalytic naphtha reformers remain key units in essentially every refinery and petrochemical plant throughout the world.

This chapter provides an overview of catalytic naphtha reforming with sections on the role of catalytic naphtha reforming in the refining and petrochemical industries, naphtha feedstock characteristics, reforming reactions, reforming catalysts, catalyst contaminants, process and catalyst evolution, and catalyst regeneration.

18.1	Objective of Catalytic Reforming	589
18.1.1	Role of Reforming in the Motor Gasoline Pool	590
18.1.2	Reforming for Aromatics Production	591

18.1 Objective of Catalytic Reforming

The major objective of catalytic reforming is to transform low-octane naphtha (C_6 – C_{10} hydrocarbons) into high-octane gasoline and by-product hydrogen. The principal means of obtaining the increase in octane is the conversion of paraffins and cycloparaffins (naphthenes) into aromatics (Fig. 18.1). Catalytic reforming accounts for a large share of the world's gasoline production and is the most important source of aromatics

for the petrochemical industry. Reforming is also a major source of refinery hydrogen, the demand for which is growing rapidly as a result of escalating hydrotreatment requirements.

In order to achieve these objectives, specialized multifunctional precious metal catalysts are employed in fixed bed or moving bed reactors. As a result of catalyst aging or deactivation by coke deposition, the

Fig. 18.1 Simplified main reactions in catalytic reforming

catalyst must be periodically or continuously regenerated in a process referred to as semiregenerative, cyclic, or continuous catalyst regeneration (CCR) catalytic reforming.

18.1.1 Role of Reforming in the Motor Gasoline Pool

The petroleum refining industry now processes almost 90 million barrels per day (BPD) of crude oil to supply the transportation motor fuels and other petroleum-based products to meet the world demands. The main transportation fuels are gasoline, jet, and diesel, and each has a set of specifications on physical and chemical properties for their efficient use in engines. Although motor gasoline demand accounts for about 25% of the crude oil processed, it is not found in the required amount or quality in the raw crude oil. The refining industry has, therefore, developed processes to transform and/or convert much of the crude oil into high-quality gasoline meeting engine and regulatory requirements.

There are over 600 petroleum refineries worldwide employing varying process configurations to produce gasoline and other products. Gasoline, like other fuels, is a composite of several blending components from within the refinery forming a product pool meeting both volume and quality requirements. An example of a refinery gasoline pool configuration is shown in Fig. 18.2.

Today there are over 700 catalytic reforming units in operation for fuels and aromatics production.

The catalytic reforming unit plays an important role in upgrading or reforming low octane material that boils in the gasoline range but does not meet finished product specifications. As shown in Fig. 18.2, the reforming unit is typically part of an integrated *naphtha complex* to upgrade not only *straight run* naphtha found in the crude oil, but also cracked naphtha produced by thermal or catalytic conversion of heavier crude components: delayed or fluid coking (Coker), distillate or resid hydrotreating (HDT) or hydrocracking (HC). Various local regulations on quality often require additional processing of gasoline components, such as hydrodesulfurization (HDS) of naphtha from fluid catalytic cracking (FCC), isomerization of light naphtha, and benzene saturation of the reformer product.

The gasoline pool must meet final product specifications, but individual blend components may not. In fact, each processing unit has certain product gasoline characteristics which complement each other to make a pool that meets specification. Table 18.1 shows a worldwide average gasoline composition with typical component property ranges and typical pool specification. Other specifications on fuel boiling range, sulfur content, stability, corrosion characteristics, and much more also apply.

The hydrocarbon liquid product from the reformer (reformate) is a vital gasoline blend component to meet pool octane requirements and is the only process unit with wide flexibility in product octane, typically 90 to 102. Higher severity operation is possible with octane greater than 102, but this is typically reserved for reformers dedicated to aromatics production as discussed later. On the other hand, reformer gasoline or reformate is the leading source of gasoline aromatics and benzene which are both subject to regulatory controls.

18.1.2 Reforming for Aromatics Production

The other major application for catalytic reforming is aromatics production for petrochemicals and polymers. The most important aromatics are the so-called BTX components: benzene, toluene, and xylenes. Historically, BTX has been readily available as a by-product mainly from ethylene plants (so-called steam crackers) that thermally convert feedstock into light olefins and by-product pyrolysis gasoline, or PyGas. When the ethylene plant feedstock is naphtha, the aromatics-rich PyGas yield can be on the order of 25–40% thereby supplying valuable aromatics for the petrochemical and polymer industry. In recent years, low-cost ethane from the Middle East and North American Shale-Gas has caused ethylene plants to shift toward ethane cracking which produces very little by-product PyGas. As the worldwide demand for BTX and particularly paraxylene (PX) has rapidly grown, on-purpose production of aromatics has become the norm in large aromatics complexes based on the catalytic reforming of naphtha.

Today, catalytic reforming has established itself as the most important process for the production of

aromatics with more than one-third of all worldwide reformers configured for maximum aromatics production. Figure 18.3 shows the worldwide demand for BTX and the strong dependence on reformate from catalytic reformers to supply BTX, particularly xylenes.

The demand for polyethylene terephthalate (PET) polymer accounts for the largest consumption of xylenes, and in particular PX. With worldwide growth

Fig. 18.3 Worldwide supply of BTX aromatics by source

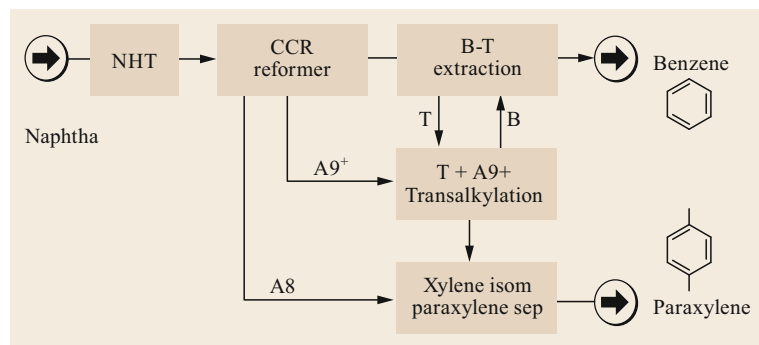

Fig. 18.4 Simplified scheme of an aromatic complex oriented to benzene and PX

of PET projected to be an impressive 6% per year, on-purpose aromatics production is growing rapidly. Highly integrated complexes with high-severity catalytic reformers coupled with aromatics transformation processes are able to produce BTX. When desired, such

complexes can be designed to selectively produce approximately 55–65% of PX from a typical naphtha feedstock.

Figure 18.4 provides a very simplified scheme for an aromatics complex.

18.2 Feedstock Characteristics and Treatment

The reforming unit processes a naphtha cut or petroleum fraction with an initial and final boiling point range from about 80 up to 200 °C, roughly corresponding to C₆–C₁₀ hydrocarbons.

In a straight-run naphtha cut, the main hydrocarbon types are paraffins, naphthenes (cycloparaffins), and aromatics. Naphtha originating from thermal or catalytic cracking (coking, visbreaking, pyrolysis, FCC) also contain olefinic hydrocarbons. An important characteristic of naphtha is the octane number as this relates to combustion performance in an engine, where a higher octane is preferred. Research octane numbers (RONs) for representative components in the C₆–C₈ range are shown in Table 18.2. Linear paraffins have the lowest RON and the aromatics have the highest [18.1, 2]. Paraffin-rich naphtha, therefore, has a low octane and requires reforming to increase the aromatics content and RON to meet motor gasoline requirements, typically over 90 RON.

A convenient measure of the quality of a reformer feed and indication of octane potential is its content of

aromatics (A) plus naphthenes (N) which are readily converted to aromatics in the reforming unit. A useful correlating parameter for feed quality is the combination N+2A in the feed, which represents the sum of the naphthene content and two times the aromatic content. Higher values of this parameter correspond directionally to more easily converted or reformed feeds resulting in higher reformate yield for a given octane.

The main sources of naphtha for catalytic reforming are as follows:

- Straight-run (SR) naphtha
- Naphtha produced in hydroprocessing units (HDT and HC)
- Coker naphtha (naphtha produced in delayed or fluid coking unit)
- VB naphtha (naphtha produced in a vis-breaker unit)
- Selected portions of FCC naphtha (naphtha produced in a FCC unit)
- PyGas from an ethylene plant or steam cracker.

These naphtha streams have widely different elemental and molecular compositions and contaminant levels as shown in Table 18.3. Sulfur, nitrogen, and silicon are harmful contaminants to the precious metal-reforming catalyst and, therefore, must be removed in an upstream naphtha hydrotreating unit (NHT). The limits on S and N are typically 0.5 ppm weight to limit precious metal catalyst inhibition and salt formation leading to corrosion and fouling in the catalytic reforming unit. Olefins are saturated to less than 0.5–1 wt% in order to minimize coke formation in the reforming unit.

When comparing cracked naphtha to SR naphtha, the first obvious difference is that the sulfur and nitrogen levels can be much higher, especially in thermal cracked naphtha. The sulfur can be readily removed in the NHT, but the nitrogen compounds are more problematic with cracked stocks containing more basic, cyclic nitrogen compounds such as pyridines and anilines. These nitrogen species require a two-step reaction of ring saturation and opening followed by nitrogen removal as controlled by an overall equilibrium relationship that is favored by higher pressure. The combined effect of these compositional differences has a significant impact on the NHT design and pressure requirements.

Thermally cracked naphtha from vis-breaker or coking units, and FCC naphthas contain a high concentration of olefins, and some diolefins that require very specific NHT catalysts and designs to overcome gum and coke formation due to diolefin polymerization, and handle the high exotherm from diolefins and olefins saturation.

Additional precautions must be taken when processing coker naphtha that contains silicon from antifoaming additives injected in the coking process. Silicon is a poison to both the NHT catalyst and the downstream-reforming catalyst. A silicon guard bed at the inlet of the NHT, and in extreme cases a separate guard reactor, can be mandatory to protect the downstream catalyst. As seen in Figs. 18.5 and 18.6, the presence of these contaminants has a significant impact in NHT unit design.

In a straight-run NHT flow scheme, the feed and hydrogen are heated before entering the reaction section. The reactor effluent is cooled by preheating the feed in the feed-effluent exchanger and then in an air or water cooler before entering a separator drum. The hydrogen-

rich gas leaving the drum is recycled to the reactor, while the liquid phase is sent to the stripper where small amounts of light ends are removed. There is a make up of hydrogen (M/U H₂) to compensate for hydrogen consumption by chemical reaction and dissolution, while in the stripper section methane and ethane (FG – fuel gas) together with H₂S and NH₃ are removed.

When processing coker naphtha, a lead liquid phase diolefin reactor is used to saturate the diolefins present in the feed and avoid fouling, coking, and pressure drop in the downstream main hydrotreating reactor. The gas phase HDT reactor is more complex than the straight-run feed case with multiple catalyst beds to complete olefin saturation, trap silica contaminants, and finally remove sulfur and nitrogen.

In the case of a highly olefinic feed, a quench system can be added between catalyst beds to control the exotherm from olefin saturation.

7	1.7	0.3	0.5	0.3
8	2.0	0.6	1.5	0.5

After pretreatment in the NHT, the naphtha product should have essentially no sulfur, nitrogen, or olefins. The molecular composition in terms of paraffin, naphthene, and aromatics (PNA) will then determine the potential yield in the reforming unit subject to its design, catalyst type, and operation.

An illustration of the importance of feedstock quality on reformer performance is shown in Fig. 18.7. A feed rich in paraffins (low N+2A content) is more difficult to reform into high-octane aromatics than a low paraffin feed. When processing a paraffin-rich naphtha, the severity of the process (temperature and/or catalyst contact time) must be higher to attain the desired RON octane resulting in a higher yield loss to undesirable light by-products. Reformate RON octane is, therefore, the commonly used measure of overall unit severity. When the feed is rich in naphthene and aromatics (low in paraffins), milder operating conditions can be used to achieve the same RON and with a higher reformate yield.

An important concept is that the product reformate yield decreases as the severity of the unit is increased to produce a higher octane reformate. The economics based on feed quality determines the practical RON that can be obtained as balanced against yield loss and rate of coke formation that will limit unit operation.

18.3 Main Reforming Reactions

There are many possible chemical reactions in the reforming process. For any chemical reaction, thermodynamics dictates the possibility of its occurrence and the amount of products and unconverted reactants. Under certain conditions (pressure and temperature), some reactions are 100% completed, that is, all the reactants are converted into products. Others are in equilibrium, that is, only a part of the reactants are converted. Note that the thermodynamic equilibrium does not mention the time required to reach the equilibrium or the extent of a reaction.

Kinetics dictates the rate of a chemical reaction (i.e., the amount of feed that disappears in, say, 1 s). Kinetics (rate of reaction) is dependent upon operating conditions but can also be widely modified by using

**Fig. 18.7** Impact of N+2A and RON on reformate yield

Although N+2A is a convenient feed parameter and naphthenes are relatively easier to convert to aromatics than paraffin, the type of naphthenes are important in terms of reaction kinetics and potential products. Looking in greater detail into molecular composition, cracked naphthas have a much lower ratio of naphthenes with a six-carbon ring (cyclohexanes) to naphthenes with a five-carbon ring (cyclopentanes) than SR naphthas as shown in Table 18.4. The cyclohexanes are much more easily transformed into aromatics than the cyclopentanes. As a consequence, cracked naphtha is more difficult to reform.

properly selected catalysts. One reaction (or a family of reactions) is generally enhanced by a specific catalyst.

In other words, thermodynamics dictates the ultimate equilibrium composition assuming that the time is infinite. Kinetics enables the prediction of the composition after a finite time. Since time is always limited, when reactions are competing, kinetics is generally predominant.

As for all processes, the chemical reactions involved in reforming are of two types:

- *Desirable reactions*, that is, reactions that lead to an increased aromatics production and octane number as well as a high-purity hydrogen production. These are the reactions to promote.

- *Undesirable reactions*, that is, reactions that lead to a decreased octane number, a decrease in hydrogen purity, or a loss in desired products yield. These are the reactions to minimize.

Moreover, these chemical reactions can also be sorted in two other families:

- *Endothermic reaction*. These reactions require heat energy to proceed and according to Le Chatelier's principle are promoted at high temperature
- *Exothermic reaction*. These reactions give off heat and according to Le Chatelier's principle are thermodynamically hindered at high temperature.

In the case of catalytic reforming, most of the desirable reactions are endothermic while most of the undesirable reactions are exothermic.

18.3.1 The Role of the Catalyst

The role of the catalyst is to improve the rates of desirable reactions while reducing the rates of undesirable reactions, but it does not change the thermodynamics. In reforming dehydrocyclization, cycloparaffin dehydrogenation, and isomerization reactions are desirable as they increase RON, produce aromatics and hydrogen as shown in Fig. 18.1. The undesirable side reactions are mainly hydrogenolysis and hydrocracking which are to be avoided as they produce low-value gases and consume hydrogen [18.3]. Both reaction types are summarized in Fig. 18.8.

Reforming catalysts are composed of active metallic crystallites supported on an alumina (Al–OH) ma-

trix, which is acidic in nature and modified by the addition of chloride to achieve a complex catalyst system of metallic and acid reaction sites. The metallic catalyst particles can include one or more active catalyst components to achieve the desired activity and selectivity.

In the following sections, when a reaction is promoted by:

- The metallic function of the catalyst, (m) is written on the reaction scheme.
- The acidic function of the catalyst, (a) is written on the reaction scheme.

As a reminder, an acid is a compound which can donate a proton to a base. In the reforming system, the acid is an Al–OH group while the base is mostly an olefinic-type compound.

18.3.2 Desirable Reactions

Naphthene Dehydrogenation to Aromatics

Naphthenic compounds such as cyclohexane, methyl cyclohexane, dimethyl cyclohexane up to C₁₀ naphthenes are dehydrogenated, respectively, into benzene, toluene, xylenes, C₉ and C₁₀ aromatics with the production of 3 moles of hydrogen per mole of naphthene. The methyl cyclohexane reaction, for instance, proceeds as shown in Fig. 18.9.

Thermodynamically, the reaction is highly endothermic and is favored by high temperature and low pressure. In addition, higher carbon number cyclohexanes yield higher aromatics production at equilibrium [18.4].

Fig. 18.8a,b Desirable (a) and undesirable (b) catalytic reforming reactions

Fig. 18.9
Methylcyclohexane aromatization

From a kinetics view point, the rate of reaction increases with temperature and is not affected by the hydrogen partial pressure. The dehydrogenation reaction rate is high compared to other reforming reactions as discussed in Sect. 18.3.5.

The kinetic and thermodynamic effects are complex with adsorption and desorption of reaction intermediates influencing the reaction rate. The competing effects as influenced by the main parameters governing the dehydrogenation reactions are summarized in Table 18.5.

Under normal reformer operating conditions, the reaction is very fast and almost complete. It is promoted by the metallic function of the catalyst. Since it produces aromatics with a high octane, promoting this reaction is most desirable.

Paraffins Dehydrocyclization

The dehydrocyclization of paraffins is perhaps the most important reaction in reforming, and the most difficult. This is a multiple step process that applies to the normal paraffins (linear) and isoparaffins (branched). It involves a dehydrogenation with a release of one hydrogen mole followed by a molecular rearrangement to

Table 18.5 Impact of operating parameters on naphthene dehydrogenation

Increase of	Effect on dehydrogenation due to	
	Thermodynamics	Kinetics
Pressure	Decreases	Unaffected
Temperature	Increases	Increases
H ₂ /HC ratio ^a	Slightly decreases	Slightly decreases

^a Ratio of pure hydrogen (mol) to hydrocarbon feed (mol)

form a naphthene and the subsequent dehydrogenation of the naphthene. The molecular rearrangement to build a naphthene is the most difficult reaction to promote, however, the subsequent aromatization of the naphthene yields a noticeable octane increase [18.5]. It is important to note that most of the naphthenes initially formed are built on a five-carbon ring nucleus, which are thermodynamically favored.

The reaction can be summarized as shown in Fig. 18.10 [18.5].

The paraffin dehydrocyclization step becomes easier as the molecular weight of the paraffin increases; however, the tendency of paraffins to hydrocrack increases concurrently (discussed later related to Fig. 18.22).

Kinetically, the rate of dehydrocyclization increases with low pressure and high temperature (discussed later related to Figs. 18.20 and 18.21), but at typical operating conditions this rate is much lower than that of naphthene dehydrogenation by a factor of roughly 30:1. The reaction is promoted by both metallic and acidic functions of the catalyst with the formation of the naphthene being the rate-controlling step. Table 18.6 summarizes the impact of operating parameters on the dehydrocyclization reaction.

The positive impact of pressure and temperature on the thermodynamics is, as for the naphthenes, explained by Le Chatelier's principle. Contrary to naphthenes dehydrogenation, the pressure has a negative impact on the reaction rate due to a more complex reaction scheme and formation of specific intermediates.

Table 18.6 Effect of parameters on paraffin dehydrocyclization

Increase of	Effect on dehydrocyclization due to	
	Thermodynamics	Kinetics
Pressure	Decreases	Decreases
Temperature	Increases	Increases
H ₂ /HC ratio	Slightly decreases	Slightly decreases

Fig. 18.10 Dehydrocyclization of paraffins

Linear Paraffin Isomerization

The acid-promoted isomerization reaction is important to convert linear paraffins into higher octane-branched paraffins. The reaction can be seen as shown in Fig. 18.11.

If the intermediates are taken into account, the actual scheme changes (Fig. 18.12).

These reactions are fast, slightly exothermic, and the number of carbon atoms does not change. The thermodynamic equilibrium of isoparaffins to normal paraffins depends mainly on the temperature (low temperature favorable) and increases with the carbon number of the paraffin as shown in Table 18.7. The pressure has no effect on the equilibrium.

The paraffins isomerization results in an increase in the octane number. From a kinetic view point (Figs. 18.20 and 18.21), high temperature favors isomerization but hydrogen partial pressure has no effect. These reactions are promoted by the acidic function of the catalyst support.

Naphthenes Isomerization

The isomerization of an alkylcyclopentane into an alkylcyclohexane involves a ring rearrangement and is desirable because of the subsequent dehydrogenation of the alkylcyclohexane into an aromatic. By virtue of the difficulty of the ring rearrangement, the risk of ring opening resulting in paraffin is high.

The reaction is slightly exothermic and is summarized in Fig. 18.13.

Theoretically, at typical reforming operating temperature (about 500 °C), thermodynamics limits the alkylcyclohexane formation. However, the subsequent dehydrogenation of the alkylcyclohexane into an aromatic is very fast and shifts the reaction toward the desired direction. This type of reaction is also easier for higher carbon number molecules.

The octane number increase is significant when considering the end product (aromatics) as shown in Table 18.8.

18.3.3 Undesirable Reactions

Hydrocracking

Hydrocracking affects either paraffins (normal or iso) or naphthenes. It involves both the acid and metallic functions of the catalyst. It is, to some extent, a parallel reaction to paraffin dehydrocyclization.

As shown in Fig. 18.14, hydrocracking can be represented schematically by a first step of dehydrogenation, which involves the metallic function of the catalyst, followed by a cleavage of the resulting olefin and the hydrogenation of the subsequent short-chain olefin. The second step of the reaction is promoted by the acidic function of the catalyst [18.6, 7].

At the selected operating conditions, hydrocracking reactions would be almost complete according to thermodynamics. Fortunately, however, the cracking reactions are somewhat limited by kinetics. Compared to its desirable concurrent reaction (dehydrocyclization), hydrocracking becomes even more significant as the temperature increases.

Fig. 18.13 Naphthene isomerization

Fig. 18.12 Paraffin isomerization mechanism

Fig. 18.14 Schematic representation of paraffin cracking

The main effects of hydrocracking are as follows:

- A decrease in paraffins in the reformat, which results in an increase in the aromatics by concentration, that is, an increase in octane and a loss of reformat yield.
- A decrease in hydrogen production.
- An increase in LPG production.

Hydrogenolysis

This undesirable reaction has some similarity with hydrocracking since it involves hydrogen consumption and cleavage of bonds. However, it is promoted solely by the metallic function of the catalyst and, as opposed to hydrocracking, leads to lighter $C_1 + C_2$ hydrocarbons, which are even less valuable than LPG ($C_3 + C_4$) (Fig. 18.15).

Hydrogenolysis also affects the naphthenes, mainly C_5 ring naphthenes. The carbon-carbon bond cleavage results in opening of the ring and formation of paraffinic products. The overall reaction is summarized in Fig. 18.16.

In this latter case, an increase in the hydrogen partial pressure has a positive effect on the reaction kinetics.

Alkylation and Dealkylation of Aromatics

Alkylation is a condensation reaction, which adds an olefin molecule on an aromatic ring (Fig. 18.17). It results in an aromatic with an increased molecular weight.

This reaction, promoted by the catalyst acid function, does not consume hydrogen, but it leads to heavier molecules that may increase the end point of the product. In addition, the high-molecular-weight hydrocarbons also have a high tendency to form coke that deposits on the catalyst and suppresses activity. This reaction must be avoided.

On the other hand, dealkylation, the reverse reaction, occurs mainly for alkyl chains having more than three carbon atoms on an aromatic ring and results

Fig. 18.15 Schematic representation of the hydrogenolysis of paraffin

Fig. 18.16 Schematic representation of naphthene cracking

Fig. 18.17 Schematic representation of alkylation and dealkylation

in reduction of liquid and hydrogen yield and increased production of benzene (Fig. 18.17). Operation at higher pressure and temperature favors dealkylation and presents a challenge in meeting low benzene in gasoline regulations.

Coking

Coke formation on the catalyst results from a very complex group of chemical reactions, the detailed mechanism of which is not fully known. The coke has a negative impact on catalyst performance as it remains on the catalyst, covers the active surface area, and hence reduces catalyst activity.

In reforming, two types of coke can be distinguished according to their combustion temperature. The coke located on or nearby the metallic function contains relatively more hydrogen and burns at a low temperature of around 300°C , whereas coke on the alumina support contains relatively less hydrogen and requires a high temperature from 400°C to 500°C to oxidize during regeneration. Moreover, the coke deposited on the alumina is not homogenous, indeed even at high overall coke content on the catalyst, there are areas on the alumina support free of coke [18.8].

The coke is characterized by its hydrogen-to-carbon ratio, on a mole basis the ratio is around 1–1.2 indicating a polyaromatic deposit.

According to nuclear magnetic resonance (NMR) spectroscopy, coke is made from condensed aromatics rings with some methyl groups. A typical representation of a *high-temperature* coke is given in Fig. 18.18, with the stacking of aromatic rings.

Even if there is no detailed coke formation mechanism, coke formation is linked to the presence of heavy unsaturated products such as polynuclear aromatics resulting either from the feed or from the reforming reactions. Traces of heavy olefins or diolefins produced by the reforming reactions will promote coke formation.

The presence of cyclopentanes also promotes coke formation. At the light end of the feed spectrum, large quantities of methylcyclopentane and cyclopentane can promote naphthalene (diaromatic) formation via ring reorganization and condensation. At the other end of the spectrum, heavy molecules with more than nine carbon atoms can intracyclize to make indene type components, which are also coke precursors.

With their high ratio of five-carbon ring naphthenes versus six-carbon ring naphthenes, coker and FCC naphthas make more coke compared to straight-run naphthas. Straight-run naphtha and hydrocracked naphtha also contain five-carbon ring naphthenes, but their overall better reformability reduces operating tem-

perature requirement and results in less coke formation.

As mentioned earlier, coke is linked to the formation of heavily dehydrogenated compounds, therefore low hydrogen partial pressure and high temperature favor coke formation when all other parameters remain constant.

Other factors leading to coke formation include poor gas distribution that leads to stagnant zones in a reactor, and increased acidity from excessive moisture and chloride on the catalyst.

18.3.4 Reaction Network

As described above, many reactions take place in the reforming process. The resulting complex reaction network involves both metallic and acidic reaction sites. Hence, a reforming catalyst must be bifunctional.

Figure 18.19 summarizes the general reaction scheme in terms of acid-catalyzed and metal-catalyzed reactions. Reactions taking place in the horizontal direction are metal catalyzed and those taking place in the vertical direction are acid catalyzed.

18.3.5 Parametric Effects

The effects of the main operating conditions on the rate of the reactions involved in the reforming process are summarized below.

Effect of Hydrogen Partial Pressure

Figure 18.20 shows the relative rate of the various reactions as a function of hydrogen partial pressure on a logarithmic scale. The dehydrogenation rate of a naphthene to aromatic is used as reference and taken at 100 ($\log 100 = 2$). Other reaction rates are measured against this reference.

At lower hydrogen partial pressure (10 bar), the dehydrogenation of naphthene is about 10 times faster than isomerization, 30 times faster than the desired dehydrocyclization reaction of paraffins, and 50–60 times faster than the undesirable cracking reactions (hydrocracking and hydrogenolysis) (Table 18.9) [18.3]. Note that the main cause of increased cracking as the hydrogen partial pressure increases is linked to C₅ naphthene ring opening.

Figure 18.20 shows that there is an incentive to operate at low pressure where the cracking rate is relatively low and the slower dehydrocyclization of paraffin rate increases. Thermodynamics also favors low pressure for dehydrogenation and dehydrocyclization. The only drawback of low pressure is the higher coking rate, which is the reason why low-pressure reformers are equipped with a CCR system.

Isomerization: paraffins	+2	3
Naphthenes	+4	
Cracking	+10	0.5

^a If the heat of reaction is negative, the reaction is endothermic
^b For pressure below 12 bar

Effect of Temperature

Temperature influences the rate of the various reactions as shown in Fig. 18.21. The activation energy can be calculated from the slope of the curves. Dehydrogenation and isomerization have moderate activation energy (≈ 20 kcal/mol) and consequently temperature only slightly increases the rate of these reactions. Dehydrocyclization has a higher activation energy (≈ 35 kcal/mol) and consequently temperature has a greater impact on the rate of this reaction [18.9].

Cracking and coking have higher activation energies (≈ 45 and 35 kcal/mol, respectively). The rate of these undesirable reactions is more significantly increased by increasing temperature.

Considering the activation energy, highly active new or freshly regenerated catalyst and low severity permit lower temperature operation, which favors the desirable reactions over the side reactions. As the cat-

Fig. 18.21 Relative rate (V) of reaction versus temperature. E_a is the activation energy for the respective reaction

alyst deactivates or severity increases, higher operating temperature is required, which favors the undesirable reactions and yield selectivity to desired products declines.

Effect of Carbon Number

The kinetic study of the chemical reactions becomes even more complicated owing to the presence of molecules with different numbers of carbon atoms.

As is the case for thermodynamic equilibrium, the rates of the reactions are affected by the length of the carbon chain of the reactant. Figure 18.22 presents the rates of dehydrocyclization and cracking of C_6 to C_{10} paraffins relative to that of n -heptane.

Figure 18.22 shows that the cracking reaction rate (the curve represents the sum of hydrocracking and hydrogenolysis) increases regularly with the number of carbon atoms, whereas the dehydrocyclization rate exhibits a sudden sharp increase between hexane and heptane as well as between heptane and octane, while

Fig. 18.22 Relative rate of reaction (V) versus carbon number. V_n/V_7 is the relative rate of dehydrocyclization of $C_nH_{2n} + 2VSC_7H_{16}$ cracking

the variation between the higher homologs remains relatively slight.

As a result, the dehydrocyclization of C_6 paraffins to benzene is more difficult than that of C_7 paraffin to toluene, which itself is more difficult than that of C_8 paraffin to xylenes. Accordingly, the most suitable reactive fraction to feed a reforming process is the C_7 – C_{10} fraction. Conversion of the C_6 paraffin to aromatics is one of the most difficult reactions in reforming.

Impact on Catalyst Distribution in Reactors

Thermodynamics and kinetics have shown that there is an optimum operating temperature range of approximately 480–535 °C in order to simultaneously favor the rate of the desirable reactions and limit the undesirable ones to an acceptable level.

Due to the highly endothermic nature of the most important and desirable reactions (naphthene dehydrogenation and paraffin dehydrocyclization), this optimum temperature cannot be sustained throughout

Table 18.10 Reactions distribution as a function of the reactor number

First reactor	Second reactor	Third and fourth reactors

Isomerization	Isomerization	Dehydrocyclization
	Cracking	
	Dehydrocyclization	

the whole catalyst volume in an adiabatic system (Fig. 18.23). Upon entering the reactor and contacting the catalyst, the fast dehydrogenation reaction results in a rapid drop in process temperature. In order to restore the catalyst activity when the temperature has dropped below a critical level, the partially converted reactor feed must be reheated. To achieve this, the catalyst is distributed into several reactors (3 or 4 as shown in Fig. 18.23) and intermediate heaters are provided. The resulting conversion profile for the feed into products is also shown as a function of percentage of total catalyst contacted.

So, in a somewhat simplified but practical way, and for operational guidance, the main reactions that take place in the various reactors are represented in Table 18.10.

From the above analysis, it can be concluded:

- Dehydrogenation reactions are very fast, about one order of magnitude faster than the other reactions and produce high endotherm.
- Low pressure favors all desirable reactions and reduces cracking. To compensate for the detrimental effect of low pressure on coking, a low-pressure reformer requires CCR.
- An increase in temperature favors the kinetics of dehydrogenation, isomerization, and dehydrocyclization, but accelerates the degradation reactions (cracking, coking) even more. Consequently an increase in temperature leads to higher octane reformate product but is also associated with a decrease in reformate yield.
- The reaction rates of important reactions such as paraffins dehydrocyclization increase noticeably with the number of carbon atoms. Cyclization is faster for C_8 paraffin than for C_7 , and for C_7 than for C_6 . Consequently the C_7 – C_{10} fraction is the most reactive feed and C_6 paraffin is the last to be dehydrocyclized to aromatics in the last reactor.

18.4 Reforming Catalyst Overview

18.4.1 Metallic Function

As mentioned previously, reforming reactions require the presence of a metal function dehydrogenation cata-

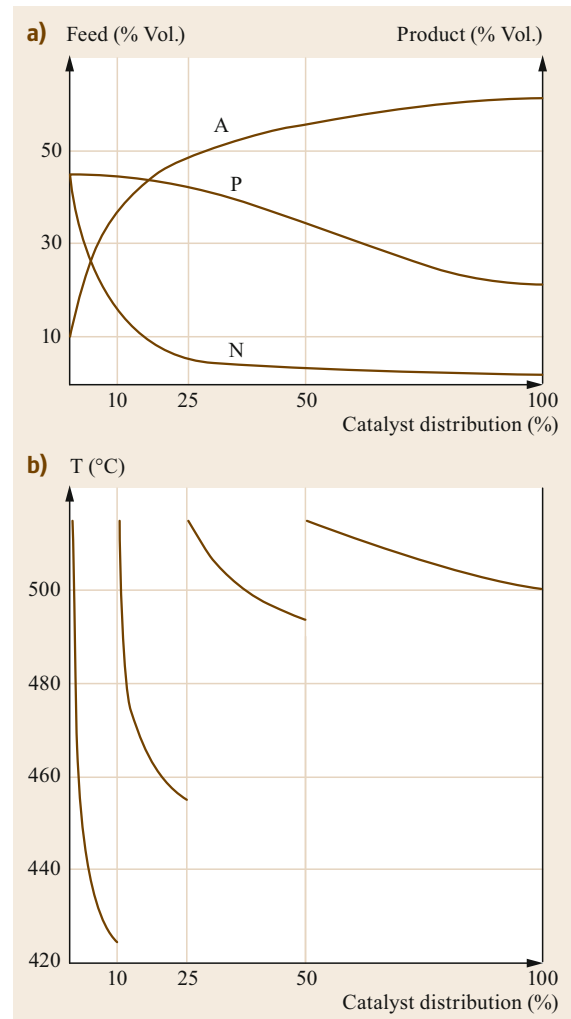

Fig. 18.23a,b Endotherm, catalyst distribution, and hydrocarbon conversion. *P*: Paraffin concentration profile, *N*: naphthene concentration profile, *A*: aromatic concentration profile

lyst and an acid function catalyst for dehydrocyclization and isomerization. Table 18.11 shows the relative dehydrogenation activity of several active metals. The most effective dehydrogenation catalyst is platinum and de-

Table 18.11 Relative catalyst naphthene dehydroisomerization activity (after [18.10])

Metal	Dehydrocyclization activity ratio	
Pt	1	
Ir	0.7	
Re	0.3	
Pd	0.15	

spite its high price, it is the metal of choice for the reforming application.

In order to efficiently utilize the precious metal, platinum is present as very small aggregates with a size close to or even below 1 nm as illustrated by the molecular model shown in Fig. 18.24 obtained by quantum calculations [18.11, 12].

18.4.2 Acid Function

The origin of the catalyst acidity comes from the carrier itself. The carrier is a high-purity γ -alumina doped with chlorine. At reforming conditions, the surface of the alumina is partially hydroxylated and partially chlorinated. These hydroxyl groups act as the acid sites. The strength of their Brønsted acidity is inversely related to their O–H bond strength: a stronger bond makes a weaker acid. By itself, this hydroxyl group does not exhibit sufficient acidity to catalyze the acid–base reac-

Fig. 18.24 Molecular model of Pt₁₃ particle supported on γ -alumina. Hydrogen pressure $p(\text{H}_2) = 10$ bar (platinum particle exhibits ≈ 1 H/Pt atom)

tions at a reasonable rate. Thus the addition of chloride to the catalyst promotes the required acidity since the chloride weakens the O–H bond strength by polarizing electron density away from it to help satisfy its nearly complete outer valence shell. Hence, the presence of chlorine induces a weakening of the hydrogen network of the OH groups on γ -alumina and makes them more available for protonation as shown by recent quantum simulations [18.13]. Catalyst acidity is controlled by the amount of chloride added to the support and the water partial pressure in the reactor. A schematic representation of a reforming catalyst is given in Fig. 18.25.

It is worth mentioning that chloride is also helpful to stabilize the platinum cluster.

Acidity Control

The relative balance between the Al–OH and Al–Cl groups is critical to ensure appropriate catalyst activity and selectivity [18.14]. The number of acid sites is controlled by the water partial pressure above the catalyst. Higher moisture level in the gas results in more acid sites on the surface. The water-to-chloride ratio of the gas above the catalyst determines the catalyst chloride content. Lower water-to-chloride ratios result in more chloride on the catalyst [18.13].

Catalyst surface area and temperature also impact the moisture and water-to-chloride ratio required to achieve the appropriate number and strength of acid sites. As catalyst surface area declines with age (number of regenerations), higher chloride partial pressure and lower water-to-chloride ratio are required to maintain appropriate acidity. As catalyst temperature is increased to increase reactivity, higher chloride partial pressure and lower water-to-chloride ratio are again required to maintain appropriate acidity.

As a basic rule, any increase in catalyst chloride content will increase the acidity and therefore the cracking; on the other hand, any increase in the water content in the feed without appropriate chloride increase to maintain the appropriate water-to-chloride ratio will strip chloride from the catalyst and consequently reduce the acidity and catalyst activity (Fig. 18.26).

In reforming, optimum acidity is typically obtained when the recycle gas moisture is in the range of

Fig. 18.25 Simplistic representation of reforming catalyst acidity

Fig. 18.26 Water and chloride balance

15–25 ppm volume. The associated recycle gas HCl content should be approximately 0.2–0.5 ppm volume depending on temperature, catalyst surface area, and contaminants.

Benefits of a Stable Surface Area

The catalyst carrier provides the surface area over which the acid and metal sites are distributed and the activity and selectivity controlled. As previously mentioned, the catalyst carrier is γ -alumina and has a fresh surface area on the order of 200 m²/g. As the catalyst ages and is subjected to regeneration cy-

cles, the surface area slowly declines primarily due to hydrothermal exposure during periodic regenerations. As the catalyst surface area drops with each successive regeneration cycle, catalyst acidity, Pt dispersion, and coke tolerance become progressively less effective. Thus, a catalyst with superior hydrothermal stability maintains its high surface area, which facilitates hydroxyl and chloride retention to provide the requisite acidity and Pt dispersion for superior performance. It has also been confirmed that chlorine itself improves the stability of small Pt particles [18.15].

18.5 Contaminants and Unit Troubleshooting

The importance of feed contaminants was discussed in general terms in Sect. 18.3. A more detailed review of the impact of contaminants on reforming catalysts is considered in this section.

Catalyst contaminants are classified into three categories: temporary (sometimes called inhibitors), semipermanent, and permanent poisons (Fig. 18.27) [18.16].

Temporary poisons are those that can be removed from the catalyst, either by dilution or release when the source of the contaminant is removed. Normal catalyst activity and selectivity is substantially or fully restored once the contaminant disappears.

The most common temporary poisons (inhibitors) of reforming catalysts are sulfur, organic nitrogen, water, and oxygenated organics. When the contaminant is no longer introduced, normal operation of the unit will return.

Coke is a type of temporary poison that requires interruption of unit operation to regenerate the catalyst and renew catalyst performance. As a result of this discontinuity in operation, it is considered to be a semipermanent poison.

Permanent poisons are those that induce a loss of performance which cannot be recovered, even with regeneration, and which is so severe that the catalyst must be replaced.

For conventional fixed-bed catalysts as well as for continuously regenerated catalysts, the main permanent

poisons are arsenic, lead, copper, iron, sodium, potassium, and silicon. Some of these, like silicon from coker naphtha, only become an issue once the upstream hydrotreater catalyst becomes overloaded with the contaminant.

Both the metallic and acidic sites on reforming catalyst are subject to poisoning. A summary of the main poisons and the type of site each impacts is shown in Fig. 18.28.

18.5.1 Impact of the Main Temporary Poisons

Sulfur

Sulfur is the most common impurity found in the feed of any reforming unit. The maximum allowable concentration is typically specified as 0.5 ppm weight expressed as S. Whenever possible, it is recommended to operate the NHT feed treater to attain an even lower sulfur content and provide additional catalyst stability and selectivity.

Poisoning is caused by H₂S, either contained in the unit feed or resulting from the decomposition of sulfur compounds contained in the feed. H₂S reacts with platinum according to the following equilibrium reaction (Fig. 18.29), and consequently it reduces the activity of the catalyst by decreasing the number of active metallic sites available to catalyze reactions as PtS is inactive for promoting dehydrogenation.

Fig. 18.27 Difference between inhibitors and permanent poisons. Temporary poison: *green curve*; semipermanent poison: *brown curve*; permanent poison: *black curve*

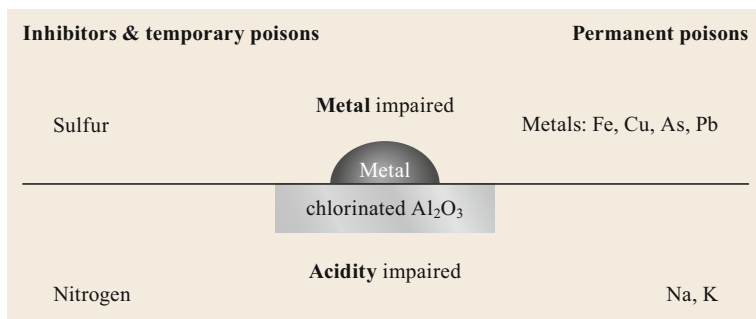

Fig. 18.28 Main reforming catalyst contaminants

Fig. 18.29 Interaction between sulfur and platinum

Catalyst contamination by sulfur is indicated by:

- A decrease in hydrogen yield
- A decrease in recycle gas purity (gas yield increase)
- An increase in hydrocracking (LPG yield increase)
- An increased coking rate
- A reduced temperature drop in the reactors, especially the first reactor where rapid naphthene dehydrogenation occurs, and sometimes an increase in temperature drop across the second reactor as this reaction shifts to the second reactor.

Normally, sulfur removal is achieved by pretreating the naphtha feed in a hydrotreating unit (NHT). Poor operation of the NHT or mechanical issues can result in sulfur breakthrough to the reforming catalyst. Possible causes for this breakthrough include the following:

- Low activity of the hydrotreater catalyst or low hydrogen partial pressure

- Change in NHT feed quality: higher final boiling point, sulfur or nitrogen content
- Excessive NHT temperature resulting in recombinant sulfur formation (H_2S reaction with olefins to produce mercaptans near the reactor outlet)
- A leak in the NHT feed-effluent heat exchanger that allows untreated naphtha to bypass the reactor
- Poor operation of the hydrotreater stripper resulting in dissolved H_2S and H_2O carryover to the reforming unit.

Whenever H_2S contamination is present, the reformer temperature should be maintained in the normal temperature range (despite a drop in octane) to avoid excessive coking of the catalyst. The recycle gas compressor rate should also be maximized to increase the sulfur stripping effect and minimize catalyst coke formation.

These conditions must be maintained until the cause of the upset has been found and corrected. High-severity operating conditions can be resumed once the H_2S content in the recycle gas is lower than 1–1.5 ppm volume.

Nitrogen

In contrast to sulfur, organic nitrogen is less frequently present in the reforming feed and scarcely present in straight-run naphtha. It is a common impurity of cracked naphtha and may also result from injection of amine-based corrosion inhibitors.

The maximum allowable concentration of organic nitrogen in the feed is typically specified at 0.5 ppm weight. Molecular nitrogen (N_2) has no detrimental effect.

Organic nitrogen is a problem because NH_3 forms by decomposition of organic nitrogen compounds in the presence of hydrogen on the reforming catalyst. In the reaction section, NH_3 , which is alkaline, reduces the acidity of the catalyst and increases its rate of chlorine loss. The increase in dechlorination is linked to the lower HCl partial pressure. Overall, these two effects reduce the catalyst activity. In the cold section of the unit, NH_3 reacts with chlorine to form NH_4Cl , which becomes solid below $80^\circ C$. The resulting salt deposition can foul downstream coolers, separators, recycle gas compressor, export gas compressor valves, and cold trays in the stabilizer creating mechanical problems. For a 25 000 BPD reformer, 0.5 ppm weight of organic nitrogen in the feed can lead to approximately 2 t/y of NH_4Cl deposition. Ammonium chloride deposits also raise the risk for under deposit corrosion with trace moisture present. Failure to replenish this lost chloride will reduce the acidic function of the catalyst and result in decreased catalyst activity.

Indicators of nitrogen contamination include:

- Decrease in octane
- Slightly increased hydrogen and C_5+ production.

Like sulfur, organic nitrogen removal is achieved by NHT pretreating of the feed; however, nitrogen removal is more difficult than sulfur removal and often requires the use of a Ni-Mo catalyst operating at higher hydrogen partial pressure than a typical NHT with Co-Mo catalyst. Naphtha with high nitrogen-content requires a NHT specifically designed for high nitrogen feed.

When nitrogen contamination is detected in the reformer:

- Avoid increasing reformer reactor temperature to compensate for lost catalyst chloride and the concomitant drop in reformate octane number as this will only increase the loss of chlorine.
- Take the necessary actions in the NHT to lower the nitrogen content down to the acceptable level of 0.5 ppm weight.
- Increase organic chloride injection into the reformer naphtha to compensate for the lost chloride.

- Reduce the end point of high nitrogen containing naphthas to the NHT to reduce nitrogen in the reformer feed.

Water Upset

The acidity of the catalyst is controlled by two main factors: the moisture in the feed and the chloride on the catalyst. An increase in the feed moisture without a compensating increase in the feed chloride content will strip chloride from the catalyst, thereby reducing its acidity. Conversely, too little moisture in the feed will severely dehydroxylate the catalyst, thereby reducing its overall acidity despite the fact that its chloride level may be building if no parallel adjustment has been made in feed chloride level. This phenomenon is most likely to occur in a fixed-bed reformer. Proper control of the water/chloride balance is crucial to maintain the correct metal/acid balance on the catalyst. Insufficient on-stream chloride, moisture addition, or both can ultimately compromise the acid function, and as a result, the metal function will become dominant producing increased formation of methane (C_1) and ethane (C_2) relative to propane (C_3) and butanes (C_4). Conversely, excess on-stream chloride addition, moisture addition, or both can ultimately increase catalyst acidity to the point where it begins to overwhelm the metal function, and as a result, C_3 and C_4 formation will overtake C_1 and C_2 production.

The water content of reformer feed is a combination of the intrinsic moisture found in the naphtha and the moisture added to the feed. Feed moisture should be controlled to achieve approximately 20 ppm volume in the recycle gas for typical conditions.

Water removal is usually achieved in the stripper of the NHT. Generally contamination by water results from poor operation of this equipment. Water can also be introduced indirectly in the form of oxygenates which will be reacted to form water in the reformer.

When feeding a reformer unit with low-sulfur naphtha from storage, the naphtha should be routed through the NHT stripper or splitter to remove excess water present.

If recycle gas water content exceeds 50 ppm volume, the reactor inlet temperature must be lowered to reduce the chlorine elution (leaching) from the catalyst and sintering of the metallic sites. The following guidelines are generally accepted:

- > 50 ppm volume water, limit reactor inlet temperature to $\leq 500^\circ C$
- > 100 ppm volume water, limit reactor inlet temperature to $\leq 480^\circ C$.

If recycle gas moisture drops too far below 10 ppm volume, the catalyst surface becomes sufficiently dehy-

droxylated to limit its acidity. Injection of 1 ppm weight water in the feed will increase recycle gas moisture by 2–5 ppm volume depending on the operating conditions.

Coke

The coke that deposits on the catalyst is a temporary poison since its detrimental effect is reversible through regeneration. Since coke formation is inherently associated with the reforming reactions, there is no real way to avoid it. One can only minimize coke formation.

Operating conditions directly impact coking rate. Higher severity (temperature) operation accelerates coke formation while higher hydrogen partial pressure and hydrogen recycle gas rate retards its formation due to coke's hydrogen deficiency.

The feed end boiling point can have a significant impact on coking rate. High-end-point naphtha, especially cracked naphtha, tends to accelerate coke formation due to the incremental presence of heavier aromatics and polyaromatic precursors.

Unfortunately, D86 final boiling point does not provide sufficient information in the case of mixed feeds. Each feed must be analyzed separately to know the true final boiling point of each stream to be able to specifically limit the heavy components in the cracked feeds. Very often mixed feeds are responsible for short catalyst cycle life, even though the final boiling point of the mixture stays within acceptable values.

18.5.2 Permanent Poisons

Permanent poisons have been defined as contaminants which irreversibly damage the catalyst.

Table 18.12 lists the main permanent poisons as well as their acceptable level in reformer feed and their most likely source.

Most metals poison the metal functions (platinum and promoter) of the catalyst. Their impact tends to progress sequentially through the reactors in a fixed-bed reformer. The first reactor is typically the reactor where the poisoning is first detected. In a CCR reformer unit with circulating catalyst, poisons can affect the whole catalyst inventory if the cause of pollution is not found.

Table 18.12 Main contaminant max level in feed and origin

Poisons	Maximum level (wt)	Source
Arsenic	5 ppb max	SR, cracked naphthas, or gas condensates
Lead	1 ppb max	Recycled slops
Iron	< Detection limit	Corrosion, metal dusting
Sodium	< Detection limit	Crude Fixed bed regeneration with caustic carryover
Silicon	< Detection limit	Additives (antifoaming)

Metal contamination is characterized by:

- A dramatic decrease in the ΔT (temperature drop) in the first reactor associated with an increased ΔT in the second reactor, then decrease in ΔT with the second reactor, etc.
- A decrease in octane number
- An increase in liquid product yield
- A decrease in hydrogen production and purity.

In addition to poisoning the catalysts functions, mechanical problems may result from the collection of corrosion products (scale, rust, etc.) in the top layer of the first catalyst bed in a fixed reactor system, or the accumulation of scale or rust in the stagnant zone of the first reactor.

The contaminants and the source of contamination are listed in Table 18.12. Prevention consists of adequate feed pretreatment in a NHT and appropriate material selection to limit corrosion. Metal poisons are generally partially retained on the upstream hydrotreating catalysts. However, their retention capacity is limited and breakthrough may occur. Such a breakthrough would result in a very harmful situation for the unit since these poisons would not be eliminated by the catalyst regeneration.

It is very important to periodically check the metal content of the hydrotreater feed and product. Monitoring the performance of the hydrotreater with regard to demetallization not only protects the reformer but also gives an indication of when the hydrotreatment catalyst needs to be replaced.

18.6 Reforming Evolution

18.6.1 Commercialization of Catalytic Reforming

Perhaps the earliest reference to catalytic reforming is found in US patent 2288336 entitled *Catalytic Re-*

forming of Naphthas filed in 1939 by Standard Catalytic Company, a subsidiary of Standard Oil. The process was developed as a means of producing aviation gasoline and toluene to meet the demands of World War II. The *Hydroforming* process was com-

mercialized in 1941 utilizing molybdenum-alumina and chromium-alumina catalyst in fixed-bed reactor systems. Rapid catalyst deactivation led to the development and commercialization of moving bed and fluid bed units by some of the major oil companies in the early 1950s.

The modern catalytic reforming process was first commercialized by UOP in 1949 using a bifunctional catalyst composed of platinum impregnated on a slightly chlorinated γ -alumina [18.17]. The process trademarked by UOP as Platforming represented a significant improvement in catalyst activity to produce high-octane gasoline. The process was widely applied for gasoline and aromatics production; however, frequent catalyst regeneration was required to maintain activity. Operation at relatively high pressure with recycle of product hydrogen was necessary to suppress coking reactions due to the poor stability of the catalyst system. Cyclic reformers with the capability to isolate and regenerate individual reactors while the remainder of the unit remained on oil were developed and commercialized by Standard Oil of Indiana (Ultraforming) and Standard Oil of New Jersey (Powerforming) in the early 1950s.

Development work on promoted or multimetallic catalyst formulations resulted in Chevron's commercialization of rhenium-promoted platinum catalysts in 1969 (Rheniforming). The significant improvement in catalyst stability (lower coke formation) obtained by using other metals, such as rhenium, in combination with the primary reforming catalyst metal, platinum, prompted a rapid development in catalyst formulations. With bimetallic catalysts, fixed-bed catalytic reforming processes could achieve cycle lengths of 1–2 years at higher severity operation before coke build-up on the catalyst reduced activity to the point where periodic shut down and catalyst regeneration was required. These units are referred to as semiregenerative, or Semi-Reg, reforming processes.

18.6.2 Semiregenerative Catalytic Reforming

A typical configuration of a fixed-bed semiregenerative reforming process is shown in Fig. 18.30.

In this flow scheme, hydrotreated naphtha feed is combined with hydrogen-rich recycle gas, preheated by heat exchange with the reactor effluent and then further heated in a fired heater before entering the first reactor. As the endothermic reforming reactions cool the feed and product mixture, the effluent from the first reactor must be reheated to the required reaction temperature in a fired heater before entering the second reactor, and similarly for the last reactor (refer also to Fig. 18.23).

The product liquid and gases are cooled and separated in a simple flash separator into a hydrogen-rich gas stream and a liquids product stream. Some of the hydrogen-rich gas is recycled to the reactors to suppress coke formation and the remaining product or *make gas* is sent to the refinery hydrogen system. The separator liquids are stabilized to recover a C_5+ reformatate product stream and LPG by-product stream, along with a small off-gas stream.

Over time, the catalyst in the fixed-bed reactors age (deactivate due to coke) and when the performance is no longer economic the unit is shut down and the catalyst regenerated on a periodic or semiregenerative basis. The catalyst may be removed for ex-situ regeneration and subsequent reloading, or regenerated in-situ. Catalyst regeneration can be a rather complex and precise operation as will be described later.

18.6.3 Cyclic Catalytic Reforming

A typical configuration for a fixed bed, cyclic reforming process is shown in Fig. 18.31.

This process scheme utilizes a *swing* reactor in addition to the 3–5 on-oil reactors and a separate re-

Fig. 18.30 Semiregenerative catalytic reforming process scheme

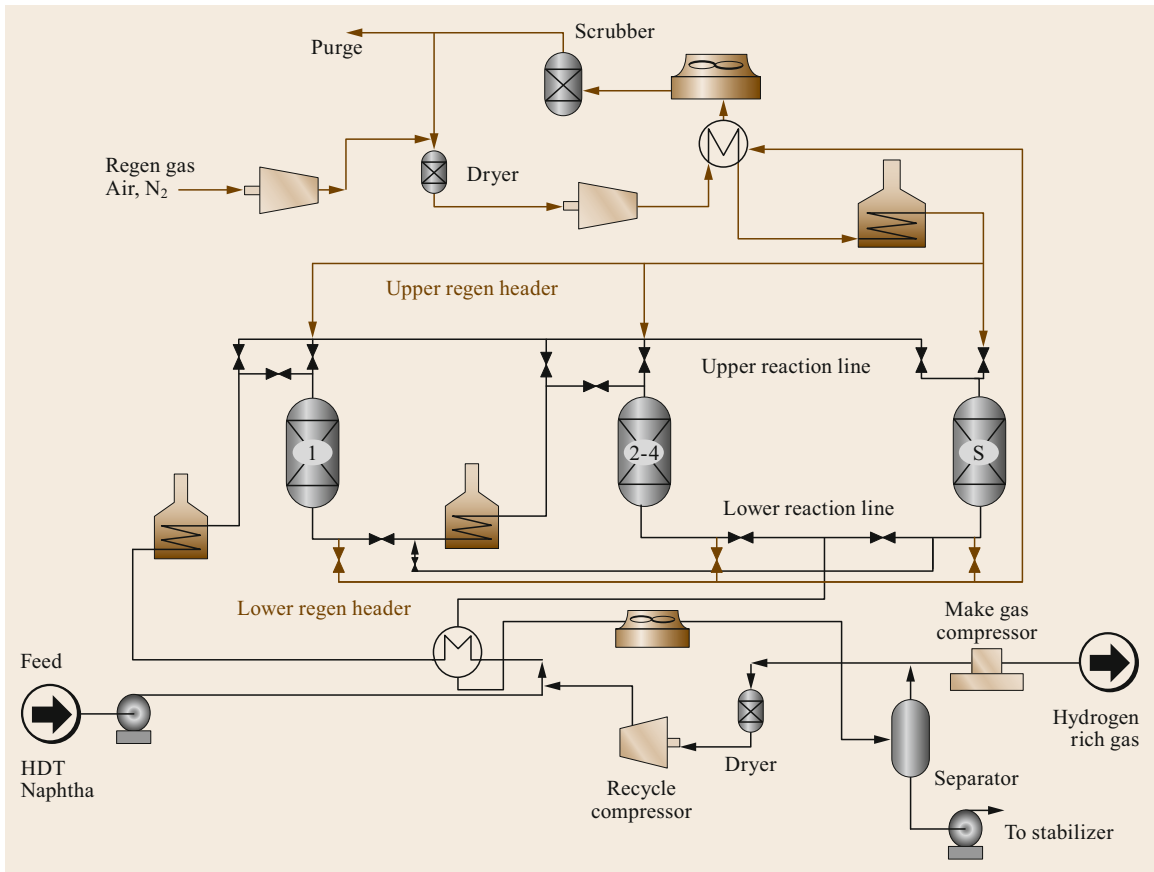

Fig. 18.31 Typical cyclic reforming process scheme. S: Swing reactor; regeneration process line *in brown*; reaction process line *in black*

generation system to maintain continuous operation of the reaction system, while individual reactors are regenerated in the regeneration system. As a reactor becomes sufficiently deactivated, the *swing* reactor replaces it in the on-oil reactor series through a sequence of valve movements in the reaction and regeneration headers. At the same time, a parallel sequence of valve movements transfers the deactivated reactor from the reaction header to the regeneration header for regeneration. The tail reactors are typically regenerated more frequently than the lead reactors, and the *swing* reactor is regenerated as often as needed to maintain on-oil performance. Units operating at high enough severity to require continuous operation of the regeneration section are said to be in full cyclic mode. As severity drops below the threshold for full cyclic operation, discontinuous use of the regeneration section becomes possible and the unit operates in semicyclic mode. At low enough severity, the unit operates more like a semiregenerative reformer, and occasionally regenerates the full complement of reactors one at a time.

In a cyclic reformer, reaction system H_2O and H_2S concentrations spike well above the desired operating target and catalyst performance declines for the duration of the disturbance every time a freshly regenerated reactor swings into on-oil service. Addition of a dryer in the recycle gas loop, regeneration loop, or both reduces the magnitude and impact of this disturbance.

18.6.4 Radial Flow Reactor Design

The first reforming reactors were spherical due to the high pressure of operation with monometallic catalysts. Catalyst loading and distribution problems associated with spherical reactors and thin reactor beds then led to cylindrical, axial flow fixed-bed reactors.

As the catalyst technology improved and lower pressure operation was possible for improved yield selectivity, the problem of catalyst bed pressure drop and recycle compressor duty led to the introduction of radial flow reactors (Fig. 18.32). The gas is introduced

Fig. 18.32
Typical radial
flow reactor

through the top and flows down along the outer wall of the cylindrical reactor and then flows radially inward through the thin annular catalyst bed. Screens are used to contain the catalyst in the annular bed and allow reactants to enter from the wall, pass through the bed, and then enter a center pipe collection tube to exit the vessel at the bottom. This design provides intimate and controlled contact between the feed and catalyst with a low pressure drop across the thin bed of catalyst.

18.6.5 Evolution of Reforming Catalyst

The need to operate monometallic units at relatively high pressure and with high hydrogen recycle to suppress coke formation was at odds with the thermodynamically preferred low pressure. As noted above, catalyst development focused on ways to improve stability and therefore allow for operation at more favored lower pressure. The first step of combining promoter metals such as rhenium was very successful and Pt-Re catalysts are widely used today for fixed-bed reforming [18.18].

The explanation for the improvement obtained following the addition of rhenium can be understood by Fig. 18.33 [18.19].

As the reaction proceeds, the platinum accessibility reduces due to coke formation on the catalyst. When

Fig. 18.33 Platinum stability improvement with Re addition

Fig. 18.34 Impact of rhenium on coke make (*n*-heptane feed)

only platinum is used, the activity or platinum accessibility declines rapidly. Note that recent quantum simulations have quantified the impact of H₂ partial pressure on the stability of hydrocarbon species present on the Pt nanoparticles: only high H₂ partial pressure may prevent the formation of undesired carbon species adsorbed on the Pt particle [18.20, 21]. When rhenium

is introduced along with the platinum, the platinum cluster is by far more stable with much more of the platinum accessible over a longer period of time.

Thus the desirable dehydrogenation/hydrogenation activity is more stable, which can be seen by the reduced coke make (Fig. 18.34) [18.19].

Further development work discovered other metal combinations with even greater yield selectivity and activity than either Pt alone or Pt-Re, as shown in Fig. 18.35. When Pt was combined with tin (Sn), the desired dehydrogenation reactions were greatly enhanced, but this benefit only occurred at low pressure. Indeed as seen in Fig. 18.35, Pt-Sn catalyst promotes the relative rate of aromatization of naphthene at the expense of their hydrogenolysis over a wide pressure range, but it is only at low pressure that their activity surpasses that of Pt or Pt-Re catalyst.

The challenge of lower pressure is that coke formation on the catalyst increases sharply and stability declines. This challenge was met with the introduction of CCR technology in the early 1970s.

18.6.6 Continuous Catalyst Regeneration Design

In order to realize the benefits of the new Pt-Sn catalyst, a means of operating at reduced pressure and with more frequent catalyst regeneration was required. A moving catalyst bed design was commercialized in the early 1970s so that a CCR scheme could be implemented. This innovation allowed for the development of more selective ultra-low pressure designs utilizing customized catalysts to achieve higher yields of C₅+reformate, aromatics, and hydrogen.

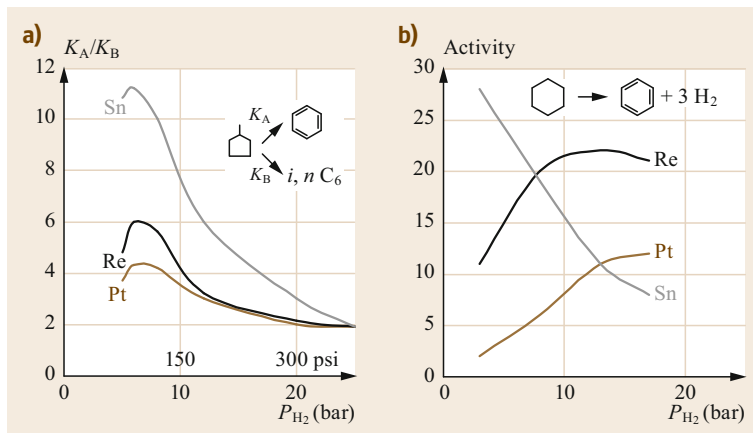

Fig. 18.35a,b Impact of metal complexes with Pt on selectivity (a) and activity (b)

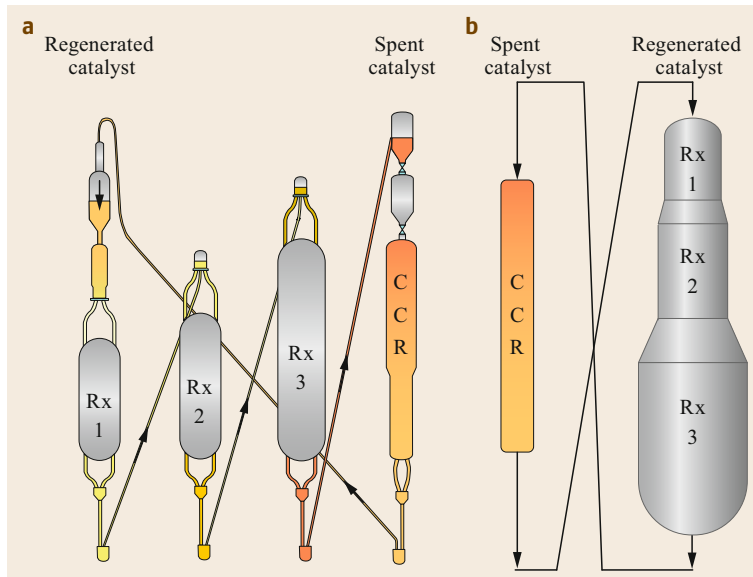

Fig. 18.36a,b Reactor configuration in CCR unit: (a) side-by-side (Axens), (b) stacked (UOP)

The CCR reforming process is offered by two licensors: Axens with a side-by-side reactor configuration (Fig. 18.36a) under the trade names Octanizing and Aromizing, and a stacked configuration offered by UOP under the trade name CCR Platforming (Fig. 18.36b).

A CCR reformer design is similar to a fixed-bed semiregenerative design with heaters between each reactor and a recycle gas compressor in order to reduce coke make. In order to ensure a continuous operation of the unit, the catalyst must move or circulate through the reactors and a regenerator so that coke is burned and the catalyst regenerated on a continuous basis.

The reactors (typically 3 or 4) can be configured in a side-by-side arrangement as practiced by Axens, or stacked in a tower as offered by UOP as shown above. In both cases, catalyst is circulated between the reactors and a regeneration section with catalyst flow within each reactor by gravity flow.

Fig. 18.37 Pressure trend in reforming and catalyst evolution

Like most modern fixed-bed designs, radial reactors are used in CCR designs to optimize catalyst and feed contact in a low pressure drop reactor design. However for CCR units, the catalyst moves slowly down and through the reactor and allowance must be made for the moving bed density. The CCR radial reactor design naturally also has special mechanical means for introducing, distributing, and removing catalyst from the annular radial bed.

In the regeneration section, four steps are performed on a continuous basis:

- Coke burning to remove coke deposits
- Oxychlorination to adjust catalyst chloride and re-disperse the active metals on the carrier support
- Calcination to dry the catalyst, and
- Reduction to convert Pt oxide to active metal.

18.6.7 From High-Pressure to Low-Pressure CCR

As was discussed in the Chemical Reaction section (Sect. 18.3), operation at high pressure causes a decline in gasoline and hydrogen production and thus has a negative impact on the overall economics. As new catalyst formulations allowed for greater stability, it was possible to reduce the reaction pressure and hydrogen recycle while still achieving an acceptable cycle length. When the CCR design was introduced, catalyst stability became less important and the operating pressure could be reduced as dictated by thermodynamics. Figure 18.37 illustrates the trend in operating pressure as catalyst formulations evolved.

As catalyst improvements allowed for a change in process configuration from high-pressure semiregenerative reforming to ultra-low-pressure CCR reforming, the yields improved dramatically. Figure 18.38 demonstrates the improvement in yields with 10 wt% more reformat and a 50% (relative) increase in hydrogen

Fig. 18.38 Yields trend versus pressure (100 RON severity, feed PNA = 54/30/16w%)

production as the average reaction pressure is reduced from 20 bar(g) (275 psig), Semi-Reg case, to 3.5 bar(g) (50 psig) at a constant 100 RON severity. Typical operation pressure for semiregenerative units are around 20–25 bar(g) while for medium pressure CCR the operating range is around 6–8 bar(g). The ultra low pressure CCR operate close to 3 to 4 bar(g).

While the low-pressure CCR provides the highest yields and economic return, the trade-off is the need to circulate catalyst and operate a CCR system with a high regeneration frequency. In some ultra-low-pressure CCR units running at high severity for aromatics production, the entire catalyst inventory circulates through the unit and regenerator every 3–5 days

18.7 Catalyst Regeneration

As the feedstock is converted, some of the hydrocarbons will form coke which will accumulate on the catalyst as noted above. The lower the unit pressure and more severe the operation, the more rapidly will coke deposit on the catalyst. Therefore, the performance will decrease over time and at a given point the catalyst needs to be regenerated. The coke level on catalyst prior to regeneration may be 20–30 wt% in the case of fixed-bed semiregenerative catalysts and 3–7% for CCR catalyst.

Between a CCR and a fixed-bed unit, the regeneration steps are fundamentally the same, only the frequency and mechanical equipment are different. For a CCR, the regeneration can be every 3–7 days while for a fixed-bed unit it can be every 6 months up to 3 years.

There are four steps involved in the regeneration sequence:

- Combustion
- Oxychlorination
- Drying
- Reduction.

A block diagram of a regeneration scheme is shown in Fig. 18.39.

18.7.1 Combustion Step

The main objective of this step is to burn the coke. But in order to avoid a high exotherm from coke burning or localized hot spots, the burning gas is recycled to limit the oxygen content, which becomes progressively more diluted with nitrogen as it recirculates. A typical oxygen content of less than 1 vol.% is maintained to achieve a controlled burn of the coke without damaging the cat-

in order to maintain a coke on catalyst level below about 5 wt%.

Most of the new reforming units are based on ultra-low-pressure CCR design as it provides superior yields and the highest economic return. The frequent regenerations with a CCR subject the catalyst to severe conditions that reduce the carrier surface area and activity over time. Improvements in catalyst formulation and regeneration system design have been necessary to ensure long catalyst and equipment life.

Today, low-pressure reforming with moving catalyst beds and CCR technology is the norm to realize the benefits of new Pt catalysts using multiple promoter metals and optimized carrier systems [18.22].

alyst. The catalyst temperature during regeneration is generally limited to less than 600 °C. Staged oxygen addition is also implemented to limit the exotherm and protect the catalyst.

The regeneration process, consisting mainly of coke burning, has a negative impact on the surface area of the catalyst due to hydrothermal instability of the alumina and potential hot spots created by maldistribution. The reduction of the specific surface of the catalyst has

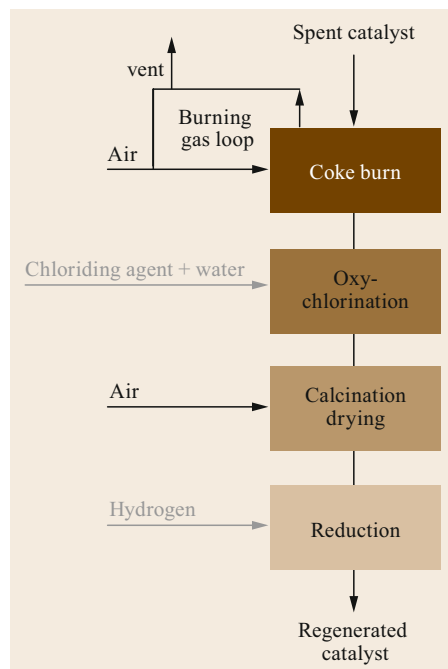

Fig. 18.39 Schematic representation of catalyst regeneration steps

a direct impact on the chloride retention of the carrier and acid function of the catalyst. This can have several drawbacks for the day-to-day operation of the unit. The activity of the catalyst will decline and this can lead to the formation of olefins and polymers called green oils. As chloride is lost, more must be injected resulting in downstream equipment corrosion and salt deposits that foul colder parts in the recovery section.

Thus the catalyst and regeneration system must be designed to limit surface area loss during regeneration, or an economic penalty of more frequent catalyst replacement will result.

The optimal design of the regeneration section is, therefore, of paramount importance for CCR applica-

tion with a high frequency of catalyst regeneration. Exposure to high temperature and particularly in the presence of steam is a well-known cause of surface area reduction in alumina systems. One means of reducing catalyst degradation as practiced in the Axens design, shown in Fig. 18.40, is to reduce the water partial pressure in the burning section by means of a dryer system and to implement staged combustion (air injection) to avoid localized hot spots. In addition to these process changes, the catalyst itself can be designed for high hydrothermal stability by the addition of promoters.

18.7.2 Oxychlorination Step

During the combustion step, the small platinum particles undergo sintering or agglomeration into larger clusters due to exposure to high temperature, moisture in the combustion gas, and elution or loss of chloride. As only the surface platinum atoms are active for re-

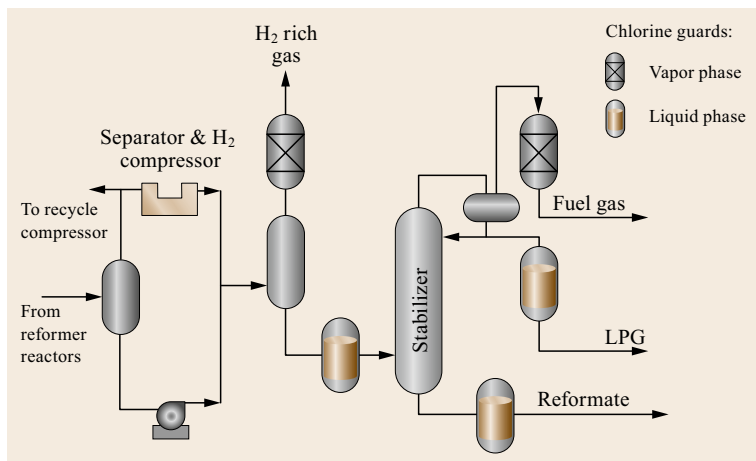

Fig. 18.43 Standard chloride trapping mass locations

forming reactions, larger clusters must be redispersed into smaller crystallites [18.23].

This redispersion is done under an oxygen atmosphere, typically above 5 vol.%, in the presence of chloride at temperatures typically above 480 °C. The proposed mechanism [18.24] assumes the formation of an oxychlorinated platinum complex. At the end of this oxychlorination step, the platinum is well dispersed as small clusters on the carrier and in an oxide form (PtO_xCl_y) (Fig. 18.41).

18.7.3 Drying Step and Reduction Step

The final regeneration step is the reduction to convert the oxide form of platinum to the active metallic form in order to ensure a good reduction. This catalyst needs to be dry and hence a calcination or drying step precedes the reduction step.

18.8 Conclusions

Since its development over 60 years ago, the reforming process and catalysts have significantly been improved.

Unit pressure has dropped from 40 bar(g) down to 3.5 bar(g) while reformat yields have been increased by more than 10 wt% (absolute). Catalyst and process developments continue to improve yield selectivity and

The transformation of the catalyst during regeneration is illustrated in Fig. 18.42, where the catalyst color goes from creamy white when oxychlorinated to gray under reduced form to black when coked.

18.7.4 Chloride Control

The control of chloride addition to the catalyst and loss to products and effluents is very important for reformer design and operation.

Since some chlorine loss from the catalyst always occurs, the products of reforming will be contaminated with chlorides. In order to protect process equipment in the reformer and downstream processes and catalysts, it is common to install a chlorine guard or trapping mass in one or more locations in the reforming unit. Figure 18.43 illustrates the possible locations of the trapping mass for vapor and liquid.

catalyst stability to provide greater operational flexibility and profitability.

From an economic stand point, reforming is still a key process in the refineries as it provides high octane components for the gasoline pool and hydrogen for hydrocracking and hydrotreating units. For the aromatics market, it is the main producer of xylenes.

Fluid-Bed Ca

19. Fluid-Bed Catalytic Cracking

James G. Speight

Catalytic cracking is the thermal decomposition of petroleum constituents in the presence of a catalyst. Refineries use the process cracking to correct the imbalance between the market demand for gasoline and the excess of heavy, high boiling range products (as well as heavy oil and tar sand bitumen) resulting from the distillation of the crude oil.

The typical catalytic cracker that accepted a single-source gas oil feedstock is almost extinct and in the modern refinery is more inclined to be a blend of several high-boiling fractions – often with heavy oil and/or residuum as part of the blend, which has led to the development of residuum fluid catalytic cracking units. In addition to designing new units, as part of the evolutionary process many of the older catalytic cracking units were modified to accommodate more complex feedstocks as well as feedstock blends containing residua. Feedstocks to the modern units now range from blends of gas oil fractions (included in normal heavier feedstocks for upgrading) to residua (*reduced crude*), heavy oil, and even tar sand bitumen.

Fluid catalytic cracking is the most important conversion process used in petroleum refineries to convert the high-boiling feedstock constituents to more valuable naphtha, olefin gases, as well as other products and is likely to remain predominant in the refining industry for at least another three-to-five decades.

Catalytic cracking is a conversion process that was originally designed for gas oil but can also be applied to a variety of hydrocarbonaceous feedstocks ranging from heavy oil, residua, and also to certain types of biomass-derived feedstocks [19.1–7]. The concept of catalytic cracking is the thermal decomposition of feedstocks constituents in the presence of a catalyst, which in theory, is not consumed in the process. Catalytic cracking is one of several practical applications used in a refinery that employ a catalyst to improve process efficiency and product slate.

The process – in the typical commercial sense in a refinery – involves contacting the feedstock with a catalyst under suitable conditions of temperature, pressure, and at a residence time that will reduce the amount of coke (carbonaceous residue) formed in the process. The goal of the process is to convert as much as possible of the feedstock into hydrocarbon gases (if needed), naphtha, and kerosene-type products [19.1–4, 7, 8]. However, if coking occurs, a carbonaceous material is deposited on the catalyst, which markedly reduces catalyst activity and efficiency. Removal of the deposit from the catalyst is usually accomplished by cleaning the catalyst through burn-off of the deposit in the presence of air until catalyst activity is reestablished.

This history of catalytic cracking started in the early-to-mid decades of the twentieth century as the need for gasoline arose – especially the need for higher octane gasoline than could be produced as a straight-run distillation product from petroleum which was accompanied by advances in catalyst science and technology (Table 19.1) [19.9]. This has been ongoing and as the technology moves into the 21st century there are both new and continuing challenges:

1. There is the continued use of heavy oil and tar sand bitumen as feedstock.
2. Biomass will become a more common feedstock for fluid catalytic cracking (FCC) units, possibly blended with petroleum-based feedstocks.
3. Feedstocks derived from waste – also blended with petroleum-based feedstocks – will see more common use.

In the beginning, the early (pre-1940s) thermal cracking units produced approximately 50 vol.% of the total gasoline manufactured with an octane number on the order of 70 (the octane number of straight-run naphtha was on the order of 60). The naphtha produced by thermal cracking and the straight-run product were then blended together and also with lower boiling fractions and sometimes with *polymer gasoline*, *alkylate*, and *reformate* to produce gasoline base stock with an octane number of about 65 [19.1–7]. Additives, such as *tetraethyl lead (ethyl fluid)* were used to increase the octane number to 70 for the *regular-grade* gasoline and 80 for *premium-grade* gasoline. The thermal reforming and polymerization processes that were developed during the 1930s could be expected to further increase the octane number of gasoline to some extent, but a different approach was needed to generate a product with a higher octane number in order to keep pace with the development of more powerful automobile engines.

This occurred with the introduction (in 1936) of the catalytic cracking process that brought about major improvements in process efficiency and product yields, and which continued to evolve along with the advances in the chemistry and physics of the catalysts as well as an understanding of the chemistry of catalytic cracking [19.10, 11]. Major advances in reactor design, such as the evolution of catalyst bed design, have led to different design innovations for the reactors currently in use – such as, for example, single-stage cracking and dual-stage cracking.

When cracking is conducted in a single stage, the more reactive constituents of the feedstock will be decomposed showing a high conversion to gas and coke in the reaction time necessary for reasonable conversion of the more thermally stable feedstock con-

Table 19.1 The evolution of catalytic cracking

Catalytic cracking process	
Batch reactor (1915)	Catalyst: aluminum chloride (AlCl_3) – a Lewis acid, electron acceptor Alkane – electron (abstracted by AlCl_3) to produce a carbocation (C^+) Ionic chain reactions to crack long chains Product: low-boiling distillate
Houdry process (1936)	Continuous feedstock flow with multiple fixed-bed reactors Cracking/catalyst regeneration cycles Catalyst: clay, natural alumina/silica particles
Thermoform (1942)	Continuous feedstock flow with moving-bed catalysts Catalyst: synthetic alumina/silica particles
Fluid (1942)	Continuous feedstock flow with fluidized-bed catalysts
New catalysts (1965)	Synthetic alumina/silica and zeolite catalysts

stituents. Conversely, in a two-stage process, gas and naphtha from a short-reaction-time high-temperature cracking operation (which may occur in a flow line or vertical riser with minimal coke formation) are separated before the main cracking reactions take place in a second-stage reactor. Cracked gases are separated and sent to a fractionator whereas the catalyst and noncracked feedstock material together with recycle oil from a second-stage fractionator are recycled to the main reactor for further cracking to

produce gas, naphtha, gas oil streams, and recycle oil.

Finally, and to avoid confusion in nomenclature, there is no one process in the modern refinery that produces gasoline – gasoline for sales is a blend of several streams, including additives [19.7]. Thus, the fraction of the requisite boiling range produced by the fluid catalytic cracking process is, in this chapter, referred to as *naphtha* (often called FCC gasoline, but not true sales gasoline).

19.1 Catalytic Cracking Chemistry

Catalytic cracking is the thermal decomposition of petroleum constituents in the presence of a catalyst (Table 19.2) and discussions still remain about the influence of thermal decomposition as well as catalytic decomposition during the reaction. It is, essentially, the role of the influence of free radical species (thermal decomposition) and the influence of ionic species (catalytic decomposition) that may be in competition. Nevertheless, the reactions that occur during catalytic cracking are complex but, as a result of advances in catalyst science with a better understanding of catalyst activity, there is a measure of predictability of the outcome of the process. Each type of constituent of the feedstock will undergo reactions that are specific to that type of chemical.

For example, the major catalytic cracking reaction exhibited by paraffins is carbon–carbon bond scission into lighter paraffins and olefins. Bond rupture occurs at specific locations within the paraffin molecule, rather than at random locations as occurs in thermal cracking. For example, paraffins tend to crack toward the center and branch points of the molecule, the long chains cracking in several places simultaneously. In either case, catalytic cracking tends to yield products containing three or four carbon atoms rather than the one-carbon or two-carbon atom molecules produced in thermal cracking.

19.1.1 General Chemistry

As in thermal cracking [19.1–5, 7], high molecular weight constituents usually crack more readily than small molecules, unless there has been some recycle and the constituents of the recycle stream have become more refractory and are less liable to decompose. Paraffins having more than six carbon atoms may also undergo rearrangement of their carbon skeletons before cracking, and a minor amount of dehydrocyclization also occurs, yielding aromatics and hydrogen.

Olefins are the most reactive class of hydrocarbons in catalytic cracking and tend to crack from 1000 to 10 000 times faster than in thermal processes. Severe cracking conditions destroy olefins almost completely, except for those in the low-boiling naphtha and gaseous hydrocarbon range and, as in the catalytic cracking of paraffins, *iso*-olefins crack more readily than *n*-olefins. Furthermore, olefins tend to undergo rapid isomerization and yield mixtures with an equilibrium distribution of double-bond positions and, in addition, the chain-branching isomerization of olefins is fairly rapid and often reaches equilibrium. These branched-chain olefins can then undergo hydrogen transfer reactions with naphthenes and other hydrocarbons. Other olefin reactions include polymerization and condensation to

Table 19.2 Comparison of thermal cracking and catalytic cracking

Thermal cracking	Catalytic cracking
No catalyst	Uses a catalyst
Free-radical reaction mechanisms	More flexible in terms of product slate
Moderate yields of gasoline and other distillates	Ionic reaction mechanisms
Gas yields feedstock dependent	High yields of gasoline and other distillates
Low-to-moderate product selectivity	Low gas yields
Low octane number gasoline	High product selectivity
Low to moderate yield of C ₄ olefins	Low <i>n</i> -alkane yields
Low to moderate yields of aromatics	High octane number
	Chain-branching and high yield of C ₄ olefins
	High yields of aromatics

yield aromatic molecules, which in turn may be the precursors of coke formation.

In catalytic cracking, the cycloparaffin (naphthene) species crack more readily than paraffins but not as readily as olefins. Naphthene cracking occurs by both ring and chain rupture and yields olefins and paraffins, but formation of methane and the C_2 hydrocarbons (ethane, CH_3CH_3 , ethylene, $CH_2=CH_2$, and acetylene, $CH\equiv CH$) is relatively minor.

Aromatic hydrocarbons exhibit wide variations in their susceptibility to catalytic cracking. The benzene ring is relatively inert, and condensed-ring compounds, such as naphthalene, anthracene, and phenanthrene, crack very slowly. When these aromatics crack a substantial part of their *conversion* is reflected in the amount of coke deposited on the catalyst. Aromatic systems containing attached alkyl groups (C_2 or longer chains) typically form benzene and the corresponding olefins, and the thermal sensitivity (susceptibility to cracking) increases with an increase in the size of the alkyl group.

Although thermal cracking is a free radical (neutral) process, catalytic cracking is an ionic process involving carbonium ions, which are hydrocarbon ions having a positive charge on a carbon atom. The formation of carbonium ions during catalytic cracking can occur by: (1) addition of a proton from an acid catalyst to an olefin and/or (2) abstraction of a hydride ion (H^-) from a hydrocarbon by the acid catalyst or by another carbonium ion. However, carbonium ions are not formed by cleavage of a carbon-carbon bond.

More generally, the chemistry of catalytic cracking is not random involving the generation of free radical species but involves the generation of charged species that are dictated by the interactions between the feedstock constituents and the catalyst [19.12]. Thus, carbonium ions can be generated by protonation of carbon-carbon or carbon-hydrogen bonds at specific Brønsted sites. In addition, carbenium ions can be generated by:

1. Elimination of alkane or hydrogen from carbonium ions
2. Protonation of olefins
3. Abstraction of hydride by Lewis sites (including sorbed carbenium ions).

The reaction products are largely determined by carbenium ion chemistry (isomerization, β -scission, H-transfer, oligomerization/alkylation) which is influenced by acid-site strength, density and distribution and also by pore/cage effects. Shape selectivity (both primary and secondary) can influence the product distribution and, at higher temperatures, at lower conversions,

and in reactions in smaller pore zeolites, product distributions over strongly acid catalysts increasingly reflect carbonium-ion chemistry. However, the participation of free radical intermediates – particularly at higher temperature régimes – cannot be excluded but there is little evidence for a major influence of free radicals on the product distribution [19.12].

In essence, the use of a catalyst permits alternate routes for cracking reactions, usually by lowering the free energy of activation for the reaction. The acid catalysts first used in catalytic cracking were amorphous solids composed of approximately 87% silica (SiO_2) and 13% alumina (Al_2O_3) and were designated low-alumina catalysts. However, this type of catalyst is now being replaced by crystalline aluminosilicates (zeolites) or molecular sieves.

Once the carbonium ions are formed, the modes of interaction constitute an important means by which product formation occurs during catalytic cracking; for example, isomerization either by hydride ion shift or by methyl group shift, both of which occur readily. The trend is for stabilization of the carbonium ion by *movement* of the charged carbon atom toward the center of the molecule, which accounts for the isomerization of α -olefins to internal olefins when carbonium ions are produced. Cyclization can occur by internal addition of a carbonium ion to a double bond which, by continuation of the sequence, can result in aromatization of the cyclic carbonium ion.

Like the paraffins, naphthenes do not appear to isomerize before cracking. However, the naphthenic hydrocarbons (from C_9 upward) produce considerable amounts of aromatic hydrocarbons during catalytic cracking. Reaction schemes similar to that outlined here provide possible routes for the conversion of naphthenes to aromatics. Alkylated benzenes undergo nearly quantitative dealkylation to benzene without apparent ring degradation below $500^\circ C$ ($930^\circ F$). However, polymethylbenzene derivatives undergo disproportionation and isomerization with very little benzene formation.

Catalytic cracking can be represented by simple reaction schemes. However, questions have arisen as to how the cracking of paraffins is initiated. Several hypotheses for the initiation step in catalytic cracking of paraffins have been proposed but the kinetics picture remains complex [19.13–16], as might be expected when dealing with such complex feedstocks as are used in refineries. The Lewis site mechanism is the most obvious, as it proposes that a carbenium ion is formed by the abstraction of a hydride ion from a saturated hydrocarbon by a strong Lewis acid site: a tri-coordinated aluminum species. On Brønsted sites a carbenium ion may be readily formed from an olefin by the addition of

a proton to the double bond or, more rarely, via the abstraction of a hydride ion from a paraffin molecule by a strong Brønsted proton. This latter process requires the formation of hydrogen as an initial product. This concept was, for various reasons that are of uncertain foundation, often neglected.

19.1.2 Coke Formation

Higher boiling feedstocks that contain substantial amounts of aromatic constituents typically produce higher yields of coke than feedstocks of lesser aromaticity. Furthermore, condensed polynuclear aromatic systems and aromatic ring systems containing heteroatoms (i. e., nitrogen, oxygen, and sulfur) are more facile coke makers than simpler nonheteroatom ring systems [19.17].

Coke formation is considered, with just cause to be a malignant side reaction of normal carbenium ions. However, while chain reactions dominate events occurring on the surface, and produce the majority of products, certain less desirable bimolecular events have a finite chance of involving the same carbenium ions in a bimolecular interaction with one another. Of these reactions, most will produce paraffin products and leave carbene/carboid-type species on the surface. This carbene/carboid-type species can produce other products but the most damaging product will be one which remains on the catalyst surface and cannot be desorbed and results in the formation of coke, or remains in a noncoke form but effectively blocks the active sites of the catalyst.

A general reaction sequence for coke formation from paraffins involves oligomerization, cyclization, and dehydrogenation of small molecules at active sites within zeolite pores:

- Alkenes → alkenes
- Alkenes → oligomers
- Oligomers → naphthenes
- Naphthenes → aromatics
- Aromatics → coke.

Whether or not these are the true steps to coke formation can only be surmised. The problem with this reaction sequence is that it ignores sequential reactions in favor of consecutive reactions. And it must be accepted that the chemistry leading up to coke formation is a complex process, consisting of many sequential and parallel reactions.

There is a complex and little understood relationship between coke content, catalyst activity, and the chemical nature of the coke. For instance, the atomic hydrogen/carbon ratio of coke depends on how the coke

was formed; its exact value will vary from system to system [19.13]. And it seems that catalyst decay is not related in any simple way to the hydrogen-to-carbon atomic ratio of the coke, or to the total coke content of the catalyst, or any simple measure of coke properties. Moreover, despite many and varied attempts, there is currently no consensus as to the detailed chemistry of coke formation. There is, however, much evidence and good reason to believe that catalytic coke is formed from carbenium ions which undergo addition, dehydrogenation and cyclization, and elimination side reactions in addition to the main-line chain propagation processes [19.13].

The major coke-formers are constituents of the asphaltene fraction. The reactions leading to the formation of coke typically involve thermolytic removal of alkyl chains from the aromatic nuclei to form olefins and lower molecular weight higher polar species (carbenes and carboids) which then react to form coke. Indeed, as opposed to the bimolecular approach, the initial reactions in the coking of petroleum feedstocks that contain asphaltene constituents appear to involve unimolecular thermolysis of asphaltene aromatic-alkyl systems to produce volatile species (paraffins and olefins) and nonvolatile species (aromatics) [19.17–20].

Nitrogen species also appear to contribute to the pattern of coke formation. For example, the hydrogen or carbon-carbon bonds adjacent to ring nitrogen undergo thermolysis quite readily, as if promoted by the presence of the nitrogen atom [19.21, 22]. If it can be assumed that heterocyclic nitrogen plays a similar role in the thermolysis of asphaltene constituents, the initial reactions therefore involve thermolysis of aromatic-alkyl bonds that are enhanced by the presence of heterocyclic nitrogen. An ensuing series of secondary reactions, such as aromatization of naphthenic species and condensation of the aromatic ring systems, then leads to the production of coke. Thus, the initial step in the formation of coke from asphaltene constituents is the formation of volatile hydrocarbon fragments and nonvolatile heteroatom-containing systems. Furthermore, models of petroleum asphaltene constituents (which, despite evidence to the contrary, invoked the concept of an average structure involving a large polynuclear aromatic system) offer little, if any, explanation of the intimate events involved in the chemistry of coking [19.7].

Thus, it is now considered more likely that molecular species within the asphaltene fraction, which contains nitrogen and other heteroatoms (and have lower volatility than the pure hydrocarbons), are the prime movers in the production of coke [19.17]. Such species, containing various polynuclear aromatic systems, can be denuded of the attendant hydrocarbon moieties and

are undoubtedly insoluble [19.23–25] in the surrounding hydrocarbon medium. The next step is gradual carbonization of such entities to form coke [19.26–29]. This type of chemistry is also applicable to catalytic decomposition of feedstock constituents, especially in the case of reactions between basic nitrogen species and acidic sites on the catalyst. The attraction between the nitrogen atom and catalyst base is strong

and decomposition of the organic species on the catalyst results in a coking reaction leaving a carbonaceous residue on the catalyst. This newer concept of the behavior of asphaltene constituents offers doorways to understanding the behavior of asphaltene constituents in the presence of catalysts and the potential to markedly reduce coke formation in catalytic cracking units.

19.2 Feedstocks and Products

Many of the older refinery fluid catalytic cracking units were designed for specific feedstocks, such as high-boiling gas oil fractions. As petroleum refining evolved into the era of heavy oil and more complex feedstocks, the ability of any single unit to accommodate wide variations in feedstock became an issue related to the flexibility of the process, particularly the ability of the catalyst to accommodate the notorious catalyst poisons that are part of such feedstocks. The typical single-source gas oil feedstock became (almost) extinct and in the modern refinery is more inclined to be a blend of several high-boiling fractions – often with heavy oil and/or residuum as part of the blend, which has led to the development of residuum fluid catalytic cracking (RFCC) units. In addition to designing new units, as part of the evolutionary process many of the older catalytic cracking units were modified to accommodate more complex feedstocks as well as feedstock blends containing residua [19.6, 7]. Feedstocks to the modern units now range from blends of gas oil fractions (included in normal heavier feedstocks for upgrading) to residua (*reduced crude*), heavy oil, and even tar sand bitumen.

19.2.1 Feedstock Quality

In addition to a series of standard test methods for determining feedstock quality [19.30], improving feedstock quality (by removal of catalyst poisons such as *metallic constituents* and *high-molecular weight nonvolatile materials*) is usually carried out through the application of any one of several other processes [19.31, 32]:

- Controlled coking-visbreaking
- Propane deasphalting
- Furfural extraction
- Vacuum distillation
- Hydrodesulfurization (HDS).

Vacuum gas oil (initial boiling point: 315–345 °C or 600–650 °F; final boiling point: 510–565 °C or 950–1050 °F), as produced by vacuum flashing or vac-

uum distillation, has typically been the feedstock of choice with final boiling point being limited by the presence of coke-forming constituents (measured by the Conradson carbon residue) or metals content, since both properties have adverse effects on cracking characteristics and catalyst activity. The vacuum residua (565 °C⁺ or 1050 °F⁺) are occasionally included in feedstocks for a fluid catalytic cracking unit – especially when the units (residuum catalytic crackers) are capable of handling such materials [19.1–4, 6, 7]. In such cases, the residua have either (1) low propensity to form coke and/or (2) low metals content (as, for example, a residuum from a waxy crude) so that the effects of these properties are relatively minor and do not shorten the catalyst life by any large amount compared to the unblended gas oil. Many units also use recycle slurry oil (455 °C⁺ or 850 °F⁺) and a heavy cycle oil stream as feedstocks. Gas oils from thermal cracking or coking operations, hydrotreated gas oil, and deasphalted oil are often included in the feedstock to a catalytic cracking unit [19.1–4, 6, 7]. In some cases, the higher boiling fraction of bio-oil (produced by conversion of biomass to liquids) may also be included as blend stock [19.5].

However, the high levels of contaminants in heavy oil, residua, and bitumen – such as carbon-forming constituents that yield high levels of (Conradson) carbon residue and the overall coke production (as carbon on the catalyst) is high. Burning this coke requires additional regeneration air that might be a constraint that limits the capacity of the unit. In addition, there is a near-quantitative deposition of metallic constituents on to the catalyst where two significant effects are caused: (1) the deposited metals accelerate certain metal-catalyzed dehydrogenation reactions, thereby contributing to light-gas (hydrogen) production and to the formation of additional coke, and (2) the deposition of the metals on to the catalyst causes a decline in catalyst activity because the deposited metals tend to block the active catalytic sites, which requires frequent (and expensive) catalyst makeup practices (addition of fresh catalyst and withdrawal of spent or poisoned catalyst).

Finally, the amount of sulfur and nitrogen in the products, waste streams, and flue gas generally increases when high-boiling feedstocks are processed because these feed components typically have higher sulfur and nitrogen contents than gas oil. However, in the case of nitrogen, the issue is not only one of higher nitrogen levels in the products but also (because of the feedstock nitrogen is basic in character) catalyst poisoning that reduces the useful activity of the catalyst [19.33, 34].

In order to offset the effects of feedstock contaminants on the efficiency of fluid catalytic cracking units (as well as on other refining units), considerable use has been made of the chemical and physical relationship to *estimate* feedstock quality. For example, general feedstock quality and the suitability of the feedstock can be indicated by characterization factor (K)

$$K = \frac{\sqrt[3]{(\text{MABP})}}{\text{specific gravity at } 60^\circ\text{F}/60^\circ\text{F}}$$

In this equation, MABP is the mean average boiling point expressed in degrees Rankin ($^\circ\text{R}$, which is $^\circ\text{F} + 460$). However, the mean average boiling point is a single physical parameter, which can only indicate a *general trend* in feedstock quality [19.6, 7] and the accuracy and meaningful nature of the data remain questionable. However, the characterization factor and the boiling range of the feedstocks are generally insufficient for anything other than *approximate comparisons*. A more detailed description of the feedstock is needed to reflect and predict the variations in feedstock composition and cracking behavior [19.1–4, 7].

On the more physical equipment-related aspects of the process, heat-balance control may be the most immediate and troublesome aspect of processing high-boiling feedstocks. As the contaminant carbon increases, the first response is usually to increase regenerator temperature. Adjustments in operating parameters can be made to assist in this control, but eventually, a point will be reached for heavier feedstocks when

the regenerator temperature is too high for good catalytic performance. At this point, some external heat removal from the regenerator is required and would necessitate a mechanical modification like a catalyst cooler.

19.2.2 Pretreating and Contaminant Removal

Feedstocks for catalytic cracking can be any one (or blends) of the following [19.7, 35]:

1. Straight-run gas oil
2. Vacuum gas oil
3. Recycle stock
4. Atmospheric residuum
5. Vacuum residuum
6. Heavy oil
7. Tar bitumen
8. And on occasion used lubricating oil.

However, when blends of the above-named feedstocks are employed, compatibility of the constituents of the individual blends must be assured or excessive coke will be laid down on the catalyst as a result of the incompatibility (phase separation) of the feedstock constituents.

As a result of any such potential issues that may arise and cause coke formation and/or catalyst deactivation, there are several pretreatment options for the feedstocks for catalytic cracking units and these are [19.1–4, 7, 31, 35–37]:

1. Deasphalting to prevent excessive coking on catalyst surfaces
2. Demetallization, i. e., removal of nickel, vanadium, and iron to prevent catalyst deactivation
3. Use of a short residence time as a means of preparing the feedstock
4. Hydrotreating or mild hydrocracking to mitigate the possibility of excessive coking in the fluid catalytic cracking unit.

Table 19.3 Feedstock and product data for the fluid catalytic process with and without feedstock hydrotreating

Feedstock (> 370 °C, > 700 °F)	No pretreatment	With hydrotreatment
API	15.1	20.1
Sulfur (wt%)	3.3	0.5
Nitrogen (wt%)	0.2	0.1
Carbon residue (wt%)	8.9	4.9
Nickel + vanadium (ppm)	51.0	7.0
Products		
Naphtha (C ₅ -220 °C, C ₅ -430 °F) (vol.%)	50.6	58.0
Light cycle oil (220–360 °C, 430–680 °F) (vol.%)	21.4	18.2
Residuum (> 360 °C, > 680 °F) (wt%)	9.7	7.2
Coke (wt%)	10.3	7.0

In fact, hydrotreating the feedstock to the fluid catalytic cracking unit improves the yield and quality of naphtha (Table 19.3) and reduces the sulfur oxide (SO_x) emissions from the unit, but it is typically a high-pressure process and, furthermore, manipulation

of feedstock sulfur alone may not be sufficient to meet future gasoline performance standards. Refineries wishing to process heavy crude oil and/or tar sand bitumen may only have the option to desulfurize the resulting high-sulfur naphtha produced in the process.

19.3 Reactor Design

The main design focus of any fluid catalytic cracking process is the reactor and regenerator which are considered to be the heart of the fluid catalytic cracking unit and the various options have evolved accordingly [19.10, 38, 39]. The reactor is the vessel in which the cracked product vapors are separated from the so-called *spent catalyst* by flowing the vapors through a set of two-stage cyclones within the reactor, after which the *spent catalyst* flows downward through a steam stripping section to remove any hydrocarbon vapors before the spent catalyst returns to the *catalyst regenerator*. The flow of spent catalyst to the regenerator is regulated by a control valve in the spent catalyst line.

The major process variables are temperature, pressure, catalyst-feedstock ratio (ratio of the weight of catalyst entering the reactor per hour to the weight of feedstock throughput on an hourly basis), and space velocity (weight or volume of the feedstock charged per hour per weight or volume of catalyst in the reaction zone). Wide flexibility in product distribution and quality is possible through control of these variables along with the extent of internal recycling necessary. Increased conversion can be obtained by applying higher temperature or higher pressure. Alternatively, lower space velocity and higher catalyst-feedstock ratio will also contribute to an increased conversion.

When cracking is conducted in a single stage, the more reactive hydrocarbons may be cracked, with a high conversion to gas and coke, in the reaction time necessary for reasonable conversion of the more refractory hydrocarbons. However, in a two-stage process, gas and naphtha from a short-reaction-time, high-temperature cracking operation are separated before the main cracking reactions take place in a second-stage reactor.

The several processes currently employed in catalytic cracking differ mainly in the method of catalyst handling, although there is an overlap with regard to catalyst type and the nature of the products. The catalyst, which may be an activated natural or synthetic material, is employed in bead, pellet, or microspherical form and can be used in *fixed-*, *moving-*, or *fluid-bed* configurations.

19.3.1 Fixed-Bed Processes

The *fixed-bed process* was the first to be used commercially and uses a static bed of catalyst in several reactors, which allows a continuous flow of feedstock to be maintained [19.40]. Thus, the cycle of operations include:

1. Flow of feedstock through the catalyst bed
2. Discontinuance of feedstock flow and removal of coke from the catalyst by burning
3. Insertion of the reactor on-stream.

Feedstocks may range from naphtha to atmospheric residuum (*reduced crude*). Feed preparation (to remove *metallic constituents* and *high-molecular weight non-volatile materials*) is usually carried out through any one of the following ways [19.31, 32]:

- Coking
- Propane deasphalting
- Furfural extraction
- Vacuum distillation
- Viscosity breaking
- Thermal cracking
- Hydrodesulfurization.

Historically, the Houdry fixed-bed process, which went on-stream in June 1936, was the first of the modern catalytic cracking processes [19.41]. It was preceded only by the McAfee batch process, which employed a metal halide (aluminum chloride) catalyst but has long since lost any commercial significance.

In a fixed-bed process, the catalyst in the form of small lumps or pellets is made up in layers or beds in several (four or more) catalyst-containing drums (converters). The feedstock is vaporized at approximately 450°C (840°F) and less than 7–15 psi (0.5–1 bar) pressure as it passes through one of the converters where the cracking reactions take place. Deposition of coke on the catalyst renders it ineffective, and using a synchronized valve system, the feed stream is directed to a neighboring converter while the catalyst in the first converter is regenerated by carefully burning the coke deposits with air. After about 10 min, the catalyst is ready to go on-stream again.

Although fixed-bed catalytic cracking units have been phased out, they represented an outstanding chemical engineering commercial development by incorporating a fully automatic instrumentation system which provided a short-time reactor/purge/regeneration cycle, a novel molten salt heat transfer system, and a flue gas expander for recovering power to drive the regeneration air compressor.

The requirement of complete vaporization necessarily limited feeds to those with a low boiling range and higher boiling feedstock constituents are retained in a separator before the feed is passed into the bottom of the upflow fixed-bed reactors. The catalyst consisted of a pelletized natural silica alumina catalyst and was held in reactors or *cases* about 11 ft (3.4 m) in diameter and 38 ft (11.6 m) length for a 15 000 bbl/day operation. Cracked products are passed through the preheat exchanger, condensed, and fractionated in a conventional manner. The reactors operated at about 30 psi (207 kPa) and 480 °C (900 °F).

The heat of reaction and some of the required feed circulating a molten salt through vertical tubes distributed through the reactor beds. The reaction cycle of an individual reactor was about 10 min, after which the feed was automatically switched to a new reactor that had been regenerated. The reactor was purged with steam for about 5 min and then isolated by an automatic cycle timer. Regeneration air was introduced under close control and carbon was burned off at a rate at which the recirculating salt stream could control the bed temperature. This stream comprised a mixture of potassium nitrate (KNO_3) and sodium nitrate (NaNO_3), which melts at 140 °C (285 °F), and was cooled in the reactors through which the feed was being processed. The regeneration cycle lasted about 10 min. The regenerated bed was then purged of oxygen and automatically cut back into cracking service. There were 3–6 reactors in a unit but naphtha yields decreased by up to 20 vol.% over the life of the catalysts (approximately 18 months).

Equilibrium was never reached in this cyclic process. The gas oil conversion, i. e., the amount of feed converted to lighter components, was high at the start of a reaction cycle and progressively diminished as the carbon deposit accumulated on the catalyst until regeneration was required. Multiple parallel reactors were used to approach a steady-state process. However, the resulting process flows were still far from steady state. The reaction bed temperature varied widely during reaction and regeneration periods, and the temperature differential within the bed during each cycle was considerable.

Since the catalyst in the reactor becomes contaminated with coke, the catalyst is continuously withdrawn

from the bottom of the reactor and lifted by means of a stream of air into a regenerator where the coke is removed by controlled burning. The regenerated catalyst then flows to the fresh feed line, where the heat in the catalyst is sufficient to vaporize the fresh feed before it reaches the reactor, where the temperature is about 510 °C (950 °F).

Fixed-bed processes have now generally been superseded by moving- or fluid-bed processes.

19.3.2 Moving-Bed Processes

The fixed-bed process had obvious capacity and mechanical limitations that needed improvement and, thus, was replaced by a moving-bed process in which the hot salt systems were eliminated. The catalyst was lifted to the top of the reactor system and flowed by gravity down through the process vessels.

The *moving-bed process* uses a reaction vessel in which cracking takes place and a kiln in which the spent catalyst is regenerated; catalyst movement between the vessels is provided by various means.

In the moving-bed processes, the catalyst is in the form of pelletized (approximately 0.125 in (3 mm) diameter) beads that flow by gravity from the top of the unit through a seal zone to the reactor that operates at about 10 psi (69 kPa) and 455–495 °C (850 to 92 °F). The catalyst then flows down through another seal and countercurrently through a stripping zone to the regenerator or kiln that operates at a pressure that is close to atmospheric.

Two advances in the technology of moving-bed catalytic cracking have greatly changed the operation compared to the early processes. The more important of these advances was the introduction of crystalline aluminosilicate cracking catalysts and the second advance was the development of techniques to reduce catalyst attrition and metal erosion in moving-bed cracking units.

The *airlift Thermofor catalytic cracking (Socony airlift TCC) process* is a moving-bed, reactor-over-generator continuous process for conversion of heavy gas oils into lighter high-quality naphtha and middle distillate fuel oil [19.42, 43]. Feed preparation may consist of flashing in a tar separator to obtain vapor feed, and the tar separator bottoms may be sent to a vacuum tower from which the liquid feed is produced.

The gas-oil vapor-liquid flows downward through the reactor concurrently with the regenerated synthetic bead catalyst. The catalyst is purged by steam at the base of the reactor and gravitates into the kiln, or regeneration is accomplished by the use of air injected into the kiln. Approximately 70% of the carbon on the catalyst is burned in the upper kiln burning zone and the remainder in the bottom burning zone. Regenerated,

cooled catalyst enters the lift pot, where low-pressure air transports it to the surge hopper above the reactor for reuse.

The *Houdrifiow catalytic cracking process* is a continuous, moving-bed process employing an integrated single vessel for the reactor and regenerator kiln [19.40, 44]. The charge stock, sweet or sour, can be any fraction of the crude boiling between naphtha and soft asphalt. The catalyst is transported from the bottom of the unit to the top in a gas lift employing compressed flue gas and steam. The reactor feedstock and catalyst pass concurrently through the reactor zone to a disengager section, in which vapors are separated and directed to a conventional fractionation system. The spent catalyst, which has been steam purged of residual oil, flows to the kiln for regeneration, after which steam and flue gas are used to transport the catalyst to the reactor.

The *Houdresid catalytic cracking process* is a process that uses a variation of the continuously moving catalyst bed designed to obtain high yields of high-octane naphtha and light distillate from reduced crude charge [19.45]. Residuum cuts ranging from crude tower bottoms to vacuum bottoms, including residua high in sulfur or nitrogen, can be employed as the feedstock, and the catalyst is synthetic or natural. Although the equipment employed is similar in many respects to that used in Houdrifiow units, novel process features modify or eliminate the adverse effects and catalyst and product selectivity usually resulting when heavy metals – iron, nickel, copper, and vanadium – are present in the fuel. The Houdresid catalytic reactor and catalyst-regenerating kiln are contained in a single vessel. Fresh feed plus recycled gas oil are charged to the top of the unit in a partially vaporized state and mixed with steam.

The *suspensoid catalytic cracking process* was developed from the thermal cracking process carried out in tube and tank units [19.46, 47]. Small amounts of powdered catalyst or a mixture with the feedstock are pumped through a cracking coil furnace. Cracking temperatures are 550–610 °C (1025–1130 °F), with pressures of 200–500 psi (14–34 bar). After leaving the furnace, the cracked material enters a tar separator where the catalyst and tar are left behind. The cracked vapors enter a bubble tower where they are separated into two parts, gas oil and pressure distillate. The latter is separated into naphtha and gases. The spent catalyst is filtered from the tar, which is used as a heavy industrial fuel oil. The process is actually a compromise between catalytic and thermal cracking. The main effect of the catalyst is to allow a higher cracking temperature and to assist mechanically in keeping coke from accumulating on the walls of the tubes. The normal catalyst employed is spent clay

obtained from the contact filtration of lubricating oils (2–10 pound/barrel of feed).

19.3.3 Fluid-Bed Processes

The application of fluidized solid techniques to catalytic cracking resulted in a major process breakthrough. It was possible to transfer all of the regeneration heat to the reaction zone. Much larger units could be built and higher boiling feedstocks could be processed. In fact, the improvements in catalysts and unit configurations have permitted the catalytic cracking of higher boiling (poorer quality) feedstocks such as residua. Presently, there are a number of processes that allow catalytic cracking of heavy oils and residua [19.1–4, 7, 35].

The *fluid-bed process* differs from the fixed-bed and moving-bed processes insofar as the powdered catalyst is circulated essentially as a fluid with the feedstock [19.48]. The several fluid catalytic cracking processes in use differ primarily in mechanical design [19.49, 50]. Side-by-side, reactor-regenerator configuration or the reactor either above or below the regenerator are the main mechanical variations. From a flow standpoint, all fluid catalytic cracking processes contact the feedstock and any recycle streams with the finely divided catalyst in the reactor.

The first fluid catalytic cracking units were model I upflow units in which the catalyst flowed up through the reaction and regeneration zones in a riser type of flow regime. Originally, the model I unit was designed to feed a reduced crude to a vaporizer furnace where all of the gas oil was vaporized and fed, as vapor, to the reactor. The nonvolatile residuum (bottoms) bypassed the cracking section. The original model I upflow design (1941) was superseded by the model II downflow design (1944) followed by the model III (1947) balanced-pressure design with the later introduction of the model IV low-elevation design (1952).

A typical modern fluid catalytic cracking process involves mixing a preheated hydrocarbon charge with hot, regenerated catalyst as it enters the riser pipe leading to the reactor. The charge is combined with a recycle stream within the riser pipe, vaporized, and raised to reactor temperature (485–540 °C; 900–1000 °F) by the hot catalyst. As the mixture travels up the riser pipe, the charge is cracked at 10–30 psi (0.7–2 bar). In the more modern fluid catalytic cracking process units, all cracking takes place in the riser pipe and continues until the oil vapors are separated from the catalyst in the reactor cyclones. The resultant product stream (cracked product) is then charged to a fractionating column where it is separated into fractions, and some of the heavy oil is recycled to the riser pipe. Spent catalyst is regenerated to get rid of coke that collects on the catalyst during the

process. Spent catalyst flows through the catalyst stripper to the regenerator, where most of the coke deposits burn off and fresh catalyst is added as spent catalyst is removed to optimize the cracking process.

The three main components of a fluid-bed catalytic cracking unit are:

1. The reactor
2. The stripper
3. The regenerator.

Thus, in the unit, the catalyst and the feed and product hydrocarbons are lifted up in the riser pipe to the *reactor* where the predominately endothermic cracking processes take place. Since the reactions are endothermic, reaction temperature declines from bottom to top. At the top, the mixture enters a solid-gas separator, and the product vapors are led away. Cracked gases are separated and fractionated; the catalyst and residue, together with recycle oil from a second-stage fractionator, pass to the main reactor for further cracking. The products of this second-stage reaction are gas, naphtha and gas oil streams, and recycle oil.

The coked catalyst enters the *stripper* where steam is added and unreacted-reacted hydrocarbons adsorbed on the catalyst are released. The stripped catalyst is then directed into the *regenerator* where air is added and the combustion of coke on the catalyst (and any hydrocarbons still adsorbed which were not stripped) occurs with the liberation of heat. Regenerator temperatures are typically 705–760 °C (1300–1400 °F). Heat exchangers and the circulating catalyst capture the heat evolved during regeneration to be used in preheating the reactor feed to appropriate cracking temperatures (usually in the range 495–550 °C (925–1020 °F)).

During operations, the entire catalyst inventory is *continuously* circulated through the unit. Catalyst residence time in the riser reactor section is typically 1–3 s (with current trends to even shorter residence times), and the entire reactor-stripper-regenerator cycle is less than 10 min. To achieve cycle times of this order, catalyst circulation rates as high as 1 T/s in large units are required. To withstand such movement, the catalyst must be sufficiently *robust* to withstand the operational stress.

Process temperatures are high, coke is repeatedly deposited and burned off, and the catalyst particles are moving at high speed through steel reactors and pipes. Contact between the catalyst particles and the metal walls and interparticle contact are unavoidable. Thus, catalyst loss from the unit caused by poor attrition resistance can be a serious problem, since the quantities lost must be replaced by fresh catalyst additions to maintain constant unit performance. Catalyst manufacturers work hard to prevent inordinate losses due to attrition,

and refineries keep a close watch on catalyst quality to be sure the product conforms to their specifications. Therefore, the robustness of the catalyst is carefully monitored and controlled to a high attrition resistance that is determined by rigorous test methods that place their focus on a semiquantitative evaluation of attrition resistance, which is generally related to breakdown with time in commercial units.

As intimated above, in some units cracking does not always take place in the reactor and reaction often occurs in the vertical or upwardly sloped pipe called the *riser* (giving credence to the name *riser reactor*, with this *riser pipe cracking*) forming products, including coke [19.51]. Preheated feedstock is sprayed into the base of the riser via feed nozzles where it contacts extremely hot fluidized catalyst at 1230–1400 °F (665–760 °C). The hot catalyst vaporizes the feed and catalyzes the cracking reactions that break down the high molecular weight oil into lighter components including liquefied petroleum gas (LPG), constituents, naphtha, and diesel. The catalyst-hydrocarbon mixture flows upward through the riser for just a few seconds and then the mixture is separated via cyclones. The catalyst-free hydrocarbons are routed to a main fractionator for separation into:

- Fuel gas
- Propane and butanes
- Naphtha
- Light cycle oils used in diesel and jet fuel
- Heavy fuel oil.

Since the catalyst in the reactor becomes contaminated with coke, the catalyst is continuously withdrawn from the bottom of the reactor and lifted by means of a stream of air into a regenerator where the coke is removed by controlled burning. The regenerated catalyst then flows to the fresh feed line, where the heat in the catalyst is sufficient to vaporize the fresh feed before it reaches the reactor, where the temperature is about 510 °C (950 °F).

19.3.4 Process Variables

The major process variables are temperature, pressure, catalyst-oil ratio (ratio of the weight of catalyst entering the reactor per hour to the weight of oil charged per hour), and space velocity (weight or volume of the oil charged per hour per weight or volume of catalyst in the reaction zone). Wide flexibility in product distribution and quality is possible through control of these variables along with the extent of internal recycling necessary [19.52]. Increased conversion can be obtained by applying higher temperature or higher pressure. Alternatively, lower space velocity and higher

catalyst/oil ratio will also contribute to an increased conversion.

All of the independent variables in catalytic cracking have a significant effect on conversion which is truly a dependent variable but can be shown as a function of API gravity as well as a variety of other functions [19.53]. The detailed effects of changing conversion depend on how conversion is changed, i. e., by temperature, space velocity, or catalyst/oil ratio, and catalyst activity. Increasing conversion increases yields of naphtha and all light products up to a conversion level of 60–80% by volume in most cases. At this high conversion level, secondary reactions become sufficient to cause a decrease in the yields of olefins and naphtha. However, the point at which this occurs is based on the feedstock, operating conditions, catalyst activity, and other parameters.

However, these variables are not always available for maximizing conversion since most fluid catalytic cracking units already operate at an optimum conversion level corresponding to a given feed rate, feed quality, set of processing objectives and catalyst under one or more unit constraints (e.g., wet gas compressor capacity, fractionation capacity, air blower capacity, reactor temperature, regenerator temperature, and catalyst circulation). Once the optimum conversion level is found, there are very few additional degrees of freedom for changing the operating variables.

Reactor Temperature

Increasing *reactor temperature* increases feedstock conversion, primarily through a higher rate of reaction for the endothermic cracking reaction and also through increased cat/oil (catalyst/oil) ratio. A 10 °F increase in reactor temperature can increase conversion by 1–2% absolute but, again, this is feedstock dependent. Higher reactor temperature also increases the amount of olefins in naphtha and in the gases. This is due to the higher rate of primary cracking reactions relative to secondary hydrogen transfer reactions which saturate olefins in the naphtha boiling range and lowers gasoline octane.

The principal effects of increasing reactor temperature at constant conversion are to decrease naphtha and coke yield and to increase methane (CH₄), ethane (C₂H₆), propane (CH₃CH₂CH₃), and total butane (C₄H₁₀) yield; yields of pentanes (C₅H₁₂) and higher molecular weight paraffins decrease while olefin yields are increased.

The effect of reactor temperature on a commercial unit is, of course, considerably more complicated as variables other than temperature must be changed to maintain heat balance. For example, in order to increase the temperature of a reactor at constant fresh feed rate, interrelated changes of recycle rate, space velocity, and

feedstock preheat are required to maintain heat balance in the unit by increasing circulation rate and coke yield.

The combined effects of higher reactor temperature and higher conversion resulted in the following additional changes:

1. Increased yields of butanes and propane
2. Increased yields of naphtha
3. Decreased yield of light catalytic cycle oil.

Thus, the effects of an increase in reactor temperature on an operating unit reflect not only the effects of temperature per se but also the effects of several concomitant changes such as increased conversion and increased catalyst/oil ratio.

Pressure

Higher conversion and coke yield are thermodynamically favored by higher *pressure*. However, pressure is usually varied over a very narrow range due to limited air blower horsepower. Conversion is not significantly affected by unit pressure since a substantial increase in pressure is required to significantly increase conversion.

Catalytic cracker pressures are generally set slightly above atmospheric by balancing the yield and quality debits of high pressure plus increased regeneration air compression costs against improved cracking and regeneration kinetics, the lower cost of smaller vessels, plus, in some cases, power recovery from the regenerator stack gases. Representative yield and product effects show, at the same conversion level, that coke and naphtha yields are increased marginally and light gas yields are reduced at the higher pressure – in addition, the sulfur content of the naphtha fraction is reduced.

Pressure levels in commercial units are generally in the range 15–35 psi (103–241 kPa). Lowering the partial pressure of the reacting gases with steam will improve yields somewhat, but the major beneficial effect of feed injection steam is that it atomizes the feed to small droplets that will vaporize and react quickly. If feed is not atomized, it will soak into the catalyst and possibly crack to a higher coke make.

Both pressure and partial pressure of the feedstock, or steam/feedstock ratio, are generally established in the design of a commercial unit and thus are usually not available as independent variables over any significant range. However, in some units, injector steam is varied over a narrow range to balance carbon make with regeneration carbon burn off.

Recycle Rate

With most feedstocks and catalyst, the yield of naphtha increases with increasing conversion up to a point, passes through a maximum, and then decreases. This phenomenon (*over-cracking*) is caused by the increased

thermal stability (*refractory character*) of the unconverted feed as conversion increases and the destruction of valuable naphtha constituents through secondary reactions, primarily cracking of olefins. The onset of secondary reactions and the subsequent leveling off or decrease in yield of naphtha can be avoided by recycling a portion of the reactor product, usually a fractionator product with a boiling point on the order of 345–455 °C (650–850 °F).

Furthermore, starting from the fractionator bottom, the slurry oil cooler is a very demanding position, where fouling is a major problem. Some of the suspended catalyst will go into the fractionator and end up in the unit bottom fraction (slurry oil), which has the potential to cause fouling and significant problems when cooled in a traditional shell-and-tube system. If the slurry oil is clarified (to become what is known as clarified slurry oil, CSO) it has a much lower tendency to cause fouling than the catalytic cracker bottom fraction.

Other tests have shown the following effects of increasing recycle rate when space velocity was simultaneously adjusted to maintain constant conversion:

1. Naphtha yield increased significantly
2. Coke yield decreases appreciably
3. Decrease in the yield of dry gas components, propylene, and propane
4. Butane yields decreased while butylene yields increased slightly
5. Light catalytic cycle oil and clarified oil yields increased, but heavy catalytic cycle oil yield decreased.

With the introduction of high-activity zeolite catalysts, it was found that in once-through cracking operations with no recycle, the maximum yield of naphtha was much higher. In effect, the higher activity catalysts were allowing higher conversions to be obtained at severity levels that significantly reduced the extent of secondary reactions (*over-cracking*). Thus, on many units employing zeolite catalysts, the recycle stream has been eliminated or reduced to less than 15 vol.% of the fresh feed rate.

Reaction Time and Space Velocity

An increase in *reaction time* available for cracking also increases conversion. Fresh feed rate, riser steam rate, recycle rate, and pressure are the primary operating variables that affect reaction time for a given unit configuration. Conversion varies inversely with these stream rates due to limited reactor size available for cracking. Conversion has been increased by a decrease in the rate of injection of fresh feedstock. Under these circumstances, over-cracking of naphtha to liquefied petroleum gas and to dry gas may occur due to the in-

crease in reactor residence time. One approach to offset any potential naphtha over-cracking is to add additional riser steam to lower hydrocarbon partial pressure for more selective cracking. Alternatively, an operator may choose to lower reactor pressure or increase the recycle rate to decrease residence time. Naphtha over-cracking may be controlled by reducing the availability of catalytic cracking sites by lowering cat/oil ratio.

The role of space velocity as an independent variable arises from its relation to *catalyst contact time* or *catalyst residence time*. Thus,

$$\Theta = \frac{60}{(\text{WHSV} \times \text{C/O})}$$

where Θ = catalyst residence time (min), WHSV = weight hourly space velocity on a total weight basis, and C/O = catalyst/oil weight ratio.

The catalyst/oil ratio is a dependent variable so that catalyst time becomes directly related to the weight hourly space velocity. When catalyst contact time is low, secondary reactions are minimized, thus naphtha yield is improved and light gas and coke yields are decreased. In dense bed units the holdup of catalyst in the reactor can be controlled within limits, usually by a slide valve in the spent-catalyst standpipe, and feed rate can also be varied within limits. Thus, there is usually some freedom to increase space velocity and reduce catalyst residence time. In a riser-type reactor, holdup and feed rate are not independent and space velocity is not a meaningful term. Nevertheless, in dense-bed and riser-type reactors, contact times are usually minimized to improve selectivity. An important step in this direction was the introduction of high-activity zeolite catalyst. These catalysts require short contact times for optimum performance and have generally moved cracking operations in the direction of minimum holdup in dense-bed reactors or replacement of dense-bed reactors with short-contact-time riser reactors.

Strict comparisons of short-contact-time riser cracking versus the longer contact time dense-bed mode of operations are generally not available due to differences in catalytic activity, carbon content of the regenerated catalyst, or factors other than contact time but inherent in the two modes of operation. However, in general, improvements in catalyst activity have resulted in the need for less catalyst in the reaction zone.

Many units are designed with only riser cracking, i. e., no dense-bed catalyst reactor cracking occurs and all cracking is done in the catalyst–oil transfer lines leading into the reactor cyclone vessel. However, in some of these instances the reactor temperature must be increased to the 550–565 °C (1020–1050 °F) range in order to increase the intensity of cracking conditions to achieve the desired conversion level. This is because

not enough catalyst can be held in the riser zone, since the length of the riser is determined by the configuration and elevation of the major vessels in the unit. Alternatively, superactive catalysts can be used to achieve the desired conversion in the riser.

Significant selectivity disadvantages have not been shown if a dispersed catalyst phase or even a very small dense bed is provided downstream of the transfer line riser cracking zone. In this case the cracking reaction can be run at a lower temperature, say 510 °C (950 °F), which will reduce light gas make and increase naphtha yield when compared to the higher temperature (550–565 °C or 1020–1050 °F) operation.

Heat Balance

In the operation of a fluid catalytic cracking unit where heat balance is necessary, increasing the temperature of the feedstock to the unit reduces the heat that must be supplied by combustion of the coked catalyst in the regenerator. Feedstock preheating is usually supplied by heat exchange with hot product streams, a fired preheater, or both. When feed rate, recycle rate, and reactor temperature are held constant as feed preheat is increased, the following changes in operation result:

1. The catalyst/oil ratio (catalyst circulation rate) is decreased to hold the reactor temperature constant.
2. Conversion and all conversion-related yield, including coke, decline due to the decrease in catalyst/oil ratio and severity.
3. The regenerator temperature will usually increase. Although the total heat released in the regenerator and the air required by the regenerator are reduced by the lower coke yield, the lower catalyst circulation usually overrides this effect and results in an increase in regenerator temperature.
4. As a result of the lower catalyst circulation rate the usual outcome is that residence time in the stripper and overall stripper efficiency is increased, liquid recovery is increased, and there is a corresponding decrease in coke. However, these effects must be weighed against the cost of the excess heat applied to the unit.

Thus, in order to maintain a dynamic heat balance in the process, hot regenerated catalyst supplying the net heat demand is required by the reactor. Finely sized solid catalyst continuously circulates in a closed loop between the reactor and the catalyst regeneration system (Fig. 19.1). The feedstock and catalyst are in intimate contact in the riser reactor in a controlled ratio and with the residence time and temperature required to achieve efficient conversion. The products are disengaged from the spent catalyst using a catalyst stripper

(Fig. 19.1) where any carbon product vapors entrained with the catalyst are removed and recovered. The regenerator (Fig. 19.1) system removes coke deposited on the catalyst and restores catalytic activity by combustion of the catalyst/coke in air. The system also provides heat of reaction and heat of vaporization (of the feedstock) by returning hot, freshly regenerated catalyst back to the reaction system.

The hot regenerated catalyst flows to the base of the reactor system riser where it is contacted with feed supplied through feedstock injectors. Vaporized feedstock and catalyst travel up the riser where catalytic reactions occur. The reacted vapor is rapidly disengaged from the spent catalyst in direct-coupled riser cyclones and routed directly to product fractionation, which minimizes the time available for nonselective, postriser cracking (typically, thermal cracking). The vapors from the reactor are quenched and fractionated in the product recovery system, which yields C₄ and lower molecular weight gases, naphtha (often called FCC gasoline, but not true sales gasoline), and middle distillate products (Fig. 19.1). The spent catalyst separated by the riser cyclones is degassed of most of the reaction vapor while flowing into the catalyst stripper, where the catalyst is steam-stripped to produce more hydrocarbon product.

The spent catalyst is transported from the stripper into the regenerator where the carbonaceous deposits on the coke start to react with the lift air at a lower combustion temperature relative to the regenerator dense-bed temperature, which reduces hydrothermal deactivation of the catalyst. The remainder of the carbonaceous deposit is burned off in the regenerator and the flue gas is routed through cyclones to minimize catalyst losses and then sent to energy recovery. Hot regenerated catalyst overflows into an external catalyst hopper where it is aerated to the necessary density before flowing back to the base of the riser. Furthermore, it is often considered to be advantageous to use any feedstock preheating effects, including the reduced air requirement, by increasing the total feed rate until coke production again requires all of the available air.

Additives

In addition to the cracking catalysts described above, a series of *additives* has been developed that catalyze or otherwise alter the primary catalyst's activity/selectivity or act as pollution control agents. Additives are most often prepared in microspherical form to be compatible with the primary catalysts and are available separately in compositions that:

1. Enhance gasoline octane and light olefin formation
2. Selectively crack heavy cycle oil

3. Passivate vanadium and nickel present in many heavy feedstocks
4. Oxidize coke to carbon dioxide
5. Reduce sulfur dioxide emissions.

Both vanadium and nickel deposit on the cracking catalyst and are extremely deleterious when present in excess of 3000 ppm on the catalyst. Formulation changes to the catalyst can improve tolerance to vanadium and nickel but the use of additives that specifically passivate either metal is often preferred.

19.3.5 Regenerator Temperature

Catalyst circulation, coke yield, and feedstock preheating are the principal determinants of regenerator temperature that is generally allowed to respond as a dependent variable within limits. Mechanical or structural specifications in the regenerator section generally limit regenerator temperature to a maximum value specific to each unit. However, in some cases the maximum temperature may be set by catalyst stability. In either case, if regenerator temperature is too high it can be reduced by decreasing feedstock preheat; catalyst circulation is then increased to hold a constant reactor temperature and this increased catalyst circulation will carry more heat from the regenerator and lower the regenerator temperature. The sequence of events is actually more complicated as the shift in catalyst/oil ratio and, to a lesser extent, the shift in carbon content of the regenerated catalyst will change coke make and the heat release in the regenerator.

19.3.6 Regenerator Air Rate

The amount of air required for regeneration depends primarily on coke production. Regenerators have been operated with only a slight excess of air leaving the dense phase. With less air, carbon content of the spent catalyst increases and a reduction in coke yield is required of air, burning of carbon monoxide (CO) to carbon dioxide (CO₂) above the dense bed will occur. This *after burning* must be controlled as extremely high temperature in the absence of the heat sink provided by the catalyst in the dense phase.

In terms of catalyst regeneration, higher stability catalysts are available and regenerator temperatures can be increased by 38–65 °C (100–150 °F) up to the 720–745 °C (1325–1370 °F) range without significant thermal damage to the catalyst. At these higher temperatures the oxidation of carbon monoxide to carbon dioxide is greatly accelerated and the regenerator can be designed to absorb the heat of combustion in the catalyst under controlled conditions. The carbon burning rate is improved at the higher temperatures, and there are usually selectivity benefits associated with the lower carbon on regenerated catalyst; this high temperature technique usually results in carbon on regenerated catalyst levels of 0.05% by weight or less. In addition, the use of catalysts containing promoters for the oxidation of carbon monoxide to carbon dioxide produce a major effect of high temperature regeneration, i. e., low carbon monoxide content regenerator stack gases and the resultant regenerator conditions may result in a lower carbon content regenerated catalyst.

Fig. 19.1 Detailed schematic of a fluid catalytic cracking reactor (after [19.54])

19.4 Catalysts

Cracking of crude oil fractions occurs over many types of catalytic materials, but high yields of desirable products are obtained with hydrated aluminum silicates. These may be either activated (acid-treated natural clays of the bentonite type) or synthesized silica-alumina or silica-magnesia preparations. Their activity to yield essentially the same products may be enhanced to some extent by the incorporation of small amounts of other materials, such as the oxides of zirconium (zirconia, ZrO_2), boron (boria, B_2O_3 , which has a tendency to volatilize away on use), and thorium (thoria, ThO_2). Both the natural and the synthetic catalysts can be used as pellets or beads, and also in the form of powder; in either case replacements are necessary because of attrition and gradual loss of efficiency [19.55, 56].

The catalysts must be stable to physical impact loading and thermal shocks and must withstand the action of carbon dioxide, air, nitrogen compounds, and steam. They should also be resistant to sulfur compounds; the synthetic catalysts and certain selected clays appear to be better in this regard than average untreated natural catalysts. The silica-alumina catalysts are reported to give the highest-octane naphtha and silica-magnesia the largest yields, with the natural clays falling between them.

The catalysts are porous and highly adsorptive, and their performance is affected markedly by the method of preparation. Two catalysts that are chemically identical but have pores of different size and distribution may have different activity, selectivity, temperature coefficient of reaction rate, and response to poisons. The intrinsic chemistry and catalytic action of a surface may be independent of pore size, but small pores appear to produce different effects because of the manner and time in which hydrocarbon vapors are transported into and out of the interstices.

Commercially used cracking catalysts are *insulator catalysts* possessing strong acidic properties. They function as catalysts by altering the cracking process mechanisms through an alternative mechanism involving *chemisorption* by *proton donation* and *desorption*, resulting in cracked oil and theoretically restored catalyst. Thus, it is not surprising that all cracking catalysts are poisoned by proton-accepting vanadium.

The catalyst/oil volume ratios range from 5 : 1 to 30 : 1 for the different processes, although most processes are operated using a 10 : 1 ratio. However, for moving-bed processes the catalyst/oil volume ratios may be substantially lower than 10 : 1.

In addition to zeolite and matrix activity, many of the physical and chemical properties of the catalyst (*catalyst design*) contribute to increased conversion

through selectivity differences. These include zeolite type, pore size distribution, relative matrix to total surface area, and chemical composition.

Increasing the concentration of catalyst in the reactor, often referred to as cat/oil ratio, will increase the availability of cracking for maximum conversion, assuming the unit is not already operating at a catalyst circulation limit. This can be achieved by increasing reactor heat load or switching to a lower coke selective (i. e., lower delta coke) catalyst. Reactor heat load can be raised by increased reactor temperature or lower feed preheat temperature. This, in turn, increases the cat/oil ratio to maintain the unit in heat balance.

The lower the *carbon on regenerated catalyst* the higher the availability of cracking sites since less coke is blocking acid cracking sites. The carbon on the regenerated catalyst is reduced by increasing regeneration efficiency through the use of carbon monoxide oxidation promoters. Carbon on the regenerated catalyst can also be reduced by more efficient air and spent catalyst contact. Increased regenerator bed levels also reduce the amount of carbon on the regenerated catalyst through increased residence time but this must be traded off with reduced dilute phase disengager residence time and the possibility for increased catalyst losses.

19.4.1 Catalyst Types

The cracking of crude oil fractions occurs over many types of catalytic materials and cracking catalysts can differ markedly in both activity to promote the cracking reaction and in the quality of the products obtained from cracking the feedstocks [19.57–63]. Activity can be related directly to the total number of active (acid) sites per unit weight of catalyst and also to the acidic strength of these sites. Differences in activity and acidity regulate the extent of various secondary reactions occurring and thus the product quality differences. The acidic sites are considered to be Lewis-acid or Brønsted-acid sites, but there is much controversy as to which type of site predominates.

The first cracking catalysts were acid leached *montmorillonite clays*. The acid leach was to remove various metal impurities, principally iron, copper, and nickel that could exert adverse effects on the cracking performance of the catalyst. The catalysts first used in fixed-bed and moving-bed reactor systems were in the form of shaped pellets. Later, with the development of the fluid catalytic cracking process, the clay catalysts were made in the form of a ground, sized powder. Clay catalysts are relatively inexpensive and have been used extensively for many years.

The desire to have catalysts that were uniform in composition and catalytic performance led to the development of *synthetic catalysts*. The first synthetic cracking catalyst consisting of 87% silica (SiO_2) and 13% alumina (Al_2O_3) was used in pellet form and used in fixed-bed units in 1940. Catalysts of this composition were ground and sized for use in fluid catalytic cracking units. In 1944 catalysts in the form of beads about 2.5–5.0 mm diameter were introduced and comprised about 90% silica and 10% alumina and were extremely durable. One version of these catalysts contained a minor amount of chromia (Cr_2O_3) to act as an oxidation promoter.

Neither silica (SiO_2) nor alumina (Al_2O_3) alone is effective in promoting catalytic cracking reactions. In fact, they (and also activated carbon) promote hydrocarbon decompositions of the thermal type. Mixtures of anhydrous silica and alumina ($\text{SiO}_2 \cdot \text{Al}_2\text{O}_3$) or anhydrous silica with hydrated alumina ($2\text{SiO}_2 \cdot 2\text{Al}_2\text{O}_3 \cdot 6\text{H}_2\text{O}$) are also essentially noneffective. A catalyst having appreciable cracking activity is obtained only when prepared from hydrous oxides followed by partial dehydration (*calcining*). The small amount of water remaining is necessary for proper functioning.

Commercial synthetic catalysts are amorphous and contain more silica than is called for by the preceding formulae; they are generally composed of 10–15% alumina (Al_2O_3) and 85–90% silica (SiO_2). The natural materials, montmorillonite, a nonswelling bentonite, and halloysite, are hydrosilicates of aluminum, with a well-defined crystal structure and approximate composition of $\text{Al}_2\text{O}_3 \cdot 4\text{Si}_2\text{O} \cdot x\text{H}_2\text{O}$. Some of the newer catalysts contain up to 25% alumina and are reputed to have a longer active life.

In addition to synthetic catalysts comprising silica-alumina, other combinations of *mixed oxides* were found to be catalytically active and were developed during the 1940s. These systems included silica (SiO_2), magnesia (MgO), silica-zirconia ($\text{SiO}_2\text{-ZrO}$), silica-alumina-magnesia, silica-alumina-zirconia, and alumina-boria ($\text{Al}_2\text{O}_3\text{-B}_2\text{O}_3$). Of these, only silica-magnesia was used in commercial units but operating difficulties developed with the regeneration of the catalyst which at the time demanded a switch to another catalyst. Further improvements in silica-magnesia catalysts have since been made. High yields of desirable products are obtained with hydrated aluminum silicates. These may be either activated (acid-treated natural clays of the bentonite type) or synthesized silica-alumina or silica-magnesia preparations. Both the natural and the synthetic catalysts can be used as pellets or beads, and also in the form of powder; in either case replacements are necessary because of attrition and gradual loss of efficiency [19.55, 56].

During the period 1940 to 1962, the cracking catalysts used most widely commercially were the aforementioned acid-leached clays and silica alumina. The latter was made in two versions; *low alumina* (about 13% Al_2O_3) and *high alumina* (about 25% Al_2O_3) contents. High-alumina content catalysts showed a higher equilibrium activity level and surface area.

During the 1958 to 1960 period, *semisynthetic catalysts* of silica-alumina catalyst were used in which approximately 25–35% kaolin was dispersed throughout the silica-alumina gel. These catalysts could be offered at a lower price and therefore were disposable but they were marked by a lower catalytic activity and greater stack losses because of increased attrition rates. One virtue of the semisynthetic catalysts was that a lesser amount of adsorbed, unconverted, high molecular weight products on the catalyst were carried over to the stripper zone and regenerator. This resulted in a higher yield of more valuable products and also smoother operation of the regenerator as local hot spots were minimized.

Crystalline *zeolite catalysts* having molecular sieve properties were introduced as selective adsorbents in the 1955 to 1959 period. In a relatively short time period all of the cracking catalyst manufacturers were offering their versions of zeolite catalysts to refiners. The intrinsically higher activity of the crystalline zeolites vis-à-vis conventional amorphous silica-alumina catalysts coupled with the much higher yields of naphtha and decreased coke and light end yields served to revitalize research and development in the mature refinery process of catalytic cracking.

A number of *zeolite catalysts* have been mentioned as having catalytic cracking properties, such as synthetic faujasite (X-type and Y-type), offretite, mordenite, and erionite. Of these, the faujasite minerals have been most widely used commercially. While faujasite is synthesized in the sodium form, base exchange removes the sodium with other metal ions that, for cracking catalysts, include magnesium, calcium, rare earths (mixed or individual), and ammonium. In particular, mixed rare earths alone or in combination with ammonium ions have been the most commonly used forms of faujasite in cracking catalyst formulations. Empirically, X-type faujasite has a stoichiometric formula of $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2.5\text{SiO}_2$ and Y-type faujasite $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4.8\text{SiO}_2$. Slight variations in the silica-alumina ($\text{SiO}_2/\text{Al}_2\text{O}_3$) ratio exist for each of the types. Rare-earth-exchanged Y-type faujasite retains much of its crystallinity after steaming at 825 °C (1520 °F) with steam for 12 h; rare-earth form X-faujasite, while thermally stable in dry air, will lose its crystallinity at these temperatures in the presence of steam.

19.4.2 Catalyst Manufacture

While each manufacturer has developed proprietary procedures for making silica-alumina catalyst, the general procedure consists of:

1. The gelling of dilute sodium silicate solution ($\text{Na}_2\text{O} \cdot 3.25\text{SiO}_2 \cdot x\text{H}_2\text{O}$) by addition of an acid (H_2SO_4 , CO_2) or an acid salt such as aluminum sulfate
2. Aging the hydrogel under controlled conditions
3. Adding the prescribed amount of alumina as aluminum sulfate and/or sodium aluminate
4. Adjusting the pH of the mixture
5. Filtering the composite mixture.

After filtering, the filter cake can either be (1) washed free of extraneous soluble salts by a succession of slurring and filtration steps and spray dried or (2) spray dried and then washed free of extraneous soluble salts before flash drying the finished catalyst.

There are a number of critical areas in the preparative processes that affect the physical and catalytic properties of the finished catalyst. Principal among them are the concentration and temperature of the initial sodium silicate solution, the amount of acid added to effect gelation, the length of time of aging the gel, the method and conditions of adding the aluminum salt to the gel, and its incorporation therein. Under a given set of conditions the product catalyst is quite reproducible in both physical properties and catalytic performance.

During the period 1940 to 1962, a number of improvements were made in silica-alumina catalyst manufacture. These included continuous production lines versus batch-type operation, introduction of spray drying to eliminate grinding and sizing of the catalyst while reducing catalyst losses as fines, improving catalyst stability by controlling pore volume, and improved wash procedures to remove extraneous salts from high alumina content catalysts to improve equilibrium catalyst performance.

Zeolite cracking catalysts are made by dispersing or imbedding the crystals in a matrix. The matrix is generally amorphous silica-alumina gel and may also contain finely divided clay. The zeolite content of the composite catalyst is generally in the range of 5–16% by weight. If clay (e.g., kaolin) is used in the matrix, it is present in an amount of 25–45% by weight, the remainder being the silica-alumina hydrogel *glue* that binds the composite together. The zeolite may be pre-exchanged to the desired metal form and calcined to lock the exchangeable metal ions into position before compositing with the other ingredients. In an alternate scheme, sodium-form zeolite is composited with the other components,

washed, and then treated with a dilute salt solution of the desired metal ions before the final drying step.

As stated above, the matrix generally consists of silica-alumina, but several catalysts have been commercialized and contain (1) silica-magnesia, kaolin and (2) synthetic montmorillonite-mica and/or kaolin as the matrix for faujasite.

19.4.3 Catalyst Activity and Selectivity

The primary variables available to the operation of fluid catalytic cracking units for maximum unit conversion for a given feedstock quality include catalytic variables such as: (1) catalyst activity and (2) catalyst design, which includes availability of cracking sites and the presence of carbon on the regenerated catalyst.

Catalyst activity as an independent variable is governed by the capability of the unit to control the carbon content of the spent catalyst and the quantity and quality of fresh catalyst that can be continuously added to the unit. The carbon content of the regenerated catalyst is generally maintained at the lowest practical level to obtain the selectivity benefits of low carbon on the catalyst. Thus, catalyst addition is, in effect, the principal determinant of catalyst activity.

The deliberate withdrawal of catalyst over and above the inherent loss rate through regenerator stack losses and decant or clarified oil and a corresponding increase in fresh catalyst addition rate is generally not practiced as a means of increasing the activity level of the circulating catalyst. If a higher activity is needed, the addition of a higher activity fresh catalyst to the minimum makeup rate to maintain inventory is usually the more economical route.

The general effects of increasing activity is a reduction in severity and thus reduce the extent of secondary cracking reactions. Higher activity typically results in more naphtha and less coke. In other cases, higher activity catalysts are employed to increase the feed rate at essentially constant conversion and constant coke production so that the coke burning or regenerator air compression capacities are fully utilized.

In the catalytic cracking process, the most abundant products are those having 3, 4, and 5 carbon atoms. On a weight basis the 4-carbon-atom fraction is the largest. The differences between the catalysts of the mixed oxide type lie in the relative action toward promoting the individual reaction types included in the overall cracking operation. For example, silica-magnesia catalyst under a given set of cracking conditions will give a higher conversion to cracked products than silica-alumina catalyst. However, the products from a silica-magnesia ($\text{SiO}_2\text{-MgO}$) catalyst have a higher average molecular weight, hence a lower volatility,

lesser amounts of highly branched/acyclic isomers, but more olefins among the naphtha-boiling-range products ($C_4 - 220^\circ\text{C}$, 430°F) than the products from a silica-alumina catalyst. With these changes in composition, the naphtha from cracking with a silica-magnesia catalyst is of lower octane number.

These differences between catalysts may also be described as differences in the intensity of the action at the individual active catalytic centers. That is, a catalyst such as silica-alumina would give greater intensity of reaction than silica-magnesia as observed from the nature and yields of the individual cracked products and the gasoline octane number. Titration of these two catalysts shows silica-alumina to have a lower acid titer than silica-magnesia but the acid strength of the sites is higher.

While each of the individual component parts in these catalysts is essentially nonacidic, when mixed together properly they give rise to a titratable acidity as described above. Many of the secondary reactions occurring in the cracking process may also be promoted with strong mineral acids, such as concentrated sulfuric and phosphoric acids, aluminum halides, hydrogen fluoride, and hydrogen fluoride-boron trifluoride (BF_3) mixtures. This parallelism lends support to the concept of the active catalytic site as being acidic. Zeolites have a much higher active site density (titer) than the amorphous mixed oxides, which may account in large part for their extremely high cracking propensity. In addition, these materials strongly promote complex hydrogen transfer reactions among the primary products so that the recovered cracked products have a much lower olefin and higher paraffin content than are obtained with the amorphous mixed oxide catalysts. This hydrogen transfer propensity of zeolites to saturate primary cracked product olefins to paraffins minimizes the reaction of polymerizing the olefins to form a coke deposit, thus accounting in part for the much lower coke yields with zeolite catalysts than with amorphous catalysts.

Activity of the catalyst varies with faujasite content as does selectivity of the catalyst to coke and naphtha. As the faujasite content drops below 5% by weight the catalyst starts to show some of the cracking properties of the matrix, while for zeolite contents of 10% by weight or higher very little change in selectivity patterns is noted. The various ion-exchanged forms of the faujasite can result in slightly different cracking properties e.g., using high cerium content mixed rare earths improves carbon burning rates in the regenerator, use of H-form of faujasite improves selectivity to propane-pentane fractions, use of a minor amount of copper-form faujasite increases light olefin yield and naphtha octanes.

19.4.4 Catalyst/Oil Ratio

The dependent variable catalyst/oil ratio is established by the unit heat balance and coke make that in turn are influenced by almost every independent variable. Since catalyst/oil ratio changes are accompanied by one or more shifts in other variables, the effects of catalyst/oil ratio are generally associated with other effects. A basic relation, however, in all catalyst/oil ratio shifts is the effect on conversion and carbon yield. At constant space velocity and temperature, increasing catalyst/oil ratio increases conversion. In addition to increasing conversion, higher catalyst/oil ratios generally increase coke yield at a constant conversion. This increase in coke is related to the hydrocarbons entrapped in the pores of the catalyst and carried through the stripper to the regenerator. Thus, this portion of the catalyst/oil ratio effect is highly variable and depends not only on the catalyst/oil ratio change but also on the catalyst porosity and stripper conditions.

The following changes, in addition to increased coke yield, accompany an increase in the catalyst/oil ratio in the range of 5–20 at constant conversion, reactor temperature and catalyst activity:

1. Decreased hydrogen yield
2. Decreased methane to butane(s) yields
3. Minimal effect on the naphtha yield or octane number.

19.4.5 Catalyst Deactivation

A cracking catalyst should maintain its cracking activity with little change in product selectivity as it ages in a unit [19.64, 65]. A number of factors contribute to degrade the catalyst:

1. The combination of high temperatures, steam partial pressure, and time
2. Impurities present in the fresh catalyst
3. Impurities picked up by the catalyst from the feed while in use.

Under normal operating conditions, the catalyst experiences temperatures of $480\text{--}515^\circ\text{C}$ ($900\text{--}960^\circ\text{F}$) in the reactor and steam stripper zones and temperatures of $620\text{--}720^\circ\text{C}$ ($1150\text{--}1325^\circ\text{F}$) and higher in the regenerator accompanied by a substantial partial pressure of steam. With mixed oxide amorphous gel catalysts, the plastic nature of the gel is such that the surface area and pore volume decrease rather sharply in the first few days of use and then at a slow inexorable rate thereafter. This plastic flow also results in a loss in the number and strength of the active catalytic sites.

Zeolite catalysts comprising both amorphous gel and crystalline zeolite degrade from instability of the gel, as stated above, and also from loss in crystallinity. The latter also results from the combined effects of time, temperature, and steam partial pressure. When crystallinity is lost, the amorphous residue is relatively low in activity, approximating that of the amorphous gel matrix. The rate of degradation of the amorphous gel component may not be the same as that of the zeolite crystals e.g., the gel may degrade rapidly and through thermoplastic flow effectively coat the crystals and interfere with the diffusion of hydrocarbons to the catalytic sites in the zeolite. Catalyst manufacturers try to combine high stability in the matrix with high stability zeolite crystals when making zeolite catalysts.

Residual impurities in freshly manufactured catalysts are principally sodium and sulfate. These result from the use of sodium silicate and aluminum sulfate in making the silica-alumina gel matrix and subsequent washing of the composite catalyst with ammonium sulfate to remove sodium. Generally, the sodium content of the amorphous gel is < 0.1% by weight (as Na₂O) and sulfate < 0.5% by weight.

With zeolite catalysts the residual sodium may be primarily associated with the zeolite, so that sodium levels may range from about 0.2–0.80% for the composite catalyst. Sulfate levels in zeolite catalysts are still < 0.5%. An excessive amount of sodium reacts with the silica in the matrix under regenerator operating conditions and serves as a flux to increase the rate of surface area and pore volume loss. Sodium faujasite is not as hydrothermally stable as other metal-exchanged (e.g., mixed rare earths) forms of faujasite. It is most desirable to reduce the sodium content of the faujasite component to < 5.0% by weight (as Na₂O) with rare earths or with mixtures of rare earths and ammonium ions.

Finally, catalysts can degrade as a result of impurities picked up from the feed being processed. These impurities are sodium, nickel, vanadium, iron, and copper. Sodium as laid down on the catalyst not only acts to neutralize active acid sites, reducing catalyst activity, but also acts as a flux to accelerate matrix degradation. Freshly deposited metals are effective *poisons* to cracking catalysts because of the loss of active surface area by metal deposition. Zeolite catalysts are less responsive to metal contaminants than amorphous gel catalysts. Hence, equilibrium catalysts can tolerate low levels of these metals so long as they have enough time to become buried. A sudden deposition of fresh metals can cause adverse effects on unit performance. Metals levels on equilibrium catalysts reflect the met-

als content of the feeds being processed, typical ranges are 200–1200 ppm V, 150–500 ppm Ni, and 5–45 ppm Cu. Sodium levels are in the range of 0.25–0.8% by weight (as Na₂O).

19.4.6 Catalyst Stripping

Catalyst leaving the reaction zone is fluidized with reactor product vapors that must be removed and recovered with the reactor product. In order to accomplish this, the catalyst is passed into a stripping zone where most of the hydrocarbon is displaced with steam.

Stripping is generally done in a countercurrent contact zone where shed baffles or contactors are provided to insure equal vapor flow up through the stripper and efficient contacting. Stripping can be accomplished in a dilute catalyst phase. Generally, a dense phase is used, but with lighter feeds or higher reactor temperature and high conversion operations a significant portion of the contacting can be done in a dilute phase.

The amount of hydrocarbon carried to the regenerator is dependent upon the amount of stripping steam used per pound of catalyst and the pressure and temperature at which the stripper operates.

Probes at the stripper outlet have been used to measure the composition of the hydrocarbon vapors leaving the stripper. When expressed as percent of coke burned in the regenerator, the strippable hydrocarbon is only 2–5%. Very poor stripping is shown when the hydrogen content of the regenerator coke is 10% by weight or higher. Good stripping is shown by 6–9% by weight hydrogen levels.

The proper level of stripping is found in many operating units by reducing the stripping steam until there is a noticeable effect or rise in regenerator temperature. Steam is then marginally increased above this rate. In some units, stripping steam is used as a control variable to control the carbon burning rate or differential temperature between the regenerator bed and cyclone inlets.

In summary, the catalytic cracking unit is an extremely dynamic unit, primarily because there are three major process flow streams (the catalyst, hydrocarbon, and regeneration air), all of which interact with each other. Problems can arise in the equipment and flowing streams which are sometimes difficult to diagnose because of the complex effects they can create.

19.4.7 Catalyst Treatment

The latest technique developed by the refining industry to increase naphtha yield and quality is to treat the catalysts from the cracking units to remove metal poi-

sons that accumulate on the catalyst [19.66]. Nickel, vanadium, iron, and copper compounds contained in catalytic cracking feedstocks are deposited on the catalyst during the cracking operation, thereby adversely affecting both catalyst activity and selectivity. Increased catalyst metal contents affect catalytic cracking yields by increasing coke formation, decreasing naphtha and butane and butylene production, and increasing hydrogen production. The recent commercial development and adoption of cracking catalyst-treating processes definitely improve the overall catalytic cracking process economics.

For the last two decades, demetallized oil (produced by the extraction of a vacuum-tower bottoms stream using a light paraffinic solvent) has been included as a component of the feedstock in fluid catalytic cracking units. Modern solvent-extraction processes, such as the Demet process [19.66, 68], provide a higher demetallized oil yield than is possible in the propane-deasphalting process that has been used to prepare fluid catalytic cracker feedstock, as well as demetallized feedstocks for other processes. Consequently, the demetallized oil is more heavily contaminated. In general, demetallized oils are still good cracking stocks, but most feedstocks can be further improved by hydrotreating to reduce contaminant levels and to increase their hydrogen content thereby becoming more presentable and amenable for processing feedstock [19.69].

Demet

In the process, a cracking catalyst is subjected to two pretreatment steps [19.66, 68, 70]. The first step effects vanadium removal; the second, nickel removal, to prepare the metals on the catalyst for chemical conversion to compounds (chemical treatment step) that can be readily removed through water washing (catalyst wash step). The treatment steps include use of a sulfurous compound followed by chlorination with an anhydrous chlorinating agent (e.g., chlorine gas) and washing with an aqueous solution of a chelating agent (e.g., citric acid, $\text{HO}_2\text{CCH}_2\text{C}(\text{OH})(\text{CO}_2\text{H})\text{CH}_2\text{CO}_2\text{H}$, 2-hydroxy-1,2,3-propanetricarboxylic acid). The catalyst is then dried and further treated before returning to the cracking unit.

Met-X

This process consists of cooling, mixing, ion-exchange separation, filtration, and resin regeneration [19.70]. Moist catalyst from the filter is dispersed in oil and returned to the cracking reactor in a slurry. On a continuous basis, the catalyst from a cracking unit is cooled and then transported to a stirred reactor and mixed with an ion-exchange resin (introduced as slurry). The catalyst-resin slurry then flows to an elutriator for separation. The catalyst slurry is taken overhead to a filter, and the wet filter cake is slurried with oil and pumped into the catalytic system. The resin leaves the bottom of the elutriator and is regenerated before returning to the reactor.

Catalyst Testing

The American Society for Testing and Materials (ASTM) has a series of standard test methods that can be applied to catalysts (Table 19.4) as a means of testing and for chemical analysis of the various forms of catalysts and catalyst carriers used to increase the rate of specific chemical reactions. The test methods and techniques presented in these catalyst standards include hydrofluoric/sulfuric acid decomposition, atomic spectroscopic analysis, potentiometric titration method,

microactivity test, volumetric vacuum method, static volumetric measurements, mercury intrusion porosimetry, electronic counting, laser light scattering, nitrogen adsorption by continuous flow method, ammonia chemisorption, x-ray powder diffraction (XRD), x-ray fluorescence spectrometry (XRF), and elemental analysis by inductively coupled plasma-atomic emission spectroscopy. These standards are helpful in allowing catalyst users to examine and assess catalysts to ensure their safe handling and use.

19.5 Process Options

Fluid catalytic cracking processes exist in several different proprietary designs that have been developed over the past several decades. Each design was in response to the characteristics and peculiarities of different feedstocks as well as the need for a balanced product slate that was often (and still is) regionally dependent. Generally, the various designs can be separated into two main configurations: (1) the *side-by-side type*, in which the reactor and catalyst regenerator are in two separate vessels, and (2) the *stacked type*, in which the reactor and catalyst regenerator are contained in a single vessel with the reactor above the catalyst regenerator.

19.5.1 Fluid-Bed Processes

A typical fluid catalytic cracking reactor (Fig. 19.1) process involves mixing the preheated feedstock with hot, regenerated catalyst as it enters the riser pipe leading to the reactor after which the feedstock is combined with a recycle stream within the riser, vaporized, and raised to reactor temperature (485–540 °C or 900–1000 °F) by the hot catalyst. As the mixture travels up the riser pipe, the charge is thermally decomposed at minimal pressure (10–30 psi). In most modern units, cracking takes place in the riser (*riser pipe cracking*) and the reactor no longer functions as a reactor but serves as a holding vessel for the cyclones where the product vapors are separated from the catalyst. The resultant product stream (cracked product) is then charged to a fractionating column where it is separated into fractions – part of the high-boiling distillate recycled to the riser for further cracking (*cracking to extinction*).

The catalyst is typically in a form such that when the catalyst particles are *aerated* with air or feedstock vapor, the catalyst behaves like a liquid and can be moved through pipes – the flow patterns through the reactor may vary depending upon the precise reactor configuration. Coke deposits collect on the catalyst during the process and the spent catalyst (catalyst with deposits of

coke and metals) sent to a catalyst stripper and thence to the regenerator, where most of the coke deposits are burned off. A portion of the regenerated catalyst – the amount is subject to feedstock quality – is exchanged for fresh catalyst to maintain the efficiency of the process.

Model IV Fluid-Bed Catalytic Cracking

The *model IV fluid-bed catalytic cracking unit* involves a process in which the catalyst is transferred between the reactor and regenerator by means of U-bends and the catalyst flow rate can be varied in relation to the amount of air injected into the spent-catalyst U-bend [19.71]. Regeneration air, other than that used to control circulation, enters the regenerator through a grid, and the reactor and regenerator are mounted side by side.

The model IV low-elevation design was preceded by the model III balanced-pressure design (1947), the model II downflow design (1944), and the original model I upflow design (1941). The first commercial model IV installation in the United States was placed on-stream in 1952.

Orthoflow Fluid-Bed Catalytic Cracking

The *Orthoflow fluid-bed catalytic cracking process* uses the unitary vessel design, which provides a straight-line flow of catalyst and thereby minimizes the erosion encountered in pipe bends [19.9]. Commercial Orthoflow designs are of three types: models A and C, with the regenerator beneath the reactor, and model B, with the regenerator above the reactor. In all cases, the catalyst-stripping section is located between the reactor and the regenerator. All designs employ the heat-balanced principle incorporating fresh feed-recycle feed cracking.

This process uses the unitary vessel design, which provides a straight-line flow of catalyst and thereby minimizes the erosion (*impingement damage*, *erosion corrosion*) encountered in pipe bends. Commercial or-

thoflow designs are of three types: model A and model C, with the regenerator beneath the reactor, and model B, with the regenerator above the reactor. In all cases, the catalyst-stripping section is located between the reactor and the regenerator and all designs employ the heat-balanced principle incorporating fresh feed–recycle feed cracking.

Shell Two-Stage Fluid-Bed Catalytic Cracking

The *Shell two-stage fluid-bed catalytic cracking process* was devised to permit greater flexibility in shifting product distribution when dictated by demand. Thus, feedstock is first contacted with cracking catalyst in a riser reactor, that is, a pipe in which fluidized catalyst and vaporized oil flow concurrently upward, and the total contact time in this first stage is on the order of seconds. High temperatures 470–565 °C (875–1050 °F) are employed to reduce undesirable coke deposits on catalyst without destruction of naphtha by secondary cracking. Other operating conditions in the first stage are a pressure of 16 psi (110 kPa) and a catalyst/oil ratio of 3 : 1 to 50 : 1; volume conversion ranges between 20–70% have been recorded. All or part of the unconverted or partially converted gas oil product from the first stage is then cracked further in the second-stage fluid-bed reactor. Operating conditions in the second reactor are 480–540 °C (900–1000 °F) and 16 psi with a catalyst/oil ratio of 2 : 1 to 12 : 1.

Universal Oil Products (UOP) Fluid-Bed Catalytic Cracking

The *Universal Oil Products (UOP) fluid-bed catalytic cracking process* is adaptable to the needs of both large and small refineries [19.49]. The major distinguishing features of the process are:

1. Elimination of the air riser with its attendant large expansion joints
2. Elimination of considerable structural steel supports
3. Reduction in regenerator and in air-line size through use of 15–18 psi pressure operation.

Other Processes

The *residuum cracking unit* (M.W. Kellogg Co./Phillips Petroleum Co.) offers feedstock conversion up to 85% by weight of atmospheric resids (an atmospheric residuum is the fraction of the feedstock boiling above 650 °F/343 °C) or equivalent feedstocks. The unit is similar to the Orthoflow C unit but there are some differences that enhance performance on residua. The catalyst flows from the regenerator through a plug valve that controls the flow to hold the reactor temperature. Steam is injected upstream of the feed point to accel-

erate the catalyst and disperse it so as to avoid high rates of coke formation at the feed point. The feedstock, atomized with steam, is then injected into this stream through a multiple nozzle arrangement. The flow rates are adjusted to control the contact time in the riser since the effects of metals poisoning on yields are claimed to be largely a function of the time that the catalyst and oil are in contact. Passing the mix through a rough cut cyclone stops the reaction.

The *Gulf residuum process* consists of cracking a residuum that has been previously hydrotreated to low sulfur and metals levels. In this case, high conversions are obtained but coke yield and hydrogen yield are kept at conventional levels by keeping metals on catalyst low.

The *deep catalytic cracking (DCC)* process is designed for selective conversion of gas oil and paraffinic residual feedstocks to C₂ to C₅ olefins, aromatic-rich naphtha, and other distillates. There is also the *Flexicracking* process, which is designed for conversion of gas oils, residua, and deasphalted oils to distillates [19.50].

19.5.2 Moving-Bed Processes

In the moving-bed catalytic cracking process, the catalyst is in the form of pellets that are moved continuously to the top of the unit by conveyor or pneumatic lift tubes to a storage hopper, then flow downward by gravity through the reactor, and finally to a regenerator. The cracked product is separated into recycle gas, naphtha, distillate, and gas oil.

Airlift Thermofor Catalytic Cracking

The airlift Thermofor catalytic cracking process (Socony Airlift TCC process) is a moving-bed, reactor-over-generator continuous process that was originally designed for conversion of heavy gas oil into naphtha and middle distillate fuel oil. Feed preparation may consist of flashing in a separator to obtain vapor feed, and the separator bottoms may be sent to a vacuum tower from which the liquid feed is produced.

The gas oil vapor-liquid flows downward through the reactor concurrently with the regenerated catalyst (usually in bead form). The catalyst is purged by steam at the base of the reactor and gravitates into the kiln, or regeneration is accomplished by the use of air injected into the kiln. Approximately 70% of the carbon on the catalyst is burned in the upper kiln burning zone and the remainder in the bottom burning zone. Regenerated, cooled catalyst enters the lift pot, where low-pressure air transports it to the surge hopper above the reactor for reuse.

Houdresid Catalytic Cracking

Houdresid catalytic cracking is a process that uses a variation of the continuously moving (synthetic or natural) catalyst bed designed to obtain high yields of naphtha and light distillate from feedstocks such as residua, ranging from atmospheric residue to vacuum residua including residua high in sulfur or nitrogen. The process features modify or eliminate the adverse effects and catalyst and product selectivity usually resulting when metals (such as nickel, vanadium, copper, and iron) are present in the fuel. The Houdresid catalytic reactor and catalyst-regenerating kiln are contained in a single vessel. Fresh feed plus recycled gas oil are charged to the top of the unit in a partially vaporized state and mixed with steam.

Houdrflow Catalytic Cracking

The Houdrflow catalytic cracking process is a continuous, moving-bed process in which the reactor and regenerator kiln are integrated as a single vessel. The feedstock can be any fraction of the crude boiling between naphtha and atmospheric resid. The catalyst is transported from the bottom of the unit to the top in a gas lift employing compressed flue gas and steam.

The reactor feed and catalyst pass concurrently through the reactor zone to a disengager section, in which vapors are separated and directed to a conventional fractionation system. The spent catalyst, which has been steam purged of residual oil, flows to the kiln for regeneration, after which steam and flue gas are used to transport the catalyst to the reactor.

Suspensoid Catalytic Cracking

Suspensoid cracking was developed from the thermal cracking process carried out in tube and tank units [19.7] and, in the process, small amounts of powdered catalyst as a mixture with the feedstock are pumped through a cracking coil furnace – cracking temperatures are on the order of 550–610 °C (1025–1130 °F), with pressures in the range 200–500 psi. After leaving the furnace, the cracked material enters a separator where catalyst and high-boiling entrained material (*tar*) are left behind. The cracked vapors enter a bubble tower where they are separated into two fractions: gas oil and pressure distillate – the latter is separated into naphtha and gases. The spent catalyst is recovered from the higher boiling product, which is used as a heavy fuel oil.

19.6 Options for Heavy Oil and Residua

In recent decades, because of an increasing demand for low-boiling products such as naphtha, most refineries perform the operation by partially blending residua into vacuum gas oil. However, conventional fluid catalytic cracking processes have limits in residue processing, so *residue fluid catalytic cracking processes* (RFCC process) have lately been employed one after another. Because the residue fluid catalytic cracking process enables efficient naphtha production directly from residues, it will play the most important role as a residue cracking process, along with the residue hydroconversion process. Another role of RFCC is to generate high-quality gasoline blending stock and petrochemical feedstock. Olefins (propene, butene derivatives, and pentene derivatives) serve as feed for alkylating processes, for polymer gasoline, as well as for additives for reformulated gasoline.

The processes described below are the evolutionary offspring of the fluid catalytic cracking process and the residuum catalytic cracking process. Some of these newer processes use catalysts with different silica/alumina ratios as acid support of metals such as Mo, Co, Ni, and W. In general the first catalyst used to remove metals from oils was the conventional

hydrodesulfurization (HDS) catalyst. Diverse natural minerals are also used as raw material for elaborating catalysts addressed to the upgrading of heavy fractions. Among these minerals are: clays; manganese nodules; bauxite activated with vanadium, nickel, chromium, iron, and cobalt, as well as iron laterite, sepiolite, and transition metal sulfides supported on silica and alumina. Other kinds of catalyst, such as vanadium sulfide, are generated in situ, possibly in colloidal states.

In the past decades, in spite of the difficulty of handling heavy feedstocks, RFCC has evolved to become a well-established approach for converting a significant portion of the heavier fractions of the crude barrel into a high-octane naphtha blending component. RFCC, which is an extension of conventional fluid catalytic cracking technology for applications involving the conversion of highly contaminated residua, has been commercially proven on feedstocks ranging from gas oil-residuum blends to atmospheric resid, as well as blends of atmospheric and vacuum residua. In addition to high naphtha yields, the residuum fluidized catalytic cracking unit also produces gaseous, distillate and fuel oil-range products.

The product quality from the residuum fluidized catalytic cracker is directly affected by its feedstock quality. In particular, and unlike hydrotreating, the RFCC redistributes sulfur among the various products, but does not remove sulfur from the products unless, of course, one counts the sulfur that is retained by any coke formed on the catalyst. Consequently, tightening product specifications have forced refiners to hydrotreat some, or all, of the products from the resid catalytic cracking unit. Similarly, in the future the emissions of sulfur oxides (SO_x) from a resid catalytic cracker may become more of an obstacle for residue conversion projects. For these reasons, a point can be reached where the economic operability of the unit can be sufficient to justify hydrotreating the feedstock to the catalytic cracking unit.

19.6.1 Asphalt Residual Treating Process

The *asphalt residual treating* (ART) process is a process for increasing the production of naphtha and kerosene for transportation fuels by reducing the production of heavy fuel oil without hydrocracking [19.1, 7].

In the process, the preheated feedstock (heavy oil, atmospheric residuum, vacuum residuum, or tar sand bitumen) is injected into a stream of fluidized, hot catalyst where efficient mixing of the feedstock with the catalyst is achieved in the contactor which is operated within a pressure–temperature envelope to ensure selective vaporization. The vapor and the contactor effluent are quickly and efficiently separated from each other and entrained hydrocarbons are stripped from the contaminant (containing spent solid) in the stripping section. The contactor vapor effluent and vapor from the stripping section are combined and rapidly quenched in a quench drum to minimize product degradation. The cooled products are then transported to a conventional fractionator and spent solid from the stripping section is transported to the combustor bottom zone for carbon burn-off.

In the combustor, coke is burned from the spent solid that is then separated from combustion gas in the surge vessel. The surge vessel circulates regenerated catalyst streams to the contactor inlet for feed vaporization, and to the combustor bottom zone for premixing. The components of the combustion gases include carbon dioxide (CO_2), nitrogen (N_2), oxygen (O_2), sulfur oxides (SO_x), and nitrogen oxides (NO_x) that are released from the catalyst with the combustion of the coke in the combustor – these components of the gas stream can be removed by conventional gas treating processes [19.1–4, 7, 72]. The concentration of sulfur oxides in the combustion gas requires treatment for their removal.

19.6.2 Residue Fluid Catalytic Cracking Process

The residue fluid catalytic cracking process (RFCC process, also called the HOC process) is a version of the fluid catalytic cracking process that has been adapted to conversion of residua that contain high amounts of metal and asphaltene constituents.

The feedstocks for the process are rated on the basis of carbon residue and content of metals. Thus, *good-quality feedstocks* have less than 5% by weight carbon residue and less than 10 ppm metals. *Medium-quality feedstocks* have greater than 5 but less than 10% by weight carbon residue and greater than 10 but less than 30 ppm metals. *Poor-quality feedstocks* have greater than 10 but less than 20% by weight carbon residue and greater than 30 but less than 150 ppm metals. Finally, *bad-quality feedstocks* have greater than 20% by weight carbon residue and greater than 150 ppm metals.

In the process, the feedstock is desulfurized and the nonvolatile fraction from the hydrodesulfurization unit is charged to the residuum fluid catalytic cracking unit. The reaction system is an external vertical riser terminating in a closed cyclone system. Dispersion steam in amounts higher than that used for gas oils is used to assist in the vaporization of any volatile constituents of heavy feedstocks. A two-stage stripper is utilized to remove other products from the catalyst. Hot catalyst flows at low velocity in a dense phase through the catalyst cooler and returns to the regenerator. Regenerated catalyst flows to the bottom of the riser to meet the feed.

The coke deposited on the catalyst is burned off in the regenerator along with the coke formed during the cracking of the gas oil fraction. If the feedstock contains high proportions of metals, control of the metals on the catalyst requires excessive amounts of catalyst withdrawal and fresh catalyst addition – but use of a pretreatment option can reduce the amount of catalyst withdrawal and addition.

19.6.3 Heavy Oil Treating Process

The heavy oil treating process (HOT process) is a catalytic cracking process for upgrading heavy feedstocks such as topped crude oils, vacuum residua and solvent deasphalted bottoms using a fluidized bed of iron ore particles [19.1, 7]. The main section of the process consists of three fluidized reactors and separate reactions take place in each reactor (*cracker*, *regenerator*, and *desulfurizer*):

- $\text{Fe}_3\text{O}_4 + \text{asphaltene constituents} \rightarrow \text{coke/Fe}_3\text{O}_4 + \text{oil} + \text{gas}$ (in the *cracker*)

- $3\text{FeO} + \text{H}_2\text{O} \rightarrow \text{Fe}_3\text{O}_4 + \text{H}_2$ (in the *cracker*)
- $\text{Coke}/\text{Fe}_3\text{O}_4 + \text{O}_2 \rightarrow 3\text{FeO} + \text{CO} + \text{CO}_2$ (in the *regenerator*)
- $\text{FeO} + \text{SO}_2 + 3\text{CO} \rightarrow \text{FeS} + 3\text{CO}_2$ (in the *regenerator*)
- $3\text{FeS} + 5\text{O}_2 \rightarrow \text{Fe}_3\text{O}_4 + 3\text{SO}_2$ (in the *desulfurizer*).

In the *cracking section*, heavy oil cracking and the steam-iron reaction take place simultaneously under conditions similar to thermal cracking. Any unconverted feedstock is recycled to the cracker from the bottom of the scrubber. The scrubber effluent is separated into hydrogen gas, liquefied petroleum gas (LPG), and liquid products that can be upgraded by conventional technologies to priority products.

In the *regenerator section*, coke deposited on the catalyst is partially burned to form carbon monoxide in order to reduce iron tetroxide and to act as a heat supply. In the *desulfurizer*, sulfur in the solid catalyst is removed and recovered as molten sulfur in the final recovery stage.

19.6.4 R2R Process

The R2R process is a fluid catalytic cracking process for conversion of heavy feedstocks [19.1, 7, 73, 74]. In the process, the feedstock is vaporized upon contacting hot regenerated catalyst at the base of the riser and lifts the catalyst into the reactor vessel separation chamber where rapid disengagement of the hydrocarbon vapors from the catalyst is accomplished by both a special solids separator and cyclones. The bulk of the cracking reactions takes place at the moment of contact and continues as the catalyst and hydrocarbons travel up the riser. The reaction products, along with a minute amount of entrained catalyst, then flow to the fractionation column. The stripped spent catalyst, deactivated with coke, flows into the number 1 regenerator.

Partially regenerated catalyst is pneumatically transferred via an air riser to the number 2 regenerator, where the remaining carbon is completely burned in a dryer atmosphere. This regenerator is designed to minimize catalyst inventory and residence time at high temperature while optimizing the coke-burning rate. Flue gases pass through external cyclones to a waste heat recovery system. Regenerated catalyst flows into a withdrawal well and after stabilization is charged back to the oil riser.

19.6.5 Reduced Crude Oil Conversion Process

In the reduced crude oil conversion process (RCC process), the clean regenerated catalyst enters the bottom

of the reactor riser where it contacts low-boiling hydrocarbon *lift gas* that accelerates the catalyst up the riser prior to feed injection [19.1, 7]. At the top of the lift gas zone the feed is injected through a series of nozzles located around the circumference of the reactor riser.

The catalyst–oil disengaging system is designed to separate the catalyst from the reaction products and then rapidly remove the reaction products from the reactor vessel. Spent catalyst from the reaction zone is first steam stripped, to remove adsorbed hydrocarbons, and then routed to the regenerator. In the regenerator all of the carbonaceous deposits are removed from the catalyst by combustion, restoring the catalyst to an active state with a very low carbon content. The catalyst is then returned to the bottom of the reactor riser at a controlled rate to achieve the desired conversion and selectivity to the primary products.

19.6.6 Shell FCC Process

The Shell FCC process is designed to maximize the production of distillates from residua (Table 19.4) [19.1, 7].

In the process, the preheated feedstock (vacuum gas oil, atmospheric residuum) is mixed with the hot regenerated catalyst. After reaction in a riser, volatile materials and catalyst are separated after which the spent catalyst is immediately stripped of entrained and adsorbed hydrocarbons in a very effective multistage stripper. The stripped catalyst gravitates through a short standpipe into a single vessel, simple, reliable and yet efficient catalyst regenerator. Regenerative flue gas passes via a cyclone/swirl tube combination to a power recovery turbine. From the expander turbine the heat in the flue gas is further recovered in a waste heat boiler. Depending on the environmental conservation requirements, a *deNO_xing*, *deSO_xing*, and particulate emission control device can be included in the flue gas train.

Pretreatment of tar sand bitumen (by hydrogenation) prior to fluid catalytic cracking (or for that matter any catalytic cracking process) can result in enhanced yield of naphtha. It is suggested that mild hydrotreating be carried out upstream of a fluid catalytic cracking unit to provide an increase in yield and quality of distillate products. This is in keeping with earlier work [19.75] where mild hydrotreating of bitumen was reported to produce low-sulfur liquids that would be amenable to further catalytic processing.

19.6.7 S and W Fluid Catalytic Cracking Process

The S and W FCC process is also designed to maximize the production of distillates from residua [19.1,

7]. In the process, the heavy feedstock is injected into a stabilized, upward flowing catalyst stream whereupon the feedstock-steam-catalyst mixture travels up the riser and is separated by a high-efficiency inertial separator. The product vapor goes overhead to the main fractionator.

The spent catalyst is immediately stripped to minimize hydrocarbon carryover to the regenerator system. The first regenerator (650–700 °C or 1200–1290 °F)

burns 50–70% of the coke in an incomplete carbon monoxide combustion mode running counter-currently. This relatively mild, partial regeneration step minimizes the significant contribution of hydrothermal catalyst deactivation. The remaining coke is burned in the second regenerator (ca. 775 °C or 1425 °F) with an extremely low steam content. Hot clean catalyst enters a withdrawal well that stabilizes its fluid qualities prior to being returned to the reaction system.

19.7 Environmental Aspects and the Future

The future of many industries will continue to be guided by the various environmental regulations [19.63, 76, 77, 77] which will ensure that contamination of the various ecosystems is minimized – rather than halted altogether. Both sides of the environmental issue need to learn that in order to survive together there must be a balance between industrial preferences and environmental preferences. Industry cannot continue to pollute the environment as was the case in the first two thirds of the 20th century. At the same time, environmental advocates seem to fail to realize (or ignore) that shutting down industry means that we will all freeze together in the green darkness. Hence, there is a need for a balanced agreement where industrial advocates and environmental advocates work together for the betterment of all concerned. In this respect, the petroleum industry has taken considerable steps to reduce emissions from recovery operations and from refining operations – with the exception of notable accidental environmental disasters (not discussed here) that have occurred during the past four decades.

Fluid catalytic cracking is the most important conversion process used in petroleum refineries to convert the high-boiling feedstock constituents to more valuable naphtha, olefin gases, as well as other products and is likely to remain predominant in the refining industry for at least another 3–5 decades [19.1–7, 48, 78]. In terms of the environment [19.79], the feedstock supplied to a fluid catalyst cracking unit is usually that portion of the crude oil that has an initial boiling point in excess of 340 °C (645 °F) and contains most of the heteroatoms (nitrogen, oxygen, and sulfur) as well as the majority of the metals in the crude oil [19.7]. In fact, refineries use the cracking process to correct the imbalance between the market demand for gasoline and the excess of heavy, high-boiling range products (as well as heavy oil and tar sand bitumen) resulting from the distillation of the crude oil.

Thus, catalytic cracking is widely used in the petroleum refining industry to convert lower value

heavy feedstocks into higher value naphtha (a gasoline blend stock) and other high-value products. In order to improve the process, several innovations have been introduced in the form of varying process options that may well fit into the refinery of the future [19.6]. Examples, as they pertain to the fluid catalytic cracking process include (1) unit integration with sulfur removal to produce low-sulfur naphtha and (2) development of new catalysts.

Furthermore, recent enhancements made to units designed for the fluid catalytic cracking of residua and similar feedstocks for processing significant amounts of such feedstocks, while simultaneously improving yields and reducing emissions, have focused on improved feed injection and dispersion, reduced contact time of products and catalyst, improved separation of products and catalyst, and regenerator heat removal. Traditional technology has been modified in key areas including:

- Catalyst design to accommodate higher metals feed and to minimize the amount of coke formed on the catalyst
- Feed injection
- Riser pipe design and catalyst–oil product separation to minimize over-cracking
- Regenerator design improvements to handle high coke output and avoid damage to catalyst structure
- Overall reactor/regenerator design concepts as a means of reducing process emissions.

There is also the possibility of pretreating the feedstock by a process such as hydrodesulfurization [19.7, 31, 32]. The hydrodesulfurization pretreatment of the fluid catalytic cracker feedstock removes some of the metals and also reduces the sulfur content of the products – a boon to the environment. Conversely, increasing fresh catalyst addition will also serve to maintain or even increase the efficiency of the process and increasing the rate of such exchange lowers the level of metals in the circulating equilibrium catalyst, but (like the hy-

drodesulfurization option) this is also quite a costly option.

In addition, hydrotreating the feedstock to the unit not only increases feedstock conversion but reduces the sulfur content of the naphtha product (gasoline blend component stock) to levels low enough to meet the future low sulfur gasoline pool specifications. In fact, with the increasing focus on reducing sulfur content in fuels, the role of *desulfurization* in the refinery becomes more and more important. Currently, the process of choice is the hydrotreater, in which hydrogen is added to the fuel to remove the sulfur from the fuel. Some hydrogen may be lost to reduce the octane number of the fuel, which is undesirable. Thus, because of the increased attention on producing low-sulfur fuel stocks by desulfurization, various new process concepts are being developed with various claims of efficiency and effectiveness.

Finally, the nickel, vanadium, iron, copper and other metal contaminants, present in fluid catalysts cracking feedstocks, all have detrimental effects on catalyst activity and performance – nickel and vanadium are particularly troublesome. However, there are a number of methods for mitigating the effects of the contaminant metals, which include processing feedstocks with low content of metals – a virtual impossibility in view of the increase in heavy oil in refinery slates unless blending with lower metals feedstocks is viable without initiating incompatibility (sediment formation, fouling) of the constituents of the blend. However, having to choose low-metal feedstocks can seriously hamper the flexibility of a refinery to process various crude oils or purchased feedstocks for the catalytic cracking unit.

The commercial Demet process removes nickel and vanadium from the withdrawn spent catalyst and the two metals are converted to the respective chlorides which are then washed out of the catalyst and, after drying, the demetallized catalyst is recycled into the circulating catalyst – the removal of the majority of the nickel (approximately 95 wt%) and vanadium (67–85 wt%) is possible. As environmental regulations become more strict [19.63] the Demet and Met-X processes might become more common either in refineries and/or in catalyst manufacturing and regenerating operations. The final option for metals removal is *passivation* – certain materials can be used as additives which can be impregnated into the catalyst or added to the feedstock in the form of metallo-organic compounds. These compounds react with the metal contaminants and passivate the contaminants by forming less harmful compounds that remain on the catalyst. For example, antimony and bismuth are effective in passivating nickel and tin is effective in passivating vanadium.

Complete process technologies for residuum catalytic cracking units are the most comprehensive ap-

proach to improving resid processing operations, but present, as might be anticipated, the most expensive option and are subject to high emission factors. Product recycle and multiple reaction sections will be the prevalent technology trends to reduce emissions as will improving feedstock injectors, riser termination and catalyst separation devices, strippers, and regenerator components.

Finally, the use of bio-feedstocks (such as animal fats and vegetable oils) in fluid catalytic cracking will increase the yield of light cycle oil and also provide high-quality products in terms of cetane number. In fact, over the next two decades of the 21st century, fluid catalytic cracking units will take on two additional roles: (1) use of biomass feedstocks and (2) reduction in carbon dioxide emissions, which will help alleviate concerns not only related to energy security but also those related to global climate change.

The implementation of bio-feedstock processing techniques in petroleum refineries can result in competitive advantages for refiners while diminishing many environmental concerns for consumers, especially as development of clays evolves [19.80]:

1. The processes provide refineries with alternative feeds that are renewable and could be lower in cost than petroleum.
2. They can reduce the costs of producing fuels and chemicals from bio-feedstocks by utilizing the existing production and distribution systems for petroleum-based products and avoiding the establishment of parallel systems.
3. The use of bio-feedstocks provides a production base for fuels and chemicals that is less threatened by changes in government policies toward fossil fuel feeds and renewable energies.
4. The use of bio-feedstocks will replace the more environmentally challenging heavy feedstocks in the fluid catalytic cracking unit, because of the flexibility of the unit to accept changing feedstocks and adapt to changing product demands [19.6, 7, 81, 82].

Bio-feedstocks that are able to be processed in the fluid catalytic cracking unit can be categorized as biomass-derived oils (both lignocellulosic materials and free carbohydrates) or triglycerides and their free fatty acids. The operating conditions and catalysts used for each type of feed to achieve a desired product slate vary, and each feed comes with inherent advantages and disadvantages [19.5, 83]. Most of the research work completed to date has been performed on relatively pure bio-feedstocks as opposed to blends of bio-based materials with traditional catalytic cracker feedstocks. In fact, biomass constituents can be blended

with petroleum-based feedstock and fed to a fluid catalytic cracking unit to produce fuels [19.81, 82]. Use of various types of waste streams is also an option for the future [19.84].

In general, bio-feedstocks, catalytic cracker catalysts or blends thereof achieve acceptable product

yields and selectivity. As bio-feedstock use or waste use in the catalytic cracking units continues toward commercialization, the market potential will begin to allow catalyst manufacturers to allocate resources for more tailored catalyst development, greatly improving the yield and quality of desired products.

Sulfur Removal and Recovery

Paul R. Robinson

Petroleum, natural gas and other fossil fuels contain significant amounts of sulfur. When burned, the sulfur becomes sulfur oxides (SO_x), which can cause significant damage to the environment and human health. To minimize such damage and to ensure that finished products meet performance specifications, the sulfur is removed and transformed into useful chemicals, primarily sulfuric acid and fertilizers.

About 57% of the world's sulfur is a byproduct of oil and gas processing. The sulfur in natural gas is primarily H_2S , sometimes accompanied by mercaptans. The sulfur compounds in heavier fossil fuels include entrained H_2S , inorganic sulfur compounds and organic sulfur compounds. For natural gas and petroleum, the predominant sulfur recovery strategy is:

1. To convert all sulfur compounds into H_2S
2. To adsorb the H_2S into a solution containing an alkanolamine
3. To transport the H_2S -laden amine to a sulfur plant
4. To convert the H_2S into elemental sulfur with the modified Claus process
5. To employ Claus tail-gas treatment to increase overall recovery to $> 99.5\%$.

Sulfur removal and recovery protects the planet from pollution by sulfur oxides and acids, which continue to threaten our atmosphere, water, land, and inhabitants. The challenge is worldwide, and so must be the solution.

20.1 About Sulfur

Sulfur is essential to life. But certain sulfur compounds, such as hydrogen sulfide (H_2S) and sulfur oxides (SO_x), are poisonous and can devastate the environment. Hydrogen sulfide is a broad-spectrum poison affecting several different systems in the body, especially the nervous system. At 50–100 ppm in air, it causes eye damage, at 100–150 ppm it shuts off the sense of smell and above 320 ppm it is deadly.

Petroleum, natural gas and other fossil hydrocarbons contain significant amounts of inorganic and/or organic sulfur. To mitigate environmental damage and to ensure that refined products meet performance specifications, sulfur is removed from fossil hydrocarbons and converted into relatively innocuous elemental sulfur.

Sulfur (also spelled sulphur) is a chemical element for which the atomic number is 16, the atomic weight is 32.065 (± 0.005) and the IUPAC symbol is S. Elemental sulfur forms more than 30 allotropes, ranging from S_2 and S_3 gases to crystalline solids with up to 20 atoms per molecule. Amorphous, glassy sulfur is formed by rapidly quenching molten sulfur; the glasses readily revert to crystalline forms. At room temperature and pressure, the predominant allotrope is orthorhombic (or rhombic) sulfur (S_8), which has the puckered cyclic structure shown in Fig. 20.1. For thermochemical calculations, orthorhombic S_8 is taken as the standard state for sulfur. It melts at 115.2 °C (239.4 °F), boils at 444.6 °C (832.3 °F) and easily sublimates. The two other cyclic S_8 species are beta monoclinic sulfur, which is stable above 95.3 °C (203.5 °F) and gamma monoclinic sulfur.

20.1.1 Sulfur in Antiquity

Sulfur was known in ancient times, due to its abundance and unique properties [20.1]. Bright yellow sulfur deposits appeared near volcanic craters and at the edges of foul-smelling hot springs. Other deposits were embedded in limestone formations [20.2]. Ancient Greeks fumigated clothing and dwellings with sulfur [20.3]. In the *Odyssey*, Homer mentioned *pest-averting* sul-

Fig. 20.1 Stick-and-ball structure of orthorhombic (rhombic) sulfur, S_8 , the standard state for elemental sulfur

fur [20.4]. Assyrian texts from the sixth century BC describe sulfur as a *product of the riverside*. In the first century AD, in his comprehensive *Natural History* [20.5], *Pliny the Elder* wrote that Melos was the best source of sulfur for medicine, fumigation and bleaching. Medicinal uses included ointments to alleviate scabies, ringworm and other epidermic ailments. Egyptians treated ocular maladies with a sulfur ointment. Roman soldiers mixed sulfur into pitch to increase the lethality of incendiary weapons.

Chinese writings indicate that sulfur was known in Hanzhong during the sixth century BC. In the third century AD, Chinese miners were recovering sulfur from pyrite. Black powder, a mixture of potassium nitrate, charcoal and sulfur, was invented during the Tang Dynasty (ninth century). Written recipes for black powder appeared in the 11th century during the Song Dynasty. The recipes arrived in Japan and Europe in the 13th century. Arab alchemists weaponized black powder by refining old formulations and standardizing production.

In Middle English texts, sulfur was called brimstone, brimston or bremston, which are corruptions of the old English brynstaen. Literally, *brimstone* means *stone that burns* or *burning stone*. The King James Bible associates *fire and brimstone* with hell, perhaps because sulfur so often is found near the mouths of active volcanoes. The German word *Bernstein* means *amber*, not brimstone; Schwefel is German for sulfur.

20.1.2 Sulfur for Life

Sulfur is essential to all life on Earth. It comprises about 0.03% of the Earth's crust and 0.3% of the human body (Table 20.1) [20.6]. In living organisms, it

Table 20.1 Elemental composition of the human body (after [20.6])

Fig. 20.3 Iron-Molybdenum cofactor in the enzyme nitrogenase. Cys = cysteine, His = histone ►

appears primarily in two amino acids, cysteine and methionine (Fig. 20.2) and in the peptides and proteins that include those amino acids. In humans, methionine is an essential amino acid contained in food. Except for the vitamins biotin and thiamine, cysteine and all other sulfur-containing compounds in the human body can be synthesized from methionine. In animals, metabolism of methionine and cysteine requires sulfite oxidase. The enzyme nitrogenase, which catalyzes biological nitrogen fixation, includes Fe_4S_4 clusters and a $\text{Fe}_7\text{MoS}_9\text{C}$ cofactor (Fig. 20.3).

20.2 Sulfur Sources

Table 20.2 gives a breakdown of worldwide sulfur production by source in 2013 [20.7]. The values include direct production of sulfuric acid from metallurgy (roasting of sulfide ores). Petroleum and natural gas accounted for 57.2% of the total. Relative amounts vary considerably from country to country. For example, in the United States, 93.4% came from oil and gas and the remainder came from metallurgy. But in China, 56.2% came from pyrites; 32.4% came from oil, gas and metallurgy; and 11.4% came from elemental sulfur mines.

Table 20.2 Breakdown of worldwide sulfur production by source in 2012

20.2.1 Elemental Sulfur

During the 18th and 19th centuries, sulfur ore was mined from limestone deposits in Italy, especially Sicily. Sulfur was recovered from the ore by careful melting, at first with direct heating and later with steam. Italian sulfur dominated world markets until the advent of the Frasch process.

Sulfur from volcanoes is still mined today. A noteworthy example comes from Kawah Ijen [20.8], a volcano in East Java, Indonesia, which rises to about 2900 m above sea level. It is a favorite destination for adventuresome tourists. Two-day excursions start with a 5 h bus ride from Surabaya to a base camp. From the camp, it is a 4 km walk up to the edge of the caldera [20.9]. Along the way, tourists enjoy a unique panorama, which includes a beautiful turquoise lake. They also begin to smell (and taste) sulfur dioxide (SO_2). SO_2 is the product of the spontaneous combustion of sulfur vapor. At the end of the trek, the acrid odors intensify, stinging sensitive eyes and throats. If they can endure the gases until sunset, tourists marvel at the blue flames that flicker upwards from the ooze that emerges from the earth and creeps down the mountainsides (Fig. 20.4). The color isn't from lava, but from burning brimstone.

Fig. 20.4 Blue flames from spontaneous combustion of sulfur vapor to form sulfur oxides at the Ijen Crater, East Java, Indonesia (after [20.10], photo by Dodi Mulyana)

Inside the crater, the environment isn't so pleasant. The lake is sulfuric acid – aqueous H_2SO_4 with pH values that range from 0.5–1, depending on how and where measurements are taken. Air concentrations of SO_2 can exceed 30 parts per million, 15 times higher than the limit set by the US Occupational Safety and Health Administration (OSHA). Sulfur vapor that isn't burned condenses and floats back down to earth as a fine powder, forming thick deposits of beautiful yellow S_8 .

For miners working 1000 m down inside the crater, the powder is as dangerous as the SO_2 , because it penetrates deeply into lungs. The men defend themselves with paper masks or strips of cloth. They use torches and metal rods to pry out slabs of sulfur and break them into chunks that can be carried in baskets on poles across their backs. Miners retrieve and carry two loads

per day. For each load, they walk 8–10 km (4–5 km each way). Each load weighs between 70–90 kg – sometimes more than the men themselves [20.11, 12]. They are paid \$ 0.078 per kg, which translates to \$ 11–15 per day. The job is far more lucrative than other manual jobs in the area. PT Candi Ngrimbi employs about 100 registered full-time miners, who recover up to 15 t of raw sulfur per day. The sulfur is used locally, primarily for refining sugar.

20.2.2 Frasch Process

In 1900, domestic sulfur in the United States came from native deposits in Louisiana, Nevada, Texas and Utah, which were mined with conventional digging [20.13]. Virtually all elemental sulfur imports came from Sicily. In 1894, German-born American chemist *Herman Frasch* invented a method for recovering underground sulfur from the surface [20.14]. Sulphur, Louisiana is the site of the first large-scale Frasch facility, which began production in 1903. The second Frasch installation opened in 1912 in Brazoria County, Texas [20.15]. By about 1915, the United States had surpassed Italy as the world's leading producer of sulfur. From then until the middle of the 20th century, Frasch sulfur from Texas and Louisiana accounted for up to 90% of US sulfur production and comprised a significant portion of total world production. Frasch sulfur hit its peak in 1974, when 12 mines yielded eight million tons. The last US Frasch facility closed in 2000, but the process is still used in Mexico and Poland and under a different name in China.

Figure 20.5 illustrates the Frasch process. A well is drilled into a sulfur deposit and three concentric tubes are inserted into the bore hole. Under pressure, water is

Fig. 20.5 The Frasch process. Superheated water is pumped into a deposit, where it melts elemental sulfur. The molten sulfur flows up the surface, propelled in part by hot air

superheated to about 165 °C and injected into the well through the outermost tube. The sulfur is liquefied and flows into the middle tube. Molten sulfur is viscous and dense and cannot be lifted with water pressure alone. Hot air is injected through the inner tube to froth the sulfur, decreasing its density and propelling it to the surface. The purity of Frasch sulfur tends to be very high – greater than 99.5%.

20.2.3 Sulfuric Acid from Metallurgy

The refining of sulfur-containing metal ores can produce sulfur, sulfuric acid and SO₂. Important sulfide ores include iron-containing pyrite (FeS₂); lead-containing galena (PbS); sphalerite, which contains both zinc and iron ([Zn,Fe]S); and copper-containing chalcocite (Cu₂S) and covellite (CuS).

Pyrite Leaching

Pyrite leaching was generating sulfuric acid in classical times. In 15th century England, leaching became an alternative to making H₂SO₄ by burning sulfur and collecting the oxides in water. By the 19th century, leaching was much preferred [20.16].

In heap leaching, the ore is gathered into piles and allowed to weather. The net initial reaction is

Green crystalline FeSO₄ · xH₂O is called ferrous sulfate, copperas, or green vitriol. Some of the aqueous ferrous ion is oxidized to ferric ion

The reactions occur spontaneously and they are expedited significantly by sulfur-oxidizing bacteria.

When heated, ferrous sulfate loses its water of crystallization. The green crystals become a brown amorphous solid. Additional heating to about 680 °C (1256 °F) generates sulfur oxides, leaving behind rust-colored hematite (Fe₂O₃). Magnetite (Fe₃O₄) also may be formed. Representative reactions (unbalanced) include

The iron oxides are reduced to iron metal by coke in a blast furnace or by electrolysis. The SO₂ is oxidized to SO₃ over a catalyst, such as supported vanadia [20.17].

The SO₃ is dissolved in water or oleum to make sulfuric acid. Alternatively, in some locales, it is vented to the atmosphere.

Chemical Refining

Prior to chemical refining, ores are sized by crushing, dry grinding and wet grinding (levigation). Methods for subsequent physical separation include hydraulic washing, gravity separation, magnetic separation and froth flotation. Levigation is commonly used for oxidic ores, froth flotation for sulfidic ores and magnetic separation for magnetic ores or impurities.

Preliminary chemical methods include leaching, calcining and roasting [20.18]. Pyrite leaching is described above. During calcination and roasting, ores are heated to drive off volatile impurities. Calcination decomposes carbonates, releasing CO₂ and leaving behind metal oxides.

Generally speaking, roasting involves reactions of solids and gases at elevated temperature. Roasting reactions can include oxidation, reduction, chlorination, sulfation and pyrohydrolysis. In the roasting of sulfide ores, the sulfides are converted to metal oxides and the sulfur is released as volatile sulfur oxides. For chalcocite (Cu₂S) and sphalerite (ZnS), the roasting reactions are

Oxidizing roasting is described above for zinc and copper oxides. The general reaction is

Complete or near-complete removal of sulfur gives a *dead roast*.

Volatilizing roasting is similar, except that the flow of air is carefully controlled. It is designed to remove volatile impurities without over-oxidizing the ore. This method is preferred for producing As₂O₃ and Sb₂O₃.

Chloriding roasting transforms certain metal compounds into chlorides. This method is preferred for uranium, titanium, beryllium and some rare earths. General reactions include

The first reaction represents chlorination of a sulfide ore of a divalent metal. The second reaction represents chlorination of an oxide ore in the presence of elemental sulfur. Chlorination of carbonate ores is preceded by calcination, which decomposes the carbonate into a metal oxide with effusion of CO₂.

Reduction roasting decomposes high-valent metal oxides into lower-valent oxides.

Magnetic roasting is a special case of reduction roasting. It converts nonmagnetic hematite (Fe_2O_3) into magnetic magnetite (Fe_3O_4).

Sinter roasting involves simultaneous oxidation and agglomeration of ores. Lead sulfide ores are refined with sinter roasting.

20.3 Sulfur from Petroleum and Natural Gas

Petroleum and natural gas provide 56% of the nonfood energy consumed by humans (Fig. 20.6) and they provide 57% of the world's industrial sulfur (Table 20.2).

Natural gas from commercial fields can contain more than 20% H_2S . Common crude oils contain up to 5 wt% sulfur. In contrast, sales-quality gas must contain less than 4 ppmv H_2S . In the United States and other countries, up to 90% of petroleum products are fuels and all but the heaviest products must be essentially sulfur-free. In the EU and the United States, the sulfur content of gasoline and diesel must be 10 ppmw or less by 1 January 2017. In much of China, similar limits will take effect in 2017.

Recovery of sulfur as a byproduct of natural gas processing and oil refining was first reported in 1938. Byproduct sulfur production grew steadily and in 1982 it surpassed Frasch sulfur in the United States. In 2000, US sulfur production totaled 10.3 million tons – 81% from recovery, 9% from one Frasch mine and 10% as

byproduct sulfuric acid from nonferrous metal smelters. Consumption was 12.5 million tons, including 2.8 million tons of imports.

20.3.1 Sulfur Removal/Recovery Strategies

For natural gas and petroleum, the choice of technology for removing and/or recovering sulfur depends on the nature of the sulfur compounds and their concentrations:

- If it is necessary to remove H_2S or SO_2 from a gas containing less than a few ppmv, caustic scrubbing may be sufficient. Flue-gas SO_x removal processes include both dry scrubbing with solid alkali and wet scrubbing. If only traces of H_2S are present, chemisorption onto zinc oxide (ZnO) may be preferred.
- Most crude oils contain between 0.5–2.5 wt% sulfur – some contain less, some contain more than 5 wt%. Many process units convert organic sulfur compounds into H_2S and sulfur-free hydrocarbons. The H_2S is adsorbed into a solution containing an alkanolamine and transported to a sulfur recovery unit (SRU).
- Sulfur appears in natural gas mostly as H_2S . Mercaptans are also present. Natural gas condensate is relatively sweet, with low concentrations of organic sulfur. It goes to a refinery, where it is blended with a suitable crude oil fraction and processed conventionally. As with offgas refinery gas, the H_2S in natural gas is adsorbed by an alkanolamine solution and transported to an SRU.
- SRUs oxidize the H_2S into elemental sulfur. With a few exceptions, oxidation is achieved by partial combustion in the modified Claus process. Alternatives employ direct catalytic oxidation instead of combustion. Examples include the Merichem LO-CAT process and the UOP Selectox process. Direct oxidation is preferred for small units or when open flames are dangerous, such as on oil production platforms or in remote locations where heat from a Claus furnace is a liability, not a benefit.
- Claus tail gas treatment units (TGTUs) bring the total sulfur recovery in an SRU up to > 99.5%. Examples include the Shell SCOT process, the Amoco cold-bed adsorption (CBA) process, the

Fig. 20.6 World energy consumption by fuel in 2014 (after [20.19]). The sum for fossil hydrocarbons is 86.0, 1.7% lower than the 2013 total. From 2013 to 2014, renewables increased from 2.5–2.7%. Petroleum includes crude oil produced from tight formations with hydraulic fracturing. Gas includes coproduced petroleum gas, condensate, dry gas and coal-seam gas. Renewable includes wind, solar, geothermal and biomass (largely ethanol and oil from plants) (data for the figure come from BP Statistical Review of World Energy 2015)

UOP BSR/Selectox process and the Merichem LO-CAT process.

- Catalytic oxidation with a UOP Merox unit or a Merichem MERICAT unit removes mercaptans from gases.
- Chemisorption onto nickel-based catalysts removes ppm levels of mercaptans from naphtha.

20.3.2 Natural Gas Processing

Natural gas comprises methane and other light hydrocarbons, up to and beyond C₅+ paraffins. It often contains H₂S, CO₂ and/or other gases, such as mercury, nitrogen, argon and helium. The sulfur in natural gas is primarily H₂S, sometimes accompanied by mercaptans. The goal of natural gas processing is to separate components into salable products. The main steps in natural gas processing are outlined in Fig. 20.7. Figure 20.8 displays a photo of a pristine natural gas processing plant operated by PTT in Map Ta Phut, Thailand [20.21].

Here are some common industry terms:

- *Consumer gas*: In the consumer gas distributed by the Union Gas system, the typical sulfur content is

5.5 mg/m³. This includes the 4.9 mg/m³ of sulfur in *t*-butyl mercaptan, which is added as an odorant for safety reasons [20.22]. When people smell that odor, they instantly know there's a gas leak and can take appropriate action.

- *Sour gas*: Natural gas is considered sour if it contains more than 4 ppmv H₂S. About one-third of world natural gas reserves are sour [20.23]. Gas from the Charlotte (Buda) well in Atascosa County, Texas contains more than 8% H₂S [20.24]. Several wells in Alberta, Canada produce gas with more than 10% H₂S and a few yield gas with more than 50% H₂S [20.25]. Sour gas can also contain mercaptans (RSH), where "R" represents alkyl groups such as methyl-, ethyl-, and so on.
- *Wet gas*: Wet gas is mostly methane but also contains C₂–C₄ paraffins.
- *Condensate*: Condensate contains C₅+ paraffins. It is also called natural gasoline.
- *Liquefied natural gas* (LNG): LNG is a mixture of ethane and propane. In certain circumstances, refinery LNG might contain traces of propane and olefins.
- *Liquefied petroleum gas* (LPG): LPG is mostly propane but can contain some butanes.

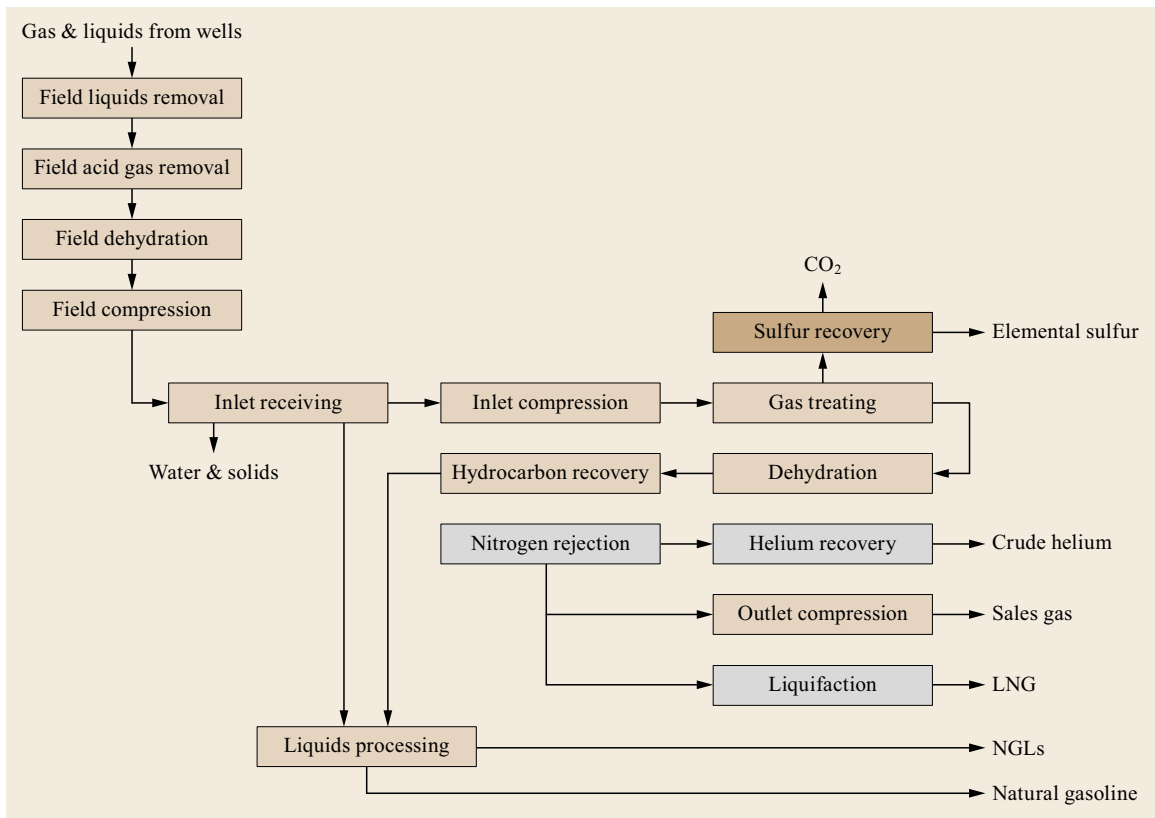

Fig. 20.7 Natural gas processing plant—block diagram (after [20.20])

Fig. 20.8 PTT natural gas processing plant in Map Ta Phut, Rayong, Thailand

- **Acid gas:** Acid gas from a natural gas process plant contains H_2S , CO_2 or a combination of CO_2 and H_2S . Acid gas goes to a sulfur plant, where the H_2S is oxidized to elemental sulfur.

Raw gas from wells contains water and condensate. These are removed in high- and low-pressure separators, as shown in Fig. 20.9. The separator overhead streams, which contain C_1 – C_4 hydrocarbons, light mercaptans, acid gas, mercury, and so on, are combined and piped to the acid gas removal section of the main plant. The water is treated and injected into disposal wells. The condensate is transported to a refinery for further processing.

Condensate production can be significant. The feed to a 90 000 barrel/day refinery in Borger, Texas includes up to 17 000 barrel/day of condensate from near-

by gas wells. The plant is owned by WRB Refining LP and operated by Phillips 66.

20.3.3 Sulfur from Refineries

The sulfur compounds in petroleum include entrained H_2S , inorganic sulfur compounds (sulfate salts and allotropes of elemental sulfur) and organic sulfur compounds including mercaptans. Most light gases – hydrocarbons, H_2S , mercaptans, nitrogen, etc. – effuse from liquid petroleum in settling tanks and are processed in upstream gas plants. When it reaches refineries, petroleum may still contain some of these contaminants. Salts are removed in refinery desalting units. Remaining light gases, entrained H_2S and remaining light mercaptans are recovered from the reflux drum at the top of the atmospheric distillation unit (ADU).

The ADU gases, along with gases from other refinery units, pass through an amine treater, which recovers H_2S and CO_2 . With few exceptions, CO_2 concentrations are very low in refineries. Amine treating does not remove mercaptans. These evil-smelling compounds are removed by special sweetening processes, such as the UOP Merox process and the Merichem MERCAT processes.

Typical refineries have more than one amine system. As in natural gas plants, H_2S is stripped from the amine in regenerator columns and conveyed to the sulfur plant.

Organic sulfur compounds are converted into H_2S by hydrotreaters and hydrocrackers. In fluid catalytic cracking (FCC) units, some organic sulfur is converted to H_2S in the riser-reactor. The remainder is converted to SO_x in the regenerator. In cokers, some sulfur is con-

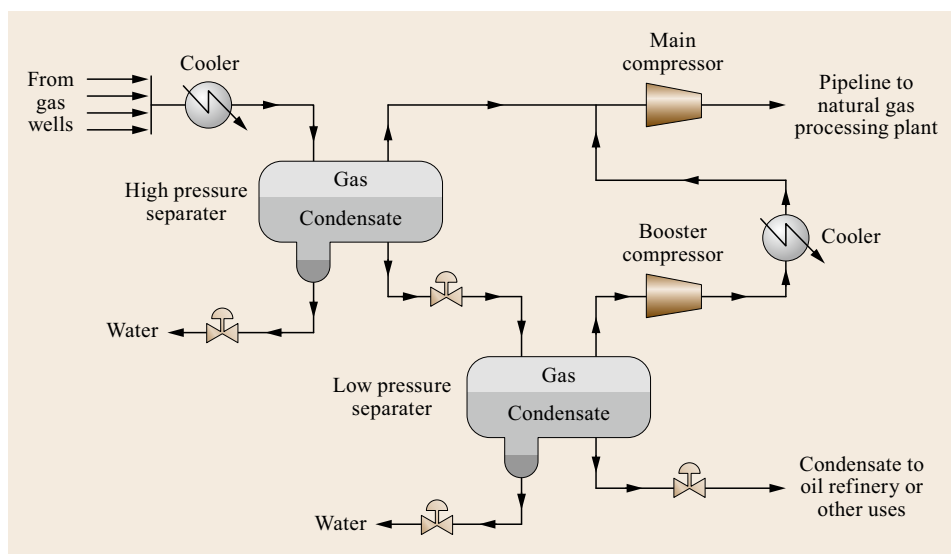

Fig. 20.9 Condensate and water removal from raw natural gas

verted to H_2S , but the remainder shows up in the liquid products. Coker liquids must be hydrotreated before they can be blended into finished products.

A large fraction of the sulfur in the feed to an FCC unit ends up in coke on the catalyst. SO_x are formed in the regenerator when the coke is burned away. Therefore, removing sulfur from the feed, usually by hydrotreating, decreases SO_x emissions. FCC feed pretreating has other substantial benefits. Removing basic nitrogen decreases deactivation of acid sites on the FCC catalyst, which allows the FCC unit to achieve higher, more selective conversion at lower temperatures. The saturation of aromatics in the feed pretreater provides the biggest benefit, because it converts hard-to-crack aromatics into easier-to-crack naphthenes. This alone can justify the installation of an FCC feed pretreater.

SO_x transfer additives, first developed by Davison Chemical, react with SO_x in the FCC regenerator to form sulfates. When the sulfated additive circulates to the riser/reactor section, the sulfates are reduced to H_2S , which is recovered by alkanolamine absorption and sent to the sulfur plant. In some units, these additives reduce FCC SO_x emissions by more than 70%. Consequently, if a pretreater or posttreater still must be installed, it can be smaller. The chemistry of SO_x transfer is summarized below:

- FCC regenerator (oxidizing environment)

- FCC riser-reactor (reducing environment)

Flue-gas scrubbing is a refiner's last chance to keep NO_x and SO_x out of the air. In wet flue-gas desulfurization, gas streams containing SO_x react with an aqueous slurry containing calcium hydroxide $\text{Ca}(\text{OH})_2$ and calcium carbonate CaCO_3 . Reaction products include calcium sulfite (CaSO_3) and calcium sulfate (CaSO_4), which precipitate from the solution. NO_x removal is more difficult. Wet flue-gas scrubbing removes about 20% of the NO_x from a typical FCC flue gas. To remove the rest, chemical reducing agents are used. In the selective catalytic reduction (SCR) process, anhydrous ammonia is injected into the flue gas as it passes through a bed of catalyst at 500–950 °F (260–510 °C). The chemical reaction between NO_x and ammonia produces N_2 and H_2O .

When sulfur-containing feeds pass through hydrotreaters or conversion units, most of the sulfur is converted into H_2S , which eventually ends up in offgas streams. Amine absorbers remove the H_2S , leaving only 10–20 wppm in the treated gas streams. H_2S is stripped from the rich alkanolamine, which is returned as lean amine to the absorbers. The H_2S goes to the refinery sulfur plant.

Another source of refinery sulfur is sour water. Wash water often is used to keep heat exchangers clean. In hydrotreaters and hydrocrackers, wash water is injected into the reactor effluent. When the effluent is cooled, the water reacts with the H_2S and NH_3 to form aqueous ammonium bisulfide (NH_4SH), which ends up in sour water streams. The H_2S and ammonia are removed in a sour water stripper and sent to the sulfur plant.

20.3.4 Amine Treating

Both in refineries and/or natural gas processing plants, H_2S and CO_2 are recovered by adsorption into aqueous solutions containing alkanolamine compounds, such as diethanol amine (DEA), monoethanol amine (MEA), methyldiethanol amine (MDEA) and diglycolamine (DGA). The structures of DEA and MDEA are shown in Fig. 20.10. Combinations of chemicals, such as MDEA plus sulfolane, also are employed. Light mercaptans are not removed by the kinds of amine treating employed by natural gas plants and refineries [20.26].

A typical layout for amine treating appears in Fig. 20.11. The absorber (contactor) is a trayed tower in which the lean amine solution mixes with natural gas. Acid gases (H_2S and CO_2) are adsorbed into the amine. The now-rich amine is withdrawn from the bottom of the tower and sent to the regenerator. Treated gas goes out the top.

In the trayed regenerator column, a steam-heated reboiler disengages the acid gases, which flow out the top through a condenser into a reflux drum. In this application, the reflux drum serves double duty as a cold low-pressure separator, from which the overhead acid gas is essentially liquid-free. Depending on the nature of the alkanolamine, the condensed solu-

Fig. 20.10a,b Structures of DEA (a) and MDEA (b)

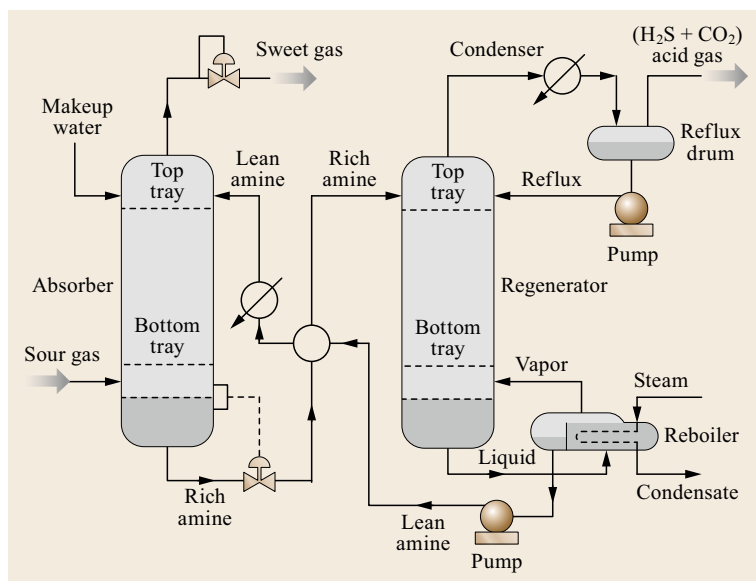

Fig. 20.11 Representative process flow sketch for removal of H₂S and CO₂ by alkanolamine adsorption

tion may still contain adsorbed gas. The solution is returned to the top of the tower. Lean amine is withdrawn from the bottom of the regenerator and returned to absorber.

The choice of amine and amine concentration depends on feed quality and process objectives. The systems used for high-CO₂ natural gas may not be optimal for refinery hydrotreaters, where the offgas is hydrogen-rich and contains nil CO₂. Some rough guidelines are given below [20.27]:

- MEA: About 20 wt% for removing H₂S and CO₂ and about 32 wt% for removing only CO₂
- DEA: About 20–25 wt% for removing H₂S and CO₂
- MDEA: About 30–55 wt% for removing H₂S and CO₂
- DGA: About 50 wt% for removing H₂S and CO₂.

According to the excellent review by *Goar and Nasato* [20.28]:

- MEA used to be the workhorse of the industry. It lost appeal because of its relatively large circulation rates, high energy consumption, high solvent vaporization losses and susceptibility to degradation by trace compounds often found in sour gas.
- DEA gained popularity due to its much lower circulation rates, lower energy consumption, lower vaporization losses and resistance to degradation. DEA is probably the most widely used gas treating solvent today.
- MDEA is popular now because it exhibits significant selectivity for H₂S in the presence of CO₂. It

is also very energy efficient. If the H₂S/CO₂ ratio in the sour gas is relatively low (say, less than 1 : 3), MDEA can be used to good advantage to absorb essentially all of the H₂S and only a small portion of the CO₂. Some CO₂ is removed indirectly by dissolution in water.

- DGA is well suited for gas processing in very hot climates, such as in the Middle East and when the gas contains appreciable trace contaminants. In many applications, it is very energy efficient. Disadvantages include the high cost of the solvent, the relatively high viscosity of DGA solutions and the tendency of solutions to absorb heavy or aromatic compounds.

The selectivity of MDEA can be explained as follows: With secondary alkanolamines, such as DEA, H₂S and CO₂ react directly and quickly with the alkanolamine by proton transfer. But MDEA is a tertiary amine. It does not have a proton attached to the nitrogen, so it cannot react directly with CO₂. When CO₂ dissolves in water, it forms a bicarbonate ion, which then reacts with the MDEA. The extent of adsorption of CO₂ by MDEA is therefore controlled by the extent of the conversion of CO₂(g) into HCO₃⁻(aq).

Separation of CO₂ from H₂S

In most existing operations, the entire acid gas stream, including both H₂S and CO₂, goes to the sulfur recovery plant. There, the H₂S is recovered, but the CO₂ is vented to the atmosphere. With the recent emphasis on CO₂ abatement, researchers are looking for ways

to recover the CO₂ for industrial use or sequestration.

Carbon Sequestration

At the Sleipner Field in the North Sea [20.29], the produced gas contains about 9% CO₂. But the sales specification limits CO₂ content to 2.5%. Sleipner-T, a special processing platform, separates and recovers the excess CO₂ for injection into a deep saline aquifer below the bottom of the sea. About one million tons of

pure CO₂ per year are captured this way. Sleipner-T is a laudable demonstration of carbon capture and sequestration (CCS) technology.

The UOP Benfield process is quite effective when feed gases contain a lot of CO₂ and very little H₂S. Benfield adsorbs CO₂ (and H₂S) into a hot potassium carbonate solution. More than 700 Benfield units have been installed primarily for hydrogen production plants. The process also is used in more than 50 natural gas processing plants.

20.4 Conversion of H₂S to Elemental Sulfur

20.4.1 The Claus Process

The Claus process was patented in 1883 by the Hesseborn chemist Carl Friedrich Claus. Educated in 1846–1848 at the University of Marburg, he moved to Liverpool, England in 1852. He became a British citizen in 1855 and lived in Liverpool, Warrington, Middlesbrough and London [20.30]. Over the years, he was granted several patents, including the ones that describe the process for which he is named [20.31, 32].

A paper by Linde Engineering North America (formerly Linde Process Plants, Inc.) provides a thorough description of H₂S conversion technology, including various versions of the Claus process [20.33]. Another good source is the presentation by *Prof. J. Jechura* of the Colorado School of Mines [20.20]. In the original Claus process, a mixture of hydrogen sulfide with air passed across a preheated catalyst bed. The end products were sulfur, water and heat. Reactions proceeded optimally at temperatures between 400–600 °F (93–204 °C). Heat recovery was poor, because heat was removed only by direct radiation. Only low concentrations of H₂S could be processed without overheating the reactor.

In 1938, engineers at I.G. Farben overcame these drawbacks by developing the modified Claus process. Modified Claus includes a combustion stage and a catalytic stage. The modified version serves as the basis of most modern sulfur recovery units (SRUs).

The feed gas to a Claus unit contains H₂S from alkanolamine treaters, along with CO₂, hydrocarbons and ammonia from a sour-water stripper (SWS). The treater gas can contain more than 75% H₂S.

A *straight-through* modified Claus unit, as shown in Fig. 20.12, works best when the H₂S concentration exceeds 60%. The feed gas is combined with a carefully controlled amount of air and sent to an open-flame burner, where 33% of the H₂S is converted to SO₂ and water at high temperature [20.34]. The standard heat of

combustion is –518 kJ/mol of H₂S. This compares to –802.3 kJ/mol for combusting methane.

From the burner, the hot gases go to a reaction chamber, where H₂S reacts reversibly with SO₂ to form sulfur and water. The reaction is governed by equilibrium, so it is incomplete.

The overall Claus process equation is

When CO₂ and/or hydrocarbons are present, they react to form carbonyl sulfide (COS) and carbon disulfide (CS₂).

The degree of conversion of H₂S to sulfur is limited by thermochemistry. Figure 20.13 shows the maximum-possible conversion of H₂S to sulfur as a function of temperature. The maximum-possible conversion is 100% below the sulfur melting point. Between the melting and 1000 °F (538 °C), maximum-possible conversion decreases as temperature goes up.

Again quoting the Linde paper: The average temperature in the combustion chamber is 2200 °F (1200 °C). Much of the combustion heat is recovered in a waste-heat boiler, which generates steam as it drops the temperature to 700 °F (370 °C). The gas then goes to a condenser, which cools it to about 450 °F (232 °C) – well below the sulfur boiling point. The sulfur vapors condense, leaving behind unreacted H₂S and SO₂ and the liquid sulfur flows through a drain to a sulfur-collection pit. The pit is heated to keep the sulfur molten. At the bottom of the drain, a seal leg maintains system pressure and keeps gases out of the

Fig. 20.12 Process flow sketch for the modified Claus process. SWS = sour water stripper. A = H₂S analyzer. FC = flow control valve. With fresh catalysts, a feed gas containing 75% H₂S and perfect flow control, the cumulative sulfur recovery at the four condensers can be approximately 50, 80, 95 and 98% respectively. Tail-gas treating brings the overall recovery to > 99.5%

Fig. 20.13 Percent conversion of H₂S to sulfur as a function of temperature (after [20.20])

pit. Sulfur vapor and other gases flow to the catalytic section. The catalyst is alumina (Al₂O₃). In a series of beds with condensers in between, additional sulfur forms from reactions between remaining H₂S and SO₂. With fresh catalyst and a stoichiometric gas composition, the cumulative recovery of sulfur across four condensers is > 50, 80, 95 and up to 98% respectively.

The *straight-through* modified Claus process (Fig. 20.12) sends all the acid gas through the burner and reaction furnace. When the feed is *rich* – when it contains more than 60% H₂S – reaction heat keeps the flame temperature above 1200°C (2200°F). When

the gas is *leaner* – less than about 50% H₂S – the flame temperature drops. If the temperature falls below about 980–1090°C (1800–2000°F) the flame cannot be maintained. Preheating the air or feed gas can alleviate the problem, but only so much. When the H₂S concentration is less than 40%, the straight-through approach becomes impractical.

Split-flow enrichment can be applied to increase the H₂S concentration. Split-flow can handle gases with 15–50% H₂S. About one-third of the acid gas goes to the burner. The rest goes straight to the first catalyst bed. In the burner, all of the H₂S is converted to SO₂. Combustion can be maintained, because there is less unreacted gas to soak up the heat of reaction. At the inlet of the catalyst section, the burner gas is mixed with the bypass gas. Flows are adjusted so that the overall H₂S to SO₂ ratio is 2 : 1.

An attractive solution to low H₂S is *acid gas enrichment*. It entails installing an additional absorber to separate H₂S from unreactive gases. Using MDEA in the extra absorber is especially effective if the unreactive gas is CO₂, because MDEA can absorb nearly all of the H₂S while leaving behind almost all of the CO₂. *Acid gas enrichment* has increased H₂S concentrations by a factor of five or more. For a new design, incorporating enrichment allows the use of a smaller SRU and increases SRU reliability.

Oxygen enrichment can enhance both straight-through and split-flow configurations. Adding pure O₂ to the feed gas increases flame temperatures and de-

creases the amount of inert nitrogen going to the furnace. Retrofitting a plant for O₂ enrichment usually requires a different burner and also can require other modifications.

Ammonia destruction is required when gas from a sour water stripper (SWS) goes to a Claus unit. The practice is common in petroleum refineries. It is crucial to achieve complete destruction. A split-flow furnace design can increase ammonia destruction. All of the SWS gas and some of the acid gas goes to the Claus burner. The burner feed contains at least one-third of the total H₂S. Sufficient air is injected for complete combustion of all H₂S, hydrocarbons and ammonia. The remaining feed gas is injected into the middle of the reaction furnace. Residence time must be long enough for the SO₂ from the burner to react with the H₂S in the bypass gas. Operators use an optical pyrometer to monitor temperatures at the inlet to the furnace. If necessary, they adjust temperature by changing the amount of bypass acid gas.

20.4.2 Catalytic Oxidation Processes

Direct oxidation processes convert H₂S catalytically. Two such processes are the Merichem LO-CAT process and the UOP Selectox process.

UOP Selectox Process

The UOP Selectox process looks a lot like straight-through Claus with the furnace replaced by beds con-

taining a bismuth/vanadium selective oxidation catalyst. As in Claus, the oxidation section is followed by three beds of alumina Claus catalyst with condensers and reboilers in between. Selectox can handle a wider range of feed-gas qualities. There is no flame, so the process isn't affected by flame instability. Commercially, it processes gas with H₂S concentrations less than 5%.

Due to the absence of a flame, Selectox was deemed safe to recover sulfur from produced gas on an offshore oil platform – Platform Irene – near the coast of California [20.35]. Removing H₂S on the platform enabled the oil company to build a less-expensive product pipeline from the platform to the shore.

Other Selectox units are found in remotely located gas plants, where the total amount of recovered sulfur is low – less than about 30t/day. An example is discussed by Jones and Bertram [20.36]. They describe seven years of operation at the Lisbon gas plant in southeast Utah. The Lisbon Selectox unit processes acid gas containing 4% H₂S and 96% carbon dioxide (CO₂). It produces about 18 long ton/day of sulfur and achieves 94% sulfur recovery at the start of a catalyst cycle.

Selectox cannot be used for ammonia destruction.

Merichem LO-CAT Process

Another Claus alternative is Merichem's LO-CAT process [20.37]. LO-CAT is a patented, wet scrubbing, liquid redox system that uses a chelated iron solution to convert H₂S into elemental sulfur. Figure 20.14 pro-

Fig. 20.14 LO-CAT process for direct oxidation of H₂S to elemental sulfur

vides a process flow sketch. LO-CAT does not require toxic chemicals and does not produce hazardous waste byproducts. Gas enters the unit through an absorber, where a chelated iron catalyst converts the H_2S directly into elemental sulfur. The sulfur travels with the solution into an oxidizer section where the catalyst is reactivated for reuse. The sulfur falls to the bottom of the reactor. From there, it is withdrawn and pumped to a pressure filter, which removes entrained liquids while forming a sulfur cake. The oxidized iron catalyst solution returns to the absorber for reuse by the process.

LO-CAT is applicable to all types of gas streams including air, natural gas, CO_2 , amine acid gas, biogas, landfill gas, refinery fuel gas, and so on. The liquid catalyst adapts easily to variations in flow and concentration. Flexible operation allows 100% turndown in H_2S concentrations. Units require minimal operator attention. More than 200 installations around the world employ the LO-CAT process to remove H_2S from gas streams.

20.4.3 Tail-Gas Treating

Claus tail-gas treating units (TGTU) can bring the total sulfur recovery up to $> 99.9\%$.

The cold-bed adsorption (CBA) process employs the same alumina catalysts as those used in Claus units, except that the catalysts operate below the sulfur dew point temperature. At the lower temperature, sulfur deposits on the catalyst. When the catalyst has adsorbed enough sulfur, the gas flow can be stopped or switched to a clean bed while the sulfur-laden bed is stripped with warm gas. CBA has achieved overall sulfur recoveries $> 99.0\%$.

The Shell Claus offgas treating (SCOT) process includes a front-end section to convert all of the sulfur compounds in the SRU tail into H_2S . This step is known as Beavon sulfur removal (BSR) – in honor of the inventor, David K. Beavon. The BSR reactions include

H_2S from the BSR step is absorbed by an amine and returned to the front of the Claus furnace. Utilities from the Claus section are used for preheating and other purposes. The SCOT process has given overall sulfur recoveries of 99.9% .

The UOP BSR Selectox tail-gas treating process also starts with BSR, reducing all tail-gas sulfur com-

pounds to H_2S . The H_2S is mixed with stoichiometric air and passed through a bed of Selectox catalyst for conversion to elemental sulfur. BSR Selectox can bring overall sulfur recovery up to 99.9% .

The LO-CAT technology also can be used for tail-gas treatment. One approach is to employ BSR technology to convert all sulfur to H_2S . The H_2S is then oxidized to elemental sulfur as described above by the LO-CAT liquid redox system. Sulfur is removed in a pressure filter and the liquid redox catalyst is recycled. The exit gas contains less than 10 ppmw H_2S . A LO-CAT TGTU can be designed to accept acid gas directly, bypassing the Claus unit entirely.

For all tail-gas treatment processes, the last traces of unrecovered sulfur go to a thermal oxidizer, where they are converted into SO_2 . Remaining CO_2 is vented to the atmosphere or sequestered and stored.

Transportation is an important aspect of sulfur recovery. Molten sulfur must be handled carefully in special equipment. So when regulations allow, the molten sulfur is transformed into powders or prills, which can be moved in bulk by rail or by sea.

20.4.4 Mercaptan Conversion

Mercaptans are foul-smelling chemicals that must be removed from gas prior to shipment. Mercaptans are not easily removed with alkanol amines. Instead, they are adsorbed into caustic solution and oxidized catalytically.

Refiners have used caustic treating for decades to remove mercaptans and other impurities, including H_2S , CO_2 , COS and organic acids. Removing these impurities from LPG, gasoline, jet fuel, diesel, light crude and condensates ensures that the streams meet specifications for odor and corrosivity.

The UOP Merox process extracts low molecular weight mercaptans from refinery gas streams with a strong aqueous caustic solution [20.38]. The Merox process was commercialized over 50 years ago by UOP. It can eliminate the need to purchase expensive proprietary equipment, it is not susceptible to fouling and it does not require feed or caustic filters. In commercial service, it typically achieves greater than 99.5% on-stream availability. UOP has licensed more than 1700 Merox units worldwide.

Given below are the main Merox reactions, where RSH = mercaptan and RSSR = disulfide. The R can denote methyl, ethyl, propyl, etc. and can be different between mercaptan and disulfide.

Fig. 20.15
Process flow
sketch for the
UOP Mercox
process

Figure 20.15 shows a process flow sketch. A high efficiency gas-liquid contactor enhances the design. The mercaptan-rich solvent, which contains the Mercox catalyst, goes to the regeneration section, where air is injected and the mercaptans are oxidized to disulfides. The disulfides are then separated from the solvent and the regenerated lean caustic is recycled back to the Mercox extractor. The disulfides are converted

to H₂S and hydrocarbons in a naphtha hydrotreater. Product mercaptan levels are reduced to less than 10 ppmw.

Merichem offers Mericat and Mericat C to remove H₂S and mercaptans from gasoline, naphtha, condensate and crude oil. The Mericat processes use a FIBER FILM Contactor for mass transfer and uses a caustic/catalyst/air mixture as the treating reagent.

20.5 Sulfur Uses

Elemental sulfur is used primarily to make sulfuric acid (H₂SO₄) [20.39, 40]. Before 1900, most sulfuric acid was made batch-wise with the *lead chamber* process. SO₂, steam and nitric oxides (NO and NO₂) were sprayed into large chambers lined with sheets of lead. The nitric oxides oxidized the SO₂ to SO₃, which dissolved immediately in the water to form H₂SO₄. The heat of reaction was controlled by running cooling water across the outside surface of the masonry chamber.

Modern processes do not require nitric oxides. In the *contact process*, sulfur is burned to form sulfur dioxide, which is then oxidized to sulfur trioxide (SO₃) over a vanadium oxide (V₂O₅) catalyst. The SO₃ is not directly dissolved in liquid water, because that interaction is highly exothermic and extremely difficult to control. Therefore, as an intermediate step, SO₃ is adsorbed into concentrated sulfuric acid to form oleum (H₂S₂O₇), also known as fuming sulfuric acid. The oleum then re-

acts with water to give sulfuric acid.

In some respects, the *wet sulfuric acid* process is similar to the contact process: it employs a V₂O₅ catalyst to oxidize SO₂ to SO₃. But the wet process avoids the intermediate oleum step by hydrating SO₃ in the gas phase. Gas-phase hydration generates less heat, so it is easier to control. The condensation of gaseous H₂SO₄ gives highly concentrated liquid H₂SO₄. In the wet process, it is possible to start with gaseous H₂S instead of solid elemental sulfur.

The main industrial application for sulfuric acid is production of phosphoric acid from phosphate minerals such as calcium orthophosphate or apatite [20.41].

About 90% of manufactured phosphoric acid becomes fertilizer. Apatite has the general formula $(\text{Ca}_5(\text{PO}_4)_3)\text{X}$, where $\text{X} = \text{OH}, \text{F}, \text{Cl}$ or Br . Shown below is the reaction of H_2SO_4 with fluorapatite, the main component of tooth enamel.

The insoluble $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ (gypsum) is removed by settling or filtration. To one extent or another, halides and other contaminants, such as arsenic, are removed to generate different grades of phosphoric acid. Near-complete removal of contaminants yields food-grade phosphoric acid. Most of the gypsum is mixed with water to form a plaster, which is pressed between two sheets of thick paper to form *drywall* for the construction industry.

Sulfuric acid is consumed by other industries, too, including metal refining, wastewater processing, petroleum processing, cement manufacturing and mineral extraction.

Sodium lauryl sulfate (SLS) is synthesized by reacting lauryl alcohol with SO_3 or oleum to generate hydrogen lauryl sulfate, followed by neutralization with a sodium salt. The chemical formula of SLS is $\text{NaC}_{12}\text{H}_{25}\text{SO}_4$. Widely used in cleaning supplies and personal hygiene products, the detergency of SLS is due to its amphoteric nature. The 12-carbon alkyl tail is oil-soluble and the sulfate group is water-soluble. Commercial formulations include sulfate surfactants derived from coconut and palm oils.

20.5.1 Elemental Sulfur and Inorganic Salts

Elemental sulfur candles consist of pure sulfur in blocks or pellets. In the past, they were burned to fumigate structures. They are no longer used in homes due to the formation of toxic and corrosive sulfur oxides.

Elemental sulfur is the only acceptable *green* fungicide and pesticide for organic farming. It is also an acceptable fertilizer. Dusting sulfur is a fungicide for grapes, strawberries, vegetables and other crops. Applied with a sulfur duster or from an airplane, it mitigates mildew, *black spot*, apple scab and other ailments. Wet sulfur is water miscible and hence can be easier to apply in certain cases. Sulfur powder, called *flow-*

ers of sulfur, can protect against ticks and mites when smeared onto clothing or bare skin.

Dilute solutions of lime sulfur, formed by mixing calcium hydroxide with elemental sulfur, is a dip to destroy ringworm fungus, mange and skin parasites on dogs and cats.

Hydrated crystals of magnesium sulfate, known as Epsom salts, can serve as a laxative, a bath additive, an exfoliant and a magnesium supplement for plants. In dry form, it is an excellent desiccant.

20.5.2 Organic Sulfur

Organosulfur compounds find uses in pharmaceuticals, dyes and agrochemicals. Sulfa drugs are sulfonamides. Sulfur is present in most β -lactam antibiotics, including penicillins, cephalosporins and monolactams.

20.5.3 Sulfites, Sulfates and Oxides

Adding small amounts of SO_2 (or potassium metabisulfite) to fermented wine produces traces of sulfurous acid or sulfite salts. This technique has been called *the most powerful tool in winemaking* [20.42]. After the yeast-fermentation stage in winemaking, sulfites absorb oxygen and inhibit aerobic bacterial growth that otherwise would turn ethanol into acetic acid, souring the wine. Without this preservative step, indefinite refrigeration of the product before consumption is usually required. Similar methods go back into antiquity. Written mentions go back to the 15th century. The practice is used by large industrial wine producers and small organic wine producers alike.

Sulfur dioxide and various sulfites have been used for their antioxidant antibacterial preservative properties in many other parts of the food industry also. The practice has declined since reports of an allergy-like reaction of some persons to sulfites in foods.

20.5.4 Other Uses

Other uses for sulfur include direct addition to alkaline soil and the vulcanization of black rubber. Sulfur is applied to plants as a fungicide and it is still a component of black gun powder. Sulfur reacts with methane to form carbon disulfide (CS_2), which is employed to make cellophane and fibers such as rayon.

20.6 Pollution from Sulfur

20.6.1 Acid Deposition (SO_x , NO_x and PM)

To paraphrase *Historica Canada* [20.43]:

Acid deposition is the wet or dry accretion of acidic substances and their precursors onto the Earth's surface. The acidic substances include sulfur oxides (SO_x) and nitrogen oxides (NO_x). Wet deposition refers to rain, snow, drizzle and other forms of precipitation. Dry deposition is the settling of particulates, especially sulfates.

Wet deposition may be acidic or alkaline. A clean water sample in equilibrium with atmospheric carbon dioxide has a pH value of 5.6. In the northern hemisphere, annual average measurements show that the pH of precipitation ranges from about 4.0–7.0. Low pH values occur over and immediately downwind of urban and industrial areas. High pH values are found over less industrial regions where the atmosphere contains significant amounts of alkaline dust. The primary cause of low pH is H_2SO_4 , which is produced in the atmosphere from the reactions between SO_x , water and oxygen. In like fashion, nitric acid (HNO_3) is generated from reactions of nitrogen oxides (NO_x) with moisture. NO_x are significant in urban areas, because they come primarily from transportation vehicles.

SO_2 comprises about 90% of ambient SO_x . Methods for reducing SO_2 emissions include:

- Using low-sulfur coal or cleaned coal for power plants

- Removing sulfur compounds from natural gas and petroleum before they are burned
- Removing sulfur from ores before they reach smelters
- Employing flue-gas desulfurization
- Consuming sulfur-neutral alternative energy sources.

Decades ago, I heard the CEO of an oil company say: *The solution to pollution is dilution.* Consistent with that philosophy, power plants and refineries installed taller emission stacks to increase the distance from the source to the ground. The taller stacks did indeed decrease ground-level SO_x and NO_x in the immediate vicinity, but they didn't solve the ultimate problem. Transported by winds, the pollutants can travel thousands of kilometers, affecting regions far away from their points of origin. In the 1980s, studies verified that 50% of the sulfate deposition in eastern Canada came from the USA.

Short-term exposure to SO_2 can impair human respiration and make breathing difficult. Children, the elderly and those who suffer from asthma are particularly sensitive. SO_x can react with other compounds in the atmosphere to form small particles. These particles contribute to particulate matter (PM) pollution. PM may penetrate deep into lungs to cause long-lasting health problems.

There are other potential adverse effects of acid rain on human health. Acid in water delivery systems accelerates the leaching of lead, copper and other metals,

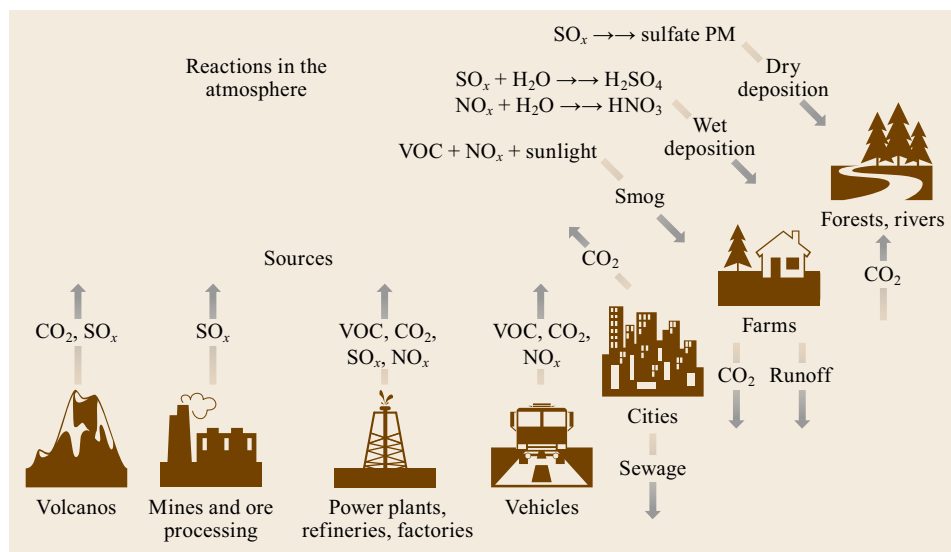

Fig. 20.16 Sources of SO_x , NO_x , CO_2 and volatile organic compounds (VOC). Generation of photochemical smog. Dry deposition of sulfate particulates, wet deposition of acids

increasing their levels in drinking water. A well-known example comes from Flint, Michigan where acid leaching due to orthophosphate led to high levels of lead in drinking water, affecting the health of thousands, including 6000–12 000 vulnerable children [20.44]. Officials became aware of the problem in April 2014, but hid the problem for more than a year. In the summer of 2015, Adam Rosenthal of the Michigan Department of Environmental Quality conspired with Patrick Cook and others to change data in lead and copper monitoring reports. The situation came to light in September 2015, when a team led Professor Marc Edwards of Virginia Tech University discovered and documented the problem. On 29 July, six officials, including Rosenthal and Cook, were officially indicted.

Increased concentrations of heavy metals in fish caught from acidified rivers and lakes could pose problems for people who consume significant quantities of these fish.

Figure 20.16 is a simplified illustration of the generation and disposition of SO_x , NO_x and other air pollutants. Ground-level ozone, chlorofluorocarbons (CFCs) and toxic metals are not shown.

In the United States, the clean air act (CAA) requires the US Environmental Protection Agency (EPA) to establish national ambient air quality standards (NAAQS) for harmful pollutants. EPA sets two types of standards – primary and secondary. Primary standards protect against adverse health effects. Secondary standards protect against damage to farm crops, vegetation and buildings. Some pollutants have standards for both long-term and short-term averaging times. The short-term standards are designed to protect against acute health effects, while the long-term standards protect against chronic health effects.

Table 20.3 lists NAAQS for six pollutants regulated by EPA.

Over time, ambient levels of SO_2 , NO_2 and other important pollutants have decreased considerably [20.45]. Table 20.4 shows percent reductions between 1990 and 2015. During the same period, the US economy grew, Americans drove more miles and overall energy use increased.

Similar improvements in pollution were achieved in the EU. Table 20.5 presents analogous data for EU nations during 1990 through 2012 [20.46].

Atmospheric sulfur oxides mostly come from fossil fuels, sulfide ores and volcanoes. Figure 20.17 plots worldwide SO_2 emissions by source from 1900–2014. Data for 1900–2005 come from *Smith et al.* [20.47]. Data after 2005 for China are from *Ma and Takeuchi* [20.48], using a normalization factor of 1.25 to match data reported by others. Data after 2005 for

Sulfur dioxide	Secondary	3 h	0.5 ppm	Not to be exceeded more than once/year

the United States come from EPA [20.49]. Table 20.6 gives reported total worldwide SO₂ emissions for 2005 and estimated emissions for 2014; the estimates include actual data from the USA and China and straight-line projections for other countries.

Figure 20.18 shows SO₂ emissions from five countries and international shipping. In 2005, these six sources accounted for nearly 58% of worldwide SO₂ emissions. SO₂ from shipping grew as oil refiners blended more high-sulfur components into bunker fuel. However, the trend will change in 2020, when the upper limit on ship-fuel sulfur outside sulfur emission control areas will drop from 3.5 wt% to 0.5 wt% [20.50].

^a Since 2000

From 1970 to 2000, worldwide emissions fell by 16%. In the USA, emissions decreased by 56% and in Germany, they plummeted by an astounding 93%. But in 2000, emissions began to rise. Steep declines in the USA, Russia, Germany and the rest of Western Europe were offset by precipitous rises in less developed countries, especially in China, where emissions rose by 58% in just five years. China's 11th five-year plan (2006–2010) included ambitious emission-reduction targets.

Table 20.6 Reported total worldwide SO₂ emissions for 2005 and estimated emissions for 2014. The estimates include actual data from the USA and China and straight-line projections for other countries and sources

	2005	2014 (est.)
Coal	52.2%	49.2%
Petroleum	18.4%	17.9%
Smelting	11.1%	10.1%
Int'l shipping	10.5%	13.5%

Volcanic, other	3.9%	4.4%
Biomass	0.8%	0.9%
Total	100.0%	100.0%
Total tonnes	115 507	102 000

Fig. 20.17 Relative contributions of coal, petroleum, smelting and international shipping to worldwide SO₂ emissions from 1900–2014. The box surrounds values computed by a combination of recent data from the USA and China with projected values from other countries

Fig. 20.18 Total SO₂ emissions for five countries and international shipping, 1900–2014

Between 2006 and 2010, total SO₂ emissions fell by more than 14% despite 10% annual economic growth.

Figures 20.19 and 20.20 compare SO₂ emissions by source for China and the United States. About 85% of Chinese SO₂ emissions are due to coal. Total emissions rose from 7300 thousand tons in 1970 to 32 700 thousand tons in 2005 – an increase of 450% – then fell by more than 14% between 2005 and 2010.

In the United States in 2005, about 72% of SO₂ emissions come from coal, compared to 62% in 1970, but overall emissions from coal were far lower in 2005. In 2005, 18% of emissions came from petroleum and less than 1% came from smelting. The remaining 9% came from other industrial activities, including shipping. Total US emissions fell from 29 800 thousand tons in 1970 to 4528 thousand tons in 2014, a decrease of roughly 85%. Much of the decline came from the implementation of ever-tighter restrictions on sulfur in fuels. A large percentage came from replacing sulfur-containing coal in power plants with sweet gas from shale produced by hydraulic fracturing [20.51].

20.6.2 Open-Air Roasting

Until the early 20th century, roasting was conducted in open-hearth roasters. The reaction was started by burn-

ing wood on top of a pile of ore. When the ore became hot enough, the sulfide oxidation reaction generated enough heat to keep the process going. The pile was stirred manually with rakes to expose unreacted ore to air.

For the health of workers and the environment, open-hearth roasting was disastrous. In addition to generating unrecovered SO₂, open-hearth roasting released toxic elements, such as arsenic and mercury. Even today, 80–100 years later, nothing grows near numerous open-hearth sites. Some dead zones occupy several square kilometers.

20.6.3 Volcanic SO_x: The Year Without a Summer

Volcanic activity, another significant source of SO₂, varies unpredictably. When SO₂ is injected into the stratosphere, it forms sulfuric acid, which condenses rapidly into fine sulfate aerosols [20.52]. The aerosols reflect sunlight back into space, cooling the lower atmosphere (troposphere). Several eruptions during the past century caused a decline in the average temperature at the Earth's surface of up to 0.5 °F for up to three years. The spectacular eruption of Mount Pinatubo on 15 June 1991 was one of the largest of the 20th cen-

Fig. 20.19 SO₂ emissions in China by source, 1900–2005

Fig. 20.20 SO₂ emissions in the USA by source, 1900–2005

ture. It blasted 20 million metric tons of sulfur dioxide into the stratosphere, where it reached an altitude of more than 20 miles (32 km). The Pinatubo SO₂ cloud was the largest since the beginning satellite observations in 1978. It caused what may be the largest injection of aerosols into the stratosphere during the 20th century. It cooled the Earth's surface for three years by as much as 1.3 °F at the height of the impact.

Pinatubo was probably smaller than the disturbances caused by Krakatau in 1883 and Tambora in 1815. The 1783–1784 Laki eruption in Iceland released six times more SO₂ than Pinatubo. Although the two eruptions were significantly different in length and style, the SO₂ caused regional cooling of Europe and North America by similar amounts for similar periods of time.

Tambora turned 1816 into the *year without a summer* [20.53, 54]. Volcanic ash and sulfate aerosols reddened and dimmed the sun, so much so that sunspots were visible to the naked eye. In northern regions of North America, Europe and China, summer frosts killed crops. In many parts of New England, killing frosts occurred in every summer month. Due to crop failures, food prices skyrocketed. In Germany, the crisis was especially severe. In India, the summer monsoon was delayed. When it finally arrived, it caused unusually severe floods. At higher elevations, the effects of Tambora lingered until the Spring of 1817.

Now-erupting volcanoes include Stromboli and Etna in Italy, Pavlof in Alaska, Kilauea and others in Hawaii, Colima in Mexico, Popocatepetl and others in Central America and several around the Pacific Rim in Western South America, Indonesia, the Philippines Japan and the Aleutians. All produce different amounts of SO₂, CO₂, H₂S, HF, HCl and HBr. An interesting example is the Kawah Ijen volcano. Instead of lava, it discharges molten sulfur.

20.6.4 International Shipping

MARPOL is the International Convention for the Prevention of Pollution from Ships.

As shown above, international shipping accounts for a significant percentage of world SO_x emissions. Starting on 1 January 2015, MARPOL Annex VI imposed tight limits on SO_x in emission control areas – the Baltic Sea; the North Sea; and the North American area, which includes designated coastal waters around the United States and Canada and the US Caribbean Sea around Puerto Rico and the US Virgin Islands. In 2020, outside the Emission Control Areas, the allowed

sulfur content of marine fuel oil will drop from 3.5 wt% to 0.5 wt%.

20.6.5 Acid Mine Drainage

Drainage from iron mines – and from copper, zinc, nickel and coal mines – is called acid mine drainage (AMD) or acid rock drainage (ARD). Simply exposing sulfur-containing ores to the elements, as in strip mining, creates conditions conducive to sulfuric acid formation. Uncontrolled AMD causes significant pollution. Acidity is the main problem. Runoff from the Iron Mountain Mine in California can have a pH as low as –3.6 [20.55]. Figure 20.21 shows the impact of pyrite leaching into the Rio Tinto in Spain.

20.6.6 Midnight Dumping

Surreptitious dumping continues to plague manufacturing industries. Recent examples include fouling of a Tennessee homeowner's yard by wastewater dumped at the side of a road [20.42], chronic illegal dumping of fracking wastewater in Ohio [20.56] and on-purpose dumping of waste oil into the sea [20.57]. Figure 20.22 shows a commonly reported method for waste-oil dumping – opening a flange to bypass pollution prevention equipment. This allows a slow, almost undetectable drip of the oil into the ocean [20.58, 59]. Waste oil (sludge) from ships typically contains up to 3 wt% sulfur and sometimes more, along with small amounts of toxic trace metals. The sludge comes from spilled fuel and oil-based lubricants.

Marine Defenders provides a succinct summary of the problem [20.60]. Almost all liquid wastes, including sludge, collect in bilge tanks at the bottom. The

Fig. 20.21 Uncontrolled acid runoff from pyrite leaching causes severe environmental damage to the Rio Tinto in Spain (photo by C. Stoke)

Fig. 20.22 (a) An illegal *magic pipe* used to bypass pollution prevention equipment on an open-sea ship. (b) Evidence photo taken with a whistleblower's cell phone. Photo credits: US Department of Justice

bilge tanks must be emptied regularly. Until the 1950s, ships pumped bilge water into the sea during a voyage and always just before reaching a port. However, as the environmental impact of oil pollution became clear, this practice was banned by MARPOL, the International Convention for the Prevention of Pollution from Ships in 1954. These rules were strengthened in the 1970s by the MARPOL treaty, after the wreck of the *Torrey Canyon* on the Cornish coast of England in 1967. The grounding and breakup of the supertanker was at that time the world's worst oil spill. It discharged 500 000–800 000 barrels of crude oil, fouling about 50 miles (80 km) of French coastlines and 120 miles (190 km) of Cornish coastlines. Some of the after-effects are visible even today in Guernsey, one of the Channel Islands.

The MARPOL treaty required that ships must use an oil/water separator to ensure that all wastewater pumped overboard has an oil content of less than 15 parts per million. It stated that all ships must carry functioning pollution control systems and maintain detailed and accurate oil record books. A 2002 report by the European Organization for Economic Cooperation and Development (OECD) estimated that the average annual cost of meeting the MARPOL regulations ranged from \$ 30 000 a year for an average cargo ship, to \$ 55 000 for a large container vessel, to \$ 150 000 per year for an oil supertanker. These values were equivalent to between 3.5–6.5% of a ship's overall operating expenses. In the case of a million-barrel supertanker, which may carry six or more cargoes per year, the cost of complying with MARPOL rules is about 0.05% of the value of the cargoes.

Interviews with crew members and ship owners indicate that saving time was the main reason for willful violations. It can take several hours to unload waste oil legally in a port.

20.6.7 Lax Regulation Enforcement

Based on work experience in 60 refineries worldwide, I can attest that regulation enforcement varies from country to country and, within countries, from region to region [20.61]. Enforcement is difficult when inspections are restricted or not allowed, when inspectors are less than diligent, or when enforcement agencies are understaffed.

In *Breakdowns in Air Quality*, Levin et al. [20.62] report that data from the Texas Commission on Environmental Quality (TCEQ) show that in 2015, 679 facilities emitted more than 34 000 t of SO₂, NO_x, benzene and other pollutants during 3421 shutdowns due to equipment failure or maintenance. Two instances stood out: Dow Chemical's plant in Freeport, which accounted for nearly 1.3 million pounds and the Keystone Gas Plant, which in 2014 emitted 11 million pounds of SO₂ versus a permit that limits SO₂ emissions to 1.6 million pounds.

The report says Texas is *well known for its hands-off approach to environmental enforcement*. In a statement, the director of Environment Texas said:

By their own admission, polluters in Texas are routinely and egregiously violating the law and endangering public health with unauthorized emissions. And too often regulators look the other way when polluters break the law. This lawlessness must come to an end.

In its own statement, the TCEQ calls the assertion [20.63]:

[...] patently untrue and misleading to the public. TCEQ consistently pursues administrative, as well as civil enforcement, against noncompliant regulated industries in accordance with a vigorous, clearly articulated regulatory framework.

Table 20.7 Budgets, staffing and workloads for environmental agencies in California and Texas

State	California	Texas
Agency	California Environmental Protection Agency (CalEPA)	Texas Commission on Environmental Quality (TCEQ)
Budget for 2016, \$ million ^a	1800	474
Employees	4550	2780
Number of oil refineries (2016)	18	29
Refining capacity, bbl/day (2016)	1 982 000	5 452 000
Oil production, thousand bbl, May 2016	15 816	99 168
Number of producing gas wells	1118	98 279
Gas production, million scf, May 2016	18 135	696 901
Petrochemical plants	Almost none	More than any other state in the USA

^a Includes permitting fees. In Texas, most of the budget comes from revenue collected from fees

Table 20.7 compares staffing, budgets and workloads for TCEQ and the California Environmental Protection Agency (CalEPA). Data on oil and gas facilities and production are from the *US Energy Information Administration* [20.64]. In both states, major activities include issuing permits and enforcing regulations. There are of course differences in purview, but it is clear

that with 40% fewer people and a budget that is 74% lower than that of CalEPA, the TCEQ has more work to do. At present in Texas, the number of new oil and gas wells and refinery expansions is unprecedented; most of the new wells employ fracking technology, for which the amount of wastewater disposal is unprecedented. TCEQ processes permits for all of those projects.

20.7 Conclusion

Petroleum, natural gas and other fossil fuels contain significant amounts of sulfur. When burned, the sulfur becomes SO_x, which can cause significant damage to the environment and human health. To minimize such damage and to ensure that finished products meet performance specifications, the sulfur is removed and transformed into useful chemicals, primarily sulfuric acid and fertilizers.

Sulfur oxides and acids continue to threaten our atmosphere, water, land, and inhabitants. I hope that the tremendous reductions in sulfur pollution in developed countries will serve as a guide to fast-growing but less-developed countries. To paraphrase Barry Commoner: On this beautiful planet we share, everyone is affected by the actions of everyone else.

21. Modern Approaches to Hydrotreating Catalysis

Joo-Il Park, Isao Mochida, Abdulazeem M. J. Marafi, Adel Al-Mutairi

Hydrotreating plays an important role in petroleum refining. Crude oil contains contaminants – sulfur, nitrogen, oxygen and trace elements – which must be removed to meet product specifications. Most refineries include at least three hydrotreating units for upgrading naphtha, middle distillates, gas oils, intermediate process streams, and/or residue. Hydrotreating catalysts are the core of the process.

This chapter reviews current progress in tackling the issues found in upgrading distillates and residues by hydrotreating and focuses on the chemistry of hydrodesulfurization (HDS), hydrodenitrogenation (HDN), hydrodeoxygenation (HDO) and hydrolytic demetalization (HDM). We discuss the composition and functions of hydrotreating catalysts, and we highlight areas for further improvement. The distillate molecules are accessed by gas chromatography–atomic emission detection (GC–AED) and gas chromatography–time of flight (GC–TOF) to identify and quantify all molecules in the feeds and hydrotreated products. Enhancement of reactivity and suppression of inhibition are discussed based on the molecular structure versus reactivity/inhibition correlations. A molecular approach towards the residue is progressed by applying ultrahigh–resolution Fourier–transform ion cyclotron resonance (FT–ICR) mass spectroscopy. Nevertheless, target molecules in resid HDS and HDN are not defined yet due to the polymeric and agglomerated nature of the molecules. Molecular images of sulfur– and nitrogen–containing species are still major targets of hydrotreating. However, porphyrinic metal compounds in the resid, even the asphaltene, can now be detected by GC–AED, gas chromatography–ionconductively coupled plasma–mass spectrometry (GC–ICP–MS) as well as FT–ICR, indicating that the porphyrinic metal compounds can be isolated for observation from the resid and asphaltene matrix under the analytical conditions. The carbon deposit on the catalyst in the HDM is reviewed to show its important influence on capacity and distribution of metal on the catalyst. The carbon deposit is the major issue in hydrotreating. The reactivity of feed molecules for

the carbon deposit includes the condensation and adsorption phase separation, which depend on reactivity and dissolution/antidissolution properties of surrounding species as well as the properties of particular molecules concerned. Further challenges in hydrotreating are also discussed concerning the issues picked up in the molecular structure reactivity/inhibition of distillates and residues.

21.1 Overview

21.1.1 Hydrotreating Process

There are a number of processes used in petroleum refining for upgrading petroleum fractions to produce valuable products, as shown in Fig. 21.1. These include:

- Isomerization
- Alkylation
- Reforming
- Thermal processes
- Catalytic cracking
- Hydroprocessing.

Hydroprocessing includes three major classes, namely:

1. Hydrotreating
2. Hydrocracking
3. Hydrofinishing.

Hydrotreating includes hydrogenative heteroatom removal and hydrogenation of olefins and aromatics. The heteroatoms include sulfur, nitrogen, oxygen and metals. Hydrocracking performs hydrogenation and cracking successively and simultaneously. There are differences between combined hydrotreating/catalytic cracking and hydrotreating/hydrocracking in terms of conditions and interactive reactions. Both have advantages and disadvantages. Hydrofinishing is really another form of hydrotreating that is used to achieve the final specifications of fuels.

Each process is individually optimized according to the boiling range and molecular composition of the specific petroleum fraction being processed [21.1]. Hence, when selecting a process or combination of processes for a particular application, it is very important to understand the feedstocks and process objectives, which determine process conditions, and costs. Before making such decisions, it is important to understand fully the underlying chemistry and reaction mechanisms associated with feedstocks, products and catalysts [21.2]. Most intermediate streams in a refinery are also hydrotreated.

This overview describes the remarkable progress in the detailed understanding of the chemistry of feeds, products, and the conversion mechanisms of hydrotreating at the molecular level, including the detailed structures of the reactants, their chemical and physical properties and conversion mechanisms. The roles of the detailed molecular interactions in the feed on reactivity and inhibition are also reviewed. The preparation, activation, composition and structure of catalysts are discussed, along with the associated causes of catalyst deactivation and ultimate catalyst lifetime in each pro-

cess. The approaches to new and improved catalytic processes and the production of more-active catalysts are also discussed.

Recently, some reviews on the hydrodesulfurization of gasoline and middle distillates have been published. *Song* [21.3] summarized the new aspects of deep HDS of diesel and gasoline fractions including a brief review of some commercial processes. *Moulijn* [21.4] also reported recent advances in deep HDS. His review described the conventional and nonconventional technology including adsorption and oxidation. French groups [21.5] summarized the chemical nature of HDS systems, including new acid catalysts and adsorption technology. Our previous chapter [21.6] is also referenced. For practical applications, new and improved catalysts have been developed and marketed by various companies such as Akzo Nobel, NEBULA, Criterion, Haldor-Topsøe, IFP, United Catalyst/Süd-Chemie, Advanced Refining Technologies, ExxonMobil, and Nippon Ketjen in Japan. These are well reviewed in *Song's* literature [21.3]. Recently, many efforts have been progressed by manufacturers. For example, Criterion developed a new CoMo ULSD catalyst, ASCENT DC-2534, for top-tier desulfurization performance in the low-to-medium pressure range, which may be designed for refiners that want to maximize diesel production while managing hydrogen consumption and operating cost [21.7]. New efforts for developing the desulfurization catalyst have been made by Haldor Topsøe with the detailed insight of interaction between support and type I/II sites in the catalyst [21.8]. The progress in fundamental HDS studies together with the elucidation of reaction pathways are expected to continue for the improvement of commercial catalysts.

21.1.2 Chemical Composition of Distillates

Figures 21.2 and 21.3 illustrate the diversity of composition by showing the elemental (C, S, N) distributions of some typical petroleum fractions, such as gasoline and light cycle oil LCO analyzed by gas chromatography with atomic emission detection (GC-AED) [21.9]. These figures also show the distributions of heteroatomic molecular species that must be converted into hydrocarbons by hydrotreating processes (HDS and HDN). AED can be replaced by other sulfur- and nitrogen-specific detectors, such as sulfur chemiluminescence (SCD) and nitrogen chemiluminescence (NCD) detectors [21.10], as well as inductively coupled plasma-mass spectrometry (ICP-MS) for high sensitivity.

Recently, comprehensive two-dimensional gas chromatography (GC×GC) has become avail-

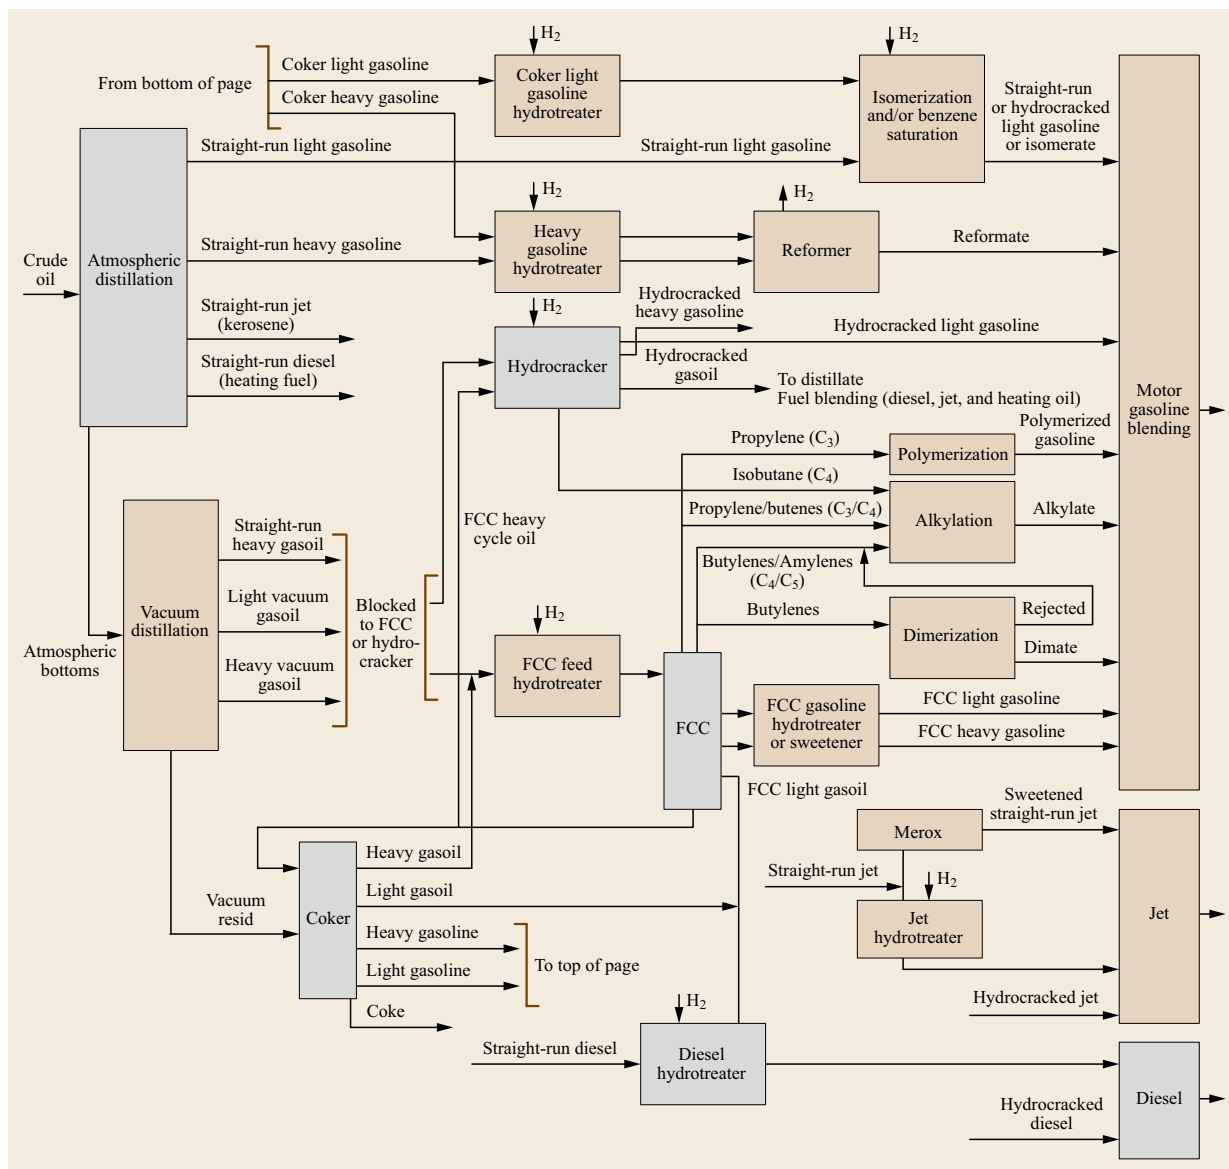

Fig. 21.1 Petroleum refining processes for production of transportation fuels

able [21.11]. A result of the GC×GC analysis of SRGO is shown in Fig. 21.3. With additional chromatographic separation the overlapping components encountered in one-dimensional GC can be resolved, resulting in sufficient resolution and sensitivity for identification and quantification of individual components. Thus, full analysis of molecular composition in petroleum distillates up to gas oils is now achievable.

An important feature of Fig. 21.3 is that the small amounts of thiophenic compounds having high retention time in second dimension are resolved from overwhelming amounts of saturated and aromatic hydrocar-

bons having lower retention time in second dimension even though they have the same retention time in the first dimension. Thus, it demonstrates the power of resolving thiophenes that are overwhelmed by co-eluting hydrocarbons in one-dimension GC and thus not able to be quantified.

Light (LCO) and medium cycle oils (MCOs) of the gas oil range in fluidized catalyst cracker (FCC) streams must be further hydroprocessed to yield high-quality fuels. The problems of high concentrations of aromatic hydrocarbons interfering with the measurement of small amounts of thiophenic compounds at

one-dimensional GC systems for the deep HDS studies of LCO and MCO can now be resolved by using GC×GC or one-dimensional GC with an AED detection system. Thermally cracked products can contain fair amounts of olefins [21.12].

21.1.3 Chemical Components in the Residues

The heavier fractions such as atmospheric residue (AR) and vacuum residue (VR) are also target fractions for hydrotreatment. The vacuum residue consists of saturates, aromatics, resins and asphaltenes (SARA) as identified by liquid chromatographic separation. The molecular compositions including heteroatom-containing species in the first two fractions are analyzed by GC and high pressure liquid chromatography (HPLC). Specific chromatographic separations of heteroatomic species are very helpful for molecular characterization [21.13].

Remarkable progresses in Fourier-transform ion cyclotron resonance mass spectrometry (FT-ICR MS) provides very high resolution and accurate mass measurement, allowing the determination of elemental composition of individual species [21.11, 14, 15]. Some examples of analyzed molecular classes are illustrated in Fig. 21.4. Recently, commercially available spiral time-

of-flight TOF MS and multipath high-resolution TOF (HRT) MS have provided high resolution for millimass accuracy at lower cost, comparing to FT-ICR MS.

Although mass spectrometry-mass spectrometry (MS-MS) can provide structure information of particular species of interest, it fails to obtain any useful structural information for asphaltene molecules due to complexity and interference of other species.

The asphaltene in the residue is the actual ultimate target for both analysis and hydrotreatment. The fraction is believed to consist of three levels of the conceptual structure as follows:

1. Aggregate of polymeric molecules
2. Polymeric or macromolecules
3. Key structural units.

Aggregate

Yen's group proposed an aggregate model [21.16] that was modified by Mullins recently [21.17]. The molecular association is schematically illustrated in Fig. 21.5. The differences between the two models are as follows:

1. Priority of aggregation driving forces among:
 - a) Aromatic planner stacking
 - b) Polymeric entanglement including London force

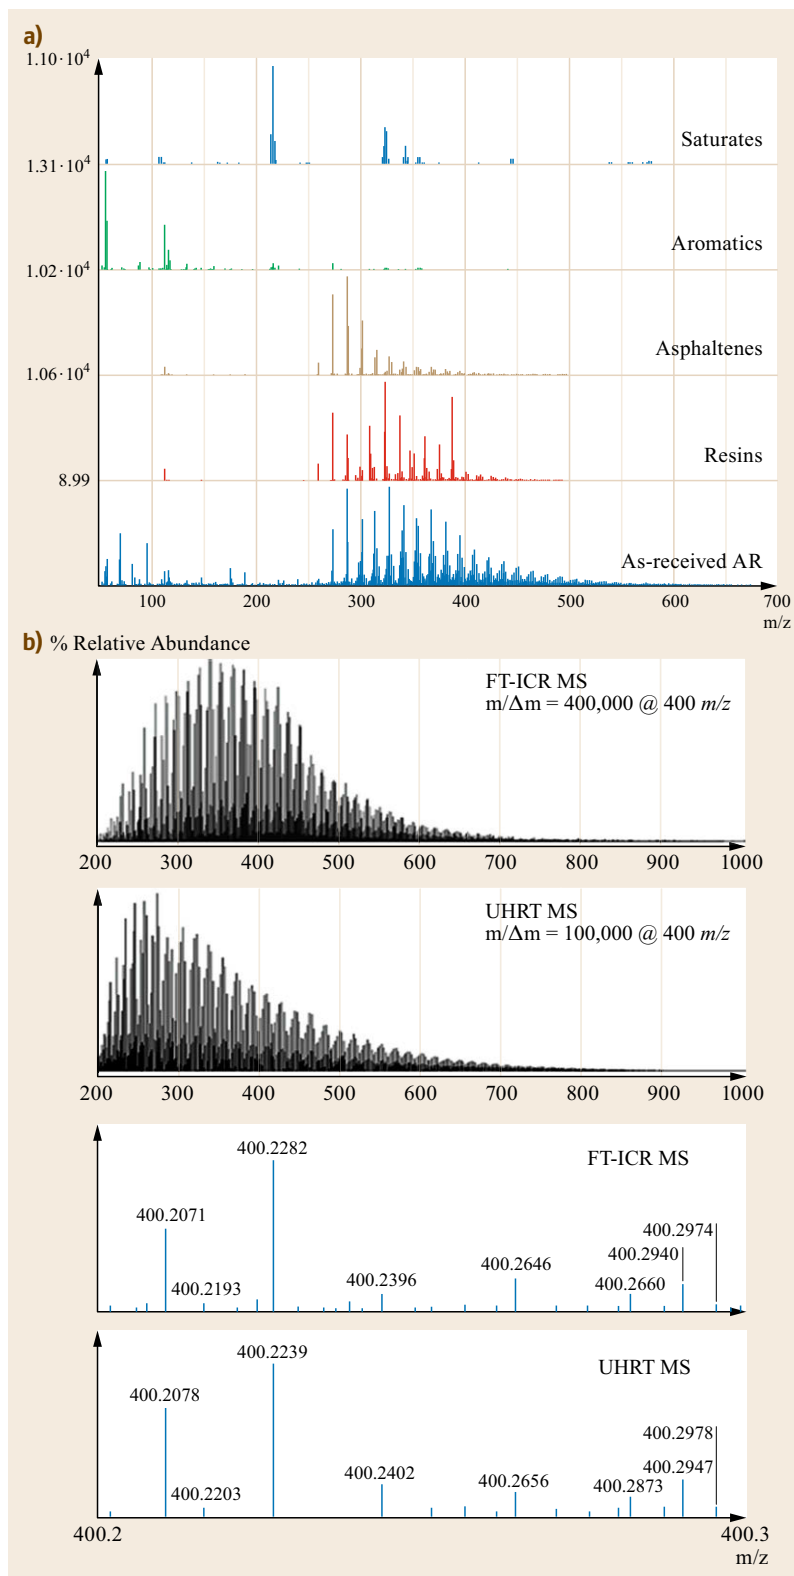

Fig. 21.4 (a) Spiral TOF-MS data for as-received AR and its fractionations of saturate, aromatic, resin and asphaltene (target plate: hairline 384 spots, mode: positive spiral, ionization: LDI, laser intensity: 40%) **(b)** ESI (+) typical broadband spectra of a representative crude oil with average levels of biodegradation and maturation obtained by FT-ICR MS and HRT MS analysis as well as expanded m/z 0.1 window views in the m/z 400.2–400.3 range (after [21.11]). (HRT system uses an innovative multipath-reflecting TOF with a folded flight path developed by Verentchikov et al. [21.14, 15])

Fig. 21.5 The modified Yen model (or the Yen–Mullins model). *Left:* The predominant asphaltene molecular architecture contains a single, moderately large polycyclic aromatic hydrocarbon (PAH) with peripheral alkanes. *Center:* Asphaltene molecules form nanoaggregates with aggregation numbers of approximately six, with a single disordered PAH stack. *Right:* Asphaltene nanoaggregates can form clusters with aggregation numbers of approximately eight (after [21.17])

- c) Hydrogen bonding or polar–polar interaction including acid–base, and coordinative metallic bridge
- d) Donor acceptor interaction.
2. Aromatic units, multinuclear or single large ring forms. Molecules in Fig. 21.5 carry a fairly large ring with alkyl pendants.
3. Metallic components are bounded to the polymeric and located within aggregated units.

Such aggregation is believed to hinder the contact of its inner units with the surface of the heterogeneous catalysts that carry polar, acidic and hydrogenation sites.

Polymeric Molecules and Nuclear Units

Asphaltene polymers carry sulfur, nitrogen, oxygen in and on their polyaromatic rings. Hydrotreatment removes such elements, hydrogenates and even ring-opens the aromatic ring to refine VR to high-quality fuel and chemicals of lower molecular weight. Hence, we must clarify the image of how the catalyst contacts to the particular reaction sites of asphaltene polymers, for removal and the chemical modification of the target atoms or atomic groups. The basic reaction scheme and mechanisms have been clarified in the hydrotreatment of the distillate where the single molecular structure has been fully identified. Hence, the first objective is to clarify the unit structure concerning the asphaltene polymer. Currently, FT-ICR MS has been used to identify numerous atomic compositions of target species in the asphaltene by carbon number and double-bond equivalent (DBE) [21.18]. Mass-mass measurement can basically provide unit structure of concerned units. According to the knowledge of distillate hydrotreating, local structure surrounding the reaction site plays very

important roles in the reactivity of the target reaction site. The mechanism suitable for the target molecules depends on the molecular-level structure. At the moment, we do not have access to the level of understanding of the detailed structure of asphaltene molecules. Some approaches are described in detail in the later sections. Very roughly speaking, the skeleton of the unit may be similar to that of distillate. We must be concerned with the locations of the target atoms. Polymeric chain entanglement may be also taken into account. The separation and concentration of particular groups of the substrate are always very helpful for the molecular analysis. The location of heteroatoms in the asphaltene molecules is not identified yet, although some structures have been proposed [21.19].

The molecular weight of asphaltene components has been discussed extensively. Two extremes are already reported:

1. Very large molecular weight approaching 10 000–100 000 daltons (Da)
2. Rather small molecular weight less than 1500 Da.

Current mass spectrometry results using carefully controlled ionization conditions favor the second claim by excluding both fragmentation and oligomerization (condensation and coupling) at desorption/ionization stages.

Metals

Petroleum includes several metallic chemical forms:

1. Vanadium and nickel complexes
2. Naphthenic irons and iron sulfides
3. Salts derived from seawater.

Among them, vanadium, nickel, arsenic and silicon are a common cause of catalyst degradation and deactivation in hydrotreatment units. Salts are almost completely removed during desalting. But this process does not remove all of the As, Hg, and Si from crude, because of their status as nonpolar molecules. In addition, volatile alkyl arsenic is the worst of all trace contaminants, showing in VGO and HGO fractions mainly originated from Russia, West Africa and Canada. Alkyl mercury compounds with volatility are nearly as bad as arsenic. Silicones used as flow improvers in pipelines are applied to antifoam agents in delayed coking units, and a lot of silicones appear in naphtha-range fractions. Soluble iron, either from the raw feed or from corrosion of piping, can cause severe operating troubles. The vanadium and nickel complexes

are concentrated in the heavier fractions, while arsenic, silicon and mercury compounds can appear in all fractions. Their removal for refining becomes more important, as described later.

Two aspects of the metal complexes are of concern:

1. Molecular structure of the metal complex (described later in this section)
2. Location or binding of the metal complexes in the asphaltene aggregate and with its polymeric chains.

Certain metals, especially Ni and V, are believed to be present in the chelate forms [21.19]. Porphyrins are most common in the rather light crudes (Fig. 21.6). Nonporphyrins are present in the rather heavier crudes. Nonporphyrins are:

Fig. 21.6a-d Typical metal porphyrin structure in petroleum (a-c) and chlorin intermediate (d): M is Ni or V=O (after [21.20])

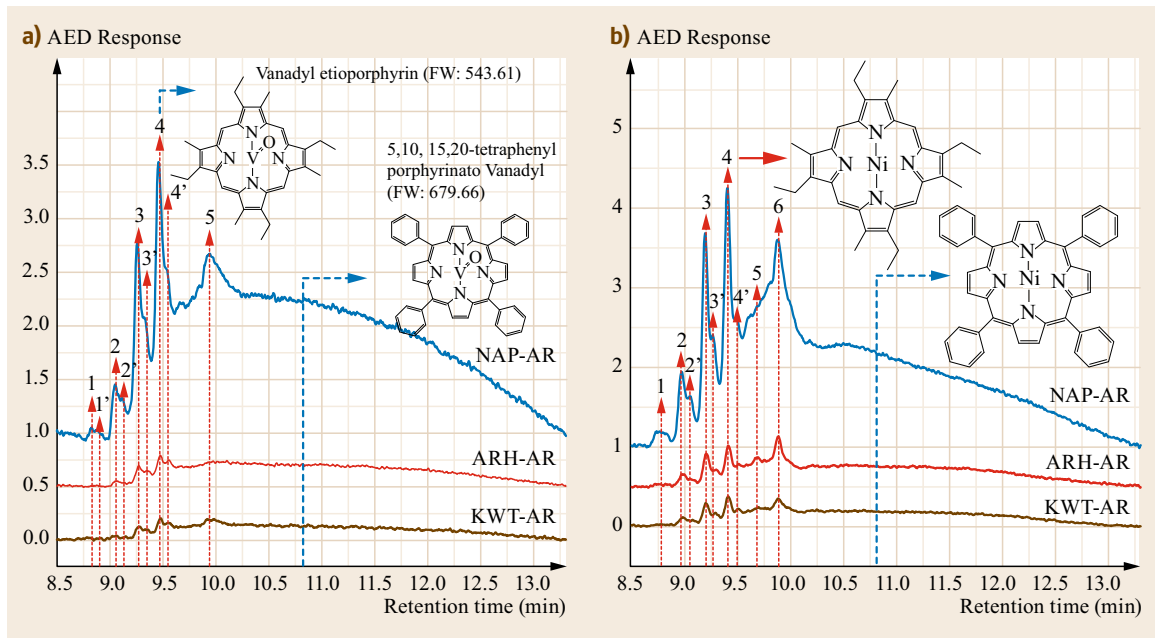

Fig. 21.7a,b The AED chromatograms on (a) V-species and (b) Ni-species in HT-GC-AED (after [21.21])

1. Hexagonal porphyrin-like complexes which carry fifth and sixth ligands in the planar porphyrins
 2. Nonnitrogen ligands in which the metals are bound to sulfur and/or oxygen.
2. Catalytic demetalization:
 - a) Direct metal extraction
 - b) Hydrogenation of the aromatic rings in the ligand, opening the coordination to liberate metal ions onto the catalyst.
 3. Sulfiding.

Currently porphyrins are identified by visible-ultraviolet (UV) spectroscopy [21.22], electron spin resonance (ESR) for vanadium [21.23, 24], GC-AED [21.21] (Fig. 21.7), GC-ICP [21.25], and FT-ICR [21.26, 27]. Nonporphyrins are detected by Visible-UV and ESR [21.23, 24]. The metal complexes are present principally in asphaltene and some in resin. According to Yen's group [21.16, 17], the metal complexes are bound with covalent bonds to the polymeric asphaltene molecules. The central metallic ion is coordinated to the ligand, which can be bound to the asphaltene molecules. Porphyrin rings are also included in the aromatic stacking of asphaltene.

Hydrodemetalation (HDM) is a hydrorefining reaction where the central metals are removed by HDM catalysts. The HDM reaction is assumed to proceed with:

1. Contact of porphyrins to the catalyst surface through their liberation from asphaltene aggregates

Metals may accumulate on the HDM catalysts as sulfides. H_2S is essential for HDM in hydrotreatment. Reactive sulfur may attack the metal ion present in the complex center or isolated on the HDM catalyst. Researchers at Chevron report that H_2S actually inhibits the rate of HDM reactions, and that without H_2S , HDM is too rapid. When HDM is too rapid, it prematurely chokes pore mouths.

Many researchers believe that some if not most of the asphaltene molecules simply plate out in large catalyst pores, where they age to form metal-containing hard coke. This explanation is plausible, because in addition to containing metals and sulfur, spent catalysts also contain significant amounts of carbon, and it is difficult to identify, on a molecular basis, how the metal atoms are bonded. Kinetics, detailed mechanisms and HDM catalyst design will be described later in this chapter.

21.2 Hydrotreating Process

The primary objectives of hydrotreating are:

1. To remove impurities, such as heteroatoms and metals from the feedstock
2. To increase the hydrogen content of the feedstock
3. To lower the molecular weight without a substantial loss in liquid product yield
4. To prepare feed for downstream processes (e.g., fluid catalyst cracking and product blending).

The impurities of concern basically depend on the molecular weight of the feedstock being processed. Lower molecular weight feedstocks such as naphtha, gasoline, middle distillates (atmospheric and light vacuum gas oils), diesel fuels and home heating oils (kerosene etc.) carry undesired impurities such as sulfur-containing compounds (S-compounds), nitrogen-containing compounds (N-compounds), oxygen-containing compounds (O-compounds), and polynuclear aromatic (PNA) compounds. Higher molecular weight feedstocks such as heavy vacuum gas oil, and atmospheric and vacuum residues, have metals in addition to the same impurities described above. In general, the concentrations of these impurities increase with their higher boiling ranges. Thus, the hydrotreating process of choice depends primarily on the boiling range of the feedstock. The boiling range is dictated by the molec-

ular weight distribution of the feedstock. The second-most important consideration in choosing a hydrotreating process is the product quality specifications, which are predominantly related to the total hydrogen content of the products that, in turn, are related to the PNA content.

O-compounds are generally not considered as major or environmental hazards in petroleum products. Nevertheless, some O-impurity compounds such as phenols and naphthenic acids lead to problems and corrosion in the transportation pipe and storage vessels [21.28]. Some crude oils that contain a large amount of naphthenic acids are classified as naphthenic crudes. Certain naphthenic crudes serve as lube base stocks. Iron dissolved by naphthenic acid in the crude causes plugging by forming FeS in the catalyst bed or on the feed filter. Finely dispersed FeS may enhance coking reactions, both in the hydrotreater and the FCC [21.29]. The O-compounds in the petroleum are much more reactive for removal than other impurities and, generally, hydrotreating is not developed specifically to remove O-compounds. However, less reactive O-compounds such as phenols and benzofurans are found in significant amounts in coal-derived oils. Hence, their removal is one of the major concerns in the hydrotreating of coal-derived oils [21.30].

S-compounds, N-compounds and M (metal) compounds have different reactivities and chemistry depending on the boiling ranges of fractions in which they are found. Thus, specific processes have been developed for the removal of each of these impurities. These are classified as hydrodesulfurization (HDS), hydrodenitrogenation (HDN) and hydrodemetallation (HDM) processes respectively. These are in turn subdivided into processes that are optimized for the boiling range of the particular feedstock being treated to achieve the highest activity, least hydrogen consumption and longest catalyst life.

In general, the sulfur impurity is of primary concern because S-compounds are major targets of environmental regulations and often are serious poisons and inhibitors for catalysts in secondary upgrading process, such as catalytic reforming and isomerization. Their combustion products create serious environmental hazards such as acid rain. Thus, the main hydrotreating processes that have been developed for distillable feedstocks are HDS processes. N-compound impurities are also removed during HDS processes. When subsequent processes employ acidic catalysts, extensive N-removal is required since the basic N-compounds poison the active site of those catalysts [21.31]. Lower-

ing aromatic content through hydrotreating is classified as hydrodearomatization (HDA). HDA reactions occur during HDS and HDN processes, but product quality often demands an HDA process that is conducted subsequently after HDS and/or HDN process. Future environmental regulations may emphasize HDA further [21.32]. Nevertheless, hydrogenation prior to HDS and HDN is often quite favorable for successive hydrotreatment.

Metal-compound impurities are found particularly in high boiling feedstocks, such as atmospheric and vacuum residues. Thus, HDM processes are tailored for high boiling and very viscous feedstocks [21.33]. Nevertheless, trace amounts of M compounds in the gas oil must not be overlooked since they cause catalyst deactivation in the long run.

The current crudes tend to be heavier and environmental regulation on petroleum fuel is becoming severer and severer. Hence, hydrotreatment becomes more important and should perform deeper refining of highly contaminated feed at acceptable cost. The future processes and catalysts must be improved to achieve the targeted product quality under milder conditions at higher productivity and long continuous operation.

21.3 Bases for Hydrotreating

21.3.1 Hydrotreating Catalysts

For Co(Ni)Mo(W) sulfide catalysts, recognition and control of the shape and size of catalyst sulfides, and their active sites for HDS and hydrogenation, are important topics for the understanding of the hydrotreatment catalysts. The basic principles can be found in [21.6].

Hydrotreating Catalyst for Residue

Hydrotreating for residue consists of HDM, HDS, HDN and hydrocracking. The commercial catalysts for the residue hydrotreatment contain MoS₂ promoted by sulfides of Co and/or Ni on an alumina support.

A support must meet several important criteria. It must be strong enough to bear the weight of tons of catalyst and the force exerted by the flow of fluids. Another important property of an alumina support is the pore size distribution to optimize the access of large molecules in the residue to the number of active sites or surface area. Dual distribution, which carries large and small pores on the same alumina, is designed for better and more effective access of large molecules and small molecules produced in the large pores and small pores respectively.

The kind and amount of sulfide catalysts depend on the target reaction: HDM catalysts carry a small amount of MoS₂, while HDS and HDN catalysts also contain sulfides of Co, Ni or both. In general, CoMoS catalysts are preferred for HDS, and NiMoS catalysts are preferred for HDN. The properties of the support and the amount of active sulfide are optimized to the feed, its sulfur and nitrogen content, and reactivity. The aromaticity and heaviness of the asphaltenes are very influential on the difficulty of HDM, HDS and HDN.

Hydrocracking after the impurity removal requires both hydrogenation and acidity, hence the catalyst must enhance both. Acidity tends to accelerate coking of the heaviest fraction on the catalyst, shortening the catalyst life. Hydrogenation suppresses the coking of adsorbed species on the acidic site, but too much hydrogenation suppresses cracking. The relative amounts of hydrogenation activity and acidity must be carefully balanced.

Progress in Support Materials for More Active HDS Catalysts

Enhancement of catalytic activity on CoMoS and NiMoS has been intended particularly for the HDS of refractory sulfur species in the gas oil, and has been

targeted to find more active support materials. Some oxides and carbon materials have shown superiority to alumina in HDS reactions, although the superiority could not be generalized due to the wide variation of reaction conditions and feed characteristics in HDS. The catalyst support influences the catalytic activity in HDS through two ways: modifying the active species itself and participating in the HDS reaction as a cocatalyst.

Acidic supports, such as zeolites, have been tested by many researchers and show superiority in the HDS reaction. Acidic zeolite was reported to facilitate isomerization and transalkylation of alkylated DBT, resulting in the enhanced HDS activity of refractory alkylated sulfur species [21.34].

Acidity has been recognized as important in deep HDS to improve resistivity against inhibition by H_2S or to enhance hydrogenolysis. Strong acidity can be inhibited by basic and polar nitrogen species, such as NH_3 , pyridines, and carbazoles. Nevertheless, HDN is also accelerated by adsorption and C–N bond fission. A series of CoMo and NiMo catalysts supported on alumina, silica-alumina, and alumina-zeolite were examined [21.10] in the deep HDS of straight run gas oil to evaluate enhanced activity by such supports in the presence of H_2S and NH_3 . Although H_2S and NH_3 inhibit the HDS of refractory sulfur species over all catalysts examined, a catalyst of high acidity achieved deep HDS even under such conditions. Adsorption of gas-phase inhibitors on the acidic sites and weakening of the metal-sulfur bond in the active sulfide caused by acidity of the support are believed to improve the resistivity against H_2S . Inhibition by NH_3 is moderate because of rather high reaction temperature where the adsorption of NH_3 is limited.

The functions of zeolite, as a representative acidic support, have been discussed from the viewpoint of enhanced hydrogenation and isomerization. In addition, zeolite itself has been found to desulfurize some sulfur species, such as thiophene. Acidic C–S bond breakage and hydrogen transfer can be postulated over the acidic zeolite. More research is needed.

In spite of the above advantages in using zeolite as a support material, an inevitable problem is present in such an acidic catalyst system: fast coking. Strong acidic sites cause extensive coking, which shortens the life of the catalyst by covering the strong acid sites, making them nonacidic. Although such behavior cannot be discussed in detail now due to the lack of information, a disadvantage such as fast coking may be moderated by blocking particular acidic sites with a third ingredient. We examined CoMoS and NiMoS catalysts supported on ultra-stable Y-zeolite (USY), modified by an alumina coating. Acidity, measured by NH_3 des-

orption, was lowered on the modified USY. However, its activity toward refractory sulfur species contained in the gas oil was basically maintained. Furthermore, cracking occurring on acid sites was much less over the alumina-coated zeolite catalyst. It is also important to locate the hydrogenation active site in the vicinity of the acidic site to hydrogenate strongly adsorbed species on the acidic site for desorption before coking.

Another issue with a zeolite support is the poor dispersion of active sulfide due to dominant coverage of SiO_2 on the zeolite surface. Incorporation of mobile composition of matter No. 41 (MCM-41) into alumina provided higher activity for the CoMo catalyst in dibenzothiophene (DBT) HDS [21.35]. MCM-41 was reported to reduce the interaction of Co and Mo with the support. As a result, it enhances the formation of polymeric Mo octahedral species, which are regarded as an active form on alumina [21.35]. Furthermore, it modifies the dispersion of Co to suppress the formation of an inactive $CoAl_2O_4$ phase. Such results indicate the importance of the acidic nature of the support in modifying active sites. Such a function can be ascribed generally to finer particles of alumina among the matrix with poor affinity for the active oxides such as SiO_2 , B_2O_3 and P_2O_5 . It is intended to incorporate active species in the pores of the zeolite. Difficulty for diffusion of large refractory species into the narrow pores of the zeolite must be considered.

Amorphous $SiO_2-Al_2O_3$ is also an acidic support like zeolites. HDS activity toward 4,6-dimethyldibenzothiophene (DMDBT) was reported to increase by the mixing of the conventional NiMo/ Al_2O_3 catalyst with $SiO_2-Al_2O_3$ [21.36]. Such an observation is believed to be caused by enhanced hydrogenation and isomerization by the acidic component in the catalyst. However, there are many questions on the fundamental aspects of HDS catalysts supported on $SiO_2-Al_2O_3$. First of all, the difference in MoS_2 morphology on Al_2O_3 and $SiO_2-Al_2O_3$ must be clarified. It is generally accepted that SiO_2 can't disperse MoO_3 well in a monolayer due to very weak interaction with MoO_3 [21.37]. However, Al_2O_3 incorporation alters the nature of surface to increase the monolayer capacity. Hence, the form of active species may be different from that observed on Al_2O_3 supports. Higher activity of $SiO_2-Al_2O_3$ -supported catalysts may come from a more favorable form of active species in addition to the stronger acidity of the support, but definite evidence has not been found yet.

The addition of P_2O_5 , ZrO_2 , and B_2O_3 to Al_2O_3 was reported to increase the acidity of catalysts and as a result enhanced the HDS of refractory sulfur species [21.38]. Other roles of P_2O_5 and B_2O_3 in the dispersion of MoS are described above. On alumina-

supported catalysts, phosphorus has been present in numerous commercial catalysts, where it stabilizes the active metals and provides acidity, for more than 25 years [21.39]. Catalysts containing NiP are a new type of species active for hydrodesulfurization [21.40]. The roles of acidic supports in HDS by sulfide catalysts are summarized in Table 21.1.

TiO₂ was evaluated as an active support material for HDS. Its main drawback, low surface area, was reported to be overcome by a kind of sol-gel process, giving as high a surface area as 120 m²/g [21.41]. It could carry a higher loading of Mo (19 wt% as MoO₃) than conventional TiO₂ supports, allowing well-dispersed Mo species. This catalyst showed higher HDS activity for 4,6-DMDBT than the alumina-supported one. An Al₂O₃-TiO₂ composite support was also tested to provide higher surface area. It showed higher activity than Al₂O₃ and TiO₂ alone in HDS of 4,6-DMDBT while its activity for the HDS of DBT was inferior to the alumina support [21.42–44]. Such binary oxides carry more Brønsted acidic sites and as a result have rather high activity. This gives another increase in the activity for 4,6-DMDBT HDS. It should be also noted that TiO₂ is believed to have much less interaction with active species than Al₂O₃, inducing a more easily reducible oxide phase of Mo and Co(Ni) due to the partial sulfidation of TiO₂ [21.45].

Carbon has been regarded as a promising catalyst support due to its very high surface area, peculiar pore structure, and surface-functional groups [21.46]. HDS catalysts supported on carbon can provide higher activity than alumina-supported ones [21.47–49]. Presumably, weak interaction of carbon with sulfide precursors provides more sulfidable species on carbon than on alumina, resulting in the more active sites for HDS. The very large surface area of carbon supports must be also helpful although the acidic contribution is not expected. Acidic or polar additives can be designed in carbon black as used in the rubber industry. The mechanical strength of carbon supports is of concern. Further development is expected.

The life of catalysts due to the sintering of active species must be carefully tested since such supports interact weakly with active species.

Deactivation and Regeneration of Hydrotreating Catalysts

Hydrotreating catalysts lose their activity in several ways [21.50]:

1. Process upsets
2. Deposition of trace contaminants such as V, Ni, Fe, As and Hg
3. Deposition of other impurities such as salts and silica
4. Covering of the active sites by reactants and/or products including coke
5. Degradation of the active phase, including degradation of sulfided forms
6. Sintering of the active phase into large crystal units.

The deactivation in HDS catalysts usually occurs in three steps: initial rapid deactivation, intermediate slow but steady deactivation, and rapid deactivation at the end of the reaction. Commercial processes usually are operated at constant conversion. This constant conversion is achieved by gradually heating the reactor to higher temperatures to compensate the slow but steady catalyst deactivation.

The initial rapid deactivation phase is believed to be due to rapid coking on active sites having very high acidity [21.50]. Deposited carbon can be characterized by temperature-programmed combustion and Raman spectroscopy [21.51]. The slow but steady deactivation is associated mainly with coking but also with metal deposition and sintering during the course of the process period. A higher reaction temperature applied at the end of the reaction may cause rapid deactivation by coking at the final stage. To avoid the rapid deactivation, the proper grading should be made both with respect to size, shape and catalyst properties in order to optimize the performance, and to obtain the desired product quality and longest catalyst life.

Table 21.1 Role of acidic supports in HDS by sulfide catalyst

Influences on the active species (catalyst–support interaction)	Catalytic functions of support (bifunctional catalysts)	Influence of active species on the substrate adsorbed on the supports
(1) Acidic modification on the natures of active sulfides – long- and short-range interaction	(1) Acidic activation of substrate-cracking, isomerization, transalkylation	(1) Hydrogen spillover for sulfide to oxide support
(2) Restriction of the area (site) for dispersion of active oxide precursors	(2) Acidic adsorption of substrate in σ - and π -coordination-spillover of coordinated substrate to active sulfide	
(3) Reverse spillover of proton from support to active sulfides		

The current design to suppress the coking is to control the pore size for no plugging at the pore mouth. Thus, the availability of the active site on the entire pore can stay through a longer time of continuous operation. Currently, adequate or optimized acidic supports are utilized to achieve high activity, hence coking deactivation appears important in current processes. Such deactivation schemes suggest that catalysts may be regenerable if suitable methods can be developed. Commercially, carbon-containing material is removed during regeneration by combustion. During regeneration of the catalyst, the active sulfide form is into the oxide form and the resulfidation must subsequently regenerate the activity. The combustion must be moderate to minimize sintering and to maintain the dispersion of active metals on the support. For some catalysts, a process called rejuvenation is used to redisperse the active metals prior to reloading and resulfidation.

One of the important points in the design of the catalyst is to improve the hydrogenation activity in the vicinity of acidic sites. This could hydrogenate the coke precursors to make them more susceptible to cracking or to be more soluble in the reaction matrix, so that they can be removed from the catalyst surface. The hydrogenative pretreatment as well as removal of asphaltenes can be attempted before the hydrotreatment of the heavy feed to reduce the coking tendency of the asphaltene. Another achievement can be used with catalyst grading [21.52].

21.3.2 Chemistry of Hydrodesulfurization

Distillate

The removal of sulfur from a petroleum stream depends greatly on the structure of the sulfur compound being treated. The rates of sulfur removal can vary by several orders of magnitude. Generally, acyclic sulfur compounds such as thiols and disulfides are highly reactive and can be removed under very mild HDS conditions. Saturated cyclic sulfur compounds and aromatic systems in which sulfur is present in six-membered rings are also highly reactive. However, compounds in which the sulfur atom is incorporated into a five-membered aromatic ring structure (such as thiophene) are much less reactive and the reactivity decreases as the ring structure becomes increasingly condensed (e.g., 1 ring > 2 rings > 3 rings) [21.2]. For highly condensed ring structures (four or more rings), the reactivity trend reverses and reactivity tends to increase slightly as the ring structure increases in size [21.2] as described later. A reason for such behaviors is that there are several different chemical pathways through which sulfur can be removed from a molecule and the preferred pathway

changes for different sulfur compound structures as shown Fig. 21.8, where 4,6-dimethylbenzothiophene is selected as the substrate of very low reactivity (refractory sulfur species).

In this scheme, there are three major pathways to desulfurized products. The first is called direct hydrodesulfurization, in which the sulfur atom is removed from the structure and replaced by hydrogen, without hydrogenation of any of the other carbon-carbon double bonds. The rate constant associated with this direct route is shown as k_{D0} in Fig. 21.8. Because of the steric hindrance by two methyl group adjacent to the sulfur atom, direct HDS becomes very hard. The second route is called the hydrogenative route and assumes that at least one aromatic ring adjacent to the sulfur-containing ring is hydrogenated before the sulfur atom is removed and replaced by hydrogen. The associated rate constants for hydrogenation and hydrodesulfurization routes are shown as k_{HS1} and k_{D1} in Fig. 21.8. In addition to hydrogenation of an aromatic ring before sulfur is removed, an aromatic ring may be hydrogenated after sulfur removal, and the associated rate constant for this reaction is shown as k_{HP1} in Fig. 21.8. Hydrogenation of one or two phenyl rings liberates the steric hindrance due to the nonplanar structure. This often leads to confusion in interpreting the results of experimental data as both routes can produce the cyclohexylbenzene final product.

It should also be noted that the hydrogenation pathways are subject to thermodynamic equilibrium constraints. Thus, the partially hydrogenated intermediates (such as tetrahydrodibenzothiophenes) have lower

Fig. 21.8 Reaction mechanism of 4,6-dialkyl DBT (assuming the formation of dihydro-intermediate) for HDS (after [21.5])

equilibrium concentrations at higher temperatures. This results in a maximum in the observed rates of HDS via the hydrogenative routes, as a function of temperature. Thus, the hydrodesulfurization via the hydrogenative route becomes limited at low pressures and high temperatures.

Another route includes the isomerization and transmethylation of methyl groups at 4- and/or 6-positions, which reduce the steric hindrance as shown in Fig. 21.8. The direct pathway is believed to involve the insertion of a metal atom on the surface of the catalyst into a sulfur-carbon bond in the sulfur-containing compound [21.2]. This insertion can occur even for fully aromatic sulfur compounds, such as thiophene, benzothiophene and dibenzothiophene. Such a pathway is possible because the resultant metal-sulfur bond is energetically favorable. After the insertion, several other steps occur in which the sulfur is expelled as hydrogen sulfide and the catalyst is restored to its original state.

The hydrogenative pathway involves the initial hydrogenation of one or more of the carbon-carbon double bonds adjacent to the sulfur atom in the aromatic system. Hydrogenation destabilizes the aromatic ring system, weakens the sulfur-carbon bond and provides a less sterically hindered environment for the sulfur atom. Metal insertion is thus more facile.

There are two active sites (functions) postulated on HDS catalysts based on the above discussion, S-extrusion and hydrogenation. The active center is a coordinatively unsaturated metal site where the S ligand is facile. Sulfur in aromatic rings can coordinate to the active center of both functions. It is believed that the initial adsorption of the S-compound is through σ -bonding, in the case of direct S-extrusion. However, in the hydrogenative function, S-compound coordination is through π -bonding. Neighboring S-H groups are believed to be involved in the hydrogen transfer for both S-extraction and hydrogenation. Differences in the active sites for S-extraction and ring hydrogenation are not yet clear although they appear to be interconvertible.

H₂S-, NH₃- and nitrogen-containing compounds can also coordinate to the active center, inhibiting the S-extraction and hydrogenation as discussed later.

The direct pathway becomes more difficult as the ring structure becomes larger because the aromatic structures become increasingly more stable and because the insertion becomes more hindered for the more condensed rings. To illustrate these factors, Table 21.2 provides examples of hydrodesulfurization reactivities of sulfur compounds having different ring structures [21.53, 54]. For ease of discussion, all of the rate constants in this and following illustrations have been normalized relative to dibenzothiophene having a value of 100.

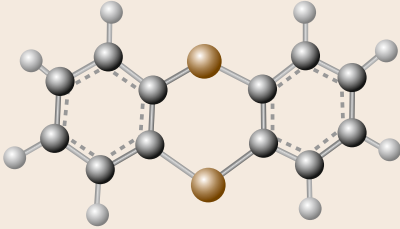

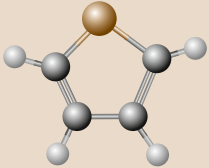

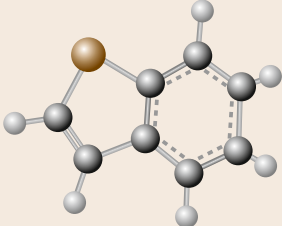

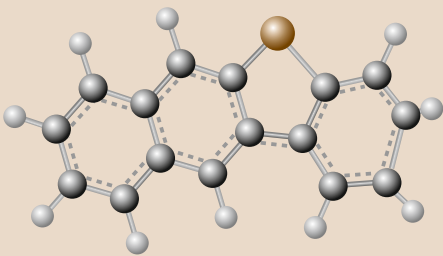

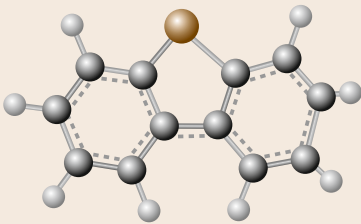

In Table 21.2, the overall hydrodesulfurization reactivity of the sulfur compounds decreases with increasing ring condensation from one ring to two rings to three rings, but then increases significantly for the four-ring system. As mentioned above, increasing ring condensation is detrimental to the insertion step in the direct route. However more ring condensation beyond four may not further hinder the insertion while the adsorption becomes stronger to facilitate the insertion. A switch in the preferred pathway from the direct route to the hydrogenative route must be also taken into account. Hydrogenation becomes more facile with increasing ring number.

Another complicating factor in reactivity is the proximity of the alkyl group to the sulfur atom in the aromatic ring structure. Generally, as the sulfur atom becomes more crowded by adjacent alkyl groups the reactivity decreases. This has been attributed to steric crowding around the sulfur during adsorption on the catalyst surface or at the some transition state in the desulfurization. This steric crowding affects the direct hydrodesulfurization route most severely. Table 21.3 illustrates this factor for several alkyl-substituted benzothiophenes and dibenzothiophenes. In Table 21.3, the reactivity for hydrodesulfurization decreases as the number of substituents around the sulfur atom increases [21.53]. Alkyl groups that are not close to the sulfur atom have little effect. Recently, migration of alkyl groups before the hydrodesulfurization was proved to enhance the direct hydrodesulfurization on the catalysts of strong acidity.

The hydrogenative routes are not significantly affected by alkyl substitution on the aromatic rings, while the rate of the direct route becomes lower when alkyl groups are adjacent to the sulfur atom. Thus, the relative rate changes summarized in Table 21.3 are primarily due to loss in the ability for hydrodesulfurization to proceed via the direct route. For this reason, the catalyst, which is preferred for hydrodesulfurization, is often different for light and heavy feedstocks, as the numbers of alkyl groups and of condensed aromatic rings in the sulfur-containing compounds increases markedly with boiling point.

Refractory sulfur species in distillates contain alkyl groups. Alkyl groups are especially inhibitory when they are neighboring the S-atom in the dibenzothiophene core. Compounds containing additional or larger alkyl groups, such as methylethyl dibenzothiophenes and trimethyl dibenzothiophenes, appear in the heavier fractions and are even more refractory. The addition of a cyclohexyl group to the two alkyl groups at the 4,6-positions on the dibenzothiophene make it extremely difficult to remove the sulfur by HDS due to strong steric hindrance. It resembles the nitrogen species of

Table 21.2 Desulfurization reactivities of compounds having different ring structures (after [21.53, 54])

Sulfur compound structure	Compound type	Relative reactivity

	Benzothiophene	1300
	Benzo[b]naphtha[2,3-d]thiophene	100
	Dibenzothiophene	100

similar structure in vacuum gas oil, which has been identified as the most refractory species for HDN of distillates [21.56].

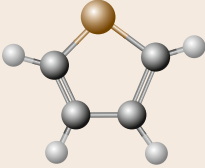

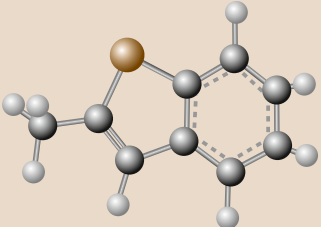

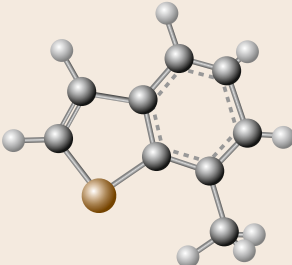

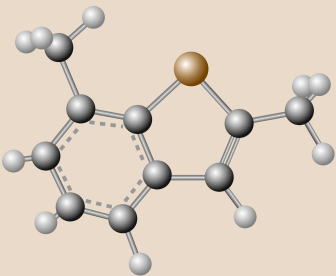

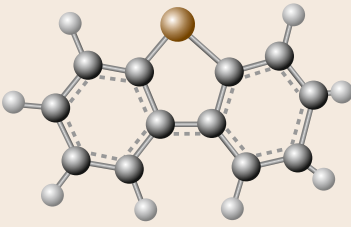

Residue

HDS of the residue is different in terms of its polymeric and aggregate structure from that of distillates where the macromeric sulfur species must approach the active sites of HDS (hydrogenation and hydrogenolysis C–S bond breakage). In the aggregate structure, poly-

meric components are entangled together around the sulfur species in the aggregate. The polymeric structure may carry more than one sulfur-containing unit as well as nonsulfur-containing units [21.57]. The units neighboring the particular target sulfur-containing unit in the polymeric chain may inhibit the HDS of the unit – a kind of polymeric intramolecular inhibition must be taken into account.

The sulfur species must be liberated to approach to the active sites over the solid catalyst. The sulfur to be

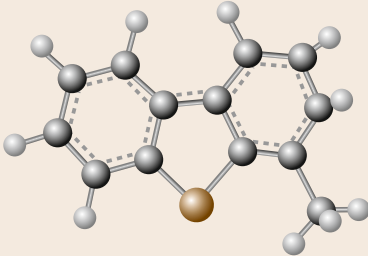

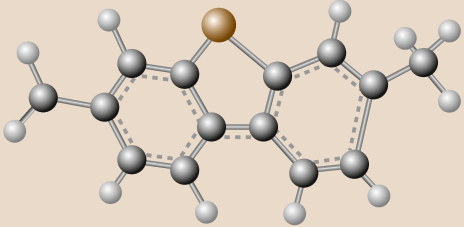

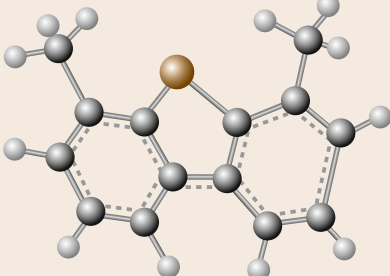

Table 21.3 Desulfurization reactivities of alkyl-substituted aromatic compounds (after [21.55])

Sulfur compound structure	Compound type	Relative reactivity

	7-Methyldibenzothiophene	466
	2,7-Dimethyldibenzothiophene	310
	Dibenzothiophene	100

removed is located in a variety of unit structures with various alkyl substitutes. Some of them found in the aromatic fraction are listed in Table 21.4 according to Anderson et al. [21.58]. Their procedure for enhancing the measurement of the sulfur species using a Pd complex is very helpful for the detailed molecular analysis of sulfur compounds in complex mixtures by FT-ICR MS.

The sulfur-containing species are mostly either in benzothiophene or dibenzothiophene type, even if the connecting aromatic units are of a wide variety. Their HDS reactivity may not be very different as far as the unit structure is concerned. Their reactivity can be influenced by the alkyl substitution as observed with the sulfur species in the distillates. The IFP group reports a structure of sulfur species in the asphaltene

Table 21.3 (continued)

Sulfur compound structure	Compound type	Relative reactivity
	4-Methylthiophene	38
	3,7-Dimethylthiophene	90
	4,6-Dimethylthiophene	11

based on the stochastic reconstruction as shown in Fig. 21.9 [21.59].

The chains connecting cores provide the polymeric molecule where SH and dibenzothiophene are indicated as sulfur-containing parts. Neighboring alkyl and cyclopentyl groups may influence the reactivity sterically. The numbers of cores in the polymers, benzene and cyclohexane rings in the core are shown in Fig. 21.9.

Recent FT-ICR MS analyses reported the presence of multiple heteroatoms, such as S and N, S and O, as well as N and O, in the same molecules [21.60]. Since these compound types are very rare in the distillate, their HDS reactivity must be studied for residue.

The HDS mechanism and reactivity in residue appear basically similar to those of the distillates as far as those of unit structures. The different aspects are present as the polymeric and aggregated molecules in the residue. At least, steric effects due to coiled polymer and aggregation must be involved. The HDN, HDO, HDM and coking reactivities of the residue are in the same situation as those of HDS.

The catalysts for the distillate and the residue should have different diameters and depths of optimum pores

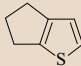

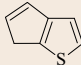

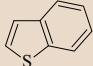

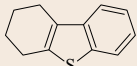

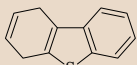

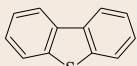

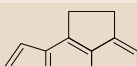

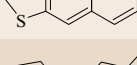

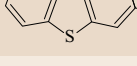

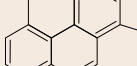

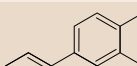

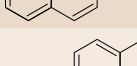

because their substrates must have different molecular size and degree of aggregation. More chemical factors must be emphasized with the catalysts for the residue, since coking takes place more easily. Liberation of polymeric entanglement aggregation is another chemical issue in the catalysts.

Inhibition of HDS

The active sites postulated for HDS catalysts promote sulfur extraction, hydrogenation and acid-catalyzed reactions regardless of whether the feed is distillate or residue. Such active sites are all commonly or selectively subject to occupancy by the inhibitors in the feed.

As mentioned above, several species in the feed and product are inhibitors for HDS. Reactive sulfur species appear to be less inhibited than the refractory species. This is because the naked S atom in the reactive species can easily or preferentially undergo metal insertion to break the C–S bond via the direct HDS route. They are also the major S-compounds present and can compete effectively with inhibitors for the active sites on the catalysts. Their concentrations become lower while H₂S and NH₃ inhibitors increase their concentration during

Fig. 21.9 Stochastic reconstruction to estimate S-containing species (after [21.59])

the initial stage of the HDS process, while the refractory species of very low content must be desulfurized for the deep HDS. It must be recognized that the initial and last stages of the HDS of refractory species are very different in their rates. Some processes have been developed that remove H_2S and NH_3 between stages to minimize this problem in the later stage as described above. Inhibition of H_2S for the direct HDS is very significant unless the H_2S desorption from the active site is very much accelerated. Neighboring acidity is proved to enhance H_2S desorption as described above.

Inhibition of H_2S on the hydrogenation site is not straightforward. An optimum amount of H_2S is necessary to maintain the hydrogenation site activity by keeping proper coordination of sulfur in $\text{Co}(\text{Ni})\text{MoS}$, particularly under conditions where the sulfur is replaced by other ligands such as oxygen and nitrogen. Strong acidity of the catalyst is often favorable for HDS of both mechanisms, whereas NH_3 can be an inhibitor. However, the acidity in the catalyst for the residue is lost almost immediately before the feed is cleaned up.

Other feed impurities such as N-compounds, especially heavy gas oil and LCO with high contents of N (over 500 ppm), are severe inhibitors for the HDS of both routes. N-compounds are basic or polar (acidic or neutral) to coordinate through their lone pair to the sulfur deficient site for the direct HDS and the acid site, and form strong π -bonding to hydrogenation sites and neighboring adsorption sites. The basic N-compound is a stronger inhibitor than the polar one. The nitrogen species are removed during the HDS, reducing their

concentration through concurrent HDN. The basic one is removed first due to its strong occupancy against the active sites. Hence, its inhibition is strong, but its removal takes place earlier in the initial stage. In contrast, polar nitrogen species are moderate inhibitors but, because of rather low reactivity for HDN, tend to stay in the feed and to continue the inhibition, until the refractory sulfur species remain to be desulfurized. Hence, their behaviors during HDS are very problematic for deep HDS.

The overall HDS process is much more facile when nitrogen species in the feed are removed prior to HDS. However, their removal is not practically feasible in any form even if a number of procedures have been proposed [21.61–64].

Aromatic species are also inhibitors for the HDS (hydrogenative HDS of refractory sulfur species) because aromatic species compete for the hydrogenation site with the refractory sulfur species. In theory, selective hydrogenation of sulfur species in the presence of the π -sulfur coordination. So far, such a catalyst has not been developed. Aromatic species, particularly multi-ring aromatics, are highly concentrated in some feeds such as FCC cycle oil and heavy fractions. The problem is that they survive in the last stages of HDS to inhibit the HDS of refractory sulfur species. The hydrogenation to reduce their inhibition cannot be practical in industrial processes because of the required increase of hydrogen consumption. To overcome this difficulty is not easy. Direct HDS is not so much inhibited by aro-

matic species, since σ -coordination of sulfur at the direct HDS site is much stronger than that of the aromatic species. The thermal moderation of steric hindrance of the sulfur species at higher temperature can provide another path for the solution [21.65] if the coking deactivation and excess cracking are avoided. However, this may be offset by the fact that removal of difficult sulfur requires saturation prior to hydrogenolysis, and saturation is more difficult at higher temperature.

21.3.3 HDN and HDO Reactions

The removal of nitrogen (HDN), oxygen (HDO) and metals (HDM) is also important to purify petroleum products. Such reactions progress concurrently together with HDS. Activated hydrogen can break C–X bonds over the same catalyst, although the affinity to the active site, the necessity of hydrogenation in the ring structure, and C–X bond reactivity are very different according to their individual mechanisms. In general, the ease of reactions are HDM < HDS < HDN < HDO, although the HDS and HDN of refractory sulfur and nitrogen species are comparable at the deepest levels of removal.

HDN of the nonbasic carbazoles is completed before HDS reaches the 10 ppm level. Basic nitrogen species compete for active sites with sulfur compounds. HDN of aromatic nitrogen species proceed through the initial hydrogenation of aromatic rings, because the aromatic C–N bond is too strong to be fissioned by hydrogenolysis. In contrast, the aliphatic C–N bond is easily broken. Thus, NiMoS and NiWS catalysts are often applied for HDN due to their higher hydrogenation activities. Due the required prior saturation, high hydrogen consumption is inevitable. An acidic support helps HDN on NiMoS by accelerating hydrogenation, although it also enhances the chance of deactivation due to coking on the acidic site. There is a competition between hydrogenation and acidic reactions on the same catalysts for nonheavy oil fractions.

Recently, the C–N bond cleavage was proposed by Prins et al. [21.66, 67] to be associated with H₂S in the formation of C–SH and NH₃. The C–SH bond is easily eliminated under hydrotreating conditions. They reported that 2-methylcyclo-hexylamine (MCHA) is hydrodenitrogenated through three ways:

1. Direct elimination of ammonia
2. Nucleophilic substitution of the NH₂ group by H₂S followed by removal of the SH group
3. Direct hydrogenolysis of the C–N bond.

They estimated the contribution of each pathway as shown in Fig. 21.10 [21.67]. Such a contribution of nucleophilic substitution is dependent on H₂S partial pressure. The natures of the catalysts are also impor-

tant since a variety of catalysts are now available. The involvement of aromatic C–N, especially alkylated derivatives from carbazoles, is not definite yet in such a mechanism, since it would be desired to reduce hydrogen consumption. Moreover, it should be considered by the fact that even if HDN requires more H₂ on a per-atom basis, the overall impact on H₂ consumption is relatively low.

Gas oils and LCOs from particular crudes have high nitrogen contents. Their extensive HDN is required because nitrogen species often inhibit the deep HDS. If significant amounts of nitrogen go to an FCC, it could increase NO_x emissions from the FCC regenerator if the FCC is not equipped with NO_x reduction technology.

HDO of dibenzofuran is very slow. An acidic support is helpful for the HDO of dibenzofuran species.

HDN and HDO of residue are not well studied yet. Some crudes are found to carry higher nitrogen and oxygen contents than those imagined before. Their problematic behaviors in upgrading must be overcome through extensive HDN and HDO. More research is needed. A certain amount of research on the catalytic decomposition of naphthenic acids in the petroleum products has been reported [21.68].

21.3.4 Chemistry of HDM

Removal of metals is the primary challenge for the fixed-bed hydrotreating of residue. Many commercial units are designed based on the capacity of catalysts to hold metals.

The metals in the petroleum are removed after the deposition of metal-containing molecules around or inside catalyst pores. Subsequent removal of metals from the coordinated forms in porphyrins and analogous ligands through two routes [21.57]:

1. Stepwise ring-opening of the cyclic ligand leading to the liberation of the metal ion onto the HDM catalyst.
2. Direct metal ion extraction from the complex onto the HDM catalyst.

The sulfiding of the liberated metal ion by H₂S in the surrounding atmosphere always follows the above elimination. The monomeric metal sulfides meet each other over the catalyst surface to form the bulk metal sulfide.

In commercial units, a small amount of MoS₂ or another sulfide catalyst is certainly favorable for initial HDM. But some catalysts acquire HDM activity as they remove metals removed from the feed. This could be seen as supporting route 2. Acidic sites on alumina and silica-alumina can remove metal ions from

Fig. 21.10a,b Selective for elimination (A), nucleophilic substitution (B), and hydrogenolysis (C) in the HDN of 2-methylcyclohexylamine (MCHA), and the observed selectivities of methylcyclohexene (MCHE) and methylcyclohexane (MCH) in the HDN of 2-ethylcyclohexylamine and in the HDS of 2-methylcyclohexanethiol (MCHT) (20 and 200 kPa H₂S (after [21.67]))

the complex [21.21]. More acidic surfaces are more effective than alumina for the elimination. Again, there must be a balance between the relative activities of acid components for HDM and coking. Sometimes acidity is supplied by phosphorous. Liquid acid is known to be also effective for the extraction [21.69].

The role of hydrogenation is principally to suppress the coking of heavy components, which can cover the surface or plug the pore, killing the effective sites. Thus, hydrogenation activity is very important to maintain the HDM capacity of a catalyst. For this reason, process upsets involving the loss of hydrogen are particularly damaging to fixed-bed residue hydrotreating units.

Hydrogen sulfide is very essential for HDM, at least to form a metal sulfide. Desulfurization of reactive sulfur species in the feed provides sufficient H₂S for HDM. With some low-sulfur feeds, such as coal liquids, sulfur must be added to the process.

The nonporphyrin forms of metals in residue can show the different reactivity for removal, depending on the strength of coordinative bonds within the metal-containing compound [21.70]. At this moment, no direct information can be found. Other heteroatomic ligands appear to slow down HDM, as observed with the very heavy asphaltenes such as those in the Mayan crude, which contains metal ions in nonnitrogen ligands [21.71, 72].

The metal complexes are principally located in resin and asphaltene fractions [21.73]. Hence, the metal complex is believed to be bound or surrounded by polymeric constituents in the aggregate. The metal complex must contact with the HDM catalyst through the liberation from such locations in the aggregate. Thus the hydrogenation can accelerate such liberation although some metal complexes can be thermally isolated from the aggregate on the surface as observed in GC

columns as shown in the GC-AED chromatogram of Fig. 21.7 [21.21].

Acidic crudes often carry naphthenic iron, which is a concern when the acidic crude is refined [21.74–77]. Naphthenic iron easily reacts to form very fine FeS, which precipitates on the walls of the reactors, in transfer lines and in heat-exchange tubes. Hence, removal of Fe is particularly important. Naphthenic acids liberated by HDFe are also of concern because they may cause corrosion.

21.3.5 Chemistry of Ring-Opening Hydrocracking

Catalytic Access for the Selective Hydrocracking

The selective hydrocracking of light cycle oil (LCO) has attracted researchers to produce value-added (alkyl) benzenes, benzene, toluene, and xylene. The selective catalysis proposed here uses noble metals or molybdenum sulfide supported on suitable zeolites [21.78–81]. However, nonselective cracking of LCO leads to excess hydrogen consumption and excessive conversion into gaseous hydrocarbons, with coke deposition on the catalyst surface.

Extensive HDS is necessary for the noble metal catalyst. To avoid excessive hydrogen consumption, an HDS catalyst with low activity for saturating aromatics is used.

Achieving higher dispersion of supported NiMoS over the zeolite is another issue to be solved since the zeolite is a poor support, particularly when the alumina content is decreased to preserve its thermal stability. Hence, alumina is often blended as a binding component for the mixed support to disperse mainly NiMoS on its surface. In this case, NiMoS on alumina and acidic sites of zeolite must be geometrically separated.

The acidity of the catalysts in hydrocracking is very important for maximizing the yield of the desired products. This is why the catalysts are generally modified to control their acidity. Alumina has been an excellent support for CoMoS and NiMoS hydrotreating catalysts for aromatics saturation, HDS and HDN. But their acidity is not enough to promote the selective cracking of the hydrogenated aromatic ring.

The functions of the catalyst for the hydrocracking of naphthalene are as follows:

1. Selective hydrogenation of one of the aromatic rings
2. Immediate ring-opening of tetralin produced through the carbonic dealkylation mechanism
3. Selective fission of the alkyl side chain
4. A strong adsorption of aromatic rings leading to condensation (and possible coking)
5. Partial hydrogenation or hydrogenolysis of the strongly adsorbed species to avoid further condensation or coking.

The points to be considered for preparing the best support by the alumina/USY zeolite combination for the selective and active hydrocracking are:

1. Alumina is the good support for NiMoS.
2. Zeolite is expected to modify alumina through enhancing the hydrogenation activity of NiMoS on the alumina surface.
3. Acidic zeolite must not directly interact with hydrocarbon molecules, since too much hydrocracking may take place and coke formation on the zeolite quickly reduces its acidity.
4. Zeolite acidity must be modified to a moderate level for the selective cracking of hydrogenated aromatic rings.
5. Alumina is known to induce very strong acidity in amorphous or crystalline aluminasilicates.

Such catalytic functions are provided by a combination of hydrogenation and acid catalytic species. NiMo and USY zeolite can be selected as the catalyst components to achieve these functions. NiMo must be highly dispersed in the adequate crystal form. Alumina is much better support for NiMo than USY of high silica. Thus the first choice is a physical mixture of NiMo supported by Al_2O_3 and USY zeolite (NiMo/alumina-zeolite, NMAZ). Nevertheless, acidic and hydrogenation sites are separated on the different particles. The acidity of USY is not controlled by this combination, as it can expose the bare acidic sites of zeolite.

The second attempt is to coat USY with alumina and to support NiMo on the coated alumina. Acidic sites can be a part of uncoated USY or alumina modified by underlying USY through Al_2O_3 - SiO_2 contact. Thinner

coating of alumina is favorable to achieve this objective. Thus, very intimate cooperation of hydrogenation and acidic sites is expected. Acidic sites thus induced are moderated from that of the original zeolite or much enhanced from that of pure alumina. Hence optimum characteristics for the selective cracking of cyclohexyl group in tetralin can be expected.

In an earlier publication, alumina-modified USY zeolite for the hydrocracking of 1-methyl naphthalene (1-MN) as a model compound in LCO was been proposed by the present authors [21.82]. The selective hydrocracking activity of NiMoS supported on the alumina-coated USY zeolites varies with the coating amounts as illustrated in Fig. 21.11, since the thickness of alumina coating controls the balance between acidity and hydrogenation activity.

In detail, the least-alumina-coated USY zeolite (NMACZ-2) provides the highest production of alkyl benzenes among a series of the alumina-coated USY zeolites (NMACZ series). More hydrocracked alkyl benzenes were produced over NiMo supported on alumina coated with a thinner layer of zeolite, while NiMo supported on alumina coated with a thick layer of zeolite resulted in more hydrogenated products. In addition, a noncoated USY zeolite-supported NiMo catalyst (NMAZ) showed smaller yields of alkyl benzenes compared to the NMACZ-2 catalyst, which appears to be caused by the excess hydrocracking into gas hydrocarbons over the naked acid site.

Reaction Scheme: Chemistry of Selective Ring-Opening of 1-MN

Figure 21.12 summarizes the chemistry of principal and side-reactions for the selective ring-opening of 1-MN under the reaction temperature of 360°C and H_2 pressure of 6 MPa. The first step is the hydrogenation of one ring in naphthalene. According to the scheme, one-ring hydrogenation is preferred since the full hydrogenation produces many equivalent carbon-carbon bonds in the hydrogenated ring, which would be fissioned nonselectively or thermally on the acidic surface. Hydrogenation of one ring in 1-MN produces two isomers of methyl tetralin (1-methylcyclohexyl benzene; II_1 , and cyclohexyl-1-methyl benzene; I_1) in which the C-C bonds possess different reactivities. C-C bonds adjacent to the phenyl ring in the methyl-tetralin are most reactive when fissioned through the acidic dealkylation scheme, since the methyl group is located on the α -carbon of the cyclohexane ring to induce the secondary carbenium ion on the cyclohexyl ring over the acidic catalyst, as shown in Fig. 21.12. In contrast, I_1 produces a primary carbenium ion (I_2) over the same catalyst. I_2 provides C_4 alkenyl-toluene, which further reacts over the acidic catalyst to give

Fig. 21.11 Hydrocracking reaction pathway of 1-methyl naphthalene over the alumina coated USY zeolite (after [21.82])

Fig. 21.12 Reaction scheme for selective hydrocracking of 1-MN through dealkylation

β -fission, giving xylene and propylene. II_2 gives C_5 alkenyl-benzene, which is successively β -fissioned into toluene (II_5) or ethylbenzene (II_5') according to the positions of the carbenium ion (II_4 and II_4') derived from II_3 .

Strong adsorption of aromatic species on the strong acidic site allows their extended stay over the catalyst, leading to condensed aromatic hydrocarbons (soft coke)

and hard coke on the acidic site. Hydrogen spillover from the NiMoS in the neighbor of acidic sites or from hydrogen donors (hydrogenated product) may partially hydrogenate the strongly adsorbed species into products that are volatile or are easier to crack further. Hydrogenation-assisted removal of coke precursor from the acidic site is important for the reduction of coke in the hydrocracking of aromatic hydrocarbon.

21.3.6 Catalyst Deactivation in Hydrotreatment of Residue

The catalyst used in the hydrotreatment is more or less deactivated during the period of use. Heavier feed tends to lead to deactivation more rapidly. The life of the catalyst for residue is usually 8–12 months, whereas it can be two to three years for the straight run gas oil from the light crude.

The residue hydrotreatment performs HDM where metal sulfide derived from the feed must accumulate on the catalyst. Hence, the life of the catalyst before the saturation is limited but it is not defined the deactivation, while the slipping of metal ions or sulfide from the HDM bed may deactivate the downstream catalysts as described later.

Carbon Deposition

Carbon deposition can be the primary cause for the deactivation of the hydrotreatment catalyst. Basic polar and high boiling compounds, typically nitrogen compounds, are the precursors for the coke through the strong adsorption by acid–base and polar–polar interactions. Some of such compounds are hydrogenated or hydrodenitrogenated over the hydrotreatment catalyst and liberated from the catalyst surface. Heavy aromatics such as asphaltenic compounds less soluble in the feed matrix are also strongly adsorbed over the polar surface of the catalyst, to be coked in a certain period of time. Thus, at the initial stage of adsorption, the adsorbed species is still a tar-like substance that can be hydrogenated and/or cracked to be soluble in the feed matrix or still soft to adhere with the similar substance on another catalyst particle. More adsorption of such organic substances may lead to covering of the catalyst surface, adhering to the catalyst particles and plugging the catalyst bed.

The coke precursors tend to be adsorbed on the polar/acidic parts of the catalyst, which are dominantly located on the support surface. Alumina, silica-alumina and zeolite commercially used as the supports for Co(Ni)MoS are more acidic in the order. In contrast, adsorbed species on the Co(Ni)MoS can be preferentially hydrogenated and not converted into heavier aromatics or final coke.

The carbon produced on the outer surface can be located near the pore mouth, plugging the pore and prohibiting the substrate from penetrating into the active site in the pore. The carbon deposited on the support can grow larger to cover the Co(Ni)S and/or reduce the

acidic properties of support, which are believed to enhance the catalytic activity of Co(Ni)MoS.

Alumina is the most common support for hydrotreatment catalysts. A less polar support is favorable for less carbon deposition from the heavy and polar commercial feed. Hence, when mechanical strength and dispersion power are sufficient, such supports have been examined, although supports other than alumina and silica-alumina are very rare in commercial catalysts. Some trials by the present authors are introduced in the later part of the review.

Metal Deposition

Typically, HDM catalysts are stacked on top of the main HDS and HDN catalysts, which are poisoned by V and Ni species. NiS is a component of NiMoS catalysts, but the NiS that slips through HDM catalysts does not provide additional activity for HDS or HDN by depositing on MoS₂ because it cannot always occupy the right location on MoS₂ or because it is accompanied by coke precursors and accelerates the coking of surrounding precursors. VS₂ is not expected to be active for hydrogenation. Hence, V and Ni deposition deactivates the HDS/HDN catalysts downstream of HDM.

Sintering of Sulfide Catalyst

The sulfide nanoparticles on the support are thermally sintered and/or degraded. The reactor must be designed carefully to prevent high temperatures during the operation, since high dispersion of the catalyst particles in a particular formulation is quite important for high activity. Hence, the reaction temperature must be strictly controlled not to exceed a certain temperature, typically 450 °C. As discussed in other chapters, the main reason for controlling temperature is to prevent loss of containment due to the rupture of piping or even the reactor. Exothermic hydrogenation/condensation reactions may cause local heating in the catalyst bed. Channeling of hydrogen and feed in the catalyst bed must be avoided to prevent local heating and heat accumulation as well as lower conversion. The way to control channeling is to use effective reactor internals and to load catalysts carefully, as described elsewhere.

Oxidation, Sulfur Deficiency or Excess Sulfiding

Sulfiding the catalyst is one of keys to obtaining optimal catalyst activity. Optimal sulfiding is obtained by controlling temperatures, heat-up rates, and the reaction atmosphere.

21.4 Deep Hydrodesulfurization of Diesel

Deep HDS of diesel fuel is currently a very important topic in refining [21.83]. Basically, deep HDS of diesel involves the extensive elimination of refractory sulfur species such as 4-methyl dibenzothiophene (4-MDBT), 4,6-DMDBT, and 4,6,X-TMDBTs. Such deep HDS is difficult because of the lower reactivities of these compounds and strong inhibition by coexisting species such as H_2S , NH_3 , nitrogen species and even aromatic species, especially when the sulfur level must be lowered to < 10 ppm. H_2S and NH_3 are derived from more reactive sulfur and nitrogen species contained in the same feed. It is always true that the fast HDS of reactive sulfur species is also important for deep HDS since the HDS active site is available for the refractory sulfur species soon after the disappearance of reactive sulfur species.

There are four approaches for achieving deep HDS:

1. Preparing catalysts in novel ways to maximize the concentration of type II sites.
2. Introduction of more active sites by impregnating more active metals on the catalyst
3. Removal or reduction of inhibitors in the process by adsorption
4. Stacking a series of catalysts in two successive layers to remove reactive sulfur species in the first layer, and to remove remaining refractory sulfur species to less than 10 ppm in the second layer under the presence of H_2S , NH_3 and other remaining inhibitors, such as nitrogen species and aromatic compounds
5. Novel catalyst designs to introduce new mechanistic pathways that are less subjective to inhibition.

Currently the first method is the major commercial approach.

In the third approach, the nitrogen species are removed prior to HDS with silica gel, silica-alumina or active carbon. The present authors suggest the high efficiency of active carbon for nitrogen species removal [21.84]. Some refractory sulfur species in the heavy oils are also removed by active carbon, which significantly helps deep hydrodesulfurization. Removal of sulfur species after hydrodesulfurization can also be used to lower the total sulfur content below 10 ppm. However, the capacity for sulfur removal is rather limited, compared to the removal of nitrogen species. In addition, loss of feed among the adsorbents in the adsorptive removal is never negligible. Removed substances must be recovered for regeneration and their utilization must be considered. Hence the application of this approach is rather restricted to the preparation of

ultraclean hydrocarbon fuels for fuel cells where very little removal is required.

The fourth approach has been proposed as a two-stage HDS process. Figure 21.13 shows the efficiency of two-stage HDS, in which the produced H_2S and NH_3 in the first stage are purged before the second stage [21.10].

The fifth approach is based on a novel way of thinking. The appropriate use of acidic supports can be a third approach since the acidity can enhance catalyst activity by methyl group migration and lowering H_2S inhibition. However, coking and NH_3 inhibition also must be reduced at the same time. As mentioned above, TiO_2 is an interesting support to produce higher activity to its supporting catalyst. A unique interaction between the sulfide and partially reduced TiO_2 is claimed for the higher activity. High surface area TiO_2 is now available [21.41]. Deeper sulfiding is proposed necessary for the higher activity, since the strong interaction between active oxides and the support is postulated preferably for better dispersion of active species, but may hinder the sufficient sulfiding. Reactive sulfide is recommended for such sulfidation.

Carbon inclusion in the active sulfide species during the sulfiding stage is claimed to give higher HDS activity. Some metals are reported to give higher HDS

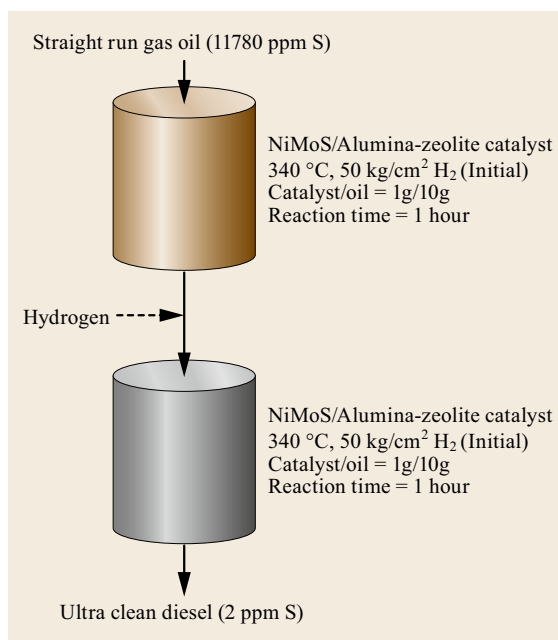

Fig. 21.13 Schematic diagram and performance of two-stage reaction concept

activity. Precise evaluation is still necessary by comparing the activity of catalysts currently lined up in the real process.

Highly aromatic feeds such as LCO and MCO appear now to require more severe conditions for deep HDS because they contain large amounts of refractory sulfur species. Catalytic species having higher affinity for sulfur than for olefins and aromatic hydrocarbons are currently targets of extensive research for achieving deep HDS of aromatic diesel. A sulfur atom can be an anchor to the soft acid site of the catalyst for the preferential hydrogenation of neighboring aromatic rings.

The present authors attempted deep HDS of aromatic-rich LCO with rather low nitrogen content by applying different supports to operate at rather high temperature [21.85]. The direct HDS of refractory sulfur species is enhanced at higher temperature, where the sulfur atom needs to approach the sulfur elimination site on the catalyst by overcoming the steric hindrance. Such direct HDS with larger activation energy is favored at higher reaction temperatures. On the other hand, the higher temperature promotes cracking and coking. Hence, high acidity is not preferred, whereas HDS activity must be enhanced by such supports. Generally, CoMo accelerates the direct HDS more selectively than NiMo and hydrogenolytic HDS

may play a minor role in the HDS of refractory sulfur species at a higher temperature [21.86].

Less polar TiO₂ and PAC (an activated carbon) supports may achieve deep HDS at 350–360 °C [21.85]. The amount of cracked products of lower boiling range was sufficiently lower on such supports under these conditions. CoMo/PAC shows the best results to achieve 12 ppm at 350 °C. The NiMo/TiO₂ catalyst was slightly better than CoMo/TiO₂, which indicates that hydrogenolytic HDS contributes to some extent even at this temperature. The higher activity of the PAC-supported catalyst can be attributed partly to its larger surface area. The chemistry of carbon surfaces and its effects on CoMoS are topics of further study. The mechanical strength of carbon supports must also be improved, perhaps by combining it with some oxide supports.

The pre-HDS of reactive species and hydrogenation of very heavy aromatic fractions before the high-temperature HDS over CoMo catalyst on nonpolar support (three stages) can be more efficient by choosing optimum catalysts and temperatures for the respective stages.

HDN, which occurs together with HDS, is hopefully much more enhanced. C–N bond breakage after adequate hydrogenation should be studied further.

21.5 Development Base of AR Hydrotreatment

21.5.1 Development of Catalyst and Reaction for AR Hydrotreatment

Petroleum companies are increasing production of heavier and more contaminated crude oils [21.87–90]. As a step toward refining these heavier crudes into low-sulfur products, some refining companies are hydrotreating atmospheric residues (ARs). These ARs often carry larger amounts of aromatics, sulfur, vanadium, and nickel, and some also are rich in nitrogen. Therefore, it is very important to understand these contaminants' reactivities, catalyst dependence, deactivation, and metal deposition profiles during hydrotreatment reactions [21.91–98].

Li et al. [21.91] suggested HD-Ni over a NiMo/ γ -Al₂O₃ catalyst by a one-pot method through the controlled precipitation of precursors using urea and ammonium carbonate as additives, and showed the influence of the urea/Al ratio on the catalytic activity for HDM. CoMo catalysts supported on the various materials (Al, Al-Ti, Al-Si, C) have been studied as heavy crude oil hydroprocessing catalysts for the early stage of deactivation by Maity et al. [21.92]. Marafi et al. [21.93, 94] reviewed spent catalyst waste manage-

ment and reported a real example through preparation of a heavy oil hydrotreating catalyst from spent residue hydroprocessing catalysts. They also reported the comparative study of the different heavy feeds over the catalyst [21.95, 96]. Interestingly, the comparative investigation on heavy oil hydroprocessing catalysts according to reactor type was studied by Rana et al. [21.97]. Long et al. [21.98] showing the mechanistic behaviors on initial decay of the HDM catalyst, which is very important to understand the phenomenon of metal adsorption on the catalyst.

A more direct comparison among reactivities of HDM and HDS of ARs from a series of crudes is informative over set of catalysts [21.99–101]. Kinetic and catalyst characterizations can further clarify their reactivity and reaction profiles. The present authors attempted to correlate the kinetic parameters of these feeds with their structural analyses.

21.5.2 Kinetic Analysis

The present authors tested catalysts in a flow reactor setup that consisted of HDM and HDS stages with two ARs from Kuwait export crude (KEC) and lower fars

(LFC) crudes [21.57]. The study aimed to accomplish the following three goals:

1. Examine the HDS performance of AR from a new and highly contaminated heavy crude oil (LFC-AR)
2. Compare the HDS and HDM reactivities of the ARs on the same catalysts in the same reactors
3. Measure the accumulation of metals on the catalysts.

A combination of commercial HDM and HDS catalysts in a series of reactors was used on the same catalyst by switching the feeds successively. The reaction temperatures were varied by 10 °C while maintaining all other conditions the same to compare the reactivities of the two ARs.

Through comparing the reactivities of these two ARs, the chemistry behind their HDS and HDM pro-

cesses can be discussed, since the metal, sulfur, and asphaltene contents are so different. Two comparisons were performed:

1. Correlations among the HDS and HDM reactions of the two ARs
2. Comparison of their kinetic parameters.

The HDS and HDM reactions were analyzed by assuming and confirming 1.0- and 1.2-order reactions, respectively, in both reactors. HDS of each AR progressed significantly in both stages with conversions reaching 47–60% in the first reactor and 80–90% in the second reactor (as shown in Figs. 21.14–21.16). Essentially, the reactive sulfur species are removed in the first reactor, and the refractory portion of sulfur species was principally removed in the second reactor. These phenomena justify the assumed 1.0-order HDS

Fig. 21.14a,b Arrhenius plots of HDS rate constants of KEC- and LFC-AR in (a) first and (b) second reactors (after [21.57])

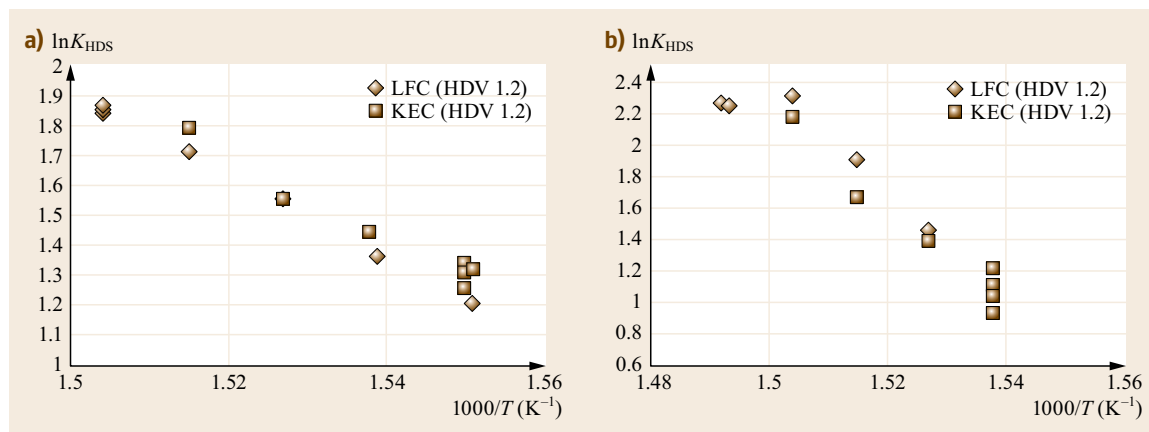

Fig. 21.15a,b Arrhenius plots of HDV rate constants of KEC- and LFC-AR in (a) first and (b) second reactors (after [21.57])

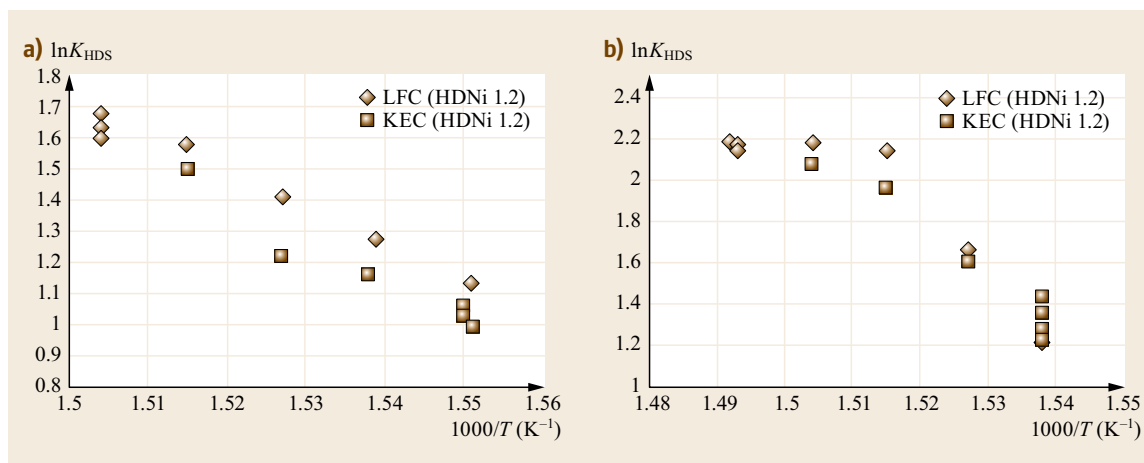

Fig. 21.16a,b Arrhenius plots of HDNi rate constants of KEC- and LFC-AR in (a) first and (b) second reactors (after [21.57])

reactions for both stages. First-order analyses of both KEC- and LFC-ARs in the first reactor provided their rate constants, which were plotted based on the Arrhenius equation; the two ARs have nearly the same rate constants at the same reaction temperatures and activation energies even though their sulfur contents were very different. The rate constants for the removal of highly reactive sulfur species of both ARs are the same despite inherent differences in the surrounding environment between the ARs. Therefore, we propose that the reaction environment of two residues does not interfere with the HDS of reactive sulfur species in the first reactor.

LFC-AR contains relatively more reactive sulfur species than KEC-AR to be desulfurized. Therefore, LFC-AR requires either longer reaction times (having the same rate constant at a given temperature) or higher temperatures than KEC-AR to achieve the same sulfur level and conversion in the first reactor.

In contrast, the rate constant of HDS for KEC-AR was certainly larger than that of LFC-AR in the second reactor. The higher reactivity of the particular sulfur species at this stage suggests that the environment of KEC-AR is less inhibitive. LFC-AR contains relatively more asphaltene, which may result in a more inhibiting environment since the refractory sulfur species in the asphaltene may be removed during this stage.

When we intend to achieve the same sulfur level at the same temperature and time, we must develop a more active catalyst via increased active sites in either the first or second stage (the latter must overcome the inhibition). Alternatively, the inhibiting environment can be overcome through the solvolysis and/or hydrogenation of inhibiting molecules and/or by liberating molecular assemblies in the asphaltene.

Rate analyses of HDV and HDNi (the removal of vanadium and/or nickel by hydrotreatment) of the ARs, giving 1.2-order reactions, provide similar rate constants and activation energies at both stages, even though the contents and environments of the ARs are very different. The rate constants of HDV and HDNi at the respective stages are also similar despite the higher activation energy and saturation of demetalization taking place at the second stage. Demetalization appears to progress very similarly regardless of the AR and metallic species, though the respective metals may have reactive and refractory species that are removed principally in the first and second reactors respectively. First-order kinetics has been often applied to HDM, but a 1.2-order reaction provided more reasonable Arrhenius plots in this study.

HDM has been proposed to progress via hydrogenation at the pyrrole rings of metal porphyrins, and hydrogenation over active HDM catalysts has been developed for enhanced HDM performance [21.57]. Another proposal has been suggested: that the hydrogenation of the resin in SARA matrix makes the asphaltene insoluble, so they simply precipitate on the catalyst. However, acidic catalysts can also remove metals from AR without any hydrogenation in H_2S and H_2 environments [21.21], which suggests direct metal extraction from the porphyrin ring and the formation of metal sulfide on the HDM catalyst. The hydrogenation may increase the contact of porphyrin rings with the surface of the catalyst through their facile liberation. Participation of such factors may take place more with feeds having higher metals. There is a higher reaction order in the metal content.

Metal porphyrins are primarily located within the asphaltenes of ARs as postulated from Yen's

group [21.16]. They can come into contact with the acidic catalyst surfaces through their liberation from the asphaltene and/or being exposed by following the deoagulation of asphaltene. Once the porphyrins are exposed during the HDM reaction, it may be easier to remove their coordinated V and Ni in the center. Given this postulation, the inability to remove the remaining refractory V and Ni species may reflect the difficulty in liberating porphyrin from the asphaltene matrix. Such species are treated in the second stage. A higher activation energy may be indicative of the bond breakage of the refractory species from the asphaltene molecules.

More V was deposited onto the catalyst than Ni, but the amounts of V and Ni are expectedly proportional to their initial content as governed by the same kinetics with similar reactivity. Previous reports have indicated a relatively high reactivity of the V species and its preferential deposition onto the surface of the HDM catalyst [21.90]. However, such overwhelming reactivity of the V species was not observed in our study. The metal content accumulated on our used catalyst was around 10%, which is much lower than that of the maximum metal capacity, and this may be one reason why preferential deposition was not observed. In order to clarify the deposition behaviors of V and Ni on the HDM catalysts, studying the used catalyst at the later stage or at the end of a long run is necessary.

This study achieved commercially required levels of HDM and HDS. However, further research of both elements may be required for commercial relevance. Refractory metals and sulfur species appear to exist in

the residue. Their studies are the target of deeper analyses and kinetics development.

The HDN process is another remaining aspect in the refining of AR. The present catalyst and conditions reached 50–60% conversion with both ARs, but the kinetics were not included in this study.

Nevertheless, we can claim the following:

1. The HDM catalyst is ineffective in its promotion of HDN.
2. HDN reactivities of KEC-AR and LFC-AR were not so different in terms of conversion (nitrogen contents of these ARs were very similar, which markedly contrasts to the differences in their sulfur and metal contents).
3. Higher temperatures are favorable for HDN.
4. There was a more apparent deactivation of the catalyst for HDN when it was compared to HDS and HDM.
5. Nitrogen elimination during both HDS and HDM reactions was not definite.

The HDS and HDM processes responsible for removing sulfur from heavy sulfur species and metals from the heavy metal porphyrins respectively progressed rather steadily, whereas HDN progressed rather slowly; this is most likely due to their limited contents (3000 ppm) as compared to those of sulfur and metals. A more active HDN catalyst must be explored to achieve deep HDN of ARs from the particular crudes with high nitrogen contents.

More study on residue HDN is expected, since some crudes are known to carry rather high nitrogen content.

21.6 Current Aims in Development of Residue Hydrotreatment

The feeds for the hydrotreatment become, in general, heavier and heavier except for shale oil. Nonconventional feeds of high metal, high sulfur, high nitrogen and even high oxygen contents must be also hydrotreated effectively and efficiently. On the other hand, environmental regulations become more stringent.

Higher activity and longer continuous operation of the catalytic reaction are always pursued. First of all, the continuous long operation requires the large capacity of metal removal. At the initial stage in the HDM process, carbon deposits must be minimized because carbon deposits may hinder HDM and restrict the metal capacity. Large capacities of the HDM catalyst for metal deposition or on-stream catalyst replacement processes are being pursued [21.102]. Deeper HDM is also expected to extend the life of HDS catalysts through less metal deposition downstream of HDM.

High activity for HDS and optimum hydrocracking are obtained commonly by high dispersion of Ni(Co)MoS on the catalyst supports. Acidic supports tend to be deactivated by rapid carbon deposition. The high catalyst dispersion is often canceled by sintering. Hence, particular catalyst materials for higher dispersion, and additives to stabilize the dispersion, are the aims of research and development in our laboratories. The selection and structural control of the support are another basic approach for better performance of the catalyst. The better materials and their better form are always looked for to achieve higher performance.

HDN and HDO become indispensable in hydrotreatment of some unique feeds.

Hydrogenation catalysts of particular performance can be a target of development for the pretreatment of particular feeds, since carbon deposition from the heavy

fraction is a large issue in the resid hydrotreatment in terms of catalyst life, aggregation of catalyst particles, plugging and fouling for pressure drop, as well as reduced yields of the light products.

Thus, better catalysts for respective objectives, and their combination in optimum amounts in the process scheme, are current aims and approaches for residue hydrotreatment.

21.7 Role and Design of Catalyst Support for Residual HDM

Concentrations of vanadium and nickel tend to be higher in heavier crudes and crude oil fractions. Unless they are removed, they may deposit on the catalysts in upgrading processes. The slipping of metals from HDM catalyst layers or beds may deactivate HDS/HDN and RFCC catalysts through deposition. They can also induce unwanted reactions, especially coking. Thus HDM can define the life of refining processes while increasing the ability of refineries to process low-cost heavy crudes.

Slippage of metals through HDM catalysts is an important phenomenon. Slippage is determined by both the capacity and completeness of metal removal at the HDM step. The removed metals on spent HDM catalysts are high-quality Ni and V ores, because they contain more Ni and V than conventional ores.

The HDM catalyst performs multiple roles: hydrogenation, metal ion extraction, HDS and accumulation of metals. Nevertheless, work is underway to reduce the amount of molybdenum on the support of alumina, both to reduce costs and provide more room for metal adsorption.

Another aim is to control the pore size of the support, which must be large enough to allow the easy access of large asphaltene molecules and metal complexes; nonasphaltic complexes are believed to behave together with the asphaltene heavy molecules. Particularly, the pore mouth must have large diameter, otherwise the coking at the mouth can plug the whole pore, reducing the capacity of the catalyst to contact with the metallic substrates.

Such approaches can be reexamined and revised from more flexible views based on the current research results.

The roles of hydrogenation have been accepted as follows:

1. Hydrogenation of ligand ring to be opened
2. Extraction of metal ion over the hydrogenation site
3. Generation of H₂S
4. Partial hydrogenation of the aggregated asphaltenes, which mobilizes metals for their better access to the pores and reduces their coking reactivity.

The current results indicate two mechanisms for the metal extractions:

1. Extraction of metal ion from the porphyrin ring on the polar catalytic surface by the aid of H₂S
2. Breakage of N–metal bonds in the porphyrin ring through the hydrogenation of ligand rings to facilitate the metal ion extraction.

Unpromoted supports, polar solvents and acids extract significant amounts of metal ions from isolated porphyrin complexes [21.103]. The hydrogenation of ligand rings has been proved with model porphyrins; however, ligand saturation has never been proposed as an exclusive mechanism.

Some industrial research has shown that H₂S inhibits HDM, but H₂S is certainly essential, at least to stabilize metal sulfides on the HDM catalyst. The various roles of H₂S are not fully elucidated. The mobility of metal ions or single sulfides from the metal extraction site to the other parts of the catalyst surface, like an open the extraction site, can make room for metal complexes coming in with fresh feed. This would increase the holding capacity of the HDM catalyst. H₂S is certainly produced from the reactive sulfur species in the HDM bed. H₂S is allowed to accumulate in the process recycle gas. Its concentration is controlled by bleeding recycle gas from the high-pressure loop to the refinery sulfur collection and recovery system.

Asphaltene deaggregation and/or dissolution is important to increase the capacity and completeness of metal removal, since the coking on the catalyst may take place in the pore mouth, preventing access to the rest of the pore. Metal porphyrins in the coke cannot be extracted from the catalyst surface.

Nitrogen species can be strongly adsorbed on the surface of the support. Hydrogenation of asphaltenes on the catalyst surface in the neighborhood of the hydrogenation site is very favorable and essential for optimum HDM capacity, through inhibiting the coke formation from the asphaltene.

Some metal porphyrins have recently been proved by GC and MS to be liberated into the gas phase from VR, as described above. Such metal porphyrins can

contact with HDM catalysts without extensive modification of the asphaltene aggregate and polymeric structure. Thermal or dissolving liberation of metal complexes can occur during HDM reactions. The acceleration of such liberation is worthwhile for further study.

The metals in the porphyrin complexes in AR have been extracted to a considerable extent on alumina and silica-alumina surfaces [21.21]. The acidic support appears more active for metal extraction than the nonacidic one. Then, the metal complexes tend to liberate metal ions according to their coordination strength to the support. The support can thus eliminate the metal ions according to its extraction activity.

The reactivity of metal complexes and the activity of the support surface interact to control the demetalation site on the solid catalyst surface. In an optimal situation, reactive metal can start by depositing at the bottom of the pore and then fill the pore completely. This can be achieved to a certain extent by layering.

In a multilayered HDM catalyst loading scheme, layering particles can be designed by arranging the weaker site on the surface and the stronger site at the bottom of the pore. Hydrogenation and some HDS are needed before HDM. The HDS before HDM is required to produce H_2S and segregate the asphaltene where easy HDM is not expected. The hydrogenation before HDM is to suppress the coking on the HDM catalyst, particularly polar metal elimination site. Thus, two layers for the first hydrogenation slight HDS and second HDM catalysts can be designed respectively. Such a catalyst concept can be applicable for both fixed and moving beds by taking the characteristics of such reactor design and performance into the consideration. The issues of moving beds are described in the next section.

So far, the reactivity of nonporphyrin metal complexes is not elucidated yet, although they appear less reactive than porphyrins. Analysis for the behavior of nonporphyrin complexes is strongly needed for understanding the upgrading of very heavy crudes [21.104].

21.8 Novel Hydrotreatment Processes for Residue Upgrading

Fixed-bed hydrotreatment process for atmospheric residue are widely used. Typically, these units look like fixed-bed gas oil or VGO hydrotreaters with two or more fixed beds of HDM, HDM/HDS/HDN and HDS catalysts to achieve targets for product metals, sulfur, nitrogen, asphaltenes and CCR. Catalyst cycles can last for 6–12 months, depending on the feedstock and process configuration. For better economics, refiners always want longer continuous operation with heavier residue containing more metal, more S- and N-species, and asphaltenes or CCR. As described previously in this chapter, each type of catalyst continues to be extensively studied to improve its performance. The major approach is to design the pore structure of the alumina support. Support materials other than alumina have also been explored. Nevertheless, alumina with well-designed shape and pore structure is most used for the practical catalyst described above.

Larger metal capacity for HDM and higher but stable activity for HDS are the keys to a longer effective operation. The intrinsic performances and smaller inhibition/deactivation of performances are both important for better catalysts. The major causes of inhibition/deactivation of HDS and HDN catalysts are leakage of metals from the HDM catalyst and deposition of carbonaceous materials. Hence, less appearance of carbon deposits and less slip of metals must be considered to improve the performance of these catalysts.

The life of HDM catalysts is first defined by metal holding capacity. In order to operate continuously within the limits of metal holding capacity, Chevron developed the OCR process, where OCR means on-stream catalyst replacement [21.102]. As illustrated in Fig. 21.17, the fresh catalysts are charged at the top of the OCR reactors and used catalysts are discharged at the bottom of the OCR reactors. The feed is charged at the bottom of the reactor and flows upward, fluidizing the catalyst. The aged catalyst, which has removed most of the metals from the feed, reaches the top of the conical screen, then slides down outside the screen to the bottom, where the metal-rich catalyst is discharged. The demetalized feed is hydrotreated and to some extent cracked. Contact time and sufficient modification of the adsorbed feed are important for the catalyst to stay dried in the charged feed. Otherwise, the catalyst particles to be discharged carry soft as well as hard carbon and adhere to each other before arriving at the cone bottom for discharge. Problems of plugging and sticking at the bottom have been reported to be important for a stable operation for a long time. The catalyst surface, catalyst transportation in the reactor and feed adjustment can be designed to avoid the adhesion. How to eliminate the adhesive nature of the soft carbon among the adsorbed fractions on the catalyst before encountering similar catalyst particles can be a key for smooth discharge. Solvents, such as FCC cycle oil, can be added

Fig. 21.17 Upflow versus downflow reaction

to this region to extract the adhesive fraction from the spent catalyst particles.

Higher hydrogenation and cracking activity of the outer layers of the catalyst can solve its adhesion issue. The separation of aged catalysts into fully deactivated and still-alive portions is another interesting topic to be studied.

A process based on p-flow reactors has been proposed by Chevron and recently commercialized by SINOPEC. Details have not been disclosed. Upflow can solve the plugging and adhesion problems seen with OCR and utilize more uniformly the HDM catalyst. Continuous charge and discharge are not clearly described in the published documents. Uniform contact of the feed with the differently aged catalyst particles in the reactor may not be favorable for deeper removal of the metal in the feed. Uniform fluidization requires the larger volumes of reactor and upflow hydrogen.

Slurry phase resid hydrocracking, such as the VCC process licensed jointly by KBR and BP, along with processes offered by ENI and UOP, can achieve < 95 wt% conversion of vacuum residue into diesel and lighter fractions. The VCC process can be used to upgrade coal. Four VCC units have been licensed. Two were completed in China (or will be as of March 2015) and another is under construction in Russia. In the VCC slurry-phase hydrocracking process, coal or VR is mixed with an additive or catalyst and hydrogen and bubbled upwards through the reactors, where they are thermally cracked. Slurry-phase hydrocracking is discussed in another chapter. The VCC process employs a noncatalytic

additive. The VCC process is based on coal liquefaction processes developed in the early 20th century [21.105]. ENI [21.106] announced its commercial process using a micro-MoS₂ catalyst. Excellent performances are reported. UOP applies a fine iron catalyst for its uniflex process [21.107]. In the VCC process, a noncatalytic additive is used. Recovery of additives or catalysts and the destination of removed metals may present problems in some locales, but as with fixed-bed residue hydrotreating, the pitch from these processes can be a high grade ore for Ni, V, and other metals.

Supercritical water at very high pressure and temperature is also applied in the treatment of the residue [21.108]. The erosion and corrosion of the reactor wall and let-down valves by the supercritical water that carries fine polar solids, dissolved CO₂ and salts, as well as the destination of removed metals, are the main concerns in this process.

We have proposed multistage catalyst beds as the process and design concept of each catalyst in the successive beds. The beds consist of:

1. Hydrogenative treatment without HDM with slight HDS to moderate coking properties of the heavy feed.
2. The catalyst of low activity for HDM to remove the reactive metals at the deeper site in its pore while HDM of refractory metals takes place anyway in the deeper pore. Such a design is expected to allow the homogeneous deposition of the metal through the whole pore wall.

3. The catalyst with high activity of HDM for deep and complete removal of the metals in the feed.
4. More active sulfides loading, larger surface area and selected supports can be still possible approaches as described above.

21.9 Challenges in Hydrotreatment

The foremost challenges for progressing hydrotreatment processes are the molecular characterization of feeds up to asphaltenes. Thus, the reaction mechanisms/schemes in every step of hydrotreatment process and catalyst designs best fitted to the feeds, intermediates and products can then be elucidated on a molecular basis. The advances in effective characterization of solid catalysts, spent and fresh, is another challenge.

Process improvements such as combining HDS with adsorption and staged configurations to accomplish the deep HDS of very difficult gas oils are issued with great importance. In addition, process and catalyst flexibility should be significantly considered. Depending on circumstances, refiners process different feeds at different severities. A catalyst that can achieve both high HDS and high HDM can provide such flexibility, even though it may not be optimal for a single type of operation.

In the case of biofeeds, traditional MoS₂-based catalysts may not be best for them, as they carry low sulfur content. Hence, nonsulfur-containing catalysts for such applications have been studied and developed.

Brainstorming ideas to improve catalyst activation procedures are also issued. Wet sulfidation preserving the activity of type II catalysts (Akzo) showed the nearly double activities compared to commercial HDS and HDN catalysts.

21.9.1 Analysis of Heavy Feedstocks

As described above, all molecules in the petroleum fractions can be analyzed by modern MS at least at the level of chemical formulae of desorbed and ionized species [21.109]. Careful MS/MS analysis of the respective MS peak can provide structural information based on the fragmentation pattern. However, MS coupling with GC would be necessary for the determination of isomers in feed, intermediates and product for the reaction mechanism studies and the effectiveness of catalyst and process conditions in hydrotreatment. However, this GC-MS technique is limited to fractions up to gas oils.

For deep HDS and other hydrotreatment beyond gas oils, such as resid refining, the use and development of liquid chromatography or effective class fractionation

schemes would benefit the studies of refractory species and the effectiveness of catalyst systems. On the other hand, ultrahigh resolution mass spectrometry, such as FT-ICR, orbitrap and multipath TOF, can provide compound type and carbon number distributions, but not information on isomeric structures.

However, the identification of the matrix molecules is necessary to clarify their inhibiting roles. The molecules adsorbed on the catalysts can be extracted for the analysis to find their roles in the reaction mechanisms and inhibiting schemes.

21.9.2 Coking

The coking of catalysts should be also studied, even if the coke in various forms and the substrates just before coke formation may be difficult to extract and analyze. The identification of locations of adsorbed species and the coke on the catalyst could lead to the design of better supports and placement of the catalytic species on the support.

Another challenge is to identify remaining species, intermediates and product molecules. Clarification of competing and inhibiting species may overcome the problems and solve difficulties in the hydrotreatment of particular feeds. The identification of reaction steps and schemes can be thus better understood on a molecular basis.

21.9.3 Polymerization and Aggregation of Feeds

The remaining issues in residue hydrotreatment involve the analysis of particular substrates found in the polymeric and the aggregate structures. The presence of a polymeric structure indicates that the reactive part of the substrate must approach the active site on the solid catalyst and overcome the inhibition by the other part of the same polymeric chain. The polymeric structure must fit the pore in its size and avoid unwanted side reactions before the molecule arrives on the active site in the pore.

The first point is the diffusivity of the substrate to active sites in the pore. The size and wall chemistry of the pore, as well as the size and all functional groups on the polymer substrates, must be considered. The cok-

ing of the polymeric chains is the largest issue in their catalytic reaction over a solid catalyst.

The aggregate structure of the heavy fraction in petroleum is now being studied extensively. Its behaviors under hydrotreating conditions are to be clarified. The effects of temperature and surrounding solvent-like fractions on the dissolution of the aggregate structure may be the remaining question. The solvent fractions can be present in the original feed, produced through the hydrotreatment, or added or induced from the added solvent. The solvent fraction, thus, can be the key to controlling the hydrotreatment of the heavy fraction in the aggregate dissolution, polymeric diffusivity and the structural modification of reactive unit. The minor amount of the target or problematic molecules must also be of concern in the aggregate.

The aggregate structure includes a variety of non-covalent bonding among the constituents. Some of bonding may be quite weak to release molecules or units rather easily from the aggregate and even polymeric structure. The authors believe some porphyrins in the asphaltene to behave so. It is quite important to design the HDM by taking account of such behaviors as described above.

21.9.4 Catalyst and Additive Improvements

The hydrotreating catalysts in the respective catalytic steps are now optimized and/or designed to enhance the wanted reaction, selectively reduce the difficulties of the wanted reaction with the particular feed and moderate the unwanted reaction.

So far, with one exception, catalysts for fixed-bed hydrotreating are limited to Mo and W sulfides promoted by Ni and/or Co sulfides. The exception is NEBULA, which uses a base metal support instead of alumina. Iron sulfide of lower price may play a role, particularly in the moving bed. There is still active research

on the use of nonalumina supports. For all supports, the uses of different materials, pore sizes, and their combination continue to be investigated. The multilayered concept of designing a catalyst particle consisting of an outer surface, mouth, intermediate wall and bottom of the pore may hold promise. It must have the right size and right materials for the intended functions in order to provide optimum activity for treating the coming feed components.

For HDM and HDS catalysts designed for the heavier feeds, the surface coking issue remains important for efficiency and long life without losing the catalyst performance. For HDM, it is also important to improve utilization of pore volume and decrease slippage of metals. The goal is to achieve complete removal of the metal before the feed leaves the HDM catalyst layer.

HDS catalysts for heavy fractions must be able to overcome the difficulty coming from the aggregate, polymeric, multihindered and multi-inhibiting substrates. At this moment, refractory sulfur units in the polymeric chains are not well defined. However, we have well-defined refractory sulfur species in the distillates. We can thus apply the principles of effective and deep HDS from the distillate by taking account of aggregate and polymeric difficulty with the residue.

Finally the authors claim the multibeds carrying a series of respective optimum catalysts with respective unique functions are strongly expected to realize the deep refining.

Acknowledgments. We would like to thank the Japan Cooperation Center, Petroleum (JCCP) for funding our research project on the refining of Kuwait Crudes through the support of Japan Ministry of Economy, Trade and Industry (METI), through which this chapter has been prepared. The authors would like to express gratitude to Dr. M. Marafi, ED/PRC at the Petroleum Research Center for her continued managerial support.

Hydrocracking

22. Hydrocracking

Paul R. Robinson, Geoffrey E. Dolbear

Hydrocracking converts heavy petroleum fractions into lighter products by breaking C–C bonds in the presence of hydrogen. It is in fact a collection of processes which transform a variety of feedstocks into both finished products and streams for further upgrading by downstream units. Hydrocrackers with fixed-bed reactors process straight-run VGO and/or streams with similar boiling ranges – FCC (Fluid catalytic cracking) cycle oils, coker gas oils, deasphalted oils, etc. Hydrocrackers designed for residue conversion employ ebullated bed (e-bed) reactors or slurry-phase reactors. All commercial units consume hydrogen at high pressure, typically 100–200 bar and generate considerable heat.

Fixed-bed and e-bed hydrocrackers employ dual-function hydrocracking catalysts, which contain both acid sites and hydrogenation sites. Acidity comes from amorphous aluminosilicates (ASA), crystalline zeolites, and related materials such as silica-alumina phosphates (SAPO). Hydrogenation activity comes either from noble metals (Pd or Pt) or metals sulfides (MoS_2 or WS_2). The acid sites catalyze C–C bond cleavage and the resulting fragments are stabilized by hydrogenation on the metal sites. In fixed-bed units, feed contaminants are removed first in a separate catalytic hydrotreating (pretreat) section. The most critical contaminant is organic nitrogen, which inhibits cracking by neutralizing cracking-catalyst acid sites.

In slurry-phase processes, the cracking is thermal and the cracked fragments are hydrogenated on highly dispersed additives. Some slurry-phase processes use noncatalytic additives. Additives for other processes are infused with catalytic metal compounds to enhance the conversion. Conversion of vacuum residue can exceed 95 wt%.

Products contain only ppm levels of nitrogen and sulfur and low amounts of olefins. Product aromatics are considerably lower than feed aromatics. From fixed-bed units, the heavy naphtha is a preferred feed for catalytic reformers. With some

feedstocks under appropriate process conditions, middle distillates meet sales-quality specifications for jet and/or diesel fuels without further treatment. The unconverted oil (UCO) is a premium feedstock for FCC units. UCO also can go to olefin production plants or lube base stock plants. The UCOs from e-bed and slurry-phase units can go to FCC units, but they tend to contain high concentrations of poly-ring compounds, which makes them less suitable for producing olefins and lube base stocks.

Safe operation requires tight control of reaction heat. This is achieved with proper design and effective training of operators, engineers, and managers. Poor decisions based on inadequate understanding of process dynamics and reaction chemistry have caused serious accidents, dozens of injuries, and at least one fatality.

22.1 Role of Hydroprocessing in Petroleum Refining

22.1.1 Overview of Petroleum Refining

Hydrocracking processes convert heavy petroleum fractions into lighter products by cracking C–C bonds in the presence of high-pressure hydrogen, while removing essentially all nonhydrocarbon contaminants. Catalytic hydrocracking units (HCUs) with fixed-bed reactors process straight-run VGO and/or streams with similar boiling ranges – FCC cycle oils, coker gas oils, deasphalted oils, etc. Units designed for residue conversion employ ebullated bed (e-bed) reactors or slurry-phase reactors. Ebullated bed units employ formed catalysts, while slurry-phase units, in which the hydrocracking is thermal, use finely divided proprietary additives; the additives may be catalytic or non-catalytic.

Commercial units operate at high pressure, typically 120–200 bar with H₂ purity > 70 vol.%. They generate considerable heat.

Process flow schemes for fixed-bed hydrotreaters and fixed-bed hydrocrackers are similar and much of the chemistry is the same. For this reason, industry professionals use the term *hydroprocessing* when discussing them together. The difference is the cracking part. Hydrocracking breaks carbon–carbon (C–C) bonds, but hydrotreating does not.

Figures 22.1 and 22.2 illustrate the role of hydroprocessing in a representative high-conversion petroleum refinery. Figure 22.1 includes processes for upgrading distillates that boil below about 595 °C (1100 °F), temperatures which mark the somewhat fuzzy boundary between vacuum distillates and vacuum residue. Fig-

Fig. 22.1 Top part of a representative petroleum refinery

ure 22.2 shows residue conversion processes, including residue hydrocracking. Feeds to residue FCC (RFCC) units are hydrotreated to remove metals. In locales with restrictions on sulfur in gasoline, jet fuel and diesel, all liquid products from delayed cokers are hydrotreated or hydrocracked.

Most refineries were built between the 1940s and 1970s. Over time, they have evolved (or gone out of

business) due to changes in feedstock price, quality, and availability – and also due to changes in product demand and regulations. Since the mid-1990s, ever-tightening restrictions on product sulfur have increased the need for hydroprocessing. Figure 22.1 includes five hydroprocessing units – four hydrotreaters and one hydrocracker. These days, it is rare to find a refinery with less than three hydrotreaters.

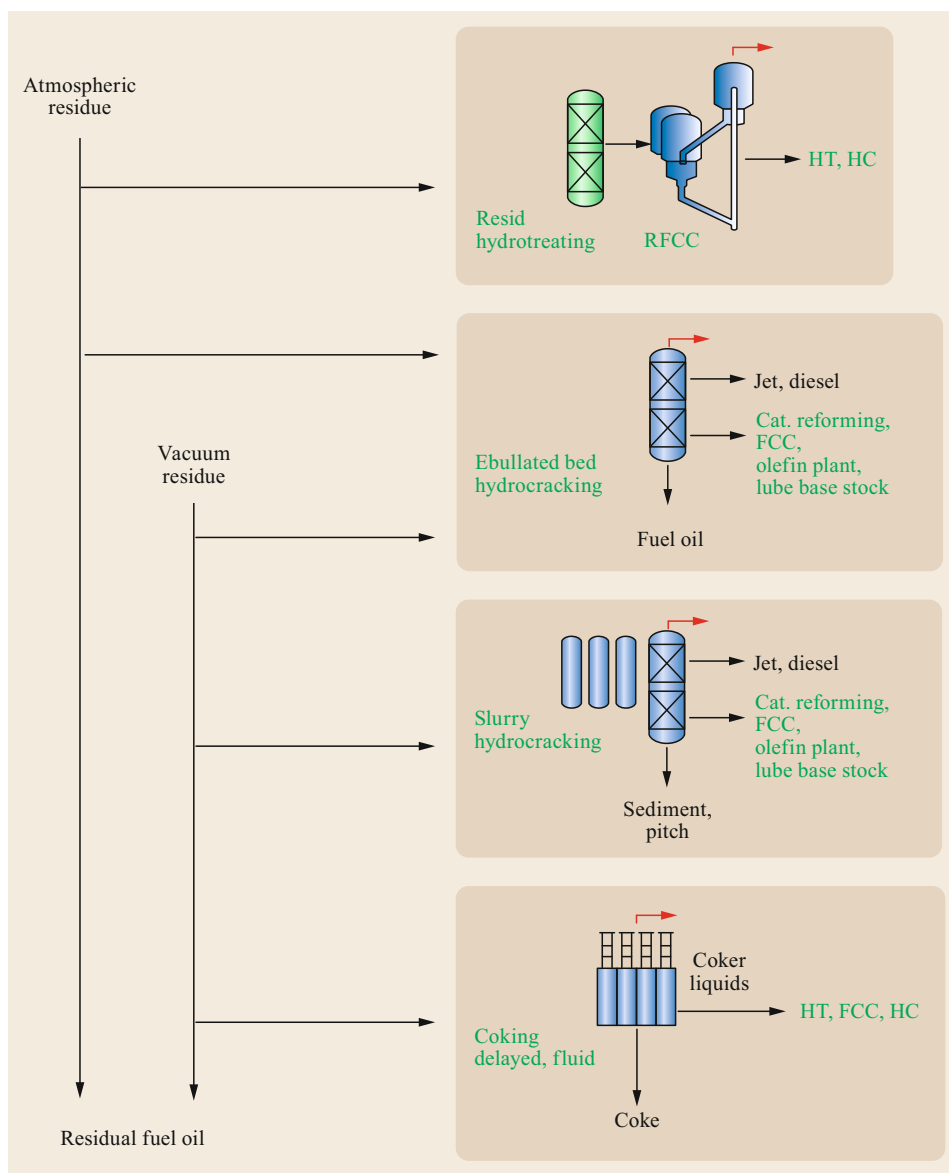

Fig. 22.2 Vacuum residue upgrading options for petroleum refining

Refining entails five major kinds of molecule manipulation:

- Removing contaminants (desalting, hydrotreating, amine treating, mercaptan oxidation)
- Separation (distillation, extraction)
- Conversion (hydrogenolysis in hetero-atom compounds and C–C bond cleavage)
- Isomerization, saturation, and reforming (no change in carbon number)
- Recombination (alkylation, polymerization).
- Feedstock management – selection, storage, blending, and transportation
- Product management – blending, storage, and distribution
- Hydrogen manufacturing, purification, and recovery
- Utilities – power, steam, water, instrument air, and industrial gases
- Waste processing and disposal.

Related activities, which may occur either inside or outside the refinery proper, include:

Soft activities – those which don't require steel – include software for design, simulation, automation, and optimization; laboratory services; planning and scheduling; training; management; and R&D.

The first major process unit in a refinery is the desalter, which removes dirt, water, salt, and other water-soluble contaminants from blended crude oils. From the desalter, the crude(s) go to an atmospheric distillation unit (ADU), which produces several streams. These include refinery fuel gas (RFG) containing mostly methane and ethane, liquefied petroleum gas (LPG) containing mostly propane and butanes, one or two straight-run naphtha streams, one or two straight-run middle distillates streams, and atmospheric residue (AR).

22.1.2 Removal of Nonhydrocarbon Contaminants

Figure 22.3 illustrates the importance of hydroprocessing for fuel production. All ADU products contain sulfur, either as H_2S , inorganic sulfur, or organic sulfur compounds. Heavier fractions also contain nitrogen, oxygen, and trace elements (Fe, Ni, V, Cu, Si, As, and Hg). Hydrotreating removes organic sulfur and the other contaminants from most C_5+ liquids. Sulfur can be removed from relatively sweet naphtha with mercaptan oxidation technology.

Nonfuel uses for straight-run petroleum distillates include the following:

- Streams heavier than naphtha – from kerosene through vacuum residue – are used to make lubricants. Hydrofinishing is an important step in base stock preparation. Hydrocracking and catalytic dewaxing are used to make group II base stocks and hydroisomerization is used to make group III base stocks.
- Light olefins (ethylene, propylene, and butylenes) are recovered and sent directly to olefin production plants. Olefins are produced from paraffin gases, petrochemical naphtha, and hydrocracker unconverted oil. Figure 22.4 illustrates how refineries interact with olefin plants.

Here are the main destinations for individual streams from atmospheric distillation units, from the bottom of the tower to the top:

- The AR goes to a vacuum distillation unit (VDU), which produces vacuum gas oil (VGO) and vacuum residue (VR). Refiners allocate VGO based on business requirements. Common VGO destinations include an FCC, a hydrocracker, a lube base stock facility, and fuel-oil blending.
- Either before or after hydrotreating, straight-run middle distillates are divided into light and heavy

fractions, which become kerosene or gas oil, respectively. Both can serve as fuel oil. If it meets specifications, the kerosene can be blended into jet fuel and the gas oil can be blended into diesel. Certain refineries produce just one middle distillate stream, typically wide-range gas oil.

- Naphtha is split into light and heavy fractions. Desulfurized light naphtha (LN) includes C_5 molecules along with differing amounts of C_4 and C_6 . LN can be blended into gasoline or separated into constituent components. Small amounts of mixed butanes can be blended into gasoline. *N*-Butane is sold as such or isomerized into *i*-Butane. *i*-Butane goes to alkylation (ALKY) units or is dehydrogenated to C_4 olefins for chemical plants. Heavy naphtha (HN) includes C_6 – C_{12} molecules; sometimes also C_{12} molecules. Catalytic reforming (CRU) and isomerization (ISOM) units are common HN destinations. C_6 compounds may be excluded from CRU feeds if a refiner wants to minimize benzene production. C_9 – C_{12} molecules can be blended into aviation gasoline.
- H_2S is removed from RFG by adsorption in alkalamine units. The H_2S is converted to elemental sulfur in Claus process units. Sweet RFG serves as fuel gas throughout the refinery. LPG is sold or exported to a chemical plant, either before or after segregation into individual components.
- Thermal cracking units, such as cokers and slurry-phase hydrocrackers, produce significant quantities of methane and ethane. In catalyst-based conversion units – FCCs and fixed-bed hydrocrackers – C_1C_2 production is low and for paraffins, the iso/normal ratio is high. Processes that operate without external hydrogen – FCC and coking – generate olefins, aromatics, hydrogen, and coke. FCC is a primary source of propylene and butylenes for downstream chemical plants. In hydrocracking units, which operate with large amounts of external hydrogen, olefins and coke are low and product aromatics are lower than feed aromatics.
- As much as anything else, VR conversion determines refinery profitability. The cost of crudes depends on their sulfur and VR content. High-sulfur, high-VR crudes cost less, so refineries configured to handle them tend to be more profitable. VR is a source of asphalt, bright-stock lubricants, greases, waxes, and specialty carbon products. To a certain extent, VR can be blended into No. 6 fuel oil (bunker fuel). Processes for converting AR and VR into lighter products include delayed coking, visbreaking, modified versions of FCC and either ebullated bed or slurry-phase hydrocracking.

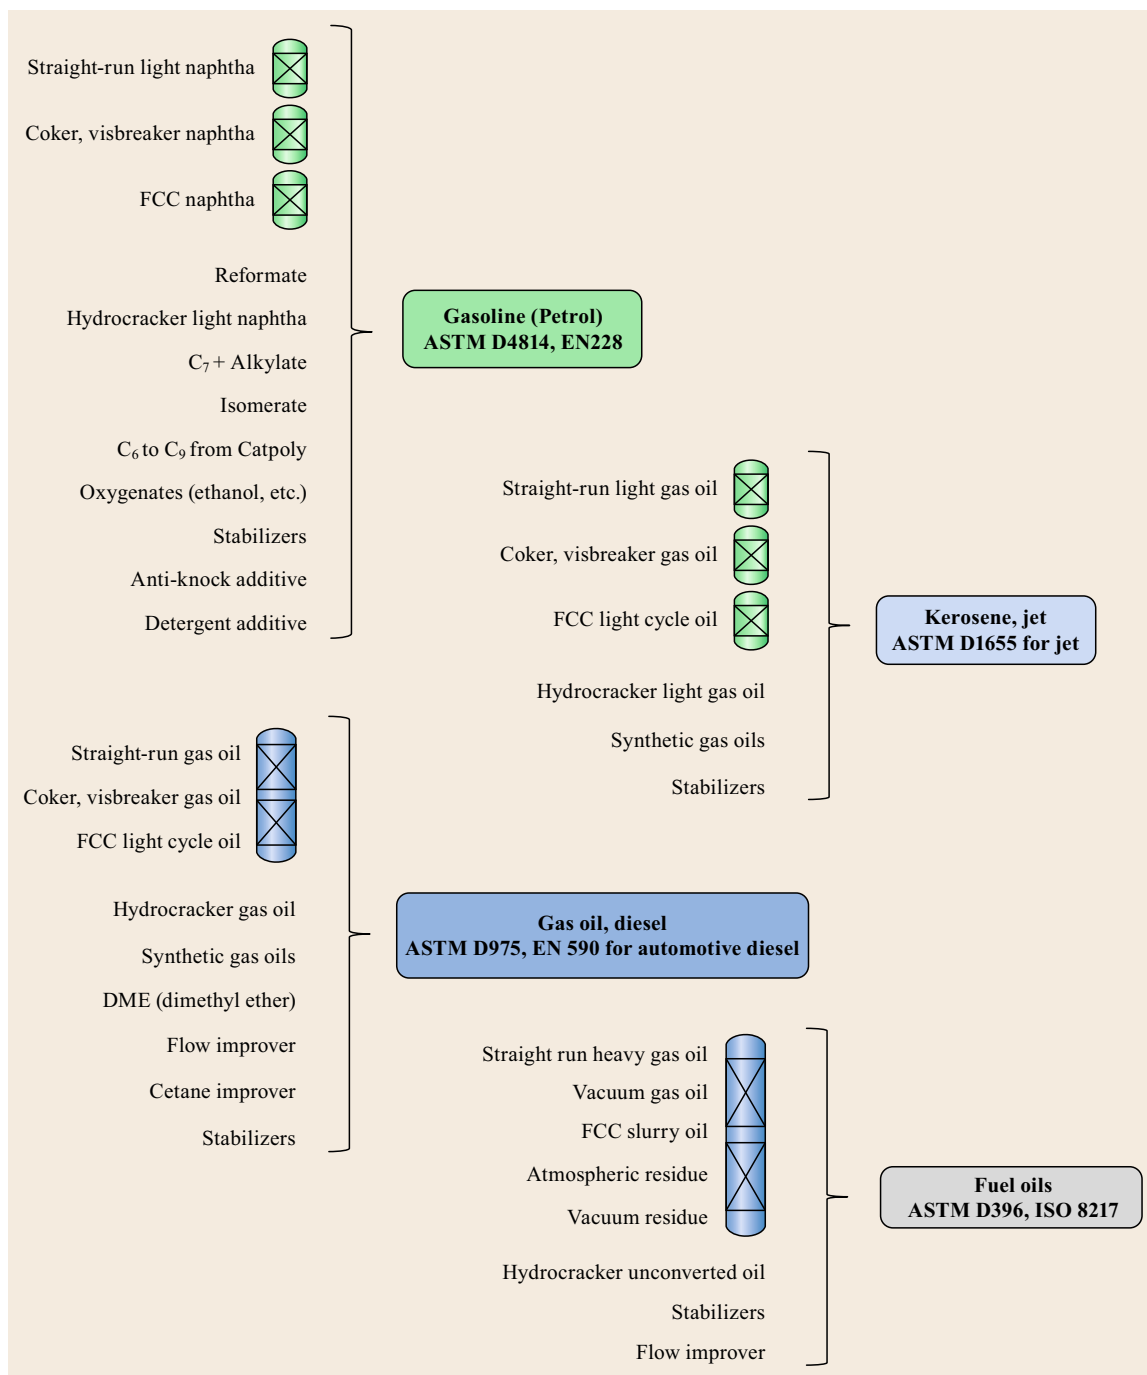

Fig. 22.3 Hydroprocessing for fuel production. Almost all C₅+ liquid streams are hydroprocessed – somewhere and to some extent. Components are shown for four types of liquid fuels: Naphthas (including gasoline), kerosenes (including jet fuel), gas oils (including diesel), and fuel oils. Destinations of key products are specified, along with approximate TBP (true boiling point) boiling ranges

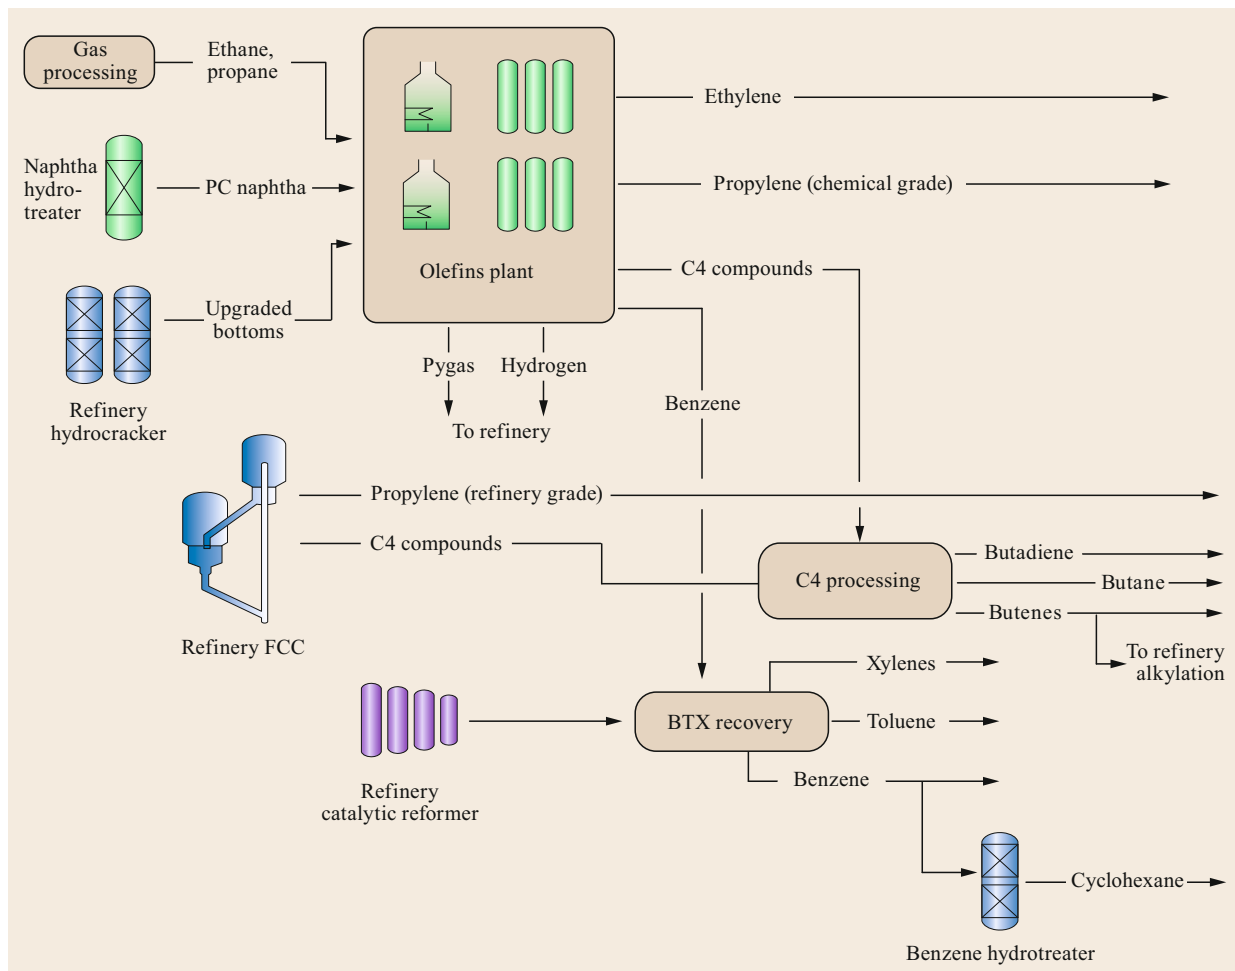

Fig. 22.4 Role of hydroprocessing in the petrochemical industry

22.2 Feedstock Molecules

First and foremost, feedstock properties determine the selection and performance of molecule manipulation technology. The properties of straight-run hydroprocessing feedstocks depend directly on the properties of the crude oils from which they are distilled.

22.2.1 Hydrocarbons

The preponderance of molecules in hydroprocessing feedstocks are hydrocarbons – alkanes (normal and isoparaffins), olefins (alkenes), and ring compounds. Figure 22.5 shows examples of hydrocarbon ring compounds that might appear in feeds to hydroprocessing units. Up to 80% of the carbon atoms in some feeds are part of a ring compound.

22.2.2 Sulfur, Nitrogen, and Oxygen

The major contaminants in feeds to hydroprocessing units are sulfur, nitrogen, and oxygen. Figure 22.6 shows some examples of hetero-atom compounds.

The sulfur content can range from < 0.2 wt% to > 4 wt%. Sulfur can be inorganic – dissolved H_2S and elemental sulfur – but mostly it is organic – sulfides, disulfides, thiophenes, benzothiophenes, and dibenzothiophenes.

The nitrogen content can range from 100 wppm to > 4000 wppm. Coal-containing feeds to residue hydrocrackers can contain > 1 wt% nitrogen. Amines are rare, but pyrroles, quinolines, and carbazoles are common.

Fig. 22.5 Examples of hydrocarbon ring compounds

Nonwater oxygen comes from a variety of sources. Feedstocks from biomass contain considerably more oxygen than conventional crude oil and petroleum distillates. While a conventional vacuum gas oil may contain 0.5 wt% oxygen, a bio-derived oil in the same boiling range might contain > 2% oxygen. Organic oxygen compounds include furans, naphthenic acids, carboxylic acids, ethers, peroxides, and ring compounds that contain both oxygen and nitrogen or sulfur. Peroxides form when crude oil and heavy petroleum distillates are exposed to air during transportation and storage.

22.2.3 Trace Contaminants

The major trace contaminants in as-produced crude oil are iron, nickel, vanadium, and sometimes arsenic and mercury. Ni and V concentrations can range from < 2 to > 1000 wppm. Water and salts are entrained in many crudes. By the time they reach a refinery, oils might also contain silicon and corrosion-product iron. All trace contaminants degrade the performance of catalytic hydroprocessing units, usually by poisoning catalyst sites but sometimes by weakening catalyst supports. As and Hg are 100× more poisonous on a weight basis than Fe, Ni, and V. Weakened parti-

cles can disintegrate into chips and dust; in fixed-bed units, these accumulate in the space between intact particles, thereby blocking flow and increasing pressure-drop buildup (dP+).

Limits on feed metal content for fixed-bed VGO hydrocrackers are considerably tighter than those for residue hydrotreaters, e-bed hydrocrackers, and slurry-phase hydrocrackers. For the catalytic units (residue hydrotreating and e-bed hydrocracking), feed metals are a major concern. Fixed-bed residue hydrotreaters are loaded with wide-pore metals-removal catalysts, which can pick up > 100% of their weight in metals. In e-bed units, adjustments in the catalyst addition rate are based largely on feed metals content.

In slurry-phase units, which operate without catalysts, feed metals do not inhibit performance. Higher metals can in fact enhance conversion.

22.2.4 Iron

Both particulate and dissolved iron can impair the performance of refineries. Organometallic iron can be a constituent of as-produced crudes, but most of the soluble iron in refineries is generated by corrosion. Corrosion can be accelerated by naphthenic acids, halide salts, and hydro-halic acids. Polythionic acids cause

Fig. 22.6 Ex-amples of ring compounds containing hetero-atoms

stress corrosion cracking in certain steels. During hydroprocessing, H_2S reacts with stainless steel to form thin layers of metal sulfides. The sulfides are converted to polythionic acids when the steel is exposed to air during a maintenance shutdown. The acids are removed by washing or spraying exposed surfaces with aqueous soda ash (Na_2CO_3).

22.2.5 Salts

During production, shipment and storage, petroleum might be exposed to salt water, which becomes entrained. Salts include chlorides and sulfates of sodium, magnesium, and calcium. Bromine is especially corrosive. A major source of Br is drilling brine, which is co-produced with oil and can end up in the VGO feed to a hydrocracker.

22.2.6 Nickel, Vanadium, Silicon, Mercury, Arsenic

Good nickel, as nickel sulfide, is a promoter for hydroprocessing catalysts. In other forms, Ni is a serious contaminant. Organic Ni and V are encapsulated in porphyrins, which are constituents of asphaltenes. Inorganic Ni and V may also be present.

Organic silicon compounds are added to crude oil as flow improvers. They are also added to delayed cokers to mitigate foaming.

Mercury appears primarily in natural gas and gas condensate. Hg is especially abundant in gas and condensate produced from offshore Thailand fields.

Arsenic is relatively abundant in synthetic crudes from Canada, heavy shale oil and in crudes from West Africa and the Ukraine.

22.3 Process Variables

Hydrotreating and hydrocracking have their own jargon. In this section, we describe and define common process-specific terms.

22.3.1 Liquid Composition

Two general classes of measurements define the liquid streams in hydroprocessing units: bulk properties and molecular composition.

Bulk Properties

Bulk properties of crude oils and imported intermediate streams include distillation, specific gravity (or API gravity), TAN (total acid number), BSW (basic sediment and water), salt content, and total sulfur. For hydroprocessing, additional bulk properties are important. These include total nitrogen, CCR (Conradson carbon residue) or MCR (microcarbon residue content), UV aromatics, asphaltenes, heptane insolubles and trace elements. The ASTM methods for determining these properties are presented in Chap. 1.

Molecular Composition

Process development and/or the formulation of models for real-time optimization require determination of *molecular composition*. But middle distillates contain hundreds of molecules and vacuum gas oils and residues contain hundreds of thousands – perhaps even millions. It is impractical (and unnecessary) to measure each and every one. It is sufficient to split the feed into cuts – light and heavy naphtha, light and heavy oil, light and heavy vacuum gas oil and vacuum residue – and to determine for each cut, concentrations of the following:

- Paraffins – normal and iso-
- Aromatics – mono-, di-, tri- etc.
- Naphthenes – mono-, di-, tri- etc.
- Olefins
- Alkyl aromatics
- Sulfur compounds – sulfides, disulfides, mercaptans, thiophenes, benzothiophenes etc.
- Nitrogen compounds – amines, pyroles, quinolines, carbazoles etc.
- Oxygen compounds – naphthenic acids, cresols etc.
- Trace elements.

Composition variables specific to hydrocracking include:

- Nitrogen slip (N slip) = organic nitrogen (ppmw) in the pretreater effluent liquid
- Sulfur slip (S slip) = organic sulfur (9 ppmw) in the pretreater effluent liquid.

For Aspen Hydrocracker, a rigorous model for on-line optimization, this approach generated 113 reactive *lumps*. Section 22.9.4 presents additional information on the use of lumping in rigorous models.

While the bulk properties of blended feeds might be measured every day – or at least after every crude switch – the molecular composition of individual blend stocks is typically measured only once.

22.3.2 Liquid Feed Rate Parameters

Space velocity corresponds to the inverse of residence time. The term enables one to compare kinetics for commercial units of different absolute size:

- Space velocity (once-through) = ratio of fresh feed rate to catalyst volume
- Space velocity (combined feed) = ratio of total feed rate (fresh feed + recycle oil) to catalyst volume
- Liquid hourly space velocity (LHSV) = feed volume (specified as once-through or combined feed)/(catalyst volume)/h. The unit of measure (UOM) is h^{-1} .
- Weight hourly space velocity (WHSV) = feed weight (specified as once-through or combined feed)/(catalyst volume)/h. The UOM is $\text{kg}/\text{m}^3/\text{h}$.

Combined feed ratio (CFR) = (total amount of feed to a specific reactor)/(total fresh feed to the first reactor). CFR is relevant to units which recycle unconverted oil or accept varying amounts of external feeds between the hydrotreating and hydrocracking sections of a unit.

22.3.3 Conversion Parameters

Measurements and calculations important for quantifying conversion include the following:

- *Conversion cut point* (CCP) in a hydrocracker = cutpoint (TBP) of unconverted oil. Refiners sometimes employ the term RCP for recycle units.
- *True conversion* (weight) = $[1 - (\text{weight of cutpoint-plus material in the product})/(\text{weight of cutpoint-plus in the feed})] \cdot 100\%$
- *Apparent conversion* (volume) = $[1 - (\text{volume of liquid product})/(\text{volume of liquid feed})] \cdot 100\%$.
- *True conversion* (volume) = $[1 - (\text{volume of liquid product})/(\text{volume of unconverted oil in the feed})] \cdot 100\%$. The volume conversion in a fixed-bed hydrocracker operating to make C_4+ naphtha can exceed 125 vol.%. Economically, this so-called *volume swell* is significant, because gaso-

line and diesel are sold by volume, not weight. Higher volume is worth more, regardless of weight.

22.3.4 Gas-Related Parameters

- *Reactor average pressure* = [(reactor inlet pressure) + (reactor outlet pressure)]/2
- *Bed pressure drop* (Bed dP) = (bed outlet pressure) – (bed inlet pressure)
- *Reactor pressure drop* (Reactor dP) = (reactor outlet pressure) – (reactor inlet pressure)
- *Pressure-drop buildup* (dP+) = rate of change pressure drop. UOM can be psig/month or kPa/month
- *Hydrogen partial pressure* (p_{H_2}) = (reactor average pressure) · (hydrogen purity). UOM can be psig or kPa.
- *Hydrogen purity* (vol.% H_2) = average hydrogen purity in the reactor(s), based on analyses of the reactor inlet gas and the CHPS overhead gas (purge gas prior to amine treating)
- *Gas-to-oil ratio* (GOR) = (volume of gas to the reactor)/(volume of liquid feed to the reactor). UOM can be scf/bbl or Nm^3/m^3
- *Hydrogen-to-oil ratio* (H2OR) = (volume of hydrogen to the reactor)/(volume of feed to the reactor,

including recycle oil if any). UOM can be scf/bbl or Nm^3/m^3

- *Gas composition* = mole percent of each component in a gas stream.

22.3.5 Reactor Temperature Parameters

Scores of temperature indicators (TIs) are associated with modern hydrocracking reactors. There can be more than 20 per bed, a dozen or so *skin TIs* affixed to the outside of the reactor wall underneath the insulation, two or three on each quench line and two or three on each pipe leading into or out of the vessel. Refiners rely on calculations to translate all that data into useful information.

Some temperature calculations include catalyst weight, catalyst volume, and gas or liquid flow rates. It is important to know whether or not catalyst weights or volumes should include grading material; it is not surprising to see a catalyst loading scheme in which all available volume in the first bed of a 4- or 5-bed reactor is occupied by particulate traps, low-activity chemisorbents for taking out trace elements, and additional activity grading.

Figure 22.7 serves a basis for illustrating reactor temperature calculations for a two-bed hydroprocess-

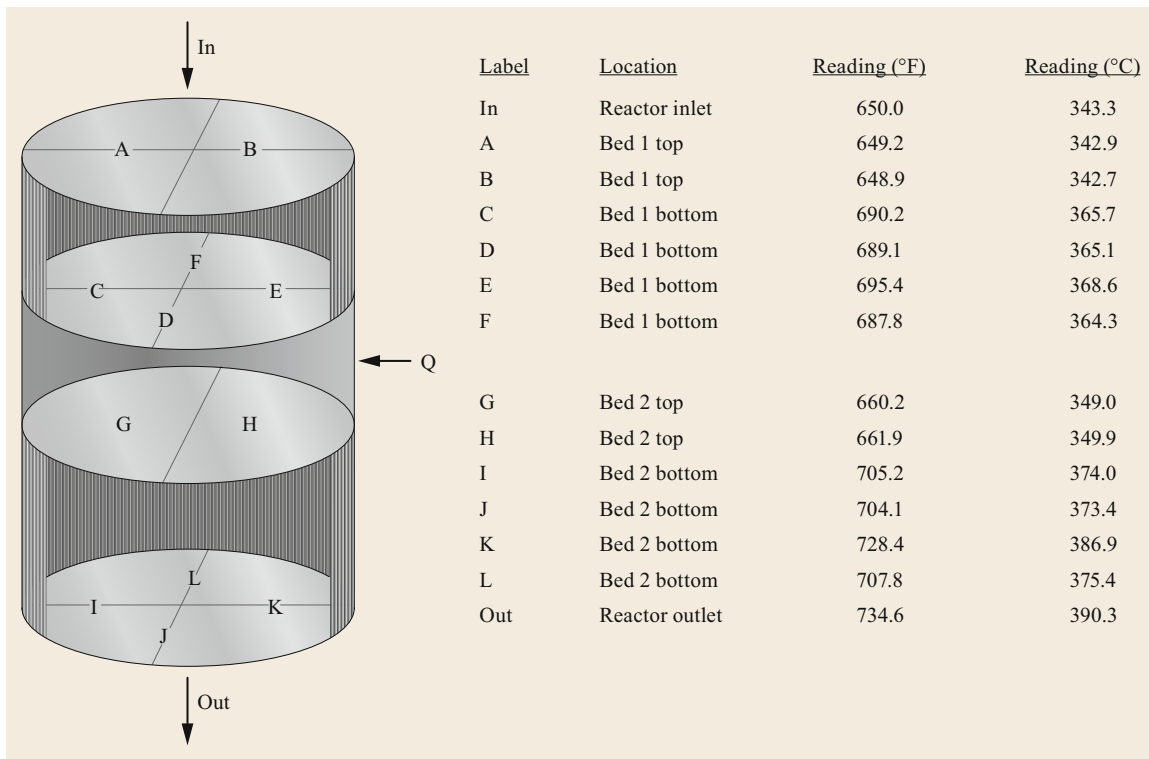

Fig. 22.7 Basis for temperature calculations

ing reactor. There are multiple temperature indicators (TIs) in horizontal planes at the top and bottom of each bed. Differences in coplanar TIs reveal uneven flow of fluids. In the figure:

- The arrows indicate the direction of flow
- Q represents quench gas flow into the deck between the beds; quenching controls the inlet temperature of bed 2
- Bed 1 contains 40% of the active catalyst. Bed 2 contains 60% of the active catalyst.

- (a) *Average bed top temperature* = average of all TI readings in a horizontal plane at the top of a given bed.
- (b) *Average bed bottom temperature* = average of all TI readings at the bottom of a given bed.
- (c) *Catalyst average temperature (CAT)* = average of Calculation (a) and Calculation (b). CAT is specific to units designed and/or licensed by Chevron Lummus Global (CLG).
- (d) *Weighted average bed temperature (WABT)* = $(1/3) \cdot (a) + (2/3) \cdot (b)$. More weight is given to the bed outlet temperature, because temperatures are higher at the outlet and reactions are faster at higher temperatures. The one-third, two-thirds weighting is arbitrary, but it has become a standard and it reflects commercial performance.
- (e) *Bed axial temperature rise (average)* = average T rise = $(b) - (a)$.
- (f) *Bed axial temperature rise (max)* = max T rise = (maximum TI reading at the bed bottom) – (a).
- (g) *Radial temperature difference (radial dT)* = (highest TI reading in a horizontal plane) – (lowest TI reading in the same horizontal plane).

- (h) *Quench temperature difference (quench dT)* = temperature difference across a quench section = $[(b) \text{ for the bed above the quench deck}] - [(a) \text{ for the bed below the quench deck}]$.
- (i) *Temperature gain* (as in a T -pulse test) = change in a TI reading at a bed outlet after a change in the bed inlet temperate, calculated after the bed outlet reaches steady state.
- (j) *Time to steady state* (as in a T -pulse test) = time required for a TI reading at a bed outlet to reach steady state after a change in the bed inlet temperate. UOM is minutes.
- (k) *Reactor axial temperature rise (reactor dT)* = sum of (e) for all beds.
- (l) *Reactor CAT* = $(\text{CAT for Bed 1}) \cdot (\text{fraction of active catalyst in bed 1}) + (\text{CAT for Bed 2}) \cdot (\text{fraction of active catalyst in bed 2}) + (\dots)$.
- (m) *Reactor WABT* = $(\text{WABT for Bed 1}) \cdot (\text{fraction of active catalyst in bed 1}) + (\text{WABT for Bed 2}) \cdot (\text{fraction of active catalyst in bed 2}) + (\dots)$.
- (n) *Required CAT or WABT* = the reactor CAT or reactor WABT required to achieve a specific process target, such as product sulfur, product nitrogen, or conversion.
- (o) *Catalyst deactivation rate* = average rate of change in required CAT or WABT ($^{\circ}\text{F}/\text{month}$).
- (p) *Catalyst cycle life* = length of time between the initial startup after catalyst loading and the final shutdown to remove catalysts.

Table 22.1 presents the results of the calculations just defined, based on the data in Fig. 22.7.

Note: The reactor outlet TI reading is higher than any TI reading inside bed 2. This indicates the presence of a hot spot, a subject discussed in some detail in Sect. 22.12.9.

Table 22.1 Results of calculations based on the data in Fig. 22.7 rounded to the nearest 0.1 degree

No.	Calculation	Bed 1 ($^{\circ}\text{F}$)	Bed 2 ($^{\circ}\text{F}$)	Reactor ($^{\circ}\text{F}$)	Bed 1 ($^{\circ}\text{C}$)	Bed 2 ($^{\circ}\text{C}$)	Reactor ($^{\circ}\text{C}$)

22.4 Hydrotreating Chemical Reactions

Satterfield [22.1], Topsøe et al. [22.2], and Prins [22.3] describe the chemistry of hydrotreating in great depth. In this chapter, we provide an overview.

Hydrocracking breaks C–C bonds, but strictly speaking, hydrotreating does not. Hydrotreating converts compounds containing hetero-atoms into hydrocarbons, plus H₂S, NH₃, H₂O, or adsorbed trace elements. It also saturates olefins and aromatics. Removal of hetero-atoms often requires prior saturation of an aromatic ring followed by hydrogenolysis of the bonds between the heteroatom and one or more carbon atoms. Fixed-bed hydrocracking of polyaromatics also requires prior ring saturation. Hydrotreating reactions fall into six broad categories:

- Saturation of olefins
- Saturation of aromatics
- HDS
- HDN
- HDO
- HDM.

HDS = hydrodesulfurization, HDN = hydrodenitrogenation, HDO = hydrodeoxygenation, and HDM = hydrodemetalation.

Within each category, relative reaction rates depend on process conditions, feed quality, inhibitors, and catalyst type. In practice, it is more meaningful to consider extents of reaction. During the HDS of straight-run gas oil in a representative deep desulfurization unit, most of the light olefins will be gone before the feed has traveled through 10–20% of the active catalyst. Roughly halfway through the catalyst, 70–80% of the total sulfur will be gone. At the reactor outlet, depending on catalyst type, catalyst age, and reaction conditions, the sulfur content will be 15 wppm and the aromatics content will be 50–70% less than the aromatics in the feed. The extent of HDN, relative to HDS, varies with feed types, PH₂ and catalyst loading. Higher pressure and NiMo catalysts favor HDN. At lower pressure, a CoMo catalyst (or alternating layers of NiMo and CoMo catalysts) improves HDS.

22.4.1 Hydrogenation of Olefins

Olefins are rare in straight-run distillates, but they can be produced in atmospheric distillation towers if the towers are too hot. Thermal cracking generates olefins in abundance, even in slurry-phase hydrocrackers where the PH₂ is very high. Hydrogenation of olefins in catalytic hydrotreating and hydrocracking units is rapid,

essentially irreversible at low-to-moderate temperatures and highly exothermic.

Conjugated diolefins can polymerize into gums, which increase pressure drop (dP). The impact of diolefins can be minimized with catalyst activity grading.

22.4.2 Aromatics, Naphthenes, and Naphthoaromatics

The equilibrium between saturated and unsaturated ring compounds (Fig. 22.8) is an important phenomenon in several petroleum refining processes. It is central to catalytic reforming, hydrotreating, and hydrocracking. Equilibrium is destroyed by the breaking or forming of C–C bonds; both are locally irreversible. Saturated C–C bonds can be broken by ring opening. C–C bonds can be formed by the condensation of polyaromatics to form larger polyaromatics.

Fig. 22.8 Examples of saturation reactions of aromatics and polyaromatics

Figure 22.9 summarizes thermodynamic calculations for the competition between the saturation of naphthalene and the condensation of naphthalene with *o*-xylene to form chrysene [22.4]. At low temperatures, the extent of aromatics saturation increases with temperature. As the temperature goes up, saturation becomes more and more difficult. Above about 750 °F (400 °C), raising temperature decreases the extent of

saturation. Hydrogen partial pressure and feed composition determine the temperature range through which this *crossover* phenomenon occurs. At high-enough temperatures, net saturation becomes impossible. At very high temperatures, equilibrium favors condensation, even at very high pressures.

Figure 22.10 shows the so-called zig-zag mechanism for the production of large polyaromatics by

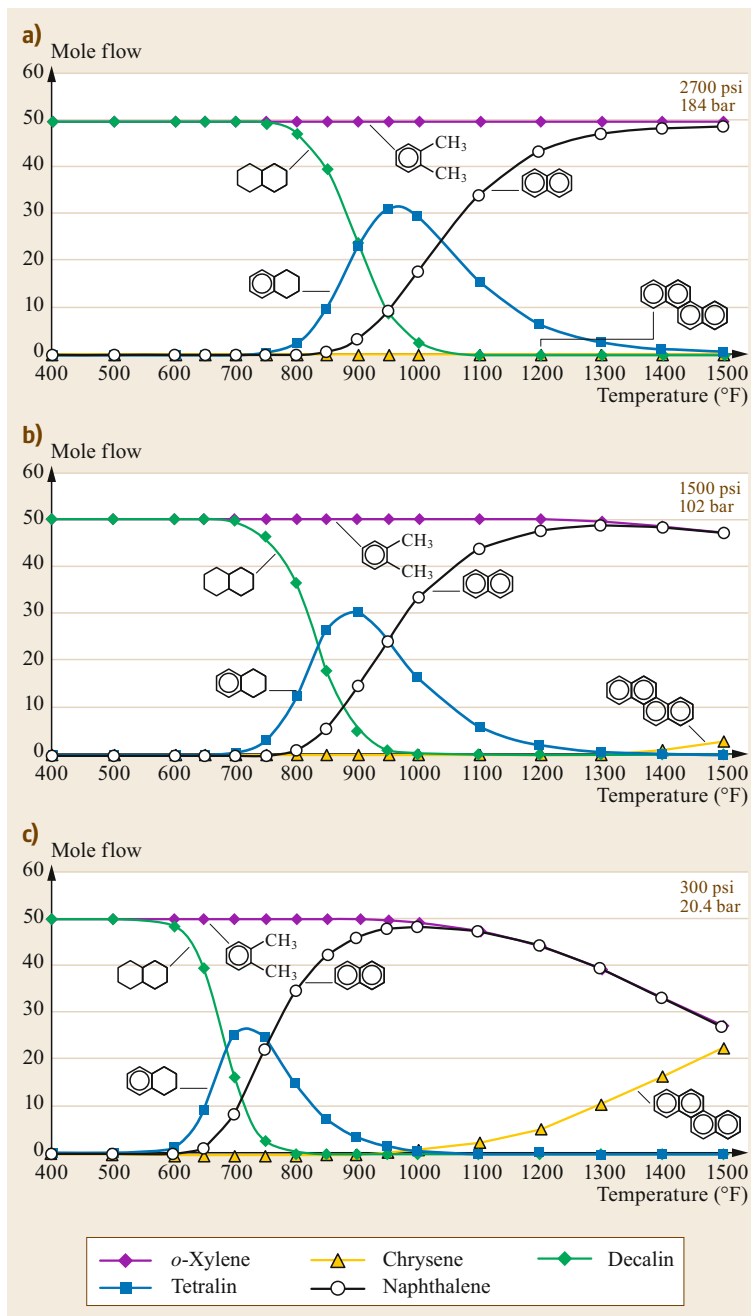

Fig. 22.9 Thermodynamic calculations showing competition between naphthalene saturation and condensation. Data for the graphs were generated by Aspen Plus for a 6-component system comprising naphthalene ($C_{10}H_8$), tetralin ($C_{10}H_{12}$), decalin ($C_{10}H_{18}$), *o*-xylene (C_8H_{10}), chrysene ($C_{18}H_{12}$), and hydrogen (not shown)

adding 2-carbon and 4-carbon species [22.5]. Note how the H/C ratio goes down as condensation increases, from 0.8 for naphthalene to 0.4375 for ovalene. The condensation of large polyaromatics via the Scholl reaction [22.6] can lead eventually to coke formation and coke-induced deactivation of catalysts.

Figure 22.11 shows a proposed mechanism for the one-at-a-time buildup of rings on a nucleus of coke [22.7]. The mechanism includes the following steps:

- Hydrogen abstraction by a radical
- Olefin addition (alkylation) to a radical on the surface
- Cyclization
- Dehydrogenation.

22.4.3 Hydrodesulfurization (HDS)

Figure 22.12 shows representative hydrodesulfurization (HDS) reactions. Per *Topsøe et al.* [22.2, p. 114], HDS

Fig. 22.10 Zig-zag mechanism for the condensation of polyaromatics by sequential addition of 2-carbon and 4-carbon units. Each reaction produces hydrogen. The isomers shown are (A) naphthalene, $C_{10}H_8$; (B) phenanthrene, $C_{14}H_{10}$; (C) pyrene, $C_{16}H_{10}$; (D) benzo[*e*]pyrene, $C_{20}H_{12}$; (E) benzo[*ghi*]perylene, $C_{22}H_{12}$; (F) coronene, $C_{24}H_{12}$; (G) dibenzo[*b,pqr*]perylene, $C_{26}H_{14}$; (H) benzo[*pqr*]naphtho[8,1,2-*bcd*]perylene, $C_{28}H_{14}$; (I) naphtho[2'.8'.2.4]coronene, $C_{30}H_{14}$; and (J) ovalene, $C_{32}H_{14}$

Fig. 22.11 Mechanism for adding rings to an existing layer of coke

rates vary as follows: sulfides \approx mercaptans $>$ thiophenes $>$ benzothiophenes $>$ dibenzothiophenes $>$ substituted dibenzothiophenes. In the figure, for removing sulfur from the first three reactants, the mechanism is straightforward. The sulfur-containing molecule interacts with an active site on the catalyst, which abstracts the sulfur atom. The sulfur-free fragment is hydrogenated and desorbs. The adsorbed sulfur is con-

verted to H_2S , which also desorbs, leaving behind a regenerated active site. The fourth reactant – 4,6-dimethyldibenzothiophene (4,6-DMDBT) – has two methyl groups near the sulfur atom. The reaction proceeds via both a direct and an indirect route. In this case, the indirect route is favored. The 4,6-DMDBT molecule is planar and the two methyl groups block the access of the sulfur atom to the catalyst surface,

Fig. 22.12 Representative hydrodesulfurization (HDS) reactions

Fig. 22.13 Hydrogenation of one of the aromatic rings in 4,6-dimethyldibenzothiophene. Not to scale

thereby inhibiting direct HDS. In the indirect route, one of the aromatic rings flanking the sulfur atom is saturated. Hydrogenation removes resonance stabilization and changes the geometry around the carbon atoms from planar to tetrahedral. This rotates a methyl group away from the sulfur atom, diminishing steric hindrance. Figure 22.13 provides a not-to-scale illustration of this phenomenon.

In ultra-low-sulfur diesel (ULSD), for which the sulfur content is less than 10–15 wppm, the only remaining sulfur compounds after hydroprocessing are alkyl-substituted dibenzothiophenes. Catalysts with an abundance of edges and corners, such as the BRIM products offered by *Haldor Topsøe* [22.8], are good for removing sterically hindered compounds such as these.

Fig. 22.14 Representative hydrodenitrogenation (HDN) reactions

Fig. 22.15 Mechanism for the HDN of quinolone

22.4.4 Hydrodenitrogenation (HDN)

Figure 22.14 shows representative HDN reactions. Relative reaction rates are: amines > pyrroles > pyridines > quinolines > carbazoles. Figure 22.15 presents a simplified version of the Satterfield mechanism for the HDN of quinoline [22.9]. As with sulfur removal from hindered DMBTs, nitrogen removal requires prior saturation of an aromatic ring adjacent to the nitrogen atom.

22.4.5 Hydrodeoxygenation (HDO)

As mentioned, in feeds to industrial hydroprocessing units, oxygen is contained in furans, cresols, phenols, naphthenic acids, other organic acids, ethers, peroxides etc. Peroxides are formed by reaction with air during the transportation and/or storage of crude oil, imported distillates, and refinery intermediate streams. Peroxides induce the formation of flow-inhibiting gums, which cause buildup of pressure drop. For some oxygen compounds, hydrodeoxygenation (HDO) proceeds rapidly, causing excessive heat release. This problem is mitigated by catalyst activity grading. Other oxygen compounds, such as phenols and cresols, are exceedingly difficult to hydrotreat.

22.4.6 Hydrodemetalation (HDM)

Soluble trace metals are removed with special guard materials. For arsenic, high-nickel adsorbents are used. Other contaminants, such as Ni, V and soluble Fe, are removed by hydrodemetalation (HDM) reactions in catalyst pores that are wide enough to admit large molecules, such as the ones in which these metals are found.

22.4.7 Conversion Due to Hydrotreating

In practice, conversion means boiling-point reduction

$$\text{Conversion} = \frac{P}{FF} \cdot 100\%$$

where P = the amount of product and FF = is the amount of fresh feed. Product is defined as the amount of material boiling below a specified distillation cut-point. In *true conversion* calculations, the amount of P in the FF prior to conversion is subtracted from the numerator.

Boiling-point reduction comes from breaking carbon-carbon bonds, but it also comes from heteroatom removal and saturating aromatic rings. Table 22.2 compares normal boiling points for reactant/product

Table 22.2 Impact of sulfur removal and aromatics saturation on normal boiling point. Reactions 6 through 8 are reversible. Temperatures for diesel-range molecules are marked in (), temperatures for naphtha-range molecules are marked in [] and temperatures for residue are marked in {}. Reactions 3, 5, and 8 convert diesel into naphtha. Reaction 6 converts VGO into diesel. Reaction 9 shows that rupturing a decalin C-C bond gives an additional boiling point shift relative to naphthalene (after [22.10, 11]). Some values are estimated by Advanced Chemistry Development (www.acdlabs.com) via [22.10])

	Reaction	Formula	MW	Boiling point		Delta	
				(°C)	(°F)	(°C)	(°F)
1. HDS	Dibenzothiophene, 4,6-dimethyl → benzene, 1-methyl-3-(3-methylcyclohexyl)-	C ₁₄ H ₁₂ S	212.31	(364.9)	(688.8)	–	–
		C ₁₄ H ₂₀	188.31	(273.4)	(524.1)	91.5	164.7
2. HDS	Dibenzothiophene → biphenyl	C ₁₂ H ₈ S	184.26	(332.6)	(630.6)	–	–

		C ₁₈ H ₂₄	240.38	(371.0)	(699.8)	77.0	138.6
7. SAT	Naphthalene ⇌ tetralin	C ₁₀ H ₈	128.17	(216.9)	(422.3)	–	–
				(207.9)	(406.1)	9.0	16.2
8. SAT	Tetralin ⇌ <i>t</i> -decalin	C ₁₀ H ₁₂	132.20	(207.9)	(406.1)	–	–
				[186.9]	[368.3]	21.0	38.7
9. HC	<i>t</i> -Decalin → <i>t</i> -butyl cyclohexane	C ₁₀ H ₁₈	138.25	[186.9]	[368.3]	–	–
		C ₁₀ H ₂₀	140.23	[171.3]	[340.3]	15.6	28.1

sets. The boiling points of the products are lower, in some cases considerably so. For the reactions 1–4 (HDS), reaction 5 (HDN) and reaction 6 (complete saturation of chrysene), boiling point drops are greater than 76 °C (138 °F). Reactions 3, 5, and 8 convert diesel molecules (in ()) into naphtha molecules (in []). Reaction 6 converts a VGO molecule into a diesel molecule.

The hydrogenation reactions are (usually) reversible. Dehydrogenation has the opposite effect –

converting naphtha molecules into diesel and diesel molecules into VGO. Such reactions, which can eventually lead to coke formation, play a significant role in catalyst deactivation [22.4]. Industrial experience shows that for feeds with high aromatics and sulfur, conversion due to hydrotreating reactions can reach 15%. An example is saturating a fraction that is rich in diaromatics, as might come from a coking unit, into a fraction that is rich in alkyl decalins.

22.5 Hydrocracking Chemical Reactions

Van Veen et al. [22.12] and Scherzer and Gruia [22.13] review hydrocracking reaction fundamentals in detail. Highlights from those works and others, are presented in this section.

22.5.1 Conversion by Hydrogen Addition versus H/C Rearrangement

In hydrocrackers, conversion consumes hydrogen during C–C bond cleavage and also during the saturation of aromatics and olefins, including reaction intermediates.

In delayed cokers and FCC units, conversion is due to H/C redistribution. In reactions that form compounds with higher H/C, paraffins are cracked and naphthene rings are opened. The side chains of alkyl aromatics are clipped, generating paraffins and leaving behind methyl-substituted aromatics. Reactions that decrease H/C generate olefins and polyaromatics. Polyaromatics condense, with release of hydrogen, to form larger polyaromatics. Successive condensation reactions eventually lead to coke.

Coke formation also occurs in hydrotreating and hydrocracking, but only to a small degree. This is due to the large excess of hydrogen, which keeps the catalyst surface clean.

22.5.2 Hydrocracking Reaction Sequence

Catalytic hydrocracking does not open aromatic rings, which are stabilized by resonance energy. The rings must be saturated before they can be opened via C–C bond cleavage. The hydrocracking of ring compounds follows the sequence illustrated in Fig. 22.16 for hydrocracking a heptyl ethyl naphthalene isomer:

- Removal of part of a side chain by dealkylation
- Saturation of an aromatic ring
- Isomerization of the saturated ring
- Opening the saturated ring
- Paraffin hydrocracking.

The ring itself remains intact due to resonance stabilization. One-ring aromatics are especially stable. The

Fig. 22.16 Reaction sequence for the hydrocracking of a heptyl ethyl naphthalene isomer

Fig. 22.17 Sequence of reactions for hydrocracking poly-ring compounds. Reactions 1–5 and 8 show saturation. In 2 and 3, saturation is accompanied by ring isomerization. Ring-opening reactions include 6–7 and 9–12. Any of the compounds in 1–11 might undergo dealkylation if R or R' contain four or more carbons. Hydrogen stoichiometry isn't shown

first dealkylation reaction (1) removes hexane isomers through β -cleavage, leaving behind a methyl group still attached to the ring. Rings do not give up methyl and ethyl groups with β -scission during catalytic cracking and catalytic hydrocracking. This is consistent with the observation that acid-catalyzed cracking in hydrocracking and FCC units produces minimal methane and ethane. Hydrogenating aromatic rings (2) removes resonance, yielding a saturated ring which is susceptible to ring opening (3). Ring opening is followed by another dealkylation reaction (4) and paraffins are hydrocracked (5).

In Sect. 22.8, we discuss how reaction rates in the absence of external inhibitors depend on a molecule's affinity to adsorb to the catalyst surface. According to *Scherzer and Gruia* [22.13, p. 190], adsorption affinity decreases as follows: heteroaromatics > polyring aromatics > monoaromatics > polyring naphthenes > mononaphthenes > paraffins. Larger molecules adsorb more strongly. But more than adsorption is involved.

Fig. 22.18 Brønsted (B) and Lewis acid sites (L) in zeolites and amorphous silica–aluminas. Brønsted sites donate a proton (H^+). Lewis sites remove a hydride ion (H^-)

Dealkylation of adsorbed polyaromatics is quite facile, but the rings themselves do not react, not until they are saturated. The net effect on the relative reaction rates for hydrocarbon molecules with similar carbon numbers is as follows: dealkylation > ring opening > paraffin hydrocracking.

Figure 22.17 gives a more general illustration of ring hydrocracking [22.14]. The figure shows ring carbons only, except for methyl groups associated with isomerization of 6-carbon saturated rings into 5-carbon saturated rings. Hydrogen is consumed in each reaction, but the stoichiometry isn't shown. Reactions 1–5 and 8 show saturation. In 2 and 3, saturation is accompanied by ring isomerization. Ring-opening reactions include 6–7 and 9–12. Any of the compounds in 1–11 might undergo dealkylation if R or R' contain four or more carbons.

Catalytic cleavage of C–C bonds requires powerful acids. Hydrocracking catalysts are bifunctional, with both acid and metal sites. The metal sites catalyze both saturation and dehydrogenation. It is important to achieve a proper balance between cracking and hydrogenation activity. For a given conversion target, too much hydrogenation activity suppresses olefin intermediates, thereby suppressing the extent of cracking. With too little hydrogenation activity, over-cracking occurs.

In commercial catalysts, hydrogenation is catalyzed by noble metals (widely dispersed palladium metal) or non-noble metal sulfides (nickel-promoted MoS₂ or

Fig. 22.19 Carbocation mechanism for hydrocracking: Initiation reactions. Reaction 4 gives three products, which are in equilibrium

WS₂). The acidity comes from zeolites and/or amorphous silica-alumina (ASA). Zeolites occur naturally, but the ones used for catalysis are synthetic. Zeolites serve as drying agents, ion-exchangers, and molecular sieves for gas separation. Their microporosity provides them with high surface area, a highly desirable characteristic.

Figure 22.18 shows how one can visualize acid sites as part of a silica (SiO₂) superstructure, in which every so often an aluminum atom replaces a silicon atom [22.15]. The silicon atoms have a valence of +4 and

each one binds to four oxygen atoms. Replacing Si (+4) with Al (+3) creates Lewis acid sites. Hydration generates hydroxyl groups, which are Brønsted acids (proton donors). Counter ions can be swapped via ion exchange. For example, when Na-Y zeolite is exchanged with an ammonium salt, the Na⁺ ion is replaced by NH₄⁺. When NH₄-Y is heated to the right temperature, the ammonium ion decomposes, releasing NH₃ (gas) and leaving behind highly acidic H-Y zeolite.

The relative acidity of zeolites depends on their Si/Al ratio (SAR). The SAR for a zeolite with high

Fig. 22.20 Carbocation mechanism for hydrocracking: Hydride shift and skeletal isomerization

Fig. 22.21 Carbocation mechanism for hydrocracking: β -scission and hydrogen transfer. Scission occurs two carbons away from the positively charged carbon (C⁺), because scission beside the C⁺ would entail going from a relatively stable 3° or 2° carbocation to a less stable 1° carbocation

cracking activity can be < 10 . In hydrocracking catalysts with less activity but greater selectivity for production of middle distillates, the SAR might be > 100 .

Figures 22.19–22.22 illustrate the carbocation mechanism of catalytic hydrocracking at a more fundamental level [22.16]:

- Figure 22.19 shows how carbocations are formed, starting with generating an olefin by reversible dehydrogenation (reactions 1 and 3), forming a carbocation by proton addition at a Brønsted acid site (reactions 2 and 4), and hydride (H^-) abstraction at a Lewis acid site (reaction 5). Reaction 4 gives three products, which are in equilibrium.
- Figure 22.20 illustrates hydrogen shift and skeletal isomerization (alkyl shift) steps, which are driven by the relative stability of carbocations: $3^\circ > 2^\circ > 1^\circ$. In reaction 4, there are three canonical forms for the alkylcyclohexenyl cation.
- In Figure 22.21, we see cracking via β -scission, which means that scission occurs two carbons away from the positively charged carbon (C^+). Scission beside the C^+ does not occur, because it would entail going from a relatively stable 3° or 2° carbocation to a less stable 1° carbocation.
- Figure 22.22 shows how addition reactions generate larger molecules, including polyaromatics, which can condense to form coke. Such reactions are suppressed in hydrogen-rich environments, (i. e., in hydroprocessing units), but they become more significant at high temperatures, where olefins and especially aromatics are more thermochemically stable.

Fig. 22.22 Carbocation mechanism for hydrocracking: Ring formation and ring growth

22.6 Hydroprocessing Catalysts

22.6.1 Hydroprocessing Catalyst Overview

In fixed-bed hydroprocessing units, catalysts must be able to drive the desired reactions, and they also must possess a high surface area and great physical strength, enough strength to resist crushing under the forces imposed by rapidly flowing high-pressure fluids and the weight of the catalyst itself. A single bed can contain more than a hundred tons of catalyst.

Chemical reactions take place inside small pores, which account for almost all of the catalyst surface area. In hydrotreating catalysts, average pore diameters range from 75 to 85 Å for catalysts that process light and heavy gas oils. For catalysts that process residue, the average pore diameters range from 150 to 250 Å.

Catalyst Composition and Activation (Sulfiding)

Commercial hydrotreating catalysts comprise sulfides of either Mo or W promoted by Co or Ni on a support such as γ -alumina (Table 22.3). In a few tri-metallic catalysts, both Ni and Co are included. The Mo content ranges from about 16 to 24 wt% as the trioxide and the Ni or Co content ranges from 2.0 to 4.5 wt% as the oxides.

With noteworthy exceptions, the oxides are activated after loading by reductive sulfidation. (The exceptions include the use of Eurecat's Totsucat technology [22.17], which activates catalysts prior to delivery).

Nebula catalyst was jointly discovered and developed by ExxonMobil and Albemarle. Nebula is supported by base-metal oxides. Overall, it possesses higher activity than alumina-supported hydrotreating catalysts. It is especially good for HDN and saturation of aromatics [22.18].

Table 22.3 Supports used in hydroprocessing catalysts

Support	Major use	Acidity
γ -Alumina	Hydrotreating catalysts	Low
Amorphous aluminosilicates	Distillate-selective hydrocracking catalysts	High
Zeolites (H-Y and others)	High-activity hydrocracking catalysts	Very high

Table 22.4 Active metals used in hydroprocessing catalysts

Metals	Major use	Activation method	Hydrogenation activity
CoMo	HDS	Sulfiding	Moderate
NiMo	HDN, hydrocracking	Sulfiding	High
NiW	HDN, hydrocracking	Sulfiding	Higher
Pd, Pt ^a	Hydrocracking	Reduction by H ₂	Highest

^a Pd and Pt are poisoned by sulfur and are used in low-H₂S environments

Table 22.4 lists the active metals in hydrocracking catalysts. As with hydrotreating catalysts, hydrocracking catalysts are delivered as low-activity oxides and activated after loading. PdO is activated via reduction by hydrogen to the metal, and oxides of Ni, Mo and W are activated by reductive sulfidation.

Shown below are sulfiding chemical reactions. Reaction 5 shows the reductive decomposition of dimethyl disulfide (DMDS), which is the most common sulfiding agent. The exact compositions of the cobalt and nickel sulfides are not well established, but the reactions shown below are consistent with sulfur uptake [22.19]:

- $\text{MoO}_3 + 2\text{H}_2\text{S} + \text{H}_2 \rightarrow \text{MoS}_2 + 3\text{H}_2\text{O} + \text{heat}$
- $\text{WO}_3 + 2\text{H}_2\text{S} + \text{H}_2 \rightarrow \text{WS}_2 + 3\text{H}_2\text{O} + \text{heat}$
- $3\text{NiO} + 2\text{H}_2\text{S} + \text{H}_2 \rightarrow \text{Ni}_3\text{S}_2 + 3\text{H}_2\text{O} + \text{heat}$
- $9\text{CoO} + 8\text{H}_2\text{S} + \text{H}_2 \rightarrow \text{Co}_9\text{S}_8 + 9\text{H}_2\text{O} + \text{heat}$
- $\text{H}_3\text{C}-\text{S}-\text{S}-\text{CH}_3 + 3\text{H}_2 \rightarrow 2\text{H}_2\text{S} + 2\text{CH}_4 + \text{heat}$

Note that reactions 1 to 4 consume H₂ and H₂S, produce water, and generate heat. Reaction 5 consumes H₂ and produces methane and heat. The progress of sulfiding is monitored by observing these variables or the consequences thereof.

ASA Versus Zeolite

Figure 22.23 shows six zeolite structures [22.20]. In cracking catalysts, H-Y zeolite is the most common, but beta and ZSM-5 are used as well. ZSM-5 is a shape-selective zeolite made by including a soluble organic template in the mix of raw materials. Templates for this kind of synthesis are quaternary ammonium salts. ZSM-5 enhances distillate yields in FCC units. In hydroprocessing units, because of its unique pore structure, it selectively cracks waxy *n*-paraffins.

Related materials are used in other processes. For example, metal-promoted silica alumina phosphates such as SAPO-11 are used to isomerize normal paraffins in catalytic dewaxing units.

Figure 22.24 provides a conceptual comparison of amorphous ASA catalysts with crystalline zeolite catalysts. The pore diameters of H-Y zeolite catalysts are uniform and relatively small – around 7.5 Å, give or

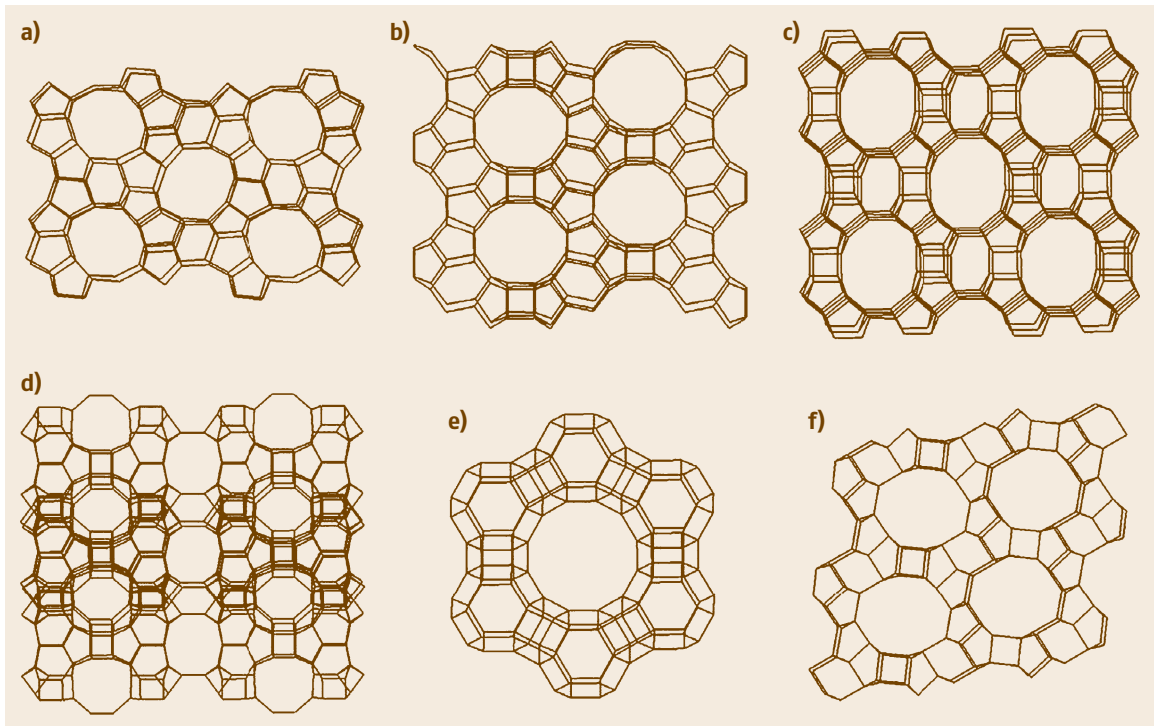

Fig. 22.23a–f Structures of zeolites ZSM-5 (a), mordenite (b), beta (c), MCM-22 (d), zeolite Y (e) and zeolite L (f)

Fig. 22.24 Schematic comparison of amorphous alumina silica (ASA) and zeolite structures. ASA structure courtesy of Yabuki et al. [22.21]. Used with permission

take. The pore diameter for ZSM-5 is 6.3 Å. The mesopores of zeolites have larger diameters, which admit mid-sized molecules such as those found in vacuum gas oils.

ASA catalysts include small, medium, and large pores. The width of ASA pores can exceed 100 Å.

This explains why ASA catalysts do a better job of cracking feeds with higher endpoints. The larger pores can accommodate larger molecules. Recently, Chevron patented a method for making highly homogeneous ASA catalysts, which provide significantly better middle-distillate selectivity [22.22].

22.6.2 Catalyst Preparation

The following steps may be involved in preparing supported metal catalysts for fixed-bed hydrotreaters and hydrocrackers [22.23]:

- Precipitation
- Filtration (or centrifugation), washing, and drying

- Forming
- Calcining
- Comulling or impregnation
- Drying and final calcining.

For some catalysts, one or more of the above-listed steps are eliminated or additional steps are added. Figure 22.25 outlines possible procedures for synthesiz-

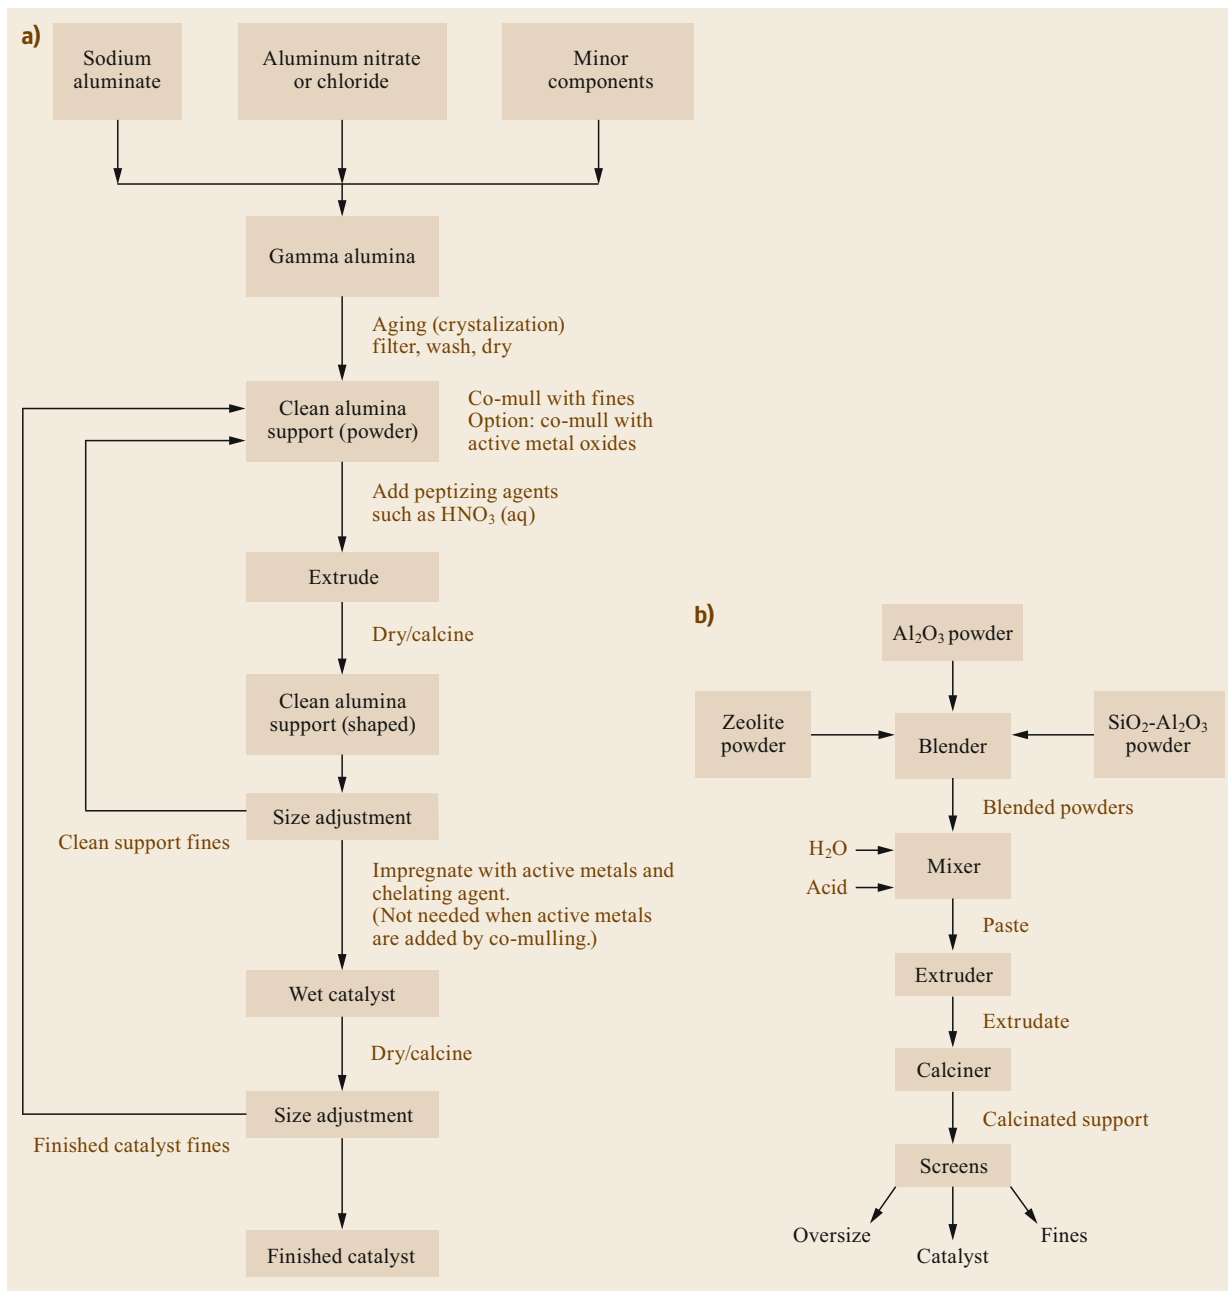

Fig. 22.25 (a) A synthesis procedure for hydrotreating catalysts. (b) A synthesis procedure for zeolite-containing hydrocracking catalysts

ing hydrotreating and hydrocracking catalysts, respectively.

Precipitation

The preferred alumina for hydrotreating catalyst supports is γ -alumina. In its final form, γ -alumina has a high surface area, great physical strength, and a well-defined pore size distribution. Its synthesis begins with mixing an aqueous solution of aluminum nitrate, $\text{Al}(\text{NO}_3)_3$, with sodium aluminate, $\text{Na}_2\text{Al}_2\text{O}_4$, to form aluminum hydroxide, $\text{Al}(\text{OH})_3$ and sodium nitrate. The $\text{Al}(\text{OH})_3$ forms a microcrystalline gelatinous solid. As the gel ages, crystals grow larger and the pore structure develops. Crystals are collected by filtration or centrifugation, then washed and dried.

Synthetic zeolites are prepared by precipitation from amorphous silica, sodium aluminate, and sodium hydroxide. The addition of seed crystals to the gel ensures that the right zeolite is formed and speeds up crystallization. The resulting Na-Y zeolite is exchanged with an ammonium salt to replace Na^+ with NH_4^+ . When $\text{NH}_4\text{-Y}$ is heated to the right temperature, the ammonium ion decomposes, releasing $\text{NH}_3(\text{gas})$ and leaving behind highly acid H-Y zeolite.

Filtration, Washing, and Drying

Filtration and washing removes undesired impurities. Subsequent air- and oven-drying removes most of the water and other volatile material. Washing requires tremendous amounts of water, because the finished product must be essentially sodium-free. Water treatment facilities can be costly to build and operate in locales with tight environmental regulations. Nearby chemical plants can accept offgases and waste water from catalyst plants and convert them into sales quality chemicals, such as nitric acid, sodium nitrate, and others.

Forming

Catalyst supports can be formed into pellets, powders, spheres, cylinders, hollow cylinders, shaped extrudates, and other forms. To make extrudates, pastes are formed from powders by mixing them with acids and solvents. The powders are either pure supports or supports commulled with active metal oxides. The pastes are forced through a die, from which they emerge as long strands that resemble spaghetti, but with a cross-sectional shape that resembles a 3-leaf or 4-leaf clover. The resulting spaghetti-like strands are dried and broken into short pieces with length-diameter ratios (L-D) ranging from 2 to 20. Screening rejects the longs and shorts, leaving behind material with L-Ds between 3 and 6. The long and short are returned to a previous step. The extrusion pressure, the acid strength, and the choice of

solvent affect the catalyst surface area and average pore size.

Multilobe extrudates have a higher surface-to-volume ratio than cylindrical extrudates and the average distance from the surface to the center of a particle is substantially shorter. If all else is constant, multilobe catalysts can be 40% more active than cylindrical. *Topsoe* et al. [22.2, p.23] present a description of the impact of shape on catalyst activity, pressure drop, and diffusional restrictions.

Figure 22.26 shows some common shapes for catalysts and supports. The shaped extrudate in the figure is a trilobe. Extrudate diameters range from 1.3 to 6 mm (1/20–1/4 in). For hydrocracking catalysts, Criterion Catalysts and Technologies offers a modified trilobe that gives lower pressure drop. Diameters for pellets, such as the wagon wheel shown in the figure, tend to be larger – up to 25 mm (1 in). Diameters for spherical silica support balls range from 3 to 25 mm (1/8–1 in).

Fine powders are made by spray-drying. To produce spherical catalysts, liquids are sprayed onto powders in a tilted rotating pan, or slurries are dripped into hot oil. Pellets, medallions, bow ties etc. are made by extrusion or by compressing powders in a dye.

Sizing

Figure 22.25 (above) identifies two size-adjustment steps. Sizing is a key step. High pressure drop results from loading shaped extrudates with a wide range of L-Ds.

Calcining

Calcination decomposes any remaining ammonium and nitrate. It also hardens the particles and increases surface area. If the calcination temperature gets too high, γ -alumina transforms into α -alumina or β -

Fig. 22.26 Common shapes for supports and catalysts. NiMo catalysts are light green, while CoMo catalysts are deep blue

alumina, for which physical properties are far less desirable; specifically, the surface area is significantly lower.

Impregnation

During impregnation, the pores of a calcined support are filled with a metal-containing solution. Pores in the support suck up the solution with capillary action. In the *incipient wetness* method, precise amounts of solution are added – just enough to leave the support dry to the touch. After a drying step, the nascent catalyst may

be treated with more solution to increase metals loading.

During dip impregnation, supports are soaked in a solution of metal salts for several minutes.

Comulling

Catalysts can be made by comulling metal oxides with the support prior to extrusion. Comulling costs less because it requires fewer steps. The method provides formulation flexibility, because it is not limited by the solubility of metal salts.

22.7 Catalyst Cycles

Catalysts in fixed-bed process units, including hydrotreaters and hydrocrackers, do not last forever. Over time, because of feed contamination, routine coking and process upsets, the catalysts lose activity. In hydrotreaters and hydrocrackers, temperatures are increased to compensate for activity loss. When the required catalyst temperature nears the safe maximum, refiners can shut the unit down and change the catalyst during a so-called turnaround. In some cases they elect to extend a run for a short time by lowering the feed rate, switching to easier feeds and decreasing conversion. But at some point, a turnaround becomes necessary.

A planned turnaround seldom includes just one single unit. At a refinery in Louisiana, turning around the hydrocracking unit (HCU) affects at least seven other units. Liquid feed to the HCU comes from the vacuum distillation unit (VDU) and the delayed coking unit (DCU). The HCU takes hydrogen from a catalytic reforming unit (CRU), the onsite steam-methane reformer (SMR), and an offsite supplier. Light naphtha from the HCU goes through a sulfur absorber to the gasoline blending pool. The heavy naphtha goes to the CRU. The HCU unconverted oil goes to the FCC unit.

Before a planned turnaround, measures are taken to minimize business disruption. Inside the plant, operators build inventories of intermediate streams, such as heavy naphtha for the CRU and hydrotreated VGO for the FCC. Product storage tanks are filled. In some cases, exchange contracts are executed with other companies; the refinery arranges to purchase products from another plant to meet its sales commitments. If revamps or new construction are planned to coincide with the turnaround, equipment must be onsite and ready to install. Orders are placed for catalysts and chemicals. Arrangements are made to accommodate the hundreds of contract personnel who will be doing most of the work.

During a planned turnaround, spent catalysts are unloaded and shipped offsite for regeneration or dis-

posal. Reactors and other equipment are inspected and serviced. Maintenance work is performed. Piping and other connections are made between new and existing equipment. In hydrotreaters and hydrocrackers, catalysts are loaded and activated, which may require large amounts of chemicals such as ammonia or dimethyl disulfide.

An unplanned HCU shutdown often costs several times more than a planned turnaround. The impact on other units is sudden and unexpected. It is relatively easy to put an SMR into hot standby, but units that normally get feed from the HCU may have to shut down or limp along at half rate for weeks. The refiner might have to delay or default on commitments to customers. Weeks can be lost waiting for catalysts, chemicals, and maintenance teams. In a recent instance, an emergency shutdown lasted 28 days. Lost HCU production amounted to \$1 million per day. Throughout the refinery, business interruption losses were even greater.

22.7.1 Catalyst Cycle Life

In turnaround planning, predicting catalyst cycle life is crucial. Cycles can be as short as 12 months and we have seen a few that lasted > 40 months. Two-year cycles are typical.

At the start of a cycle, average reactor temperatures are low – about 315–360 °C (600–680 °F). As the cycle proceeds, the catalyst deactivates and refiners must raise temperatures to maintain product qualities or conversion.

A catalyst cycle is terminated for one or more of the following reasons:

1. *Planned shutdown.*
2. *Temperature limits:* To ensure safe operation, licensors specify limits on average reactor temperature, maximum peak temperature, and maximum bed temperature rise. *Note:* For high-zeolite catalysts,

typical values are 415 °C (780 °F) (max average) and 427 °C (800 °F) (max peak). For less-active catalysts, the limits may be higher: 427 °C (800 °F) (max average) and 440 °C (825 °F) (max peak). As hydrocrackers approach these limits, process economics may suffer. High temperatures increase yields of low-value C₁–C₄ and light naphtha. Middle distillate quality suffers from high aromatics, which decrease smoke point and cetane. Units approach temperature limits gradually, so usually there is ample warning that end-of-run is approaching. Possible responses are to extend the cycle by operating at reduced feed rate or with an easier feedstock, or change the turnaround schedule.

3. **Excessive dP:** The overall pressure drop (dP) in a hydroprocessing unit is the difference in pressure between the recycle compressor suction and the recycle compressor discharge. It includes dP through high-pressure pipes and heat exchangers. At start-of-run (SOR), the dP across the reactor is low – 3–10 psi (0.2–0.7 bar) for each bed. As a run proceeds, dP across the catalyst increases. If the dP exceeds the design limit, little can be done to keep the unit running without damaging reactor internals. Most often, dP and dP+ are greatest in the first catalyst bed, which is most susceptible to fouling by trace metals, particulates, and gum formation. But we have seen instances where, due to a combination of high operating temperature and hydrogen starvation, the dP in the last bed of a hydrotreating reactor was higher than the dP in the top bed. Hydrogen starvation occurs when the hydrogen–oil (H₂OR) ratio is too low – less than about 1000 scf/bbl (175 Nm³/m³) in a hydrotreating bed and less than about 5000 scf/bbl (875 Nm³/m³) in a hydrocracking bed. A related parameter is hydrogen availability – the ratio of circulating hydrogen to hydrogen consumption. Guidelines for hydrogen availability vary from source to source, but typical recommendations are > 3 for hydrotreaters processing straight-run feedstocks and > 5 for hydrocrackers and hydrotreaters processing reactive feedstocks. While it's possible to operate at lower H₂OR, minor process upsets, including small changes in feed quality, have a larger impact. The flow distribution degrades and coke formation increases.
4. **Process upset:** Upsets include equipment failure, power failure, and sudden changes in feed quality. For a fixed-bed VGO hydrotreater, a *burp* in an upstream VDU can send a slug of residue to the unit, fouling it with particulates, asphaltenes, and/or refractory carbon. This can poison large amounts of catalyst or increase dP beyond the design limit. If the fouling is confined to the top few feet of the first

catalyst bed, the ruined catalyst can be vacuumed out and replaced within a week or so. With modern instrumentation, diligent process monitoring and proactive maintenance, most equipment problems can be detected before a failure occurs.

5. **Emergency shutdown of a related unit:** Related units include upstream hydrogen sources, sources of liquid feed, downstream units for which the hydroprocessing unit supplies feed and refinery utilities. Hydroprocessing units which get feed from intermediate tankage might be able to keep running despite temporary feed disruptions. Hydroprocessing products can be traded if they can't be used in the usual way. If hydrogen supply is reduced or lost, it may be possible to operate briefly in standby mode, by continuing to run the recycle gas compressor and lowering temperatures to reduce conversion.

Process variables with significant impact on catalyst deactivation are shown in Table 22.5.

Hydrogen keeps catalysts clean by inhibiting coke formation. This explains why increasing the hydrogen partial pressure decreases the rate of catalyst deactivation. Raising the temperature increases the rates of most hydrocracking reactions, including coke formation. Raising the H₂OR increases heat removal, which limits temperature rise. If the feed rate goes up and targets for HDS, HDN, or conversion remain the same, the temperature must go up. If the feed rate goes up and the temperature does not, then HDS, HDN, or conversion

Table 22.5 Factors affecting catalyst cycle life

	Impact	Comment
Higher H ₂ partial pressure	+	
Higher recycle gas rate	+	Increases H ₂ partial pressure
Higher makeup gas purity	+	Increases H ₂ partial pressure
Increased purge of recycle gas	+	Increases H ₂ partial pressure
Higher fresh feed rate	–	
Higher conversion	–	
Higher fresh feed endpoint	–	Increases catalyst coking. Also can increase dP and dP+
Higher fresh feed impurities ^a	–	Related to feed type and feed endpoint
Process upsets ^b	–	

^a For cycle life, the worst feed impurities are refractory carbon, asphaltenes, trace elements and particulate matter (coke fines, FCC catalyst fines)

^b Process upsets include *burps* in upstream units that feed the hydrocracker, equipment failures, or temperature excursions requiring depressuring

will decrease. Increasing the feed endpoint and/or density tends to increase the amount of coke precursors in the feed. The precursors include asphaltenes, refractory carbon, and poly-ring compounds.

An important aspect of turnaround planning is projecting catalyst life for fixed-bed process units. For decades, refiners have accomplished such projections with average catalyst temperature calculations, such as CAT and WABT.

22.7.2 Catalyst Selection and Loading

Designing catalyst loading schemes for a fixed-bed hydroprocessing unit is more sophisticated than ever. In the 1970s, refiners tended to use one main catalyst in each bed, supported by inert ceramic balls at the bottom and held down by a thin layer of inert balls at the top. A bed might contain a layer of regenerated catalyst or left-over catalyst from the warehouse. So-called trash baskets were embedded at the top to catch particulates. Post-treat catalyst was loaded at the bottom of the last hydrocracking bed to remove light mercaptans.

The historical approach to hydrotreating catalyst selection was to use CoMo catalysts for HDS and NiMo catalysts for HDN. NiMo catalysts were also preferred for saturation of aromatics.

Today, suppliers offer arsenals of guard materials that improve removal of particulates and capture specific contaminants. Figure 22.27 shows an example. Five layers of inerts and catalysts protect the main catalysts from particulates, soluble contaminants, and products of unwanted reactions. The top layer is comprised of inert particles with considerable void volume. It filters out large particulates, allowing smaller particles into the second layer. Second-layer particles are smaller, have a different shape and possess a bit of activity. The low activity removes peroxides and diolefins gradually with low gum formation. Layers may be contaminant-specific. Special high-nickel catalysts remove arsenic. Wide-pore catalysts remove Ni, V, and CCR. High-surface-area catalysts remove Si. Successive layers contain smaller and smaller particles with higher and higher activity.

It is common to see two or more main catalysts in a diesel hydrotreater. An effective configuration is a sandwich – CoMo/NiMo/CoMo. The top CoMo layer takes out easy sulfur without excessive heat release from aromatics saturation. The NiMo then provides saturation, which is a prerequisite for deep HDS. The bottom CoMo layer completes the job.

The main job of the pretreat section in a hydrocracker is nitrogen removal. Section 22.4.4 explains why saturation of aromatics is important for HDN. Pretreat

Fig. 22.27 Catalyst grading scheme for the first bed of a fixed-bed catalytic hydrotreater (courtesy of Haldor Topsøe A/S)

process conditions are catalysts are selected according to process objectives. The PH₂ is relatively high – with few exceptions it is greater than 1400 psi (95 bar) – the main catalyst is NiMo. Criterion used to recommend a low-activity hydrocracking catalyst for the bottom of pretreat sections, purportedly to enhance HDN by opening saturated rings. CLG offers hydrotreating catalysts into which cracking activity can be added as needed.

Options for hydrocracking catalysts have also expanded. Today's catalysts might contain both ASA and Y zeolite, SAPO and a dewaxing component. Non-noble active metals can be NiMo or NiW.

To get the best from any vendor, a customer must develop clear objectives and explain them clearly. It is important to know the following:

- *Operating conditions and constraints:* Expected feed rate, feed rate limitations, mechanical pressure,

hydrogen availability, hydrogen composition, temperature limitations

- *Physical and chemical properties for each feedstock:* Density, distillation, sulfur, nitrogen, oxygen, aromatics, carbon residue (CCR), trace contaminants
- *Product objectives:* Maximum diesel, maximum naphtha, maximum conversion etc.
- *Desired flexibility:* For seasonal changes, batch operation etc.
- *Information from previous catalyst cycles*
- *Product property specifications.*

Arguably, the last two points are the most important. If pressure-drop buildup (dP+) has always limited catalyst cycles, it is more important to mitigate dP+ than to maximize catalyst activity. When asked for product property requirements for a particular unit, an engineer might say, for example, *maximize Euro 5 diesel*. This is an easy answer to give, but it may not be the best. On the one hand, with a moderate-activity diesel-selective catalyst, it may not be feasible to convert high-density FCC heavy cycle oil into low-density Euro 5 diesel at full feed rate. On the other hand, with a higher-activity catalyst, it might be possible to meet the density spec., but diesel yields would suffer due to over-conversion. Refinery products are blends of streams from several sources. Not all streams must meet every specification. If the hydrocracker product meets all specifications but density with a diesel-selective catalyst, the engineer should consider a density deviation, which would increase hydrocracker diesel yields and maximize Euro 5 diesel for the entire refinery.

Poor catalyst loading limits the capability of any fixed-bed process unit. In hydroprocessing, loading affects flow distribution, dP, and dP+. Uneven flow distribution shortens catalyst life and can degrade product quality. Poor distribution can create hot spots, which have caused temperature excursions and loss of containment.

Cylindrical catalysts and shaped extrudates can be loaded in one of two ways – sock loading and dense loading. A chapter by A. Gruia describes the two and provides a useful comparison [22.24]. In either case, to ensure that loading is safe and goes according to plan, considerable pre-work is required. A simple but important task is to mark desired loading heights on the inside reactor wall. When the catalyst reaches a loading mark, the loading is paused, either to measure level, measure the loaded density, or switch to a different catalyst. The loading is then resumed.

In sock loading, a canvas sleeve conveys the catalyst from a funnel at the top of the reactor down to the loading point. At the loading point, a worker moves the sock

around to distribute the catalyst as evenly as s/he can. The worker must wear a harness, carry a supply of fresh air for breathing and should (but doesn't always) wear weight-distribution shoes (snow shoes) to minimize catalyst crushing. The orientation of sock-loaded particles is random – horizontal, vertical and in between – leaving a lot of void space. During subsequent operations, under pressure from considerable mass flux, the bed settles and the void space shrinks.

In dense loading, a special device lines up the catalyst particles as they fall, either freely or propelled by air or nitrogen. The particles land with a much more uniform orientation [22.25]. One can visualize the difference between dense and sock loading by comparing a new box of toothpicks, in which all the toothpicks are lined up in parallel, versus the pile created by spilling the toothpicks into a tall jar. Dense loading can increase the amount of catalyst in a bed by up to 17%. It can improve flow distribution during operation. Arguably, dense loading leads to safer operation, because generally it is more uniform and less likely to create maldistribution of flow. It doesn't require a person inside the reactor to level the catalyst periodically with a rake or broom. Dense loading does increase SOR dP, so despite the many advantages of dense loading, several customers sock-load reactors in which they have experienced cycle-limiting dP+ in previous cycles.

Support balls and top-of-bed grading are sock loaded. Experience shows that good sock loading can be better than poor dense loading, which can be very bad indeed. If dense-loaded catalyst is uniformly bowed or domed, flow distribution will be poor during subsequent operation. Poor distribution only gets worse as catalyst cycle proceeds.

22.7.3 Activation of Non-Noble-Metal Catalysts in Fixed-Bed Units

Chapter 2 shows that an inordinately large percentage of accidents occur during maintenance shutdowns. Why? Because turnarounds are infrequent, occurring during a month or two every two or three years. Engineering managers assign inexperienced engineers to lead the effort. Under relentless pressure from executive management, planning managers push hard to cut maintenance, purchase cheap materials and substandard equipment. Staffing plans are inadequate, prepared without accounting for delays, which are inevitable when planning is done by poorly managed people.

In this section, we discuss some tricks of the startup trade, tricks which might be useful to the inexperienced. Our information is general. For specific catalysts in specific units, it is best to follow the guidance of your licenser or catalyst vendor.

Throughout the startup of a hydroprocessing unit, the makeup and recycle gas compressors are critical. Operators should monitor compressor vibration and power consumption. *High amps* correspond to high recycle-gas molecular weight. The molecular weight can be reduced by purging recycle gas.

Sulfiding is conducted either by dry or wet procedures. In dry sulfiding, no oil is added until sulfiding is complete. In wet sulfiding, oil is flushed through the catalyst before sulfiding begins. Because of heat of adsorption, wetting the catalyst with oil generates exotherms; we have seen wetting-induced temperature rises of 55 °C (130 °F). Fortunately, wetting is a one-time physical process, not an ongoing chemical reaction. The temperature drops within minutes after the heat wave passes.

Many modern hydrotreating catalysts require wet sulfiding. As delivered, these *type II* catalysts contain organometallic compounds, which encourage the stacking of MoS₂ slabs on the catalyst during activation. The slabs are stabilized by startup oil. After wetting, the catalyst temperature is raised to just above the decomposition temperature of the sulfiding agent, which is > 205 °C for DMDS (dimethyl disulfide). DMDS is injected at a rate determined by observations, primarily temperature rise. Injection continues at 205–210 °C (400–420 °F) until breakthrough – the point at which significant amounts of H₂S appear in the recycle gas. After a hold, during which breakthrough is verified, the heating resumes until the catalyst temperature reaches the target specified by the supplier, somewhere between 330 and 345 °C (625–650 °F). Sulfiding is done when the catalyst stops consuming H₂S.

During *dry sulfiding*, a mixture containing 0.5–2 vol.% H₂S in hydrogen is circulated through the catalyst. The temperature is increased slowly to the temperature at which the unit is expected to operate. The process continues until the exit gas contains the same amount of H₂S as the inlet gas. During dry sulfiding, no liquid is present to soak up reaction heat. Consequently, controlling exotherms can be quite a challenge.

Preactivated catalysts [22.26] are available for a small surcharge. Using such catalysts can shorten a startup by a day or so. The biggest advantage is a decrease in nuisance. The smell associated with sulfiding agents can cause complaints in urban areas.

Older pre-sulfurized catalysts were only partially activated prior to loading. Additional sulfur was included as elemental sulfur, which reacted with H₂ to form H₂S inside the reactor. Such catalysts tended to auto-ignite when exposed to air, with unpleasant consequences.

22.7.4 Activation of Noble-Metal Hydrocracking Catalysts

Noble-metal hydrocracking catalysts contain small amounts of highly dispersed platinum or palladium. These metals are expensive, but their concentrations are low – 0.6–1.0 wt%. Their superior hydrogenation activity often justifies the extra cost. The metals are added to the catalysts by impregnation with tetra ammine complexes – Pt(NH₃)₄²⁺ or Pd(NH₃)₄²⁺. When the catalysts are heated in air to about 840 °F (450 °C), the complexes decompose, giving off ammonia and leaving behind divalent metal oxides.

In commercial hydrocrackers, catalysts containing noble-metal oxides are activated by direct reduction with high-pressure hydrogen at 700 °F (350 °C).

22.7.5 Catalyst Regeneration and Rejuvenation

After working 24/7 for years in a fixed-bed hydroprocessing unit, a catalyst is spent, in part due to trace element poisoning and in part due to agglomeration of active metals, but mostly due to coking. The entire unit is shut down and the catalyst is removed. It takes several days to unload catalysts, a few weeks to inspect, service and repair equipment and a week to load and activate replacement catalysts. Most refiners reload hydrocrackers with fresh catalysts. Spent catalysts go to an off-site facility, where they are disposed of or regenerated by controlled combustion. During combustion, accumulated coke is converted to CO₂ and CO plus small amounts of SO₂ and NO_x, which are formed from the sulfur and nitrogen in the coke. Typical temperatures for regeneration in air are 400–500 °C (750–930 °F).

The regenerated catalyst may also undergo rejuvenation, a wet process in which the active metals are chemically re-dispersed. A combination of regeneration and rejuvenation can restore a catalyst to more than 95% of its original activity.

Inevitably, some particles break apart during the unloading, transportation, regeneration, and rejuvenation of spent catalysts. If part of the catalyst is contaminated with excessive amounts of trace elements, that part is sent to a catalyst reclamation company or a hazardous waste disposal company. Losses due to fragmentation and fouling can exceed 10%.

In the bad old days, regeneration meant burning coke off the catalyst while it was still inside the reactor. Today, in situ regeneration is rare because it is hard to control. A poor regeneration is costly, because afterwards the unit's performance will be poor. With a crippled catalyst, the unit may have to limp along for several months at lower feed rates and/or lower severity.

Worst of all, the catalyst won't last long, which means that it will have to be regenerated or replaced sooner rather than later.

22.7.6 Catalyst Reclamation

Even though noble-metal hydrocracking catalysts contain only small amounts of Pd or Pt, these metals are so valuable that recovering them is cost-effective. Other hydroprocessing catalysts contain Mo, W, Ni, and/or Co. Spent hydrotreating catalysts – especially those used to hydrotreat residue – can be very rich in nickel and vanadium, richer than natural ores.

Reclamation companies convert these materials into salable products using different combinations of oxidation, pyrolysis, dissolution in acid or alkali, precipitation, extraction, or ion exchange. Depending on the reclamation procedure, the salable products may include the materials shown in Table 22.6.

Table 22.6 Partial list of materials sold by catalyst reclamation companies

Material	Formula
Palladium metal or chloride salt	Pd or Na ₂ PdCl ₄
Platinum metal or chloride salt	Pt or Na ₂ PtCl ₄
Molybdenum trisulfide	MoS ₃
Molybdenum oxide	MoO ₃
Ammonium molybdate	(NH ₄) ₂ Mo ₄ O ₁₃ · 2H ₂ O
Sodium molybdate	Na ₂ MoO ₄ · 2H ₂ O
Tungsten trioxide	WO ₃
Ammonium para-tungstate	(NH ₄) ₁₀ W ₁₂ O ₄₁ · 5H ₂ O
Sodium tungstate	Na ₂ WO ₄ · 2H ₂ O
Vanadium pentoxide	V ₂ O ₅
Sodium (meta) vanadate	NaVO ₃
Nickel metal or chloride	Ni or NiCl ₂
Cobalt metal or chloride	Co or CoCl ₂
Nickel-cobalt concentrate	Ni _x Co _y
Iron-molybdenum concentrate	Fe _x Mo _y
Alumina hydrate	Al ₂ O ₃ · 3H ₂ O

22.8 Hydroprocessing Thermochemistry

Hydrotreating and hydrocracking generate heat. For hydrocracking, the first reaction step requires bond breaking, which is endothermic. The reactive intermediates undergo rearrangement, hydrogenation, and other reactions, which in toto are highly exothermic. The design and operation of commercial hydroprocessing units revolve around heat control. Loss of heat control can cause a temperature excursion. Minor excursions can lead to lost production and decreased catalyst life. Major excursions have caused loss of containment, consequent explosions, and, in at least one case, a fatality.

Fully rigorous reaction thermochemistry would be based on pure-component heats of formation, molar heat capacity, and heats of vaporization. Correc-

tions would be made for molecular interactions and temperature-dependent enthalpies of formation. But typical hydrocracker feeds contain hundreds of thousands of different molecules. It may never be possible to identify all of them. To isolate them and determine their individual properties is inconceivable. But with far less analytical rigor, we have done a decent job of designing and operating hundreds of commercial hydroprocessing units, some of which are more than 50 years old. With judicious assumptions and thermochemical data for selected model compounds, we can predict commercial performance with adequate fidelity.

The next three tables quantify heat release for the major hydroprocessing reactions, with pure-compound reactions as examples. Table 22.7 shows enthalpies of

Table 22.7 Calculated enthalpies of reaction at standard temperature and pressure for representative hydrotreating and hydrocracking reactions

No.	Reaction type	ΔH_R at STP (kJ/mol)	per H ₂ consumed
Olefin saturation		Average =	-116.3
1.	Propylene + H ₂ → propane	-125.0	-125.0
2.	2,2-Dimethyl-3-hexene + H ₂ → hexane, 2,2-dimethyl	-106.6	-106.1
3.	Styrene + H ₂ → ethylbenzene	-117.0	-117.0

reaction for several hydroprocessing reactions at standard temperature and pressure (STP), organized by reaction type. Reactions 18 through 21 are hydrocracking reactions, in which C–C bonds are broken. All others are hydrotreating reactions. Reactions 9 and 16 are saturation reactions. They appear in the HDS and HDN categories, respectively, because they are mechanistic intermediates. The first column of numbers shows the results of heat-of-reaction calculations per mole of hydrocarbon reactant. The second column shows re-

sults per mole of H₂ consumed. Isomerization does not consume hydrogen, but it does release heat because branched isomers are more stable than straight-chain isomers. At STP, saturation of olefins generates the most heat per mole of hydrocarbon. Saturation of aromatics generates the most heat per mole of reactant and more heat per mole of H₂ than HDS, HDN, and hydrocracking. In the absence of cracking and at mod-

Table 22.8 Selected average bond lengths and energy

Bond	Length (pm)	Energy (kJ/mol)	Bond	Length (pm)	Energy (kJ/mol)

Reaction	Bonds broken	Bonds formed	Net bond energy	Calc. from ΔH_f
1.	C–C, H–H	2 C–H	-42	-42.3
2.	C–S, H–H	C–H, S–H	-52	-58

erate temperatures, aromatics saturation is reversible. Saturation becomes more difficult thermochemically as temperatures go up.

Table 22.8 presents selected average bond energies and Table 22.9 compares the results of bond-energy-based heat-of-reaction calculations for HDS and hydrocracking.

Reaction enthalpies calculated from bond energies come reasonably close to the averages in Table 22.7, which were calculated from heats of formation. The results are nearly identical for the hydrocracking reaction, but differ by about 10% for the HDS reaction.

22.9 Hydroprocessing Kinetics

For process design and safe operation, reaction rates are just as important as thermochemistry. It is not enough to understand how much heat is generated by various chemical reactions. One must know how fast the heat is generated, how and where the heat is controlled, and how temperature increase depends on related process parameters – the feed rate, catalysts, catalyst loading, system pressure, and chemical–physical properties of the reactants.

Operators and unit engineers might use simple first-order models to normalize plant data to a reference point; to estimate the impact of changes in feedstock quality; to estimate how to vary temperatures to meet different process objectives; and to monitor catalyst deactivation.

At the other end of the spectrum, steady-state models for real-time online optimization (RTO) do all of that and much, much more. RTO reactor models employ rigorous kinetics developed from detailed feedstock characterization. They incorporate ambient condition temperature measurements and prices for feedstocks, utilities, and products. They determine the actual capability of equipment by comparing design values with actual performance. Every hour or so, they calculate optimal setpoints for dozens of valves and automatically download the results to the DCS system.

Dynamic models calculate the rates at which reactors and other equipment respond to setpoint changes. They can be excellent vehicles for operator training. Complete dynamic models can be suitable for simulating startup, shutdown, and emergency procedures.

22.9.1 Pseudo First-Order Approximation (PFOA) Models

The simplest approach to kinetic modeling is the pseudo first-order approximation (PFOA) method. In a pseudo first-order experiment, all aspects of a system are held constant except one. The usual approach is to make the concentrations of everything else so high, that they don't change when the component of interest reacts.

For hydroprocessing, PFOA assumptions include the following:

- *Temperature assumption: The reaction environment is isothermal.* Real units are adiabatic. Hydroprocessing reactions generate heat and in a steady-state system at constant volume and pressure, adding heat increases temperature. In commercial units, reaction heat can induce considerable exotherms. More than a few times, we have seen steady-state temperature rises $> 50^\circ\text{C}$ across a hydrotreating catalyst bed. PFOA models account for adiabatic temperature rise by averaging TI measurements into isothermal equivalents, such as CAT or WABT.
- *Feed composition assumption: The feed contains only four reactive components – sulfur, nitrogen, aromatics, and unconverted oil.* We know this isn't true, but we are constrained by the fact that refiners routinely measure only distillation, density, acid number, total sulfur, and total nitrogen. Sometimes, if there is a perceived need, they measure bromine number, and trace metals. Olefins are related directly to bromine number. Aromatics are inferred from density, distillation, and sulfur. Oxygen can be estimated from acid number. For pilot plant studies, licensors and catalyst vendors measure additional feed and product properties, including aromatics, polyaromatics, and PNA ratio. The rigorous version of PNA ratio is the $C_P C_N C_A$ ratio, which is the ratio of carbon atoms in paraffins, naphthenic rings, and aromatic rings. Refractive index and the distribution of sulfur compounds might also be measures, both in feed and product samples.
- *Inhibitors:* Hydrocracking models include the impact of nitrogen and ammonia on total catalyst activity and HDS models include inhibition by H_2S .
- *Reaction reversibility assumption: All reactions are irreversible.* As discussed in Sect. 22.3, this assumption is wrong for the saturation of aromatics. Above the *crossover* temperature, the extent of saturation is determined by thermochemistry, not kinetics. In this region, the results of kinetic calculations are misleading.
- *Consecutive reaction assumption: All reactions are single-step.* As also discussed in Sect. 22.3, HDN

and the indirect mechanisms for the HDS of alkyl dibenzothiophenes, require initial saturation of an aromatic ring. When thermochemistry inhibits saturation, HDN and deep HDS are inhibited too. Again, we see how the results of PFOA kinetic calculations can be misleading.

- *Reaction environment assumption: All reactions occur in a single liquid phase.* This isn't true for naphtha hydrotreating at high temperatures, when the feed is completely vaporized.

First-order kinetic relationships [22.27] are derived from (22.1), where F is the concentration of a reactant X in the feed at time $= t$, k is the rate constant, and n is the reaction order. Rearrangement gives (22.2). For $n = 1$, integration from time $= 0$ to time $= t$ gives (22.3). In this context, reaction order is a tuning constant with limited physical significance. Having $n > 1$ does not indicate that a component reacts with itself.

$$\text{Rate}_{(t)} = -\frac{dX_t}{dt} = -kX_t^n, \quad (22.1)$$

$$\frac{dx}{X_t^n} = -kdt, \quad (22.2)$$

$$\text{If } n = 1, \text{ then } k = \left(\frac{1}{t}\right) \ln \left(\frac{X_t}{X_0}\right). \quad (22.3)$$

We can assume that the average residence time $= 1/LHSV$. If $t =$ residence time, we get (22.4), which is useful for predicting the impact of feed rate on reaction rates

$$k = -(LHSV) \ln \left(\frac{X_t}{X_0}\right) = (LHSV) \ln \left(\frac{X_0}{X_t}\right). \quad (22.4)$$

22.9.2 Temperature Dependence

The Arrhenius relationship, (22.5), quantifies the impact of temperature on reaction rate. The rate constant k , is the same as the rate constant in (22.1) through (22.4). T is the temperature, R is the gas constant, and E_a is the activation energy. A is the pre-exponential factor, a catch-all for temperature-independent factors. A bit of manipulation gives (22.6). One can determine E_a experimentally by plotting $\ln k$ versus $1/T$. The slope is E_a/R and the intercept is $\ln A$.

The assumption that E_a and A are constant at all temperatures leads to (22.7) and (22.8), which one can use to calculate rate-constant ratios at different temperatures. Equation (22.7) is especially useful for predicting the impact of temperature changes on reac-

tion rates.

$$k = Ae^{\frac{-E_a}{RT}}, \quad (22.5)$$

$$\ln k = \ln A - \frac{E_a}{RT}, \quad (22.6)$$

$$\ln \left(\frac{k_1}{k_2}\right) = \frac{E_a}{R} \left(\frac{1}{T_2} - \frac{1}{T_1}\right), \quad (22.7)$$

$$\frac{k_1}{k_2} = e^{\left[\frac{E_a}{R} \left(\frac{1}{T_2} - \frac{1}{T_1}\right)\right]}. \quad (22.8)$$

Table 22.10 presents commonly accepted activation energies for the main hydroprocessing reactions [22.28, 29].

Experiments demonstrate the futility of trying to use irreversible first-order kinetics to model reversible saturation of aromatics and by extension, reactions that require prior saturation of aromatics; mechanisms for HDN and deep HDS include indirect routes requiring initial reversible saturation of an aromatic ring adjacent to the hetero atom. To achieve a reasonable data fit for saturation, one must change either the activation energy or the reaction order for different temperature ranges. Both strategies are flawed. A temperature-dependent E_a conflicts with Arrhenius's primary assumption – that E_a is constant. Assigning a reaction order > 1.0 implies that the saturation mechanism requires some interaction of two aromatic molecules which is exceedingly improbable. Above about 440 °C (825 °F), saturation cannot occur and the calculated E_a for saturation is zero or negative.

The aromatics conundrum can be handled by adding a separate dehydrogenation reaction, with its own A and E_a . At equilibrium, the rates of saturation and dehydrogenation are equal. Knowing this enables one to derive (22.9). The system must mass-balance, so the solution requires solving simultaneous equations,

Table 22.10 Arrhenius activation energies for the main hydroprocessing reactions

Reaction	E_a (kcal/(mol K))
Bulk HDS of gas oils	16–20
Bulk HDS of VGO and AR	30–36
ULSD	12 ^a
Bulk HDN	30
Aromatics saturation	< 0–18
ASA-catalyzed hydrocracking	30
Zeolite-catalyzed hydrocracking (moderate activity)	45–50
Zeolite-catalyzed hydrocracking (high activity)	55
Thermal hydrocracking	62

^a Depends on which reaction order is being used

which is readily accomplished in programs such as MATLAB or the Solver add-in of Microsoft Excel.

$$\ln k_1 = \ln k_2 = \ln A_1 - \frac{E_{a1}}{RT} = \ln A_2 - \frac{E_{a2}}{RT}$$

$$\ln A_1 - \ln A_2 = \frac{E_{a1}}{RT} - \frac{E_{a2}}{RT}$$

$$R(\ln A_1 - \ln A_2) = \frac{E_{a1} - E_{a2}}{T}$$

$$\frac{E_{a1} - E_{a2}}{T} = \text{Const.} \quad (22.9)$$

Figures 22.28 and 22.29 illustrate the impact of activation energies on relative reaction rates as a function of temperature. The curves are based on (22.8), with $k_1 = 1$ and $T_1 = 380^\circ\text{C}$. T_2 is specified and k_2 is calculated. Figure 22.28 shows just two curves, one for ULSD and another for three reactions:

- Bulk HDS
- HDN
- ASA-catalyzed hydrocracking.

Fig. 22.28 Curves showing relative rate constant versus temperature for hydrotreating and ASA-catalyzed hydrocracking. Curves are calculated with (22.8), with $k_1 = 1$ and $T_1 = 380^\circ\text{C}$. For bulk HDS, HDN and ASA hydrocracking, E_a is 30 kcal/(mol k). Experiments show that E_a for deep desulfurization to make ULSD can range from 12–30 kcal/(mol k). For this graph, E_a for ULSD = 20 kcal/(mol k)

For the ULSD, $E_a = 20$ kcal/(mol k). In Fig. 22.29, three curves are added:

- Hydrocracking with a moderate-zeolite catalyst ($E_a = 45$)
- Hydrocracking with a high-zeolite catalyst ($E_a = 55$)
- Thermal hydrocracking ($E_a = 62$).

At 470°C , thermal hydrocracking is twice as fast as high-zeolite hydrocracking and 20 times faster than bulk HDS.

22.9.3 Langmuir–Hinshelwood/Hougen–Watson Kinetics

Researchers make limited use of PFOA models, because of their inherent drawbacks. Instead, they employ the LHHW (Langmuir–Hinshelwood/Hougen–Watson) mechanism, which was derived specifically for modeling heterogeneous catalysis [22.30]. For each component, an LHHW equation captures inherent reactivity and temperature effects, along with the impact of other reactants, inhibitors and catalyst characteristics. LHHW models are somewhat more complex than PFOA models, but they are far more informative. An

Fig. 22.29 PFOA kinetics: Similar to Fig. 22.28, $k = 1$ at 380°C with the addition of high-zeolite hydrocracking and thermal hydrocracking. Activation energies for the added curves are 45 kcal/(mol K), 55 kcal/(mol K), and 62 kcal/(mol K)

eight-component system (hydrogen, sulfur, H_2S , nitrogen, NH_3 , unconverted oil, aromatics, and saturates) can be solved with simple macros in programs such as Microsoft Excel, or by powerful solvers from MathWorks, Mathematica, and others.

The main LHHW steps are:

- Adsorption of reactants to the catalyst surface
- Reactions of adsorbed molecules
- Desorption of products.

Equation (22.10) summarizes the constituents of the equation

$$\text{rate} = \frac{(\text{kinetic factor}) \cdot (\text{driving force})}{(\text{adsorption terms})} \quad (22.10)$$

Adsorption terms include:

- Molecular: $K_A P_A$
- Dissociative: $(K_A P_A)^{0.5}$
- Includes adsorption terms for inhibitors.

Kinetic factors include:

- k = Reaction rate constant, including Arrhenius temperature effects
- N_T = Number of available adsorption sites (proportional to surface area)
- Turnover number = Max number of molecules that can be converted per active site per second (Michaelis–Menton kinetics).

Driving forces include: P_A , P_B , P_C , K_{eq} etc. The exponent n is an integer: $n = 0, 1, 2, \dots$ = Number of surface species involved, including inhibitors.

Equation (22.11) corresponds to a system with a single reactant, one type of active site, and multiple inhibitors. A molecule adsorbs to only one site and molecules do not combine with each other so

$$\text{Rate} = \frac{k N_T K_A P_A}{(1 + K_A P_A + \sum K_i P_i)} \quad (22.11)$$

where:

- k = Rate constant for conversion of A
- K_A = Adsorption constant for A
- P_A = Partial pressure of A
- $K_i P_i$ = Adsorption factors and partial pressures of inhibitors.

Catalytic hydrocracking employs bifunctional catalysts and hydrogen is a reactant, so the expression grows to

$$\text{Rate} = \frac{K N_T K_A P_A K_{H_2} (P_{H_2})^n}{(1 + K_A P_A + \sum K_i P_i) (1 + K_{H_2} (P_{H_2})^n)} \quad (22.12)$$

When several reactions are modeled at once, there is an (22.12) for each. The sets of equations are solved simultaneously. Inhibitors are generated by reactions, so their concentrations change as reaction fluids move through the unit.

When the adsorption factor for an inhibitor is considerably greater than the adsorption factor for a reactant, then (22.12) is essentially equivalent to (22.13)

$$\text{Rate} = \frac{k_A N_T K_A P_A}{(1 + K_i P_i)} \quad (22.13)$$

Equation (22.13) was used to generate Fig. 22.30 for the inhibition of hydrocracking by ammonia and organic nitrogen. The figure is based on pilot plant data. The test showed that the K_i for organic nitrogen is about $7 \times$ greater than the K_i for ammonia. The figure demonstrates that activity is very sensitive to small changes in inhibition at very low concentrations of inhibitor.

It is said that the poisoning of hydrocracking catalysts by organic nitrogen is reversible. Indeed, if a catalyst is poisoned by a high-nitrogen feed and if that feed is replaced by a low-nitrogen feed, much of the prior catalytic activity returns. But the molecules that leave have changed and they go away for different reasons. The light ones might simply be displaced, but the heavy ones undergo hydrocracking or coking. As a nitrogen-poisoned hydrocracking catalyst reacquires activity, activity remains low until the degree of inhibition is very low. Then, a small change in nitrogen has a huge effect on activity. As discussed in Sect. 22.11, failure to understand this phenomenon has been deadly.

22.9.4 Structure-Based Lumping

Rigorous process optimization relies on models with structure-based lumping (SBL), also known as structure-oriented lumping (SOL). High-fidelity SBL models can serve as the basis for closed-loop, real-time, online optimization. Examples include the models used for online refinery-wide optimization at Suncor Sarnia [22.31]. An SBL model might include < 30 to > 100 kinetic components. Table 22.11 shows one way to group hydrocarbons into structure-based lumps. Note that the sum of poly-ring compounds is 43 wt%.

For each type of structure, physical and chemical properties vary monotonically with carbon number. Figure 22.31 illustrates how density changes as carbon numbers increase. As molecules get heavier, they behave less like alkyl-substituted ring compounds (or hetero-atom compounds) and more like large paraffins. This makes sense, because each increment in carbon number comes from adding a methylene (CH_2) group.

Fig. 22.30 Langmuir–Hinshelwood inhibition of hydrocracking by ammonia and organic nitrogen, where $K_{(\text{organic N})} = 7 \times K_{(\text{NH}_3)}$. The trends are a function of inhibited catalyst sites at steady state, which is related to, but not the same as, the content of ammonia or nitrogen in the feed

Online optimization models include a representation for every piece of equipment in a unit and contain tens of thousands of equations. In open-equation parlance, the number of nonzero elements in the model matrix for each unit can be more than a million. The equations are solved simultaneously with dynamic optimization software provided by companies such as AspenTech, ABB, Schneider Electric, Honeywell, and others.

The reaction model used for real-time optimization at the Suncor Sarnia hydrocracker includes 116 components and 195 reactions. The components are organized into seven cuts, which correspond to the boiling ranges of desired products – unconverted oil, heavy VGO, light VGO, heavy gas oil, light gas oil, C_5 – C_{10} hydrocarbons, and C_4 hydrocarbons. H_2 , H_2S , and NH_3 are included. The components and reaction network are patterned after Figs. 22.16 and 22.17. In addition to hydrocarbon lumps, the model includes 13 sulfur and 10 nitrogen components – at least one per cut. Each component has an integer CHSN ratio. Physical properties include density, heat capacity, standard ΔH_f , heat of vaporization, and normal boiling point. Heat balance is calculated rigorously. Equilibrium-like behavior is captured with separate forward and reverse reactions. To simulate adiabatic behavior, each catalyst bed has six collocation points, at which composition, heat release and vapor–liquid equilibria are re-computed and passed to the next collocation point. Figure 22.32 illustrates the kind of reactor information obtainable from such a model. Four of more than sixty process variables are tracked as they flow through four beds of hydrotreating catalyst. Between each bed, quench gas is added to control temperature. At the top of bed 1, temperature jumps quickly

due to saturation of olefins. Nearly all of the sulfur is gone at the end of bed 4, while nitrogen removal is 70% and removal of total aromatics is 60%. Graphs were prepared with Aspen Hydrocracker software, a product of Aspen Technology, Inc. With the open-equation mathematics underlying the model, one can specify bed inlet temperatures and calculate the outlet temperatures; or specify conversion and desired bed outlet temperatures and calculate what the bed inlet temperatures must be to meet those specifications.

A key to commercial success is the feed-adjust block, which decreases the need for detailed analysis of every new feed. This is important, because feeds in commercial units change frequently, sometimes several times per week. Feed bulk properties can be calculated with reasonable fidelity from the model component distribution and vice versa. When the feed is different, the feed-adjust block compensates by skewing the component distribution for a known feed to match the bulk properties of the different feed.

Another important feature is the composition-based deactivation model, which adjusts for catalyst activity online. It has been used off-line for *what-if* predictions of the impact of process changes (including feed changes) on catalyst deactivation rates [22.32].

Online optimization models are superb tools for process monitoring. During every execution cycle, they calculate differences between the expected and actual performance of pumps, furnaces, heat exchangers, distillation towers etc. It is a straightforward exercise to generate trends which show how the plant/model mismatch changes with time. With that information, engineers can identify equipment fouling and opportunities for process improvement.

Fig. 22.31 Density versus molecular weight for hydrocarbons with different Z numbers at 20°C. Z represents the degree of saturation in hydrocarbons. It comes from the subscript for hydrogen in composition general formulas. For paraffins, C_nH_{2n+2} , $Z = +2$. For alkyl benzenes, C_nH_{2n-6} , $Z = -6$ (courtesy of J.W. Bunger)

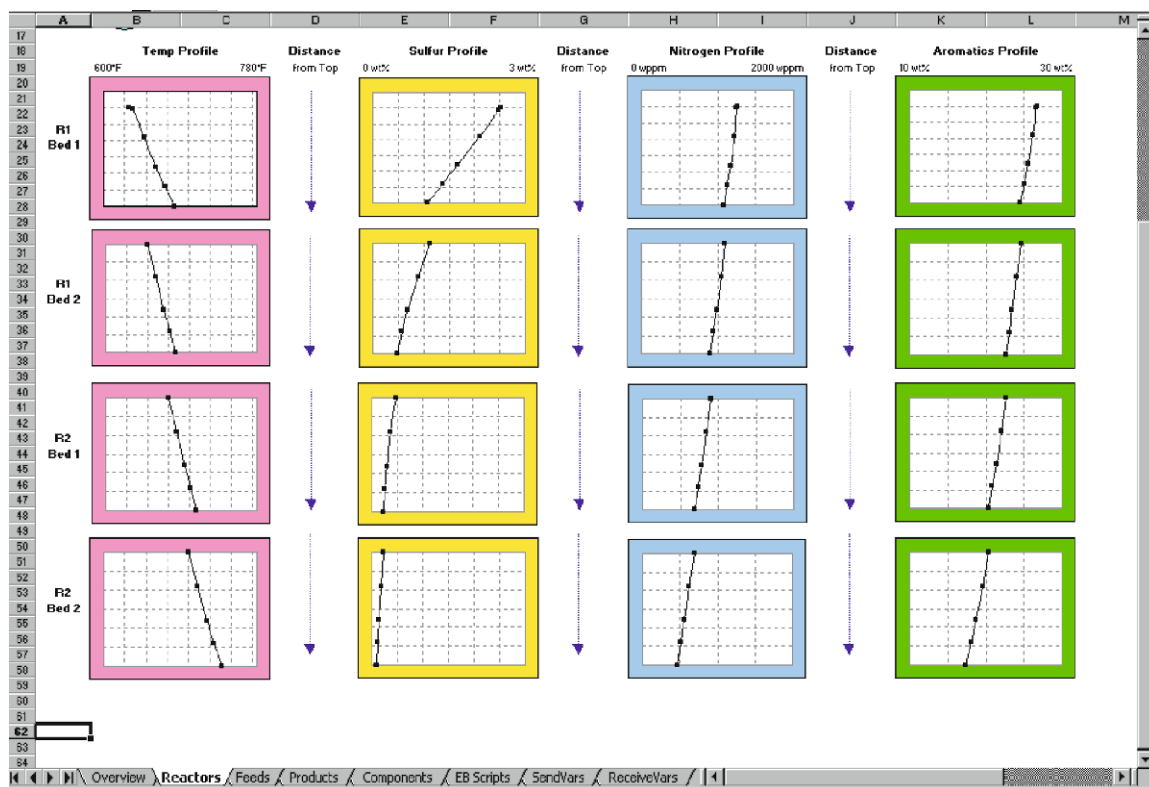

Fig. 22.32 Example output from an adiabatic SBL hydrocracking model. Four variables are tracked as they flow through four beds of hydrotreating catalyst. Between each bed, quench gas is added to control temperature. At the top of bed 1, temperature jumps quickly due to saturation of olefins. Nearly all of the sulfur is gone at the end of bed 4, where nitrogen removal is 70% and removal of total aromatics is 60%. Graphs were prepared with Aspen Hydrocracker software, a product of Aspen Technology, Inc.

22.10 Hydroprocessing Process Descriptions

22.10.1 Fixed-Bed Hydrocracking: Process Flow Schemes

In fixed-bed hydroprocessing units, the flow of reactants can be modeled with trickle-bed kinetics, with concurrent downflow of liquid and gas across a packed bed of catalyst particles. Trickle-bed kinetics [22.33] are based on plug flow of well-mixed fluids with no back-mixing or wall effects.

Figure 22.33 presents a process flow scheme for a two-reactor fixed-bed hydrocracker with four catalyst beds – two for pretreat catalysts and two for cracking catalysts. Four separators are shown:

1. HHPS = Hot high-pressure separator
2. CHPS = Cold high-pressure separator
3. HLPS = Hot low-pressure separator
4. CLPS = Cold low-pressure separator.

The emergency depressuring system (EDS) might be configured as shown or with two independent lines from the CHPS. Quench valves are moved by temperature controllers. The recycle gas compressor, as shown, is centrifugal with steam-drive. The amine unit is optional. The reactor effluent air cooler (REAC) is safety-critical because it is susceptible to erosion-corrosion induced by the deposition of $\text{NH}_4\text{SH}_{(\text{aq})}$ and $\text{NH}_4\text{Cl}_{(\text{aq})}$.

Fresh feed and hydrogen-rich gas are heated by heat exchange and a fired furnace. Liquid and gas might be mixed before entering the furnace. Alternatively, the furnace might heat just the recycle gas, which heats the oil when the two are mixed. The mixture enters the reactor and flows down through the catalyst beds in trickle-flow fashion. Commercial units contain up to six reactors and commercial reactors contain two to seven beds. Hydroprocessing reactions generate heat, which

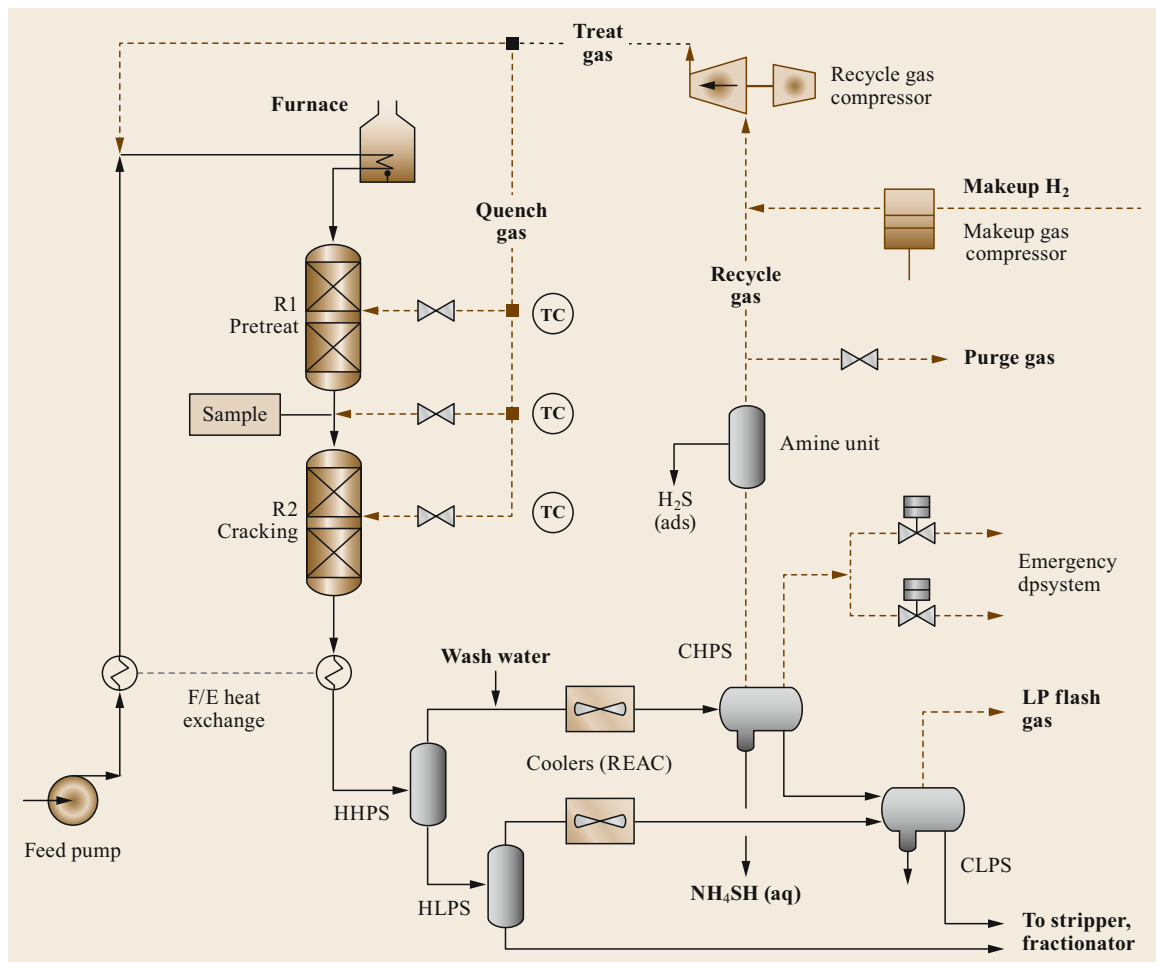

Fig. 22.33 Representative fixed-bed once-through hydrocracker

is controlled by the injection of relatively cold quench gas between catalyst beds. Quench valves are manipulated in cascade by temperature controllers, but they can also be operated manually.

In a two-separator design, the reactor effluent is combined with wash water and cooled in the feed/effluent changer. In the cold high-pressure separator, the wash water removes ammonia as aqueous NH_4SH . The CHPS overhead is recycled, sometimes after first going through an amine unit for H_2S removal. The CHPS bottom goes through a stripper to the fractionator.

HPLS liquid can go directly to the fractionator, avoiding the need to cool and reheat the product liquid. In the figure, the centrifugal recycle gas compressor (RGC) is steam-driven; sometimes the RGC is motor-driven. Units that process relatively sweet feeds may not require an amine unit. A gas-only furnace is less subject to tube fouling, especially during a sudden change in operation.

Products can include the following:

- Purge gas comprised of hydrogen, methane, ethane, and H_2S . Depending on the hydrogen source, it can also contain molecular nitrogen, argon.
- Propane.
- Butanes.
- Light naphtha (primarily C_5 paraffins).
- Heavy naphtha, which usually goes to a catalytic reformer.
- Kerosene, which often meets jet fuel specifications.
- Gas oil, which often meets specifications for ultra-low-sulfur diesel (ULSD).
- Unconverted oil, which can be recycled to achieve higher conversion, or forwarded to an FCC unit, an

olefin production plant, or a lubricant production plant.

Operating condition ranges at start-of-run (SOR) and end-of-run (EOR) are set during design and construction. They are based on specified feed qualities and process objectives. Approximate ranges are presented in Table 22.12.

Compared to hydrotreating, the LHSV for hydrocracking is higher (the residence time is shorter) due to concerns about temperature excursions. Low-pressure hydrotreaters are used to treat naphtha and straight-run light gas oil. Higher pressure is required for residue hydrotreating, lube-stock hydrofinishing, and hydrocracking. 2000 psig (135 bar) is a common pressure for VGO hydrocracking. Temperatures at SOR and middle-of-run (MOR) are situational.

During normal operation of an existing unit:

- Fresh feed rate is kept as high as possible.
- Pressure is relatively constant, as it must be to maintain hydraulic stability.
- It is tempting to try to save power or steam by automatically changing recycle gas compressor speed to maintain a constant H_2OR . Such a control scheme is risky, of questionable benefit, and difficult to implement. A high flow of recycle gas keeps a unit safe by removing process heat. The high flow provides a buffer against disturbances. Hydrocracking units are tightly integrated, so process parameters are exceedingly interactive, and they respond to changes with disparate dynamics because so many variables are so interdependent. For example: A change in feed rate often is accompanied by a change in feed

Table 22.12 Fixed-bed hydroprocessing: Approximate operating condition ranges. Exceptions are common

Process variable	Approximate range	
	Hydrotreating	Hydrocracking (zeolite catalyst)
LHSV, $\text{h}^{-1\text{a}}$	0.4 to > 2.0	1.0 to > 2.0
Metric units		
Pressure at the reactor inlet (bar)	40–200	85–200
SOR catalyst average temperature ($^{\circ}\text{C}$)	315–390	315–390
EOR catalyst average temperature ($^{\circ}\text{C}$)	427	415
Peak operating temperature ($^{\circ}\text{C}$)	440	427
Hydrogen–oil ratio (H_2OR) at reactor inlet (Nm^3/m^3)	> 360	880–1425
Treat gas ratio, recycle H_2 flow/makeup H_2 flow	> 3	> 5
American units		
Pressure at the reactor inlet (psi)	600–3000	1200–3000
SOR catalyst average temperature ($^{\circ}\text{F}$)	600–735	600–735
EOR catalyst average temperature ($^{\circ}\text{F}$)	800	780
Peak operating temperature ($^{\circ}\text{F}$)	825	800
Hydrogen–oil ratio (H_2OR) at reactor inlet (scf/bbl)	> 2000	5000–8000
Treat gas ratio, recycle H_2 flow/makeup H_2 flow	> 3	5

^a LHSV = liquid hourly space velocity = (volume of liquid feed)/hour/(volume of catalyst)

quality. If the feed rate drops but the feed is more reactive, temperatures will increase for two reasons – greater heat of reaction and longer residence time. If the recycle gas compressor slows to maintain a constant H₂OR, temperature will rise for a third reason: reduced flow of heat-removing gas. So: in a well-run hydrocracker, the recycle gas compressor is operated at a high, constant speed.

- When feed rate, pressure and H₂OR are constant, unit performance depends on temperature.

To respond to changes in feed quality, process objectives, or catalyst activity, operators manipulate temperature. For most of a catalyst cycle, temperature can be altered at will, subject to safety limits. Temperatures at EOR are constrained by metallurgy.

In the pretreat catalyst beds, sulfur and nitrogen are removed by HDS and HDN, respectively. Oxygen, olefins, and trace elements are also removed, accompanied by significant saturation of aromatics. Removing organic nitrogen is especially important, because it passivates acid sites on hydrocracking catalysts. Samples of liquid are collected at the line between the pretreating and cracking reactors and analyzed for nitrogen. On the basis of these measurements, pretreat reactor

temperatures are adjusted to maintain N slip i.e., the nitrogen content of the pretreat reactor effluent liquid. Targets for N slip are situational and can range from 5–50 wppm. HDN generates ammonia, which also passivates cracking catalyst acid sites. However, ammonia is significantly less inhibitory than organic nitrogen. The pretreated feed flows to the cracking catalyst beds, where conversion due to C–C bond cleavage occurs.

Under reaction conditions, the H₂S and NH₃ from hydrotreating are gases. But at temperatures below the sublimation temperature for ammonium bisulfide (NH₄SH), that salt can deposit and accumulate, blocking flow. It can also induce serious erosion–corrosion. In addition to reacting with H₂S, ammonia reacts with chlorides to form NH₄Cl, which also forms deposits below its sublimation temperature. Both NH₄SH and NH₄Cl are water-soluble. They can be controlled by injecting wash water into the CHPS feed. There are two guidelines for water injection: at least 25–30% of the water must remain liquid and the salt content of the CHPS sour water should not exceed a specified value. Licensor recommendations vary, but the limit usually is somewhere between 4–8 wt%.

Unconsumed hydrogen from the cold high-pressure separator (CHPS) might or might not be scrubbed with

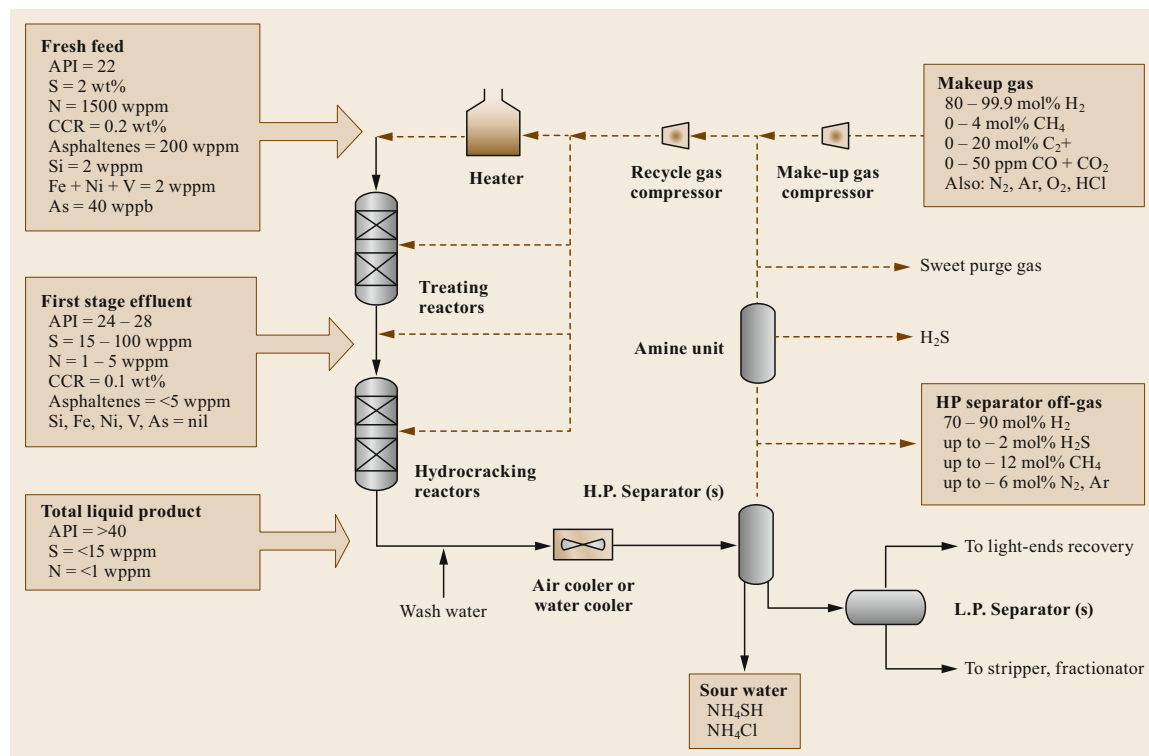

Fig. 22.34 Once-through hydrocracking process flow with representative stream compositions. Actual values differ from unit to unit and for different feeds and modes of operation

amine to remove H_2S . To control buildup of methane and nitrogen in the recycle gas, some gas can be purged to fuel gas or another process unit. The remaining gas is augmented with makeup hydrogen and recycled to the reactors.

In hydrocrackers, emergency depressuring systems quickly drop pressure when temperatures get out of control. As discussed in Sect. 22.11, in one case an excursion increased a bed TI reading by $188^\circ F$ ($104^\circ C$) in 20 s. In another, the temperature jumped $214^\circ C$ in 7 min. EDS stops excursions by removing hydrogen, an essential reactant and by pulling heat out of the unit. Failure to depressure has led to loss of containment, injuries and at least one fatality. API Recommended Practice 521 presents guidelines for pressure-relief and depressuring systems [22.34]. The document recommends sizing the system to give an initial depressuring rate of 100 psi/min (7 bar/min). Designs by hydrocracking technology licensors include two independent EDS lines, one sized for an initial rate of 100–150 psi/min (7–10 bar/min) and another with initial rates of 200–300 psi/min (14–20 bar/min). The

EDS valves are triggered automatically by high temperature or certain equipment problems. Both can be opened manually at any time. At least one licensor designs units for manual-only opening of the high-rate valve. The goal of high-rate pressuring is to reduce pressure by 50% within 15–20 min. For certain non-traditional hydrocrackers, such as integrated units comprised of a high-temperature slurry-phase section followed directly by a moderate-temperature fixed-bed section, depressuring alone may not be sufficient to abate a temperature excursion.

Figure 22.34 shows representative stream properties for a once-through hydrocracker. Actual values differ for different units, different feeds, and different types of operation.

Figure 22.35 gives a bird's-eye view of several hydrocracking process flow options. For all flow sketches, there can be either two, three, or four flash drums. Figure 22.35a shows a once-through unit in which the oil flows in series through the pretreat catalysts directly to the cracking catalysts. Figure 22.35b shows two options for recycle of unconverted oil (UCO).

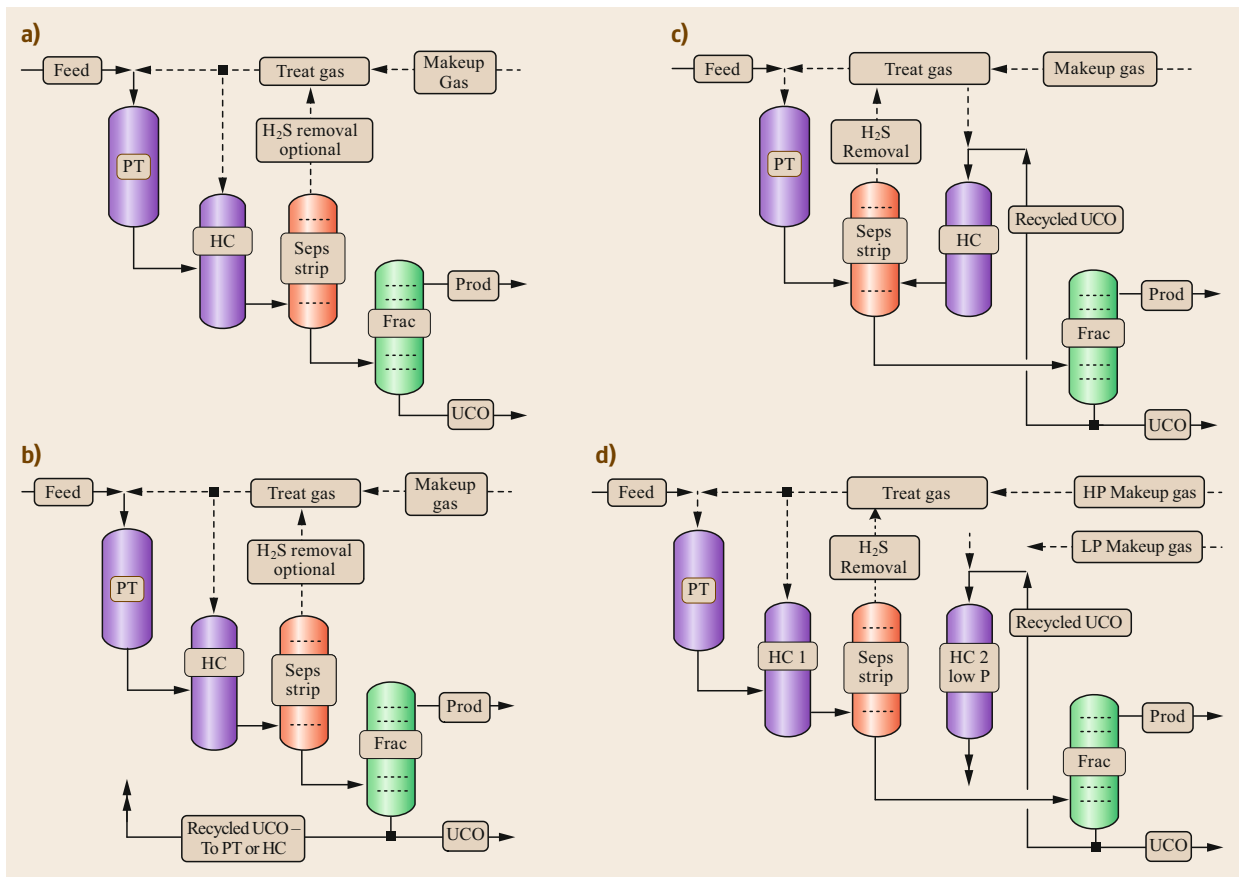

Fig. 22.35a–d Hydrocracking process configuration options

The UCO can go either to R1 or R2. Figure 22.35c shows a unit in which the pretreated oil is stripped or fractionated before moving on to a hydrocracking reactor. Figure 22.35d shows a unit with two independent recycle gas loops, one for R1 and R2 and another for R3. This configuration has two major process advantages: in R3, the pressure can be lower and the environment is nearly sweet – sweet because H_2S and ammonia are stripped and almost all of the nitrogen and sulfur are removed in R1 and R2. Temperatures required by uninhibited sweet hydrocracking are lower. This leads to increased saturation of aromatics, which improves the quality of middle distillate products. Some refiners still use noble-metal catalysts, due to the higher activity and lower gas production over such catalysts. The Fig. 22.35d option seems like it would be more expensive, because it contains additional equipment. But in one recent head-to-head comparison, due to the lower pressure and less expensive metallurgy, the estimated installation cost of a Fig. 22.35d unit was nearly the same as that for a Fig. 22.35b unit.

22.10.2 Fixed-Bed Hydrocracking: Design Considerations

Unit design starts with the definition of feed rate, feedstock qualities, the expected availability and composition of makeup hydrogen, desired product yields and qualities, and desired catalyst cycle life. With this input, reaction models generate mass-balanced yields and product qualities for different combinations of catalyst type and operating conditions. The results include estimates of reaction enthalpy. On the basis of the model results and various constraints, designers select a process configuration. The constraints include local limits on the weight and dimensions of vessels (particularly reactors), rotating equipment, and fractionators. Limits on catalyst-bed temperature rise determine the number and location of reactor quench zones. Mass flux guidelines set reactor diameters and heat exchanger design.

Startup requirements should (but don't always) determine furnace duty. A common design mistake is to size fired heaters based on normal operation, where

Fig. 22.36 Fixed-bed hydrocracking reactor internals. Alternatives to dump nozzles include intra-reactor dump tubes, through which catalysts can be conveyed from an upper bed to a lower bed. Dump tubes decrease the number of holes in the reactor wall and they make it easier to reposition quench decks if needed

a significant percentage of the required heat is supplied by chemical reactions, then adding an arbitrary margin for the extra duty required during catalyst activation. But the required startup margin strongly depends on unit-specific parameters, such as ambient temperature and piping. A 25% margin on furnace duty might be enough for some units but not enough for others.

It is common to have two feed pumps, each with 50–60% of design capacity.

The capacity of the makeup gas compressors (MUGC) is determined by expected hydrogen consumption. Units include at least two MUGCs. It is not unusual to see two MUGCs, each with 100% of design capacity, or three with 60% each. MUGCs are reciprocating, with electric or steam drive. They might draw from a dedicated hydrogen plant or from a header common to other hydroprocessing units.

The recycle gas compressor (RGC) is the single most important safety device in the plant. A high flux of recycle gas promotes plug flow for transporting heat through the reactors. Licensors recommend designing for at least 30% reserve quench. In addition, they say that the ratio of recycle gas to makeup gas, also known as the treat-gas ratio, should range from 4 : 1 for hydrotreating reactors to more than 8 : 1 for hydrocracking reactors. Different suppliers calculate treat-gas ratios in different ways. Some include 100% of the quench gas. Others include only 2/3 of the quench gas

because the top beds of catalyst don't see any quench at all. There is only one RGC. Almost always it is centrifugal. Licensors recommend steam drive, because the RGC is so safety critical. If power fails, an electric-drive machine stops immediately, while a steam-driven machine might continue to run for a while, maintaining all-important flow.

The best way to stop a temperature excursion is to depressure the unit by venting recycle gas through special valves at the CHPS. This decelerates all hydrocracking reactions by rapidly reducing H_2 partial pressure in the reactors and carrying heat out of the unit. The emergency depressuring valves and lines are sized to ensure that the flow rate does not exceed Mach 0.7 to 0.9.

Figure 22.36 shows the key elements of a fixed-bed hydrocracking reactor. The inlet device breaks the horizontal momentum of incoming reaction fluids and directs them vertically downwards. Shell Global Solutions offers particulate-trapping technology comprised of radial-flow elements. The elements stand on a deck at the top of the reactor, extending upwards into space which is usually empty. The distribution tray provides intimate mixing of oil with gas and distributes the mixture as a fine, even spray to the top of the catalyst bed underneath. The catalyst support screens, in conjunction with layers of spherical balls loaded just on top of them, keep catalysts from meandering from the bed above into the quench assembly below. Several types

Fig. 22.37 Elements of a quench section for a fixed-bed catalytic hydrocracker (after [22.23]). Quench sections mix relatively cold quench gas with hot reactants from the catalyst bed above and distribute the mixture to the top of the catalyst bed below

of quench gas introduction devices are used commercially. Six are mentioned by *Scherzer and Gruia* [22.35, p. 186]. Configurations include rings with multiple slots, spiders and slotted tubes. The goal is to distribute quench gas evenly throughout the quench deck, not just at a single point. An outlet device at the bottom of the reactor decreases bottle-necking. Catalyst dump nozzles allow catalyst beds to be unloaded independently. Simultaneous dumping of beds is possible but seldom practiced. Figure 22.37 shows additional detail for quench sections.

A typical hydroprocessing hot-wall reactor is constructed from stainless steel containing 2.25 wt% Cr and 1 wt% Mo, with a 3 mm weld overlay of 347

stainless steel on the inside wall. Reactors can be enormous, with diameters up to 6 m (18 ft), with wall thicknesses up to 0.33 m (1 ft) and with weights greater than 1400 mt.

Cold-wall reactors, such as those used for residue hydrocracking, can be just as wide. The steel shells are thinner, but they are lined on the inside with refractory up to 0.66 m (2 ft) thick.

22.10.3 Fixed-Bed Hydrocracking: Product Flexibility in Recycle Units

As shown in Table 22.13, a fixed-bed recycle hydrocracking unit can have significant product flexibility,

Table 22.13 Product flexibility with fixed-bed recycle hydrocracking

Feed	Straight-run vacuum gas oil		
Boiling range (°C)		340–550	
Boiling range (°F)		644–1020	
API gravity		22.0	
Specific gravity		0.9218	
Nitrogen (wppm)		950	
Sulfur (wt%)		2.5	
Primary product objective	Naphtha	Kerosene	Gas oil
Weighted average reactor temp (°C)	Base	–6	–12

Cetane number	–	–	55
Flash point (°C), [°F]	–	–	52 [126]
End point (°C), [°F]	–	–	349 [660]

producing either large amounts of C₄-plus naphtha or large amounts of middle distillates. In the table, SOR yields are shown. As the catalyst cycle proceeds, temperatures are increased. At higher temperatures, light-product yields go up and aromatics in heavier liquid products increase.

22.10.4 Ebullated Bed Hydrocracking

In contrast to fixed-bed hydrocrackers, ebullated bed (e-bed) units can process large amounts of residual oils. More than 20 units are now in operation. Catalyst life is not limiting, because fresh catalyst is added and spent catalyst is removed continuously. An H-Oil e-bed reactor is shown in Fig. 22.38. In operation, hydrogen-rich recycle gas is bubbled up through a mixture of oil and catalyst particles. E-bed reaction kinetics are fundamentally different from fixed-bed kinetics. The three-phase turbulent flow ensures a uniform temperature distribution. Substantial back-mixing and considerable liquid recycle cause the reactor to behave like a continuous stirred-tank reactor (CSTR). At the top of the reactor, catalyst is disengaged from

Fig. 22.38 Ebullated bed hydrocracking reactor (after [22.33])

the process fluids, which are separated in downstream flash drums. Most of the catalyst is returned to the reactor. Some is withdrawn and replaced with fresh catalyst.

When compared to fixed-bed processes, e-bed technology offers the following advantages:

- Catalyst life does not limit operation.
- Conversion of atmospheric residue can exceed 70 wt%.
- Operation can be flexible, with high-conversion and low-conversion modes.
- There is more free space between catalyst particles. This allows entrained solids to pass through the reactor without building up pressure drop.
- Smaller catalyst particles decrease diffusion limitations.
- Product selectivity is constant.

E-bed disadvantages versus fixed-bed hydrocracking include the following:

- Higher catalyst attrition, which leads to higher catalyst consumption.
- Higher installation costs due to larger reactor volume and higher operating temperatures.
- High sensitivity to feed metals, which determine catalyst addition rate.
- The formation of difficult-to-handle sediment comprised of degraded catalysts, metals from the feed, and precipitated asphaltenes.

Recent improvements include second-generation catalysts with lower attrition; catalyst rejuvenation, which allows the reuse of spent catalysts; improved reactor design leading to higher single-train feed rates; and two-reactor layouts with interstage separation. The design improvements will lead to substantial increases in conversion.

22.10.5 Slurry Phase Hydrocracking

In slurry-phase processes, finely divided additives are mixed with feedstock – vacuum residue, FCC slurry oil, coal, etc. – prior to contact with hydrogen. Additives for some modern processes are noncatalytic, while others employ catalytic additives. The technology began with the Bergius process in 1913 [22.36]. From 1933–1944, several units in Germany used modified versions to generate fuels and lubricants from coal.

The VCC process includes a slurry-phase and a fixed-bed section. The VCC additive is noncatalytic. The slurry-phase section converts vacuum residue, coal,

FCC slurry oil and other feeds into VGO and a spectrum of lighter products. The conventional fixed-bed section upgrades the VGO and distillates into finished products.

22.10.6 Hybrid Processes for Residue Hydrocracking

Chevron Lummus Global (CLG) offers a process in which CBI's LC-Slurry technology is integrated with solvent deasphalting. The asphalt can be handled conventionally. The deasphalted oil can go to an FCC unit, a separate hydrocracker or some other process unit. The activity of the catalytic ISOSLURRY™ additive enables operation at less than 3000 psig while achieving 100 wt% conversion to salable products, including asphalt. In 2016, the integrated technology was selected by Beowulf Energy and Preem for a large residue upgrading complex in Sweden [22.37].

22.11 Economics

Hydrocracker economics are determined by installation costs, operating costs, and product value. Here are some representative inside-battery limits (ISBL) estimates for the US Gulf Coast, 2012. Throughput, operating pressure, and process configuration – once-through or recycle of unconverted oil – are the major factors affecting construction costs for hydroprocessing units, which range from US\$ 3000 to US\$ 6000 per daily bbl. These estimates do not include costs for a hydrogen plant and off-site utilities.

For hydrotreaters, operating costs are roughly US\$ 1.7 per bbl. The cost of producing and compressing hydrogen accounts for 60–70% of this. For high-conversion hydrocrackers, operating costs are roughly US\$ 4.0–4.5 per bbl, of which 75–80% is due to hydrogen.

Eventually, refinery catalysts deactivate and must be replaced. In fixed-bed units, catalyst replacement requires a shutdown. For a 40 000 bbl/day hydrocracker with an upgrade value of US\$ 15–20 per bbl, every day of down time costs US\$ 600 000–800 000. Lost pro-

The advantages of slurry-phase processes include:

- The ability to achieve more than 90 wt% conversion of low-value vacuum residue, FCC slurry oil and even coal
- Insensitivity to trace metals in the feed
- Good product quality in two-stage designs, which incorporate fixed-bed hydroprocessing
- Feedstock flexibility
- For a given volume of residue feed: Lower reactor volume than e-bed processes.

Disadvantages of slurry-phase hydrocracking include high installation costs and the difficulty of getting rid of highly refractory pitch.

In this respect, the LC-SLURRY process has a tremendous advantage, because all products can be sold.

duction during a 4 week catalyst change-out can amount to US\$ 18–24 million.

For fixed-bed units, catalyst cycle life dominates economics. Catalysts can't be changed if the units are operating, so shorter catalyst cycles mean decreased production. In a given unit, higher feed rates and higher conversion are desirable economically, but they increase consumption of hydrogen and decrease catalyst cycle life. In units that can recycle fractionator bottoms, higher recycle oil rates can increase selectivity, but they may impose limits on fresh feed rate.

For many recycle hydrocrackers, switching to once-through (zero recycle) operation is attractive economically if the unconverted oil (i. e., the fractionator bottoms) goes to an FCC, olefins plant, or a lube plant for further upgrading. Conversion goes down in the hydrocracker, but it may be possible to increase fresh feed rates without decreasing catalyst cycle life. Operating costs may go down due to decreased hydrogen consumption.

22.12 Safety, Reliability, and Protection of the Environment

Safety, reliability, and protection of the environment are prerequisites to profit in modern industry. Executives know this and strive to behave accordingly. In hydrocarbon production and processing, we have learned from

tragic mistakes. But unsafe behavior continues and tragic incidents still occur, even in companies where the first priority of management really is the health and safety of its workers.

In this section, we discuss safety-related aspects of the following, especially as they apply to hydroprocessing:

- Procedures
- Management of change (MOC)
- Personnel protection equipment (PPE)
- Confined space entry
- Toxic gases: Hydrogen sulfide and carbon monoxide (CO)
- Catalyst handling
- Erosion–corrosion in reactor effluent air coolers (REAC)
- Temperature excursions
- Examples.

22.12.1 Procedures

Nothing in this chapter is a recommendation. The authors accept no responsibility for the operation of any commercial unit.

Process licensors, equipment suppliers, and catalyst vendors provide guidelines and procedures for operation. Many of the accidents and near-misses described below resulted from failure to follow procedures. Hydrocracking is mature technology, with procedures for operation that are decades old. That doesn't mean the procedures are perfect and general procedures may not apply exactly to a certain unit. Significant incidents have led to industry-wide changes. But changes must be managed properly, case-by-case.

22.12.2 Management of Change

A key concept is management of change (MOC) [22.38]. Ineffective MOC is one of the leading causes of serious incidents, according to the US Chemical Safety and Hazard Investigation Board (CSB) which said [22.39]:

In industry, as elsewhere, change often brings progress. But it can also increase risks that, if not properly managed, create conditions that may lead to injuries, property damage or even death.

Changes subject to MOC procedures can include:

- *Personnel changes*, including reorganization, staffing, and training.
- *Equipment changes*, including revamps, maintenance schedules, communications devices, control hardware, and control software.
- *Procedure changes*, including procedures for normal operation, startup, shutdown, and MOC.

- *Material changes*, including significant changes in catalysts, chemicals, and feedstock.

22.12.3 Personal Protection Equipment (PPE)

The PPE worn by workers includes fire-proof clothing, hard hats, safety glasses, steel-toed shoes, gloves, and toxic gas detectors. Harnesses are used to protect against falls. Using fresh-air breathing equipment or self-contained breathing apparatus (SCUBA) improves safety in confined spaces and in areas that might be contaminated by hazardous gases and particulates. In recent years, communication between outside and inside workers has been enhanced by allowing the use of inherently safe radios. Laboratory workers face unique hazards; hard hats are seldom needed in labs, but for some analytical procedures, special gloves and full-face shields protect against hazardous substrates, solvents, and acids.

Pocket-sized toxic gas detectors are important PPE. They sound an alarm when CO or H₂S reach dangerous levels. Some sites require all workers to wear H₂S monitors at all times when they are *inside the refinery gate*. Four-gas monitors are preferred during catalyst unloading. They detect H₂S, CO, combustible hydrocarbons, and oxygen.

In the United States, the Occupational Safety and Health Administration (OSHA) sets standards for PPE [22.40, 41]. The first standards were adopted in 1971. A major revision was issued in 1994, after OSHA discovered gaps in the existing standards. Data indicated that injuries were occurring at the same rate, whether or not employees were wearing PPE. Some regulations were so restrictive that they discouraged innovation.

Present regulations are based on effectiveness. Recent improvements are addressing the main cause of worker noncompliance before the revision: PPE could be cumbersome, uncomfortable, and even impractical.

22.12.4 Confined Space Entry

Empty hydroprocessing reactors are confined spaces. Workers enter reactors during maintenance and catalyst loading. Oxygen levels can become too low even if air is circulating. Required PPE for confined space entry includes fresh-air breathing equipment and a harness that allows colleagues to lift the worker out if necessary. Modern video technology enables outside personnel to monitor people inside directly.

22.12.5 Toxic Gases: Hydrogen Sulfide and Carbon Monoxide

Gaseous hydrogen sulfide (H₂S) is a pervasive hazard around hydroprocessing units. It is generated during

normal operation by HDS reactions and it is used during startups to activate catalysts. Workers are most likely to be exposed when taking samples of gases or liquids. It is common for gas samples to contain more than 5000 ppm H₂S – far above toxic levels.

The impact of H₂S depends on its concentration and duration of exposure [22.42]. At 0.01–1.5 ppm, the characteristic rotten-egg odor is detectable. The odor becomes offensive at 3–5 ppm, where prolonged exposure causes nausea, tearing, asthma, and headaches. Above 20–30 ppm, the odor is said to be sweet or sickly sweet. Above 100 ppm, olfactory nerves are paralyzed and H₂S can no longer be smelled. Exposure to more than 700–1000 ppm causes immediate collapse and death after one or two breaths.

H₂S is flammable. The explosive range is 4.5–45.5 percent in air.

Toxic carbon monoxide can be generated from partial oxidation of hydrocarbons during catalyst unloading; even after thorough stripping with hydrogen during a shutdown, catalyst pores can still contain traces of oil. Under particular conditions, the nickel on NiMo catalysts can react with CO to form nickel carbonyl, an exceptionally hazardous gas.

In hydroprocessing units, sample-taking stations should be well ventilated and equipped with several in-place toxic-gas monitors. Sample-taking procedures include the buddy system: one person takes the sample while another watches. In the past, workers died when rushing forward to help a stricken companion, so the watchers stand at a safe distance with quick access to a radio and SCUBA.

22.12.6 Catalyst Handling

As-delivered catalysts can be dusty. The dust can choke or suffocate workers during handling, especially during reactor loading.

During the dumping of spent catalysts, possible problems include dust, spontaneous combustion, and nickel carbonyl. If the catalysts haven't been sufficiently stripped of hydrocarbons during shutdown, they can ignite spontaneously when exposed to air. Catalysts should be cooled below about 50 °C (120 °F) before dumping, or they should be unloaded under flowing nitrogen and kept in nitrogen-blanketed containers until they are cool enough to handle in air.

22.12.7 Erosion–Corrosion Around Reactor Effluent Air Coolers (REAC)

In hydroprocessing units, erosion–corrosion in REACs can cause leakage and tube failure, leading to loss of hydrocarbon containment and catastrophic explosions.

Examples include the explosion in a German hydrocracker on December 10, 1991, which injured five people and shut the unit down for 8 months; the explosion at the Texaco refinery in Wilmington, California on October 8, 1992, which injured 16 and shut the unit down for 8 months; and more-recent events at Chinese refineries in Zhenhai and Yangzi [22.43].

HDS and HDN reactions convert organic sulfur and nitrogen into H₂S and NH₃, respectively. At reaction temperatures, they are gases. When the reactor effluent is cooled, they form ammonium bisulfide, NH₄SH, which can form solid deposits in REAC tubes. In addition to blocking flow, they induce erosion–corrosion in carbon steel. Wash water is added to the reactor effluent before it reaches the REAC. This mitigates deposition, because NH₄SH is highly soluble in water. The corrosion rate is accelerated, when the flow velocity of the NH₄SH solution is increased.

The piping areas most vulnerable to corrosion are upstream of the REAC but after water injection, between the REAC and the cold separator, and in the REAC itself. Before 1992, it was industry practice to specify carbon steel piping both upstream and downstream of the REAC. After the accidents in Germany and at Texaco, licensors started recommending the use of NH₄SH-resistant alloys.

Other recommendations include:

- Piping should be symmetrical.
- Linear velocity should be 10 to 20 ft/s.
- 30% of the injected water should be liquid.
- The salt content of the sour water should be limited. One licensor recommends < 8 wt%. Others recommend < 4 wt%.
- Corrosion and fouling should be monitored with test coupons and other appropriate means.

A personal recommendation is: Track the difference between ideal and actual performance for heat exchangers (and other equipment as well). This is an excellent way to see which exchangers are limiting unit performance, which ones need maintenance, and which ones can do without maintenance for a time; in certain cases, to opening a well-performing piece of equipment and exposing it to air is riskier than keeping it running. At least one operating company plans maintenance rigorously with design models.

22.12.8 Temperature Excursion Fundamentals

Hydroprocessing is exothermic. In hydrocrackers, loss of heat control causes temperature excursions, in which temperatures suddenly jump by as much as 104 °C (186 °F) in less than 20 s. One excursion ruptured a re-

actor wall. The excursion at Tosco Avon on January 21, 1997, ruptured a reactor outlet pipe, releasing a hot oil/hydrogen mixture, which ignited upon contact with air. The resulting explosion and fire killed one worker, injured 46 others, and shut the unit down for more than 6 months.

One can describe the fundamentals of temperature excursions by addressing the following observation and question: Per hydrogen consumed, hydrocracking releases a little less heat than HDS and 20% less heat than aromatics saturation. So why do temperature excursions occur in hydrocrackers but rarely in hydrotreaters?

The easy answer is: because hydrocracking doesn't occur in hydrotreaters. That's true, but not very instructive. It's more informative to examine additional observations as follows.

Relative Amounts of Reactants

If a feed contains 2 wt% sulfur and 86 wt% carbon, the C–S atom ratio is about 198 : 1 (Table 22.14).

Most sulfur compounds have two C–S bonds and HDS requires both to be broken with consumption of at least 2 moles of H₂. Paraffin hydrocracking breaks one bond with consumption of one mole of hydrogen. Assume that all sulfur is present as methyl thiophene isomers and that HDS entails the following reaction

Now assume that the rest of the feed is composed entirely of isomers of C₃₂H₆₆, which boil between 440 and 467 °C and have 31 crackable C–C bonds. Breaking all 31 C–C bonds would produce methane. Breaking just three bonds (10% of the total) could form four naphtha molecules

In this scenario, after correcting for the C–C bonds in sulfur compounds, hydrocracking heat production is 18.6 times greater than HDS heat production.

Disrupting Ring–Compound Equilibria

In the previous paragraph, we ignored ring compounds. In real feeds, the percentage of carbon atoms in ring compounds can range from 30% to more than 80%. Figure 22.8 shows equilibria between naphthalene, tetralin, and decalin at different temperatures and pressures. Saturation of aromatics and dehydrogenation of naphthenes involves 1 to 3 hydrogen molecules per ring. At low temperatures, exothermic saturation releases more heat per H₂ consumed than HDS, but above about 415 °C (780 °F), the reverse reaction, endothermic dehydrogenation becomes important.

At true equilibrium, there is no net heat consumption or production. As temperatures go higher, the equilibrium shifts further toward aromatics until

Table 22.14 Heat release for HDS, HDN, and HC reactions for a representative hydrocracker feed. Breaking 10% of the C–C bonds in the feed would release 18.6 times more heat than HDS

TBP distillation, IBP/50%/99.5%

HC: 10% of C–C bonds broken	–51.2	0.98	18.6

^a Ratio of carbon atoms in paraffin chains, naphthene rings, aromatic rings and olefin groups

^b Complete conversion of C₃₂ into CH₄, all 31 of the C–C bonds are broken

^c Per mole of H₂ consumed

naphthenes are nearly nonexistent. In this way, the saturation/dehydrogenation equilibrium mitigates heat release. It has been said that dehydrogenation reactions *apply the brakes* to temperature rise. Removing saturated rings, e.g., by breaking saturated C—C within rings, or by clipping off alkyl side chains, disrupts equilibria, thereby *releasing the brakes*. Breaking C—C bonds replaces heat-neutral equilibrium with irreversible exothermic hydrocracking. The net difference in ΔH_R is -42 kcal/mol of H_2 consumed.

Hydrocracking is More Temperature Sensitive Than Hydrotreating

Please refer to Fig. 22.29, which is based on Langmuir–Hinshelwood kinetics and experimentally determined Arrhenius activation energies. It shows that if reaction rates for HDS and hydrocracking are the same at 380°C , then hydrocracking over high-zeolite catalysts is 20 times faster than HDS at 470°C . The hotter it gets, the faster it gets hotter. Activation energies for hydrocracking over amorphous silica-alumina (ASA) catalysts are slightly higher than those for HDS. Excursions over ASA catalysts do occur, undoubtedly for the first two reasons described above, but probably not due to activation energy.

Thermal Hydrocracking

Refer again to Fig. 22.29. It shows that around 470°C , thermal hydrocracking becomes $2\times$ faster than catalytic hydrocracking. Thermal cracking proceeds by a different mechanism, in which far more than 10% of C—C bonds are broken. An increase in methane production is a sure sign of thermal hydrocracking. Catalytic hydrocracking produces only small amounts of methane and ethane; typical yields of C_1C_2 are <0.2 wt% of fresh feed at SOR and <0.6 wt% at EOR. In contrast, thermal hydrocracking often produces more than 4 wt% C_1C_2 .

22.12.9 Temperature Excursion Examples

Example 1: Stagnation

Flow of fluids accounts for almost 100% of heat removal. Even in a hydrotreater, stagnation can be unsafe. A serious temperature excursion occurred in a stagnant, low-pressure hydrotreater. The reactor had been blocked in pending the completion of maintenance activity elsewhere in the refinery. To save time, the reactor wasn't drained before it was isolated by closing inlet and outlet valves. Temperatures were near-ambient, at least at first. Nobody imagined that a reaction could occur. The reactor contained oil, hydrogen, and (of course) hydrotreating catalyst. Initial reactions might have involved just a few molecules, with minuscule

heat release. But without flow, reaction heat accumulates. Accumulated heat raises local temperatures, which increase local reaction rates. Faster reactions generate more heat etc. The thermochemical driving force was strong. The residence time and supply of reactants were essentially limitless. In retrospect people agreed, after the fact, that an excursion was inevitable.

Example 2: Sudden Feed Switch

A feedstock change can trigger a temperature wave, which can cascade through several catalyst beds, growing as it goes. The temperature can get high enough to trigger an excursion. If operators know that a different feed is coming to the unit, they prepare by decreasing temperatures in advance, especially if they know the new feed is more reactive.

If the change is unexpected, the resulting temperature wave won't be noticed until it reaches the outlet of the 1st bed and (less than a minute later) the inlet of the 2nd bed. An automatic feedback control loop will drop the inlet temperature of the 1st bed, but that action won't stop the wave in the 2nd bed. Intercepting the wave requires adding quench to the outlet of the 2nd and 3rd beds. If alerted by alarms, operators have plenty of time to respond appropriately. But they must respond quickly and decisively. If the wave isn't stopped before it reaches the first bed of cracking catalyst, it will trigger an excursion.

Over-response to a heavier, less-reactive feed can also cause an excursion. When a bed outlet temperature falls, the temperature controller for that bed reduces quench to increase the inlet temperature. If the increase is too large, the bed outlet temperature – and the inlet temperature for the next bed – will be too high.

A feed-switch excursion occurred in a European hydrocracker during a change from one feed tank to another. There wasn't much difference between the oils in the two tanks, but the pipe between the new tank and the hydrocracker contained flush oil – light cycle oil from an FCC unit. LCO is lighter and far more reactive than the usual heavy VGO feed. When the LCO exited the first catalyst bed, the bed outlet temperature was significantly higher than usual. Operators responded immediately and appropriately by adding quench to all downstream beds. But they didn't add enough quench. The inlet temperature for the 1st bed of cracking catalyst was just a few degrees higher than usual. But due to the higher reactivity of the feed and also due to the fact that the light feed was mostly vapor by then, the bed outlet temperature jumped, exceeding the prescribed limit. The unit depressured automatically. Three days of production were lost, but no other negative consequences were observed.

Example 3: Hot Spots

During normal operation, flowing fluids – and practically nothing else – removes reaction heat from hydrocracking reactors of all kinds. For the paragraphs above, we assumed that flow distribution through reactors is perfect from top to bottom. In real units, there is always some mal-distribution of flow. Mal-distribution starts with poor reactor design, poor installation of reactor internals, improper catalyst loading, or a process upset.

The mal-distribution shows up as a *radial temperature difference* (radial dT), defined as the difference between highest and lowest TI readings in a horizontal plane.

Figure 22.39 and Table 22.15 show how mal-distribution of flow might affect measured temperatures, true maximum and minimum temperatures and critical calculations. The measured temperatures are from a commercial unit. The *real* maximum and minimum temperatures are made up, but they are consistent with hydrodynamic calculations.

Here are some observations based on the TI readings:

- All radial dT s are higher than usual. With modern reactor internals, SOR radial dT values are $< 1^\circ\text{C}$ at the bed inlet and $< 2^\circ\text{C}$ at the bed outlet. Typically at EOR, the inlet radial dT s haven't changed and the outlet radial dT s range from $4\text{--}6^\circ\text{C}$.

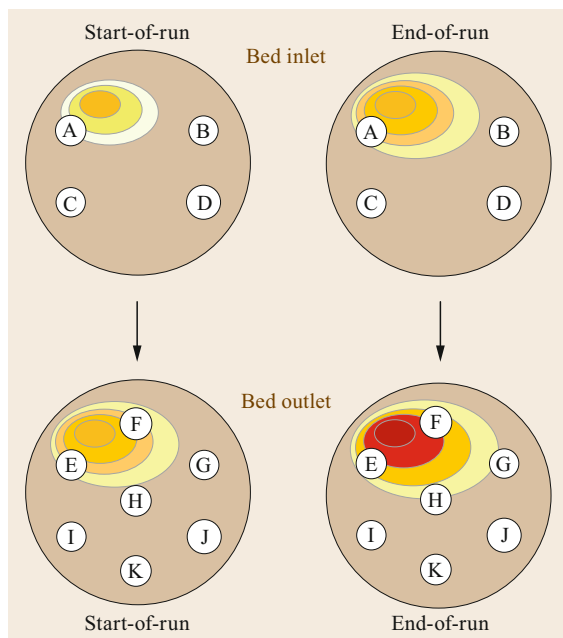

Fig. 22.39 Example: Impact of flow mal-distribution on TI measurements. This figure is associated with Table 22.14

- At EOR, the average axial dT is 14.5°C . For high-zeolite catalysts, this is slightly greater than max axial dT guidelines from some licensors (13.7°C) but lower than guidelines from another licensor (16.7°C).
- The EOR radial dT is almost the same as the average axial dT and the max axial dT is nearly $2\times$ higher than the average axial dT . Both are clear indications of severe mal-distribution of flow.

One never knows the true minimum and true maximum temperatures in a catalyst bed. If an operator sees the danger signs noted above, s/he knows there is a problem but not the severity of the problem:

- The inferred maximum temperature is 490°C and is associated with a hot spot
- 490°C is 51°C higher than the apparent maximum temperature and it is 35°C above the metallurgical limit for this particular reactor
- 490°C is $30\text{--}50^\circ\text{C}$ higher than the temperatures at which thermal cracking becomes dominant.

The customer was advised to look for other signs of a hot spot, such as off-color products and increasing methane in the recycle gas. Product color had indeed degraded since SOR and methane was indeed high. However, the refiner had not measured methane before, so it was impossible to know if there had been an increase.

A temperature pulse test was recommended but not conducted. In a pulse test, the bed inlet temperature is dropped quickly by at least 2.5°C . For each bed outlet TI, the response time is measured. When flow distribution is poor, the difference in bottom-of-bed TI response time can be more than 7 min. The leading explanation for the hot spot was poor catalyst loading, but there was no way to prove it.

Example 4: Wrap-Around Heat

The heat exchangers in hydrocrackers are highly integrated. An upset far from the reactors can cause problems. In September 2009 a temperature excursion occurred in the hydrocracker at CITGO Petroleum Company in Lake Charles, Louisiana, when a sudden loss of preheat caused a hydrogen heater to fire aggressively [22.44]. In response to the suddenly higher heater temperature, quench valves quickly opened to control a high bed inlet temperature, then quickly closed when the high bed inlet temperature was resolved. The quick closing of the quench valve permitted an even higher inlet temperature in the following bed, which led to a bed outlet temperature greater than the limit of 427°C (800°F). This initiated low-rate

Table 22.15 TI readings and process calculations for Fig. 22.39, plus calculations for inferred *true* values

TI designation	Start-of-run		End-of-run	
	Bed inlet	Bed outlet	Bed inlet	Bed outlet

depressuring at 7 bar/min (100 psig/min). The results were:

- A flaring event
- Production disruption lasting 3–4 days
- Loss of catalyst life.

Afterwards, an investigation team determined what had happened and suggested appropriate corrective action. Changes were made to the control system, including the following:

- Use setpoint tolerance and output tolerance to limit the size of changes that can be entered at the control board without a warning
- Make heater controls less aggressive
- Override feedback-based control of quench when a bed outlet temperature exceeds its setpoint
- Make the override more aggressive when the bed outlet is rising faster than 1 °F/min
- Limit how quickly the quench valves can close, but do not limit how fast they can open
- Limit how quickly heater firing can increase, but do not limit how quickly it can decrease.

Mr. Gregory Hampton developed an advanced regulatory control (ARC) application to capture the suggestions. Implementation was straightforward, except for the rate-of-rise limit. This was handled with a unique quench-demand calculation, which executes once per second in the ARC. According to enthusiastic unit operators, the application works well to detect and mitigate impending temperature excursions. It then automatically returns the unit to automatic control. The Hampton approach is now being implemented elsewhere around the world.

Example 5: Substandard Equipment, Disabled EDS Interlock, Stagnation

A serious excursion was the latest of several in a new hydrocracker. The ultimate cause was a decision by the purchasing department to order substandard items for the associated hydrogen plant. One by one, the substandard items failed and were replaced by proper ones. Each failure upset the hydrocracker. Some failures sent liquid into the suction of the recycle gas compressor (RGC), causing the RGC to shut down. The licensor's EDS interlock gave operators 15 min to restart the compressor before automatically activating the low-rate depressuring valve. Each depressuring event shut

the unit down for at least a day. To give themselves extra time to restart the RGC, the unit engineer and operators decided to disable the EDS–RGC interlock. It was acceptable, they assumed, to depressure only if the unit reached a temperature limit. These assumptions demonstrated ignorance of several fundamental concepts:

- The flow of fluids is the only significant way to remove heat from a hydroprocessing reactor.
- With zero or low flow, TI readings become meaningless.

Example 3 showed that one never knows the highest or lowest temperature in a catalyst bed. But when reactants are flowing, one can be confident that bed outlet TIs correspond to the temperatures above them. When flow stops, no TI reading is relevant to any temperature more than a few inches away.

Reactions do not stop when flow stops. Heat accumulates in catalyst beds, often without affecting the bed outlet TI readings. Hot oil sinks into pools at low points. Eventually, the pooling oil will reach one or more bed outlet TIs and/or reactor wall TIs, providing the first tangible indication that something is wrong. Undoubtedly, that is what happened in this unit. A timeline is shown in Table 22.16. A visual representation is presented in Fig. 22.40.

After the first compressor failure, it took 144 min for overheated oil to reach reactor outlet TI-3. The reading spiked at 17:38 local time (LT), initiating depressuring when it reached 440 °C. TI-3 continued to rise until it reached 487 °C. Depressuring seemed to make things worse. It decreased TI-3, but as the pressure fell, the exiting gas pulled hot, formerly stagnant

Table 22.16 Example 5 timeline

Local time	
16:14	Recycle gas compressor failed Pressure = 127 bar Maximum bed TI = 402 °C Reactor outlet TI = 398 °C
17:38	Reactor outlet TI-3 exceeded 440 °C Automatic low rate depressuring
17:44	Reactor outlet TI-3 continued up to 478 °C
18:00	Recycle gas compressor was restarted
18:27	A bottom reactor wall temperature reached 436 °C
19:17	Recycle gas compressor failed
18:20–20:54	Bed outlet TI-1 jumped 214 °C in 7 min, stayed > 618 °C for 154 min
20:28	Recycle gas compressor was restarted successfully
18:56–22:30	Bed outlet TI-2 reached > 618 °C, fell, rose to > 550 °C until 22:30

oil through the reactor. Between 17:48 and 17:55 LT, Bed Outlet TI-1 jumped from 404–618 °C, an increase of 214 °C in 7 min. The readings fell after a restart of the RGC. But then, most likely due to the arrival of more overheated oil, TI-1 jumped back up to 618 °C, where it flat-lined for more than 2.5 h. Actual temperatures were higher than 618 °C, which is top-of range. A second attempt to restart the RGC succeeded. TI-1 started to fall. But as it did, Bed Outlet TI-2 rose above 550 °C and stayed there for another 2 h.

Afterwards, the unit was operated at reduced rates for 6 months, with strict adherence to licensor-suggested temperature limits. The limits were tighter due to fears that the reactor wall and outlet pipe had been compromised. During the subsequent turnaround, workers found partially fused silica balls near the reactor wall. Pure silica melts at about 2000 °C. Impure silica melts at lower temperatures, but even so, it must have been incredibly hot near the wall of that reactor.

Example 6: Tosco Avon

On January 21, 1997 a temperature excursion led to the rupture of the reactor 3 outlet pipe at the Tosco Avon Refinery in Martinez, California [22.45]. Reactor 3 was one of three parallel Stage 2 reactors, each of which contained five beds of hydrocracking catalyst. The consequent release of hydrogen and hydrocarbons ignited on contact with air, causing an explosion and fire. One worker was killed and 46 others were injured. There were no reported injuries to the public.

Figure 22.41 shows the arrangement of the reactors in the Tosco unit. Figure 22.42 shows selected TI readings during the event. The initial excursion began in reactor 3 bed 4 (R3B4) and cascaded into R3B5 (reactor 3 bed 5). It may have started at a hot spot in R3B4. It peaked at 439 °C (823 °F). According to licensor-recommended procedures, the unit should have been depressured when TI readings reached 427 °C (800 °F). But instead of depressuring, the operators did what they had done several times since July 1992: they tried to control the excursion by manipulating quench gas. Two days earlier, on January 19, 1997, they had managed to defeat an excursion in reactor 1, but not before the outlet pipe TI exceeded 482 °C (900 °F) and the center TI in R1B4 reached 537 °C (998 °F). Along the way, an operator went outside to get a reading from a panel underneath the outlet pipe. On January 21, the operator who died went to the same place and was underneath the outlet pipe when it ruptured.

Operators said they failed to act on January 21, because they didn't know whether or not an excursion was occurring. They got readings from three different temperature systems, two in the control room and another in

Fig. 22.40 Pressure, recycle gas flow, and selected temperatures for Example 5. Bed outlet TI-1 flat-lines at 618 °C, because 618 °C is top-of-range. Actual temperatures were far higher, as evidenced by the fused catalyst in the bed when the reactor was unloaded

the outside field panel. The systems in the control room gave different information. The data logger, with most of the reactor temperature information, was fluctuating wildly. Because of sudden changes in quench flow, the makeup compressor shut down.

In other refineries, uncertainty is not an acceptable excuse for unsafe behavior. Operators are told: When in doubt, assume the worse; bring the unit down.

Root causes for the Tosco Avon accident include the following:

- When the unit was depressured at a low rate to stop an excursion on July 23, 1992, a grass fire started at the flare. A worker told the lead author of this chapter, in a private conversation, that from that time on, upper management strongly discouraged use of depressuring, fearing the consequences of a fire spreading into the nearby grassy hills and the John Muir historic site.
- Operators used three different instrumentation systems to obtain temperature data. Not all the data were immediately accessible and they often disagreed. Monitoring points capable of reading the

highest temperatures were underneath the reactors and not connected to the control room.

- Supervisory management and operator training were inadequate. Operators were not taught to understand that zero default values on the data logger might mean extremely high temperatures. They did not understand the tremendous sensitivity of cracking catalysts to organic nitrogen. They did not understand the dynamics of sampling i.e., the lag time between taking a sample, getting results, and what might have happened to the process in the meanwhile (see Table 22.17).
- Written procedures were outdated, incomplete, and contained in different documents in different locations.

The investigation team developed the following recommendations for consideration by owners of all hydroprocessing facilities:

- Management must ensure that operating decisions are not based primarily on cost and production. Facility management must set safe, achievable op-

Fig. 22.41 Arrangement of reactors in the Tosco Avon hydrocracker

erating limits and not tolerate deviations from these limits. Management must provide an operating environment in which operators can follow emergency shutdown procedures without fear of retribution.

- Process instrumentation and controls should be designed to consider human factors consistent with good industry practice. Hydroprocessing reactor temperature controls should be consolidated with all necessary data available in the control room. Backup temperature indicators should be used so that the reactors can be operated safely in case of instrument malfunction. Each alarm system should distinguish between critical alarms and other operating alarms.
- Adequate operator supervision is needed, especially to address critical or abnormal situations.
- Facilities should maintain equipment integrity and discontinue operation if integrity is compromised.
- Management must ensure that operators receive regular training on the unit process operations and chemistry. For hydrocrackers, this should include training on reaction kinetics and the causes and control of temperature excursions.

- Operators need to be trained on the limitations of process instruments and how to handle instrument malfunctions.
- Facilities need to ensure that operators receive regular training on the use of the emergency shutdown systems and the need to activate these systems.

22.12.10 Preventing Temperature Excursions

Honor Temperature Limits

To ensure safe operation, licensors specify limits on average reactor temperature, maximum peak temperature, and maximum bed temperature rise (Table 22.18). For high-zeolite catalysts, typical values are lower than for less-active catalysts. The limits provide ample cushion between operating temperatures and the actual metallurgical limit, which is 455 °C for typical hot-wall reactors constructed from stainless steel containing 2.25% chromium and 1% molybdenum.

As temperatures approach these limits, process economics may suffer. High temperatures increase production of low-value C₁–C₄ and light naphtha. Middle distillate quality suffers from high aromatics, which de-

Fig. 22.42 Reactor 3 temperatures during the TOSCO Avon incident. Temperature indicator Pt-133C2 jumped by 104 °C (186 °F) in 20 s, reaching 439 °C (823 °F). The excursion cascaded through the quench section into the next catalyst bed, causing a jump of 223 °F (124 °C) in 40 s at Pt-140C3, reaching 460 °C (860 °F)

crease smoke and cetane. Units have been shut down for a catalyst change due to poor selectivity.

Move Slowly

It can take more than an hour for changes to travel completely through a hydrocracker. For this reason, licensors recommend limits on heat-up rates.

Decrease Temperature Before Making Changes

One never really knows how a feedstock change will affect unit performance. To be safe, it is best to lower temperatures to protect against incidents such as the one discussed in Example 1.

Trends

Trends are an early warning system, indicating from history what is likely to happen next, providing time to back off before a limit is reached. Early warning also provides time to alert other units in the refinery

that a change might be coming. At a Shell refinery in Canada, the philosophy is SSS: slow down, stabilize, and (if necessary) shut down.

Software

Hampton et al. describe an advanced regulatory control (ARC) application that detects impending excursions and mitigates them with quench overrides [22.44].

22.12.11 Stopping a Temperature Excursion

Figure 22.43 shows how hydrocracking is analogous to combustion. In both cases, three factors are needed for a reaction. Combustion requires oxygen, flammable fuel, and heat. Hydrocracking requires hydrogen, oil, and heat. In both processes, removal of one factor stops the reaction.

Table 22.19 presents a qualitative overview of heat balance and heat removal in a hydroprocessing unit

Table 22.17 Abbreviated timeline with comments on nitrogen slip measurements for the Tosco Avon incident

Local time	
4:50 AM	One of three Stage 1 hydrotreating reactors was brought down to repair a leak. Stories differ about whether the total unit feed rate was kept the same or reduced and whether or not Stage 1 reactor temperatures were adjusted. Regardless, the extent of HDN was reduced.
10:00 AM	Nitrogen slip had risen from < 15 to 352 ppmw.
11:30 AM	Because of the high nitrogen slip and resulting inhibition of Stage 2 cracking activity, there was no temperature rise in one cracking reactor and very little rise in the other reactors. No light products were being formed. Stage 1 temperatures were raised to decrease nitrogen slip.
1:10 PM	Stage 2 hydrocracking reactor temperatures were raised to <i>burn off</i> inhibitory nitrogen. This was a horrendous mistake. Treating and cracking temperatures must never be raised at the same time. As discussed, catalytic cracking activity is highly sensitive to organic nitrogen.
5:38 PM	Nitrogen slip from Stage 1 was reported to be 47 ppmw. The actual nitrogen slip when the result was received was considerably lower than 47 ppmw. Since 10:00 AM, the nitrogen slip had fallen 300 ppmw in 7 ½ h, an average of 40 ppmw/h. If the lag time between taking a sample and getting results was 1 h as usual, the true nitrogen slip was < 10 ppmw at 5:38 PM and probably close to zero at 7:34 PM.
7:34 PM	In reactor 3, bed 4 (R3B4), one TI jumped 108 °C in 40 s, reaching 439 °C, 10 °C higher than allowed by procedure but not higher than in previous events.
7:34:20 PM	Quench to R3B5 opened 100%. Data logger temperatures cycled between –18 °C, 649 °C, and 343 °C. In well-run units, the associated uncertainty would have compelled someone to bring the unit down immediately (if it had not been depressured previously due to high temperature).
Sometime before 7:37 PM	An operator went outside to verify temperatures at the field panel.
7:37–7:39 PM	All R3B5 outlet TIs were > 415 °C. One reached 679 °C.
After 7:40 PM	An operator phoned an instrument technician to work on the fluctuating data logger.
7:41:20 PM	7 min after the first temperature jump. Explosion. The operator at the field panel died. A board operator activated the EDS.

Table 22.18 Common limits on temperatures in fixed-bed hydrocrackers

	High-zeolite catalyst (°C (°F))	Low-activity catalyst (°C (°F))	Hydrotreating (reference only) ^a (°C (°F))
Max WABT	415 °C (780 °F)	427 °C (800 °F)	–
Max temperature (any TI or any two)	427 °C (800 °F)	440 °C (825 °F)	440 °C (825 °F)
Max T-rise per bed	17 °C (30 °F)	19 °C (35 °F)	50 °C (70 °F)
Max deviation from setpoint	28 °C (50 °F)	28 °C (50 °F)	28 °C (50 °F)
Rate of change of T-rise	^b	^b	–

^a Hydrotreaters do not require depressuring systems. The numbers here are shown for reference only
^b Rate of change in T-rise can serve as the basis for an alarm

during normal operation and Table 22.20 compares stopping combustion with stopping hydrocracker temperature excursions.

Depressuring is immediate and always stops temperature excursions in fixed-bed hydrocrackers. As mentioned, guidelines for designing EDS are provided by API Recommended Practice 521. Emergency depressuring, especially high-rate depressuring, disrupts a unit. It has deformed reactor internals and disturbed catalyst beds, creating or aggravating flow-distribution problems.

Temperature-related EDP interlocks should never be disabled, as they were in Examples 5 and 6. Operators should never hesitate to depressure manually if necessary.

Depressuring must continue until the pressure is as low as possible, usually to just above the CLPS pressure. Operators who attempt to re-pressure sooner usually do so when the pressure is 50% of design. They don't realize that flow must be zero at some point during the switch from depressuring to repressuring and that even after extensive hydrogen stripping, some oil is still present inside catalyst pores. In our experience with two units, early repressuring led to a second excursion.

Early action prevents or mitigates excursions before they require depressuring. All of the non-depressuring actions in Table 22.20, including reduction of feed rate, can decrease the chance of an excursion before limits are reached. For these reasons, operators should be encouraged to manipulate quench valves and heater

Fig. 22.43 Comparison of combustion with hydrocracking (after [22.44])

controls promptly and decisively at the first sign of an impending excursion.

22.12.12 No DIBS

We have come a long way since 1984, when the CEO of an oil company said, in response to a question about a fatal explosion: *What can I say? It's a dangerous business.* He was truly distraught about the incident, which had killed people he knew. He took care of the families of the victims. But his old-school attitude may have been part of the problem. In 2017, *It's a dangerous business* has been replaced by Zero-Zero-Zero campaigns – to achieve zero injuries, zero loss of containment, and zero unplanned shutdowns. These campaigns are not just for show. They reflect a sincere belief that it doesn't have to be a dangerous business. They require investment, but the return on that investment in today's litigious society is enormous in many measurable ways.

Accidents do still happen. The two worst examples in this section were caused by DIBS – Did It Before

Table 22.19 Heat sinks, heat sources, and heat removal in fixed-bed hydroprocessing units

Heat sources	Proportion
Chemical reactions	Major
Feed heater	Moderate ^a
Heat sinks	
Feed heat capacity	Major
Feed vaporization	Major
Hydrogen	Major
Catalysts	Minor ^a
Reactor walls	Minor ^a
Heat removal mechanisms	
Flow of fluids	Major
Heat exchangers and coolers	Major

^a Major during startup and shutdown

Syndrome. People did the wrong things, over and over again, knowing full well that they were ignoring procedures. Eventually, they came to believe that their way was sort of okay. But as Master Michael Reade says in martial arts classes, *Practice makes permanent. Only perfect practice makes perfect.*

We know first-hand that Tosco workers wanted to operate safely and pleaded for better equipment, only to be denied by profit-obsessed executives. In that environment, executive DIBS was more responsible for the fatality than worker DIBS.

We see DIBS everywhere in our personal lives. Motorists run stop signs and drive too fast. Children are allowed to ride bicycles without helmets. DIBS, it seems, is a fundamental aspect of human behavior. We might achieve Zero-Zero-Zero, but not before we zero in on DIBS.

Table 22.20 Comparison of stopping combustion with stopping hydrocracker temperature excursions

Combustion	Action	Speed	Effectiveness
Remove air	Smother with a blanket or foam, add CO ₂	Immediate	Very
Remove fuel	Set back fires around the main fire	Slow	Moderate
Remove heat	Add water or CO ₂ from a fire extinguisher	Immediate	Very
Hydrocracker temperature excursions			
Remove hydrogen	Depressure	Fast	Very
Remove fuel	Cut feed pump	Slow	^a
Remove heat	Depressure	Fast	Very
	Add quench gas	Immediate	Moderate
	Cut furnace firing	Slow	Moderate
	F–E exchanger bypass	Slow	Very

^a Decreasing feed rate increases residence time and removes a significant heat sink. Both factors might increase the severity of an excursion. For this reason, one licensor recommends keeping the feed pump running, at least for a time. When coupled with F–E exchanger by-pass, early action to send cold feed to the furnace and reactors can be quite effective in reducing reactor temperatures

22.13 Conclusion

Hydroprocessing plays a central role in petroleum refining. Advances in hydroprocessing are driven by competitive forces, clean-fuel regulations, the advent of different feedstocks, and the ongoing need to im-

prove process safety. Improved catalysts, more-flexible reactor design, advanced process control, and online optimization will continue to enhance the safety and capability of new and existing units.

22.14 Additional Reading

For additional information, we recommend the books by Satterfield [22.1], Topsøe et al. [22.2], Gary and Handwerk [22.46], Marcilly [22.47], Scherzer and Gruia [22.13], Speight [22.48], Ancheyta and Speight [22.33], Magee and Dolbear [22.49], and Hsu and Robinson [22.50]. Satterfield's book covers most aspects of heterogeneous catalysis and serves as a source of information for many subsequent works. Topsøe's book gives a thorough overview of the fundamentals of hydrotreating. Gary and Handwerk still sets the standard for textbooks on petroleum refining. In considerable

depth, Marcilly's work describes the fundamentals of acid/base catalysis in the refining and petrochemical industries. The Speight and Speight/Ancheta books focus on hydroprocessing fundamentals, heavy oil upgrading, reactor design, and related topics. Scherzer and Gruia provide useful information on hydrocracking chemistry and catalysis. The Magee/Dolbear book covers refining catalysis in general terms and the Hsu/Robinson books include chapters by several authors on all aspects of petroleum refining, including many areas not addressed in other publications [22.50].

Hydroprocess

23. Hydroprocessing Reactor Internals

F. Emmett Bingham, Douglas E. Nelson, Daniel Morton

As discussed in other chapters, catalytic hydrotreating upgrades petroleum fractions by saturating olefins and aromatics with hydrogen, and by converting contaminants such as sulfur, nitrogen and sometimes oxygen into H₂S, NH₃, and H₂O respectively. Hydrotreating also remove trace elements such as Ni, V, Fe, Si, As and Hg. Catalytic hydrocracking converts heavy hydrocarbons into lighter material by breaking carbon-carbon bonds.

The hydroprocessing process is exothermic, and thus produces heat as the process stream and treat gas are reacted in the catalyst bed. Controlling temperature rise is a major concern during design and operation. Flow distribution is also important. Inside reactors during normal operation, fluid flow is the only significant way to remove process heat. Uneven fluid flow can impair performance. It can lead to hot spot formation, which can jeopardize process safety and catalyst life.

While proper catalyst loading and grading is very important, reactor design, specifically the internals, is the key to controlling both the exotherm and fluid flow.

This chapter provides an overview of essential components of reactor internals, with emphasis on the relative performance of different designs.

Since the introduction of fixed-bed hydroprocessing technology in the early 1950s, catalyst suppliers have made significant advances in improving the relative activities of hydroprocessing catalysts. As illustrated in Fig. 23.1, the activities of current commercial hydrotreating catalysts are an order of magnitude higher than those initially just a few decades ago.

In the mid-1990s it became apparent that the design of hydroprocessing reactors had not advanced at the same pace as the development of hydroprocessing catalysts and the existing reactors were not capable of taking full advantage of the potential benefits of the high-activity catalysts. As a result, licensors began to develop high-performance reactor internals to address the demands of ultralow sulfur diesel production.

23.1 Elements of Hydroprocessing Reactor Design

The following describes the reactor internals elements that should be considered in the design of internals for hydroprocessing reactors:

- *Inlet diffuser device*: The purpose of this device is to diffuse the velocity profile of the fluids entering the reactor inlet nozzle and create an even pattern of

Fig. 23.1 Development of hydrodesulfurization catalysts

liquid dispersion across the top liquid distribution tray.

- **Top liquid distribution tray:** The top liquid distribution tray evenly distributes the liquid charge across the surface of the top catalyst bed.
- **Catalyst support:** Multiple beds are often utilized in reactors that have high temperature rises or would benefit from redistribution of the reactants. These reactors would have catalyst support grids and beams to carry the weight of each catalyst bed.
- **Quench injection device:** In multibed reactors, quench gas or liquid is introduced into a quench zone through a quench distributor for cooling purposes or replenishment of depleted reactants. Typically, the quench injection is a slotted pipe system. Although some units employ hydrocarbon liquids

for quenching, hydrogen-rich gas is used most often. The injection is typically part of and incorporated into the entire quench chamber.

- **Quench mixing chamber:** In multibed reactors, the mixing chamber ensures that hot liquid and vapor phases from above the catalyst bed are adequately mixed with relatively cold quench gas or liquid injection. The mixing chamber ensures that all fluids reach an equilibrium temperature and composition upon exiting the mixing zone. The mixing chamber also has the job of correcting any radial spreads from the catalyst bed above. The temperatures leaving the quench chamber should be uniform and if quenching is also performed, much cooler to meet the next catalyst bed's inlet temperature requirements.
- **Liquid redistribution tray:** The redistribution tray evenly distributes the quenched liquid and vapor exiting the mixing chamber across the surface of the subsequent catalyst bed.
- **Thermocouples:** Thermocouples monitor the temperature of the fluids reacting throughout the catalyst bed. They should be located to provide sufficient data to indicate that the reaction and radial temperatures in each section of the catalyst bed is even.
- **Outlet collector:** The outlet collector supports the bottom catalyst bed and is designed to promote even flow in the bottom of the reactor.

Although the entire reactor internals elements listed above are important to the performance of the hydroprocessing reactor, the distribution trays and mixing chambers are critical to ensuring the efficient utilization of the hydroprocessing catalyst.

23.2 Liquid Distribution Tray Design

Liquid distribution trays are typically used to establish good flow distribution in hydroprocessing reactors. By obtaining even distribution of the liquid reactants over the entire reactor cross-sectional area, all the catalysts at a given level are evenly wetted, giving the catalyst bed what is called a proper *plug flow*. Thus, all the catalysts at a given level operate at the same efficiency, which optimizes the overall efficiency of the reactor. Additionally, even liquid distribution minimizes the radial temperature profile across the reactor. This minimizes the occurrence of hot spots which, over time, cause coking and high rates of catalyst deactivation. Consequently, the reactor operates more efficiently, which enables a longer cycle length. Better distribution trays increase value by reducing catalyst

requirements, improving processing capability and/or longer cycle lengths. It should be noted that all the extremely detailed and complex process calculations used to determine the catalyst type, size, loading, depth, cycle length, etc., assume a plug flow regime inside the catalyst bed(s). So when a catalyst is selected and guarantees are given, there is no way to accurately predict the cycle life and efficiency inside a new catalyst bed if the distribution and mixing are not ideal.

Most liquid distribution devices are proprietary designs developed by process licensors and internals fabricators. Most of the known designs fall into one of four categories.

The first is a series of troughs and overflow weirs that systematically subdivide the liquid into multiple

streams before it contacts the bed. This type is often used in liquid contactors or countercurrent absorbers. The trough-type distribution device is mechanically complex and very sensitive to levelness. Depending on the design of the troughs, the quality of the distribution may be susceptible to fouling. An example of this type is US Patent 5192465 by *Petrich* and *Martinengli* assigned to Glitsch, Inc. [23.1].

A second type of liquid distribution device is a perforated tray. This may or may not have notched weirs around the perforations. The tray may also have chimneys for vapor flow. This type of distribution device is often used for rough liquid distribution in conjunction with a more sophisticated final liquid distribution tray. A perforated tray is possibly the least expensive design with regards to materials and fabrication cost, and it can offer a large number of distribution points. However, it is not an efficient primary distribution device because it must be absolutely level to provide even distribution of liquids, and it is very prone to plugging by debris collecting on the tray. Examples of this type are described in US Patent 4836989 by *Aly* et al. assigned to Mobil Oil Co. [23.2] and US Patent 3824080 by *Smith* et al. assigned to Texaco [23.3].

A third common type of liquid distribution device is a chimney tray. This device uses a number of standpipes laid out typically on a regular square or triangular pitch pattern on a horizontal tray. The standpipes typically have holes or notches cut through the sides for the passage of liquid. The tops of the standpipes are open to allow vapor flow down through the center of the chimneys. Some designs use special vapor chimneys to handle the bulk of the vapor flow. Functionally, the chimney tray design is very similar to the perforated tray design, except the holes or perforations are elevated above the surface of the tray to allow some capacity to maintain a liquid level and hold debris that may collect off the tray. The chimney design is an improvement over a perforated tray, since it can be designed for a wider range of liquid/vapor loadings. However, the spacing of the chimney risers typically reduces the number of distribution points compared to a perforated tray. A properly designed chimney must either become taller or have smaller holes drilled in the side to maintain a liquid level on the tray as the liquid rate changes. At turndown, it is possible that some holes will be covered with liquid and others will not. This results in uneven liquid distribution over the surface below the tray. The key issue with chimney trays is that the liquid level is completely independent of the gas rates, as the gas flows through the center tube. As there is very little pressure at the liquid flow holes on the sides of the tubes, they are susceptible to fouling as well and are not very flexible over

a wide range of operating conditions, if these holes get plugged or the tray is uneven due to out-of-level or sagging over time. Examples of this type are US Patent 4126540 by *Grosboll* et al. assigned to ARCO [23.4] and US Patent 3353924 by *Riopelle* assigned to Shell Oil Co. [23.5].

The fourth type of liquid distribution device is a bubble-cap tray, originally designed for application in fractionation towers. This device employs a number of bubble caps laid out on a regular pitched pattern on a horizontal tray. The bubble-cap distributor works on a vapor-assist principle that offers a relatively stable operation compared to a chimney device. The bubble cap is a cap centered concentrically over a standpipe. The sides of the cap are slotted for vapor flow. Liquid flows under the cap and is aspirated by the vapor, flowing upward in the annular area between the cap and the standpipe, and then down through the standpipe.

The advantage of a bubble-cap device over a chimney-type design is the wider turndown range possible with the bubble cap. As the liquid charge rate drops the level drops on a bubble-cap tray and the slot area increases resulting in a reduced vapor velocity through the slots. The reduced vapor velocity pulls less liquid through the distributor, and the liquid level is reestablished. Another advantage of the bubble cap over the chimney-type design is that the bubble cap is less sensitive to an out-of-level tray. Due to fabricating tolerances, installation difficulties and deflection due to operating load, not all of the distribution devices will be at the same level in the vessel. With proper design, the bubble-cap device will minimize the liquid flow differences between bubble caps at different elevations better than can be achieved with a chimney-type design. A final advantage of the bubble cap over the chimney-type design is the increased contacting of the liquid and vapor phases. The intimate contacting that occurs in the upflow portion of the device provides closer approaches to thermal and compositional equilibrium than would be achieved in the chimney tray.

The primary disadvantage of a bubble-cap tray is the comparatively large size of the bubble caps relative to a chimney device. The large size and necessary wider spacing of the bubble caps reduces the number of distribution points over the cross-section of the tray and catalyst bed below. The wide spacing and pitched array of the bubble-cap tray also results in poorer distribution coverage adjacent to the reactor wall, further reducing catalyst utilization. An example of this type is US Patent 5158714 by *Shih* and *Christolini* assigned to Union Oil Co. [23.6].

A comparison of the performance characteristics of a typical multipoint chimney-type distributor and a standard bubble-cap distributor is illustrated in Fig. 23.2.

Fig. 23.2 Liquid distributor sensitivity to levelness as a function of liquid flow. Sensitivity of liquid flow to 10 mm elevation difference

The performance parameter, sensitivity %, is a measurement of the difference in the liquid delivered by adjacent distributors at different elevations. This parameter is described by the following formula

$$S = \left[\frac{(F_l - F_h)}{[F_{ave}]^*} \right] 100,$$

where:

- S performance sensitivity
- F_l liquid flow through low distributor
- F_h liquid flow through high distributor
- F_{ave} average flow through all distributors.

Figure 23.2 illustrates the deterioration in performance of a nonlevel chimney-type tray as the liquid rate is reduced and the liquid level drops. Each time the liquid level reaches the nominal elevation of one of the chimney's holes, holes of the low chimneys may be covered with liquid while holes of the high chimneys are dry. Thus some distributors deliver more liquid. This causes flow maldistribution across the catalyst bed. The same sensitivity is seen on dirty or fouled chimney trays, as their small holes will tend to plug up, thus affecting how much flows through each chimney in an uneven manner.

When Haldor Topsoe began to investigate the design of a high-performance distribution tray, several parameters were recognized as critical to achieve the desired performance efficiency. These are as follows:

23.2.1 Spacing Density

Because of the difficulty in visualizing the performance of the distribution devices under actual operating conditions of a hydroprocessing reactor, assumptions as to the effectiveness of overlapping spray patterns, or deflection splash patterns should be discounted. The only

positive approach to ensure adequate liquid distribution is to achieve a high number of liquid drip points across the surface of the catalyst by reducing the spacing of the distribution devices as much as is practically possible. Increasing the spacing density also enables a greater number of distribution points in the area adjacent to the reactor wall. This is very important for improved catalyst utilization, because over 35% of the catalyst in the reactor is contained within an annular ring between the reactor wall and 80% of the reactor diameter.

23.2.2 Sensitivity to Levelness

When first installed, reactor distribution trays are never perfectly level. Deviations from level can increase over time, in part due to thermal expansion and retraction as reactors are heated and cooled. Also trays can sag due to long life or upset in the reactors during operation. Trays should be designed so that an out-of-level condition has a very low impact on the operation of the tray. As described earlier, a distributor device operating on a vapor-assist principle will have a greater tolerance to levelness compared to a chimney-type distributor device. In addition, the geometry of the distributor device can further improve the sensitivity to levelness. Leveling devices can also be incorporated into the tray design to compensate for out-of-levelness due to ring warpage, beam deflection, or plumbness of the reactor.

23.2.3 Operating Stability

A distribution tray may have very good performance at the design conditions. However, as the operation diverges from the design point due to changes in the charge rate or changes in vaporization due to temperature or feed quality, the performance of the distribution tray can deteriorate rapidly. A high-performance tray should be capable of maintaining a relatively level height of liquid and an even flow rate through the distributor devices as the operation of the reactor changes.

The distribution device developed through the research and development efforts undertaken by Haldor Topsoe is a combination of bubble-cap and chimney devices referred to as a vapor-lift tray, or VLT. The VLT device has an operating concept similar to a bubble-cap device but has several advantages. The VLT device has a smaller footprint and closer spacing, which enables an increase in the number of liquid distribution points across the tray area. Furthermore, since the spacing pattern is square rather than triangular in pitch, gaps in liquid distribution coverage along beams and near the vessel wall are minimized. Overall wetting efficiency of the catalyst below the tray is improved when the liquid

distributors have a smaller pitch compared to a larger pitch.

A standard bubble-cap tray design is limited by the relatively large spacing, so modifications have been attempted to improve the dispersion pattern of the liquid exiting from the cap, e.g., the shear plate described in the Shih patent or the turbine baffles described in the Jacobs patent. Increasing the number of bubble caps by reducing the spacing would increase the number of distribution points. However, doing so would negatively impact the liquid/vapor flow relationships through each cap. Smaller bubble caps with fewer slots will not be as efficient as a VLT due to the geometry of the concentric caps. The geometry of the VLT enhances the stability over a wide operating range compared to a bubble cap. A further advantage for the VLT device is that its simplicity makes it easier and less costly to fabricate in the optimal size prescribed by the process conditions. The performance characteristics of a VLT compared to bubble caps and chimney tray designs are illustrated in Fig. 23.3.

Sensitivity is, as described previously, a gage of the difference in the liquid flow measured from adjacent liquid distributors positioned at different elevations. These plots show that the percentage difference in the liquid flow from VLT distributors is much smaller com-

Fig. 23.3 VLT distributor performance relative to chimney and bubble-cap distributors. Sensitivity of liquid flow to 10 mm elevation difference

pared to other distributor types. This ensures an even distribution of liquid over a broad range of operations, even though the tray may not be perfectly level. Poorly designed distributor devices can become very unstable and sensitive to differences in elevation as the liquid level on the tray drops. At very low liquid levels, a poorly designed distributor can actually cause maldistribution of liquid across the catalyst bed beneath the tray.

23.3 Quench Mixing Chamber Design

The catalyst in hydroprocessing reactors with high temperature rises or large catalyst volumes is separated into multiple catalyst beds. A quench section separating catalyst beds is designed to mix the reactants and introduce a quenching medium to typically reduce the equilibrium temperature before the reactants are distributed over the following catalyst bed. Since distributor trays are basically plug-flow devices, an apparatus is needed to mix the liquid into a homogeneous blend before it is delivered onto the distribution tray. Several different mixing chamber designs have evolved during the development of hydroprocessing reactor internals.

23.3.1 Advanced Reactor Internals for Hydroprocessing Units

Baffle mixer designs such as ribbon blenders and disc-and-donut-type mixers promote mixing by changing the direction of the fluid streams. These designs can be effective mixing devices, but they usually have comparatively high differential pressures to achieve mixing and they can be comparatively tall, requiring more

reactor shell length to accommodate the quench section.

Impingement-type quench boxes promote mixing by injecting or directing separate portions of the reactant fluids and impinging them against one another in a small area. This type of mixer can be designed with a reduced height. However, test work has shown that it is difficult to achieve an equilibrium temperature with an impingement-type mixer. In a low-pressure drop design, the vapor and liquid phases typically follow separate paths through the mixing chamber and can segregate and inhibit the mixing of liquid collected from different quadrants of the reactor.

A preferred type of mixing chamber is a centrifugal or vortex-type design, typical of the design introduced by US Patent 4836989 by Aly et al. assigned to Mobil Oil Co [23.2]. This mixer collects liquid and vapor from all quadrants of the reactor and introduces them close to the perimeter of a circular chamber where they make several rotations before being ejected out through a central exit port. This design can have a comparatively shallow depth, a very low pressure drop, and can

achieve an equilibrium temperature of the liquid passing through the mixer. Several licensors skilled in the design of hydroprocessing reactors employ a vortex-type mixing chamber.

The next generation of mixer design would have to expand upon the advantages of the success of the vortex type, while trying to minimize the side effects of the extreme velocities inside these mixer sections. The gas and liquid rates exiting these mixers can sometimes affect the distributor tray below, if not managed properly with additional hardware and baffle plates. This is especially the case in hydrocracker service. There are many challenges when trying to mix two-phase flows with very high space velocities through a small device. The process of getting the liquid and gas to mix completely usually involves increasing the pressure drop by creating significant amounts of turbulence. However, turbulence and wave action can cause as much as a 4–6 mm difference in liquid height on the distributor

tray below, which can lead to issues with differential pressure and liquid distribution. Additional baffles and/or rough cut trays are needed to offset these issues, which will in turn increase the height of the mixing device and thus be counterproductive. This also adds to the complexity and space of the manways. Haldor Topsoe has developed a new mixer design where all this additional hardware and associated issues are completely eliminated. Called the Torus mixer, this design mixes the liquid and gas in the outer chamber close to the vessel wall, and redistributes the mixture slowly onto the tray below, with a series of radial turning blades that are incorporated into the structure and angled in such a way so as to eliminate the need for further baffling hardware. The final outflow has low pressure and low velocity, while further improving on the manway access. Furthermore this concept is very compressed leaving more space for more catalyst in a given reactor.

23.4 Manway Access and Faster Access Options

Recent improvements have been made to make installation and turnaround times faster and safer, with less parts and easier fastening of the tray and manways. First-generation reactor internal trays were fastened together completely with bolts and nuts, designed to go together as one solid assembly. This included the manway panels, typically a removable center panel in each tray that can be detached so that maintenance personnel can enter the reactor during a shutdown to change the catalyst and/or inspect the vessels. The main problem with this design is that stainless steel threads will more often than not bind up when you try and remove them. Standard industry practice is to use an antiseize paste on all threaded connections when you assemble the trays, which prevents this from happening during the first assembly. But after some time in the reactor, especially under long service over the years, unfastening the threaded manway is not possible. Often most or all of the threaded bolt connections will seize and need to be cut out by torching, grinding or some other manner. This is a process that is to be repeated at each and every manway, at each turnaround. Users must then still replace the threaded connections to resecure and seal the manways for the next cycle. All of this can take hours as you can well imagine.

More recent designs have changed the manways so that they are fastened with a wedge pin device, an an-

gled piece of thin steel that can be wedged into place around the manway perimeter to secure and seal it into place, while not causing it to seize up as stainless steel does on threaded connections. This is a very effective practice and has been working now for several years. This can even be implemented and installed on current older bolted manways, at little cost compared to the time it usually takes with threaded connections. Check with the original tray licensor to see if this is an option.

Wedge pins are an easy and less expensive alternative to bolted manways. However they sometimes get damaged during removal and can be lost or broken. Additional spares are required to be ready for these issues. Also they can be hard to access and need to be hammered in place and set correctly. Topsoe has improved on this design even further with a top-access latch system that requires no spare parts like wedge pins, nor any tools to operate. This has improved the access time even further, made installation faster and time spent inside the reactor was reduced making it safer. Aside from replacement sealing gasket, there are no spare parts needed for each turnaround, and no readjustment is needed of the manway fastening hardware. The type of manway access on your internals should be considered when scheduling downtime for maintenance.

23.5 Example of Reactor Internals Revamp

The following is an example of improved performance that has been realized by replacing a classic reactor internals design with a recently developed high-performance design.

The original reactor internals included bubble-cap liquid distribution trays and impingement-type, quench mixing chambers similar to those described in US Patent No. 3218249 and US Patent No. 3502445, *Balard and Hines* [23.7, 8] assigned to Union Oil of California (Fig. 23.4). The original thermometry comprised three vertical thermowells running the length of the reactors and horizontal thermowells traversing the top and bottom of each of three catalyst beds.

23.5.1 Reactor Internals Performance (Prerevamp)

Due to changes in the plant operation subsequent to the initial installation, the performance of the impingement-type quench mixing chambers deteriorated and the distribution trays could no longer maintain an even flow distribution across the catalyst beds. The degradation in performance of the reactor internals resulted in wide radial temperature variations ranging from 7–10 °C at the catalyst bed inlets to 15–40 °C and the catalyst bed outlets. The flow/temperature maldistribution is documented by temperature profiles plotted from thermocouple measurements (Fig. 23.5).

Fig. 23.4 Pre-revamp reactor internals

Fig. 23.5 Prerevamp performance

As seen, significant radial temperature differences were measured by the thermocouples in the vertical thermowells, especially at the bottom of the second catalyst bed in the reactor. The temperature difference measured at the top of the middle and lower catalyst beds is an indication that the quench boxes were not adequately mixing the liquid to an equilibrium temperature before passing it on to the redistribution trays. Further, the vapor-liquid mixing through the distributors was not sufficient to evenly quench the liquid before it was distributed onto the next bed. In addition to the temperature maldistribution, the original redistribution trays were not providing an even liquid flow onto the following catalyst beds. This flow maldistribution is indicated by the widening of the radial temperature differences measured by thermocouples descending through the beds.

Large radial temperature differences are problematic because they reduce the length of the operating cycle between turnarounds. High peak temperature areas adjacent to the reactor wall lead to premature unit shutdown as the temperature approaches the reactor design limit. Furthermore, because of limited thermocouple coverage, there is real concern that the existing temperature indicators might not record the actual hot spot in the catalyst bed, and that damage to the reactor wall could occur unknowingly.

23.5.2 New Reactor Internals Modifications and Improvements

To improve unit performance, the existing reactor internals were replaced by high-performance vortex-type mixing chambers to optimize liquid-liquid mixing and VLT distribution trays to increase the number of drip points and minimize the dead flow zones adjacent to the reactor wall (Fig. 23.6). The VLT distribution trays also offered low sensitivity to tray levelness and improved stability over a wide operating range.

To improve monitoring of the temperature profiles, the existing thermocouple arrangement was replaced by 84 flexible-type thermocouples in the catalyst beds.

23.5.3 Performance Improvement Results

Following the restart of operations, the temperature profile across the reactor with the new internals is plotted in Fig. 23.7. The improved performance of the new internals is readily seen when comparing this plot with that previously shown in Fig. 23.5.

Several observations from such a comparison are immediately apparent.

23.5.4 Radial Temperature Differences

The radial temperature spreads for the revamped operation are significantly improved compared to the original equipment. At the start of the operating cycle conditions, the actual deviation in bed inlet temperature is approximately 1 °C. With the old internals, the temperature deviation at the bed inlets ranged from 7–10 °C. The radial temperature spread at the bed outlets ranges from 2–4 °C. This is significantly lower than the 15–40 °C bed outlet temperature deviation experienced with the old internals.

23.5.5 Weighted Average Bed Temperature

A reduction in the temperature required to achieve process objectives is typically observed when less efficient distribution trays are replaced. This is due to more efficient utilization of the catalyst resulting from improved liquid flow distribution. It appears that a directional 2–4 °C reduction in weighted average bed temperature (WABT) may have been achieved. However, it is dif-

Fig. 23.6 High-performance reactor internals

Fig. 23.7 Revamped reactor performance

Fig. 23.8 Graph comparing WABT, before and after new internals. Normalized WABT is reduced by more than 10°C ($\approx 18^{\circ}\text{F}$)

difficult to estimate the degree of improvement with any precision because the widely divergent temperatures measured by the three vertical thermowells during the prevamp operation make estimating the actual WABT very speculative.

Figure 23.8 shows another example of a diesel hydrotreater, where the internals were replaced while the process objectives and catalyst types remained the same. The data shows that the operating WABT is reduced significantly.

23.6 Conclusion

Hydroprocessing reactors originally designed for low-severity service typically are not adequate to handle increased severity with high-activity catalysts or to achieve the operating efficiency demanded by the current and future fuel specifications.

High-performance reactor mixing chamber and distribution tray designs developed by some licensors can often be incorporated into existing reactors to improve

their performance. If large radial temperature spreads are observed in the catalyst bed, replacing older internals with newer technology will result in lower operating temperatures with associated longer cycle length or higher production rates. The time savings obtained in a single turnaround by the implementation of the new manway plates can in many cases justify the entire cost of the reactor internals.

Hydrogen Production

M. Andrew Crews, B. Gregory Shumake

Many petroleum refining processes require hydrogen. Some is generated as a by-product from other units, such as catalytic reformers, but additional on-purpose production is required to meet increasing demands to process heavier feeds and meet tighter fuel and lubricant base oil specifications. In this chapter, we describe technology for on-purpose H₂ production, which is accomplished by four different processes – steam methane reforming (SMR), SMR with oxygen enrichment (SMR/O₂R), autothermal reforming (ATR), and thermal partial oxidation (POX). Designs can be adjusted to produce hydrogen, pure carbon monoxide, or mixtures of H₂ and CO (synthesis gas). All aspects of SMR, SMR/O₂R, and ATR are described: chemistry and thermodynamics, process design parameters and options, hydrogen purification, environmental protection, operation, process monitoring, processes improvements, safety, and economics.

Hydrogen is a key feedstock in many refining operations associated with the production of cleaner gasoline and diesel products, as well as high-quality premium lubricant base oils. There are several drivers for the increase in hydrogen demand in the refining industry. Crude oil continues to become heavier with higher amounts of sulfur, nitrogen, and metal species. As the demand for heavy fuel oil abates, additional upgrading of the *bottoms* is required to produce a high-

value marketable fuel. More stringent environmental regulations have reduced the level of sulfur in both gasoline and diesel products. The combined result of these trends is that refineries must add hydrogen production capacity to meet the increasing demands in hydrotreating, hydrocracking, and other hydroprocessing processes.

There are many routes to the production of hydrogen. In particular, several refinery unit operations, espe-

cially catalytic reforming and olefins production, yield hydrogen as a by-product. In order to focus the scope of discussion, this chapter will only cover on-purpose hydrogen production. The technologies discussed will be limited to those that can produce hydrogen in sufficient quantities to satisfy typical refinery operations, i. e., from 5 to 200 MMSCFD.

Hydrogen can be produced from a variety of feedstocks and technologies. Feedstocks for hydrogen production can range from natural gas to coal and includes

all hydrocarbons in-between. The availability of specific feedstocks will limit the number of technology options for the production of hydrogen. The conversion of hydrocarbons to hydrogen requires significant heat input and produces excess (waste) heat resulting from the high temperatures required for sufficient feedstock conversion. This excess heat is typically recovered to produce steam and can also be recovered to improve the overall efficiency of the technology chosen, but with a significant capital cost.

24.1 Thermodynamics of Hydrogen

The production of hydrogen from hydrocarbons can be broken down into three key sets of chemical reactions:

- Steam methane reforming
- Partial oxidation
- Water gas shift.

Strictly speaking, steam methane reforming (SMR) should be called steam/hydrocarbon reforming, because the feed gas may contain higher hydrocarbons other than methane.

The use of the term *reforming* in a refinery environment can be confusing as there are several *catalytic reforming* operations that are used to improve the oc-

tane numbers of gasoline. In the context of a hydrogen plant, a reformer is a furnace or vessel associated with the steam/hydrocarbon reforming reaction, usually called steam methane reforming (SMR) because the most common hydrocarbon feed is methane. The reaction produces hydrogen (H₂), carbon monoxide (CO), carbon dioxide (CO₂), and un-reacted methane (CH₄) from hydrocarbons and water based on the following chemical reaction

Table 24.1 Reaction and equilibrium constants (used with permission of Sud-Chemie)

The reforming reaction is endothermic and is favored by high temperature and low pressure. In other words, as the net reaction temperature is increased, the higher the conversion of methane, and as the pressure at which the reaction takes place is decreased, the methane conversion is increased. Another variable in the reforming reaction is the steam-to-carbon ratio. As the amount of water increases above the stoichiometric requirement, the amount of methane conversion also increases. Conversely, as the ratio of water to steam decreases, the greater the possibility of forming carbon precursors (coking) through alternative reaction pathways. This is an undesirable condition because the formation of carbon can destroy the reforming catalyst, increase the pressure drop through the reformer, increase the reformer tube-wall temperature, and consequently require an unscheduled plant shutdown to repair these problems. See Table 24.1 for equilibrium constant information on the steam methane reforming reaction.

Partial oxidation refers to a chemical reaction where hydrocarbons react with oxygen in a substoichiometric burn reaction to produce carbon monoxide and hydrogen. Partial oxidation technologies require oxygen as a feedstock. Several other reactions take place in the partial combustion zone and contribute to the overall

heat provided by the partial oxidation reaction.

The partial oxidation (POX) reaction is highly exothermic and provides the heat required for the steam methane reforming reaction that occurs following the conversion of hydrocarbons to carbon monoxide and hydrogen. The partial oxidation reaction is favored by high temperature and high pressure. However, the higher the pressure, the more likely are alternative reactions that will lead to the formation of carbon.

The water gas shift (WGS) reaction is where carbon monoxide is *shifted* on a mole per mole basis to hydrogen by the following reaction

Table 24.2 Equilibrium constants and heats of reaction (used with permission of Sud-Chemie)

2500	1371	-35 127.58	-81 706.75	1.3960 × 10 ⁻²

The water gas shift reaction is favored by low temperature and is mildly exothermic. The WGS reaction is typically the final reaction step that produces hydrogen in a multiple reactor train. Since the WGS reaction is fa-

vored by low temperature, it is typically included in the heat recovery train downstream of the high-temperature reactors. See Table 24.2 for thermodynamic and equilibrium data.

24.2 Technologies for Producing Hydrogen

24.2.1 Steam Methane Reforming (SMR) Technologies

Steam methane reformers generate the majority of the world's on-purpose hydrogen. A steam methane reformer (SMR) is a fired heater with catalyst-filled tubes. Hydrocarbon feedstock and steam react over the catalyst to produce hydrogen. The reacted process gas typically exits the reformer at about 1600 °F (≈ 870 °C). The flue gas leaving the reformer radiant section is typically about 1900 °F (≈ 1040 °C).

The flue gas at 1900 °F (≈ 1040 °C) must then be cooled to about 300 °F (≈ 150 °C) to achieve efficient heat recovery. This heat is recovered in the convection section of the SMR. The process gas at 1600 °F (≈ 870 °C) must then be cooled to about 100 °F (≈ 38 °C) before final product purification.

Maximum Steam Export

A maximum export steam plant (Fig. 24.1) is defined as a plant that makes the maximum prac-

tical quantity of export steam, without auxiliary firing.

Table 24.3 gives a typical feed and utility summary for a maximum export steam plant, as defined above.

Limited Steam Export

A limited export steam plant (Fig. 24.2) is defined as a plant that makes some export steam but significantly less than the maximum. This is typically achieved by adding a combustion air preheat unit (CAP). This unit consists of a modular heat exchanger that heats the combustion air to the SMR by heat exchange with the flue gas from the SMR. The hot combustion air reduces the fuel requirement for the SMR, which in turn reduces the steam production.

A typical combustion air preheat temperature for this type of plant is approximately 750 °F. This permits use of carbon steel ducting in the air preheat distribution system. Table 24.4 gives a typical feed and utility summary for a limited export steam plant, as defined above.

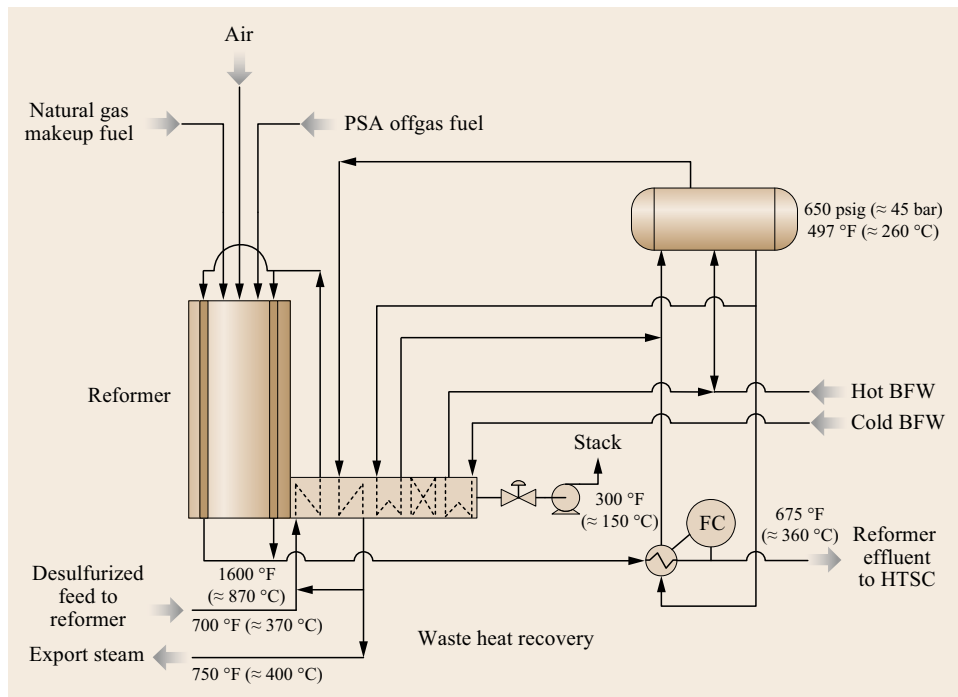

Fig. 24.1 Steam methane reforming with maximum steam export

Table 24.3 Maximum export steam feed and utility summary

	Units	H ₂ product (Units/MSCF)	H ₂ product (Units/MNCM)
Natural gas	MMBtu LHV	0.45	–
	GJ LHV	–	17.72
Export steam	lbs	86.80	–
	kg	–	1470.68
Treated water	lbs	117.00	–
	kg	–	1982.36
Power	kWh	0.55	–
	kWh	–	20.53
Cooling water circ	gal	12.70	–
	m ³	–	1.79

Fig. 24.2 Steam methane reforming with limited steam export

Table 24.4 Limited export steam feed and utility summary

	Units	H ₂ product (Units/MSCF)	H ₂ product (Units/MNCM)
Natural gas	MMBtu LHV	0.386	–
	GJ LHV	–	15.20
Export steam	lbs	38.0	–
	kg	–	643.84
Treated water	lbs	67.7	–
	kg	–	1147.06
Power	kWh	0.58	–
	kWh	–	21.65
Cooling water circ	gal	13.1	–
	m ³	–	1.85

Note that the limited export steam plant makes less than half as much export steam as the maximum steam export case, but also uses less natural gas. At

the same time, the limited steam export plant capital cost is higher, because of the addition of the air preheat unit.

Steam versus Fuel

The steam value and fuel price typically determine which of these two cases is the most economic. A high steam value (relative to fuel price) favors the Maximum Steam Export Case. A high fuel price and a low steam value (relative to fuel price) favor the Limited Steam Export Case.

Figure 24.3 is a plot of natural gas price versus steam value. For a given natural gas price, if the steam value is above the curve, then maximum steam export is favored. But if the steam value is below the curve, then CAP (limited steam export) is favored. For example, for a natural gas price of 3.00 US\$/MMBtu LHV (lower heating value), Fig. 24.3 indicates that if the steam value is above 3.30 US\$/Mlbs, then steam generation is favored. But if the steam value is below 3.30 US\$/Mlbs, then CAP (limited steam export) is favored.

Minimum Export Steam

A minimum export steam plant optimizes heat recovery to the maximum extent possible. This is often done when the value of steam is essentially zero or the price of the feedstock and fuel are exceptionally high. Minimum steam export is often achieved by first increasing the SMR process gas inlet temperature and then the combustion air preheat temperature, both of which reduce the fired duty of the SMR. Typical temperatures are 1150 °F (≈ 620 °C) for the process gas and 900 °F (≈ 480 °C) for the air preheat. These changes reduce the export steam to a low level, but typically not completely to zero. Additional modifications are required to reduce the export steam to an absolute minimum.

Adding reaction steps to the process can further reduce the amount of feed and fuel required by the hy-

drogen plant. The first reaction step that can be added is a prereformer. The prereformer is an adiabatic reactor where the feed is heated to approximately 900 °F (≈ 480 °C), and the gas is partially reformed over a catalyst bed and hydrocarbon components of ethane and heavier are converted to methane. The conversion of ethane plus components to methane is exothermic. If the feedstock is essentially methane (i. e., natural gas), the amount of heat required to drive the steam methane reforming reaction to equilibrium will produce a temperature decrease across the reactor. However, if the feedstock is butane or heavier, the methane conversion reaction produces more heat than is required by the steam methane reforming reaction and there is a net temperature increase across the reactor.

The prereformer is an excellent way to produce a consistent feed to a steam methane reformer. Heavier feedstocks to the SMR increase the potential for carbon formation. The ultimate in energy recovery can be achieved by utilizing a heat recuperative reforming step in the process. Since the steam methane reforming occurs at high temperature, the reformed gas is typically cooled by generating steam. However, if the heat can be recovered by utilizing it in an additional reforming step, the net heat input required to complete the reaction is reduced and, therefore, the quantity of fuel required to operate the furnace is reduced. The reformer effluent gas is passed through the shell side of a tubular heat exchanger with catalyst-filled tubes.

24.2.2 Oxygen-Based Technologies

Steam methane reforming (SMR) has been the conventional route for hydrogen and carbon monoxide

Fig. 24.3a,b Steam price versus natural gas price

production from natural gas feedstocks. However, several alternative technologies are currently finding favor for an increasing number of applications.

These technologies are:

- SMR/O₂R: Steam Methane Reforming combined with Oxygen Secondary Reforming
- ATR: Autothermal Reforming
- POX: Thermal Partial Oxidation.

Each of these alternative technologies uses oxygen as a feedstock. Accordingly, if low-cost oxygen is available, they can be an attractive alternative to an SMR for natural gas feedstocks. Low-cost oxygen is now available in many large industrial sites where a large air separation plant already exists or can be economically installed to serve the needs of the area. (Note that unlike ammonia plant technology, air cannot be used in place of oxygen since the contained nitrogen would dilute the hydrogen/carbon monoxide product.)

A brief description of each technology follows.

SMR/O₂R

An SMR/O₂R essentially consists of an SMR followed by an oxygen secondary reformer (Fig. 24.4). The oxygen reformer is a refractory-lined vessel containing catalyst and a burner. The reaction mixture from the SMR is fed to the top of the oxygen reformer, where it is mixed with oxygen fed through the burner. Partial oxidation reactions occur in a combustion zone just below the burner. The mixture then passes through the catalyst bed where reforming reactions occur. The gas exits at about 1900 °F.

Fig. 24.4 SMR/O₂R plant

ATR

An ATR is similar to an oxygen secondary reformer except that it does not receive feed from an SMR. Instead, it is fed directly with a natural gas/steam mixture, which is mixed directly with oxygen from a burner located near the top of the vessel (Fig. 24.5). Again, partial oxidation reactions occur in a combustion zone just below the burner. The mixture then passes through a catalyst bed where reforming reactions occur. The gas exits at about 1900 °F (≈ 1040 °C).

POX

A POX (Fig. 24.6) is similar to an ATR except that it does not contain a catalyst and does not require steam in the feed. It is fed directly with a natural gas stream, which is mixed directly with oxygen from a burner located near the top of the vessel. Partial oxidation and reforming reactions occur in a combustion zone below the burner. The gas exits at about 2500 °F (≈ 1370 °C).

Products

The exit gas from each of the above reactors consists of hydrogen, carbon monoxide, carbon dioxide, steam, and residual methane. Small quantities of nitrogen and argon from the original feedstocks may also be present. This gas mixture is then typically processed to yield one or more of the following products:

1. High-purity hydrogen
2. High-purity carbon monoxide
3. A hydrogen/carbon monoxide gas mixture.

If only hydrogen is required, the plant becomes a hydrogen plant. If only CO is required, the plant becomes a carbon monoxide plant. If both hydrogen and

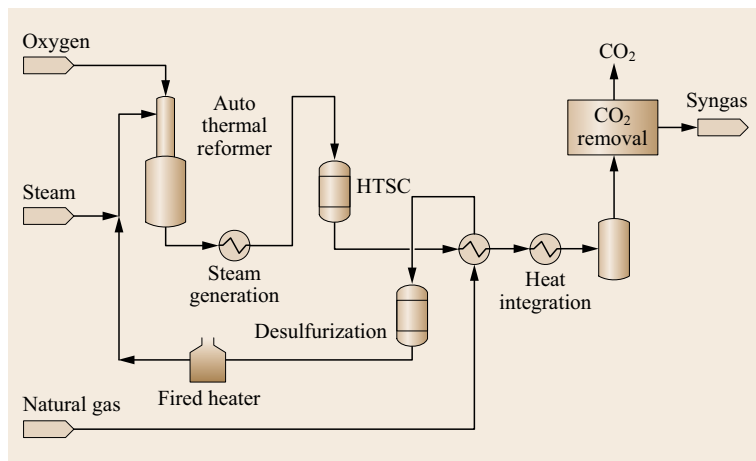

Fig. 24.5 ATR plant

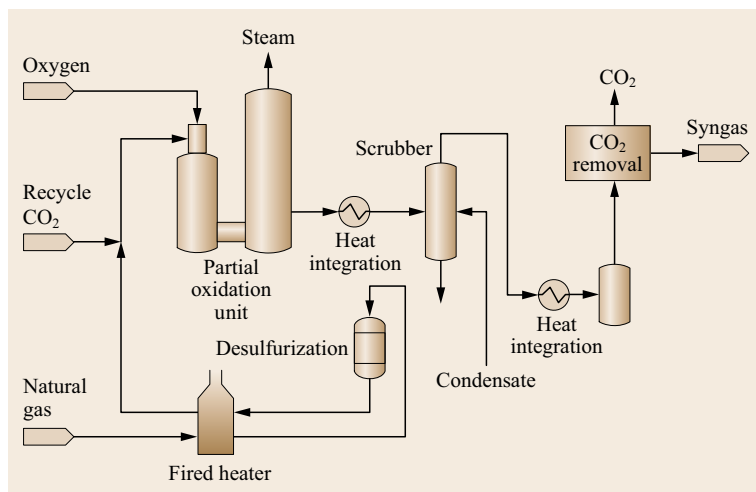

Fig. 24.6 POX plant

carbon monoxide are required as separate streams, the plant is typically known as a hydrogen and CO co-production (HYCO) plant. If only a hydrogen/carbon monoxide mixture is required, the plant is typically known as a synthesis gas (or syngas) plant. If all three products are required, the plant is considered a combination (hydrogen/carbon monoxide/syngas) plant.

H_2/CO Ratio

A key variable in the design of these plants is the product H_2/CO ratio. For HYCO and syngas plants, the product H_2/CO ratio typically varies from 1.0 to about 3.0. But for hydrogen plants, the ratio is almost infinite. And for carbon monoxide plants, the ratio is essentially zero.

Natural Ratio Range

Each of the above technologies makes products with inherently different H_2/CO ratios. The natural ratio range

is defined herein as the range of ratios that can be achieved when varying only the CO_2 recycle. The natural ratio ranges for each technology are shown in Table 24.5, as applicable to natural gas feedstocks. (Other feedstocks will produce a different set of natural ratios).

As seen in Table 24.5, the natural ranges for natural gas are as follows: For the SMR: 3.0–5.0. For the SMR/ O_2R : 2.5–4.0. For the ATR: 1.6–2.65. And for the POX: 1.6–1.8. Note that some ranges are broader than others, and that some of the ranges do not overlap.

The technology that offers a natural ratio that spans the required product ratio is considered to have an inherent advantage and merits careful consideration.

CO_2 Recycle

CO_2 recycle is the typical means of tailoring the natural ratio span to meet the desired H_2/CO product requirement.

Table 24.5 Hydrogen to CO ratio summary

	Membrane or import CO ₂	Total CO ₂ recycle	No CO ₂ recycle	Increase steam	Add shift converter
AMR	< 3.0	3.0	5.0	> 5.0	Infinity
SMR/O ₂ R	< 2.5	2.5	4.0	> 4.0	> 5.0
ATR	< 1.6	1.6	2.7	> 2.7	> 3.0
POX	< 1.6	1.6	1.8	> 1.8	> 2.0

As noted earlier, carbon dioxide is present in all the reactor effluents. Since CO₂ is considered an impurity, it must typically be eliminated. In most designs, the CO₂ is removed from the process gas by selective adsorption in a suitable solvent such as an amine solution. The CO₂ is then stripped from the solvent as a separate stream.

(Note: synthesis gas for methanol plants typically retains some or all of the carbon dioxide. This is a special case, which is outside the scope of this discussion.)

The separate CO₂ stream can be removed from the system or it can be recycled back to the reactor. If it is recycled, the CO₂ can be converted to CO in the reactor by the reverse water gas shift reaction. This reduces the final H₂/CO ratio because the carbon atoms in the original CO₂ are converted to CO. Conversely, if the CO₂ is not recycled, the H₂/CO ratio is increased, because the carbon atoms in the original CO₂ are not converted to CO. (CO₂ that is not recycled is typically vented to the atmosphere. However, sometimes it is sold as a by-product).

The natural H₂/CO range for each technology represents the spread between full CO₂ recycle and no CO₂ recycle (Fig. 24.7). By operating with partial recycle, any H₂/CO ratio within the natural range can be achieved.

But as noted earlier, some of the natural ratio ranges do not overlap; hence, for a given product H₂/CO ratio, at least some of the technologies will require additional ratio adjustment to meet the product requirements. Fortunately, a number of process techniques are available to do this. The viability of the technology will depend on the economics of using these techniques.

Fig. 24.7 Natural range of H₂/CO ratio adjustment

To decrease the ratio below the natural range, common techniques include importing CO₂; use of a membrane; or use of a cold box. To increase the ratio, common techniques include increasing the quantity of steam in the reactor feed or adding a shift converter. These techniques, along with CO₂ recycle, are summarized in Table 24.6.

Import CO₂

The H₂/CO ratio can be decreased by importing CO₂ as a feed to the reactor. The import CO₂ is added to the CO₂ already being recycled. The carbon atoms in the import CO₂ can then be converted to CO by the reverse water gas shift reaction.

Membrane

The H₂/CO ratio can also be decreased by use of a membrane unit. Hydrogen is removed from the membrane as a permeate stream, which reduces the H₂/CO ratio of the main process stream.

Cold Box

A cold box is often used to separate the hydrogen and carbon monoxide into a high-purity CO stream and a H₂-rich stream. This reduces the ratio to near zero with respect to the CO stream. The H₂-rich stream may undergo further purification (typically in a pressure swing adsorption (PSA) unit to yield a high-purity H₂ stream. This increases the ratio to near infinity with respect to the H₂ stream.

Steam

Adding steam to the reactor converts CO to H₂ by the water gas shift reaction. This increases the H₂/CO ratio.

Table 24.6 Techniques for H₂/CO ratio adjustment

	Decreases ratio	Increases ratio
Recycle CO ₂	✓	
Import CO ₂	✓	
Use membrane	✓	
Remove CO ₂		✓
Increase steam		✓
Add shift converter		✓
Use cold box	See note	

Note: A cold box decreases the ratio with respect to CO and increases the ratio with respect to H₂

Shift Converter

A shift converter is a catalytic reactor that catalyzes the conversion of CO to H₂ by the water gas shift reaction. This step can be used to increase the H₂/CO ratio to a very high value. It is widely used in hydrogen plants.

Table 24.6 summarizes the ranges achievable by each technology by inclusion of these techniques. Typically, the viability of the technology decreases with the magnitude of the added steps necessary to achieve the required product H₂/CO ratio.

Other Considerations

As stated above, these ratios are based on natural gas feedstocks. If heavier feedstocks are used, the ratios will be lower because the hydrogen-to-carbon ratio of the feed will be lower.

The above ratios are based on typical reformer outlet temperatures and pressures for each technology. The reformer outlet temperature is typically set by the residual methane requirement. The reformer outlet pressure is typically set by compression requirements. Some design flexibility often exists between these limits. However, within the normal range of flexibility, the H₂/CO ratio does not change appreciably with the reformer outlet temperature or pressure. Hence, for a given design, it is normally impractical to achieve a significant change in H₂/CO ratio by varying the reformer outlet tem-

perature or pressure. Instead, the techniques discussed above should be utilized.

If it is impractical for a given technology to achieve the desired ratio by the techniques discussed above, then excess hydrogen- or carbon monoxide-containing gas can be burned as fuel in the SMR (for SMR and SMR/O₂R plants) or in the Process Heater (for ATR or POX plants). If necessary, the Process Heater can be expanded to include a second radiant section to permit burning of excess product by generating steam. Alternatively, a package boiler can be used to burn excess gas and generate steam.

Thus far, considerable discussion has centered on the H₂/CO ratio, since as noted above, the technology that can most easily achieve the required product H₂/CO ratio has an inherent initial advantage. But there are other considerations that could override this advantage. These are outlined below.

24.2.3 Technology Comparison

Table 24.7 is a comparison of some key process advantages and disadvantages for the technologies under consideration for hydrogen/carbon monoxide plants with natural gas feedstock. Please note that while the oxygen requirement is shown as a disadvantage, it may not be a disadvantage in cases where low-cost oxygen is available.

Table 24.7 Technology comparison

SMR	ATR
Advantages: <ul style="list-style-type: none"> ● Most commercial experience ● Does not require oxygen ● Reforming temperature relatively low ● Best natural H₂/CO ratio for hydrogen product Disadvantages: <ul style="list-style-type: none"> ● Natural ratio high for CO product ● Highest atmospheric emissions 	Advantages: <ul style="list-style-type: none"> ● Natural H₂/CO ratio often favorable ● Lower reforming temperature than POX ● Low residual CH₄ ● Tailor residual CH₄ Disadvantages: <ul style="list-style-type: none"> ● Limited commercial experience ● CO₂ cycle higher than POX ● Require oxygen

Process Parameters

Key process parameters and feedstock requirements for each technology include the following:

- **Pressure:** Most SMR plants run at reformer furnace outlet pressures between 150 and 400 psig (≈ 10 and 28 bar). The maximum pressure is about 550 psig (≈ 38 bar), due to metallurgical considerations in the SMR outlet piping. The same applies to SMR/O₂R plants. This limits the final product gas pressure to about 500 psig (≈ 34.5 bar). Above this, product gas compression is required. ATR and POX plants can run at much higher pressures. For example, some plants require synthesis gas at about 800 psig (≈ 55.2 bar); this can be supplied directly from an ATR or POX without synthesis gas compression.
- **Temperature:** SMR plants typically run at reformer outlet temperatures of 1550–1700 °F (≈ 840 –930 °C). SMR/O₂R and ATR plants typically run at outlet temperatures of 1750–1900 °F (≈ 950 –1040 °C). POX plants typically run at about 2500 °F (≈ 1370 °C). This high temperature is needed to maintain low residual methane without a catalyst.
- **Steam/carbon:** Steam is typically required to prevent carbon formation on the reformer catalyst. The steam requirement is generally expressed as the steam/hydrocarbon-carbon ratio (steam/hcc). This is the ratio of the moles of steam to moles of hydrocarbon-carbon in the feed (the carbon in any CO₂ recycle is not included in computation of the ratio).
Both the SMR and SMR/O₂R plants typically use a 2.5–5 steam/hcc ratio for no CO₂ recycle, and a 2 : 1 steam/hcc ratio when all the CO₂ is recycled. (A lower ratio can be used with the CO₂ recycle since the CO₂ makes some H₂O by the water gas shift reaction). For a partial recycle, a ratio between 3 : 1 and 2 : 1 is typically used.
ATR plants can operate at a lower ratio, often about 1 to 1.5 with or without CO₂ recycle.
POX plants require no steam. Some soot is formed, but since there is no catalyst, there is obviously no possibility of catalyst bed plugging. With proper design and operation, the soot can be processed and removed in the downstream equipment without affecting plant on-stream time.
- **Methane slip:** The exit gas from each reactor contains some residual methane, which corresponds to unreacted natural gas feed. This is typically referred to as the methane slip. A low methane slip increases the purity of a synthesis gas product. It also reduces the natural gas requirement.

An SMR typically has a relatively high methane slip (3–8 mol %, dry basis). This is primarily because the SMR operates at a lower outlet temperature. The other technologies operate at higher outlet temperatures and typically have low slips (0.3–0.5 mol %, dry basis).

If a methane-wash cold box is used, typically a methane slip of at least 1 to 2 mol % is required to maintain the methane level in the box. This is not a problem for an SMR design because its methane slip is considerably more than this. It is also easily achieved by the SMR/O₂R and ATR designs by simply reducing the reactor outlet temperature. However, this methane level is more difficult to achieve with a POX, since in the absence of a catalyst, a high temperature and corresponding low methane slip should be maintained to ensure consistent performance.

- **Raw materials:** Natural gas and oxygen are the two major raw materials. For each technology, the quantities required must be considered on a case-by-case basis, since they depend on the H₂/CO requirement for each application.

For example, the product H₂/CO ratio may require that CO₂ be either recycled or vented, depending on the ratio and the technology.

If the required H₂/CO product ratio is 2.0, all the CO₂ would be recycled in an SMR or SMR/O₂R design; part of the CO₂ would be recycled in an ATR design; and no CO₂ would be recycled in a POX design.

The extent of CO₂ recycle changes the raw material requirements for a given technology, because if CO₂ is vented, its contained carbon and oxygen is not recovered.

To provide a basis of comparison, a design can be considered wherein all the CO₂ is recycled for each technology. This would normally occur in designs for a H₂/CO product ratio less than 1.6.

A typical design meeting this requirement would be a carbon monoxide only plant (H₂/CO ratio of zero). For such a design, we have compared all four technologies for a proposed plant on the US Gulf Coast. For this plant, the natural gas and oxygen requirements are given in Table 24.8. The natural gas requirement shown is the net requirement on a heating value basis and includes credit for excess hydrogen at fuel value. (For this plant, all the technologies produce excess hydrogen since CO is the only required product and there is no requirement for product hydrogen).

For the following discussion, the SMR and SMR/O₂R are called SMR-based technologies because the SMR is the dominant component. And the ATR

Table 24.8 Feedstock requirements

	SMR ^a	SMR ^b	SMR/O ₂ R ^a	SMR/O ₂ R ^b	ATR ^a	ATR ^b	POX ^a	POX ^b

Oxygen import (kg)	–	0.0	–	240.6	–	957.3	–	994.6

^a Units per 1000 SCF CO Product, ^b Units per 1000 NCM CO Product

* Includes credit for excess hydrogen at fuel value

All cases based on full CO₂ recycle

and POX are called oxygen-based technologies because the partial oxidation reactor is the dominant component.

From Table 24.8, note that the natural gas requirements for the SMR-based technologies are about the same. Note also that the natural gas requirements for the oxygen-based technologies are about the same. But also note that the oxygen-based technologies require only about 70% as much natural gas as the SMR-based technologies.

The natural gas requirement is lower for the oxygen-based technologies because most of the oxygen in the feed reacts with carbon in the natural gas to form carbon monoxide. The oxidation reaction is therefore more efficient for the formation of carbon monoxide, which is the desired product for the referenced plant.

Another reason for the lower natural gas requirement is that for the oxygen-based technologies, the heat required for the reaction is applied directly to the process gas in the reactor vessel. This is more energy efficient than the SMR-based technologies, which require a temperature driving force between the combustion gas and the in-tube process gas.

With respect to oxygen consumption, the oxygen requirement for the SMR is obviously zero. For the SMR/O₂R, the oxygen requirement is about 25% of that for the ATR or POX.

The ATR and POX oxygen requirements are about the same. This is to be expected, since both technologies use the same direct combustion process, and for the referenced plant, both technologies recycle all the CO₂ and produce essentially the same H₂/CO product ratio.

Export Steam

For the referenced plant, the export steam is relatively low since the excess hydrogen is not burned within the plant to make export steam. Accordingly, the export steam for the SMR, SMR/O₂R, and POX averaged only about 150 lbs per 1000 SCF (2541 kg per 1000 NCM) of carbon monoxide and any differences were not considered significant. However, the ATR export steam was

less than half this value because the energy requirement for the CO₂ removal system is larger.

Economic Considerations

The economics of each technology depend on the conditions and requirements of each project and must be studied on a case-by-case basis. Some of the most important considerations are as follows.

Oxygen Availability

The availability of oxygen is obviously a key parameter. Since the SMR requires no oxygen, it is the obvious choice if oxygen is unavailable or prohibitively expensive. Studies indicate that the oxygen-based technologies can be attractive if oxygen is available at less than about US\$25 per short ton. If oxygen is greater than about US\$30 per ton, the SMR is favored.

The oxygen price can be less than US\$25 per ton in large industrial sites where a large air separation plant already exists or can be economically installed to serve the needs of the area. Hence, in such cases the oxygen-based technologies merit serious consideration.

Hydrocarbon Feedstock

This section is based on natural gas feedstock. With natural gas, all technologies are technically viable. However, if the feedstock is a heavy hydrocarbon (such as fuel oil or vacuum bottoms), the POX is the only viable technology. This is because the other technologies cannot process feedstocks heavier than naphtha (to avoid carbon deposition on the catalyst).

H₂/CO Ratio

The importance of the product H₂/CO ratio has already been discussed extensively. As previously stated, the technology that offers a natural ratio spanning the required product ratio is considered to have an inherent advantage and must be seriously considered.

Natural Gas Price

Since the SMR-based technologies directionally require more natural gas, they are favored by low natural gas prices.

Capital Cost

The SMR-based technologies typically have a somewhat higher capital cost because the SMR furnace with its high alloy tubes and large flue gas heat recovery section is inherently more expensive than the ATR or POX technologies, which use refractory-lined carbon steel vessels without external flue gas heat recovery.

An SMR has a lower capital cost than an SMR/O₂R when the operating pressure is relatively low. Since low pressure favors the reforming reaction, under such conditions most of the reforming occurs in the SMR, and the O₂R does not significantly reduce the size of the SMR. But at higher pressures, an SMR/O₂R can cost less, because more of the reforming is done in the O₂R, and the size of the SMR can often be significantly reduced.

The ATR and POX technologies have offsetting capital costs, depending on the extent of CO₂ recycle.

For full CO₂ recycle, the CO₂ removal system is much larger for the ATR than the POX, and the added capital cost associated with this difference tends to make the ATR more expensive overall.

However, for no CO₂ recycle, the ATR tends to cost less than the POX because its reaction and heat recovery section is inherently less expensive and it does not carry any third-party royalty.

Section Conclusions

On the basis of the above, the following conclusions can be drawn:

1. The SMR/O₂R, ATR, and POX technologies can be attractive if low-cost oxygen is available.

2. For competing technologies, the H₂/CO product ratio is typically the most important process parameter.
3. For low methane slip, the SMR/O₂R, ATR, and POX technologies are favored.
4. For full CO₂ recycle, the POX is typically better than the ATR.
5. Relative to the POX, the ATR is a nonlicensed technology which avoids third-party involvement.
6. The economics of each technology is dependent on the conditions and requirements for each project and must be evaluated on a case-by-case basis.
7. The technology with the most favorable H₂/CO ratio for producing hydrogen is the SMR.

24.2.4 Hydrogen Purification

Old Style

Many refiners are still operating hydrogen plants that were designed and built 20 or more years ago. These older plants were generally designed with the best available technology of the time. These plants typically consist of a steam methane reformer (SMR) to convert the hydrocarbon feed to a syngas mixture followed by a high-temperature shift converter (HTSC) and low-temperature shift converter (LTSC) to shift most of the CO to hydrogen. This hydrogen-rich gas is purified by a CO₂ removal unit where a hot potassium carbonate or monoethanolamine (MEA) solution removes the CO₂ and then a methanator is used to convert the remaining CO and CO₂ to methane and water. The final product gas is typically about 95–97% hydrogen. Figure 24.8 shows a typical layout for an Old Style hydrogen plant.

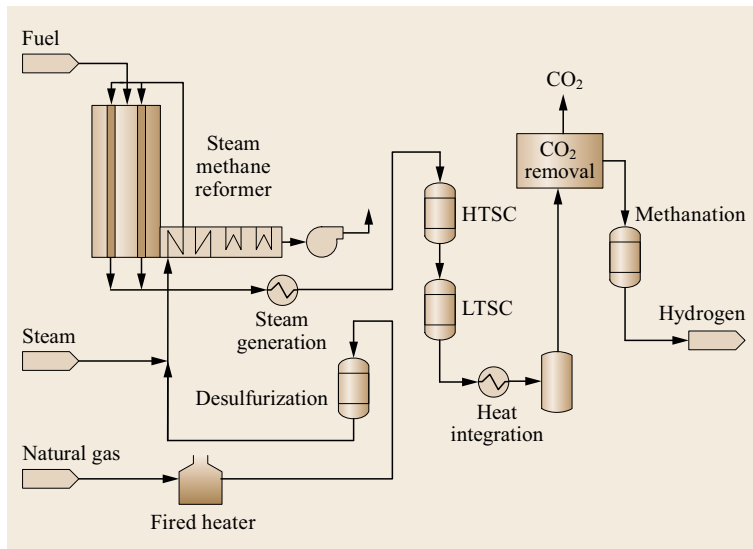

Fig. 24.8 Old style hydrogen plant

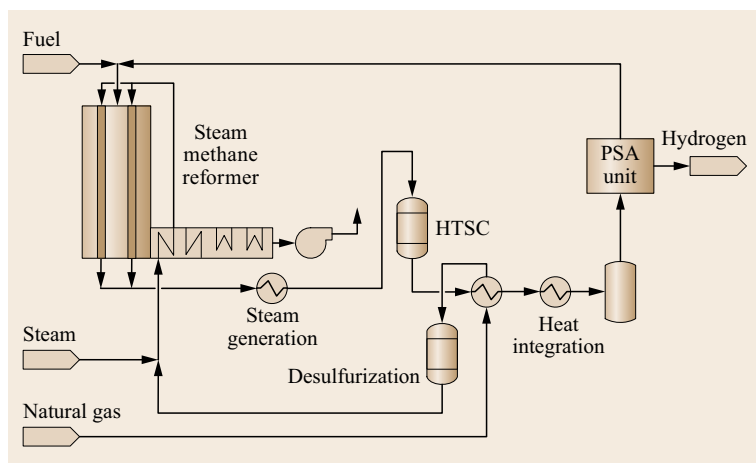

Fig. 24.9 Modern hydrogen plant

Modern

The main process difference between a Modern hydrogen plant and an Old Style hydrogen plant is the hydrogen purification technology. A Pressure Swing Adsorption (PSA) unit replaces both the CO₂ removal unit and the methanator, enabling the Modern plant to produce hydrogen product with a much higher purity, more than 99.9%. In addition, many significant improvements in technology and design allow the Modern plant to operate at much higher efficiency and with substantially lower operating costs.

A PSA unit employs a collection of solid adsorbents – molecular sieves, activated carbons, silica gels, and activated aluminas. For carbon, silica, and alumina, separation is due to their differential tendency to adsorb different gases. PSA cycles include pressurization, depressurization, and purging. The rejected gas, a low-Btu

mixture containing methane, CO, and CO₂, is burned to provide some preheat duty.

A Modern hydrogen plant includes an SMR followed by an HTSC. A PSA unit purifies the syngas effluent from the HTSC. The final product gas is typically 99.99% hydrogen. Since the PSA unit removes the impurities from the syngas, an LTSC is not required to further reduce the CO content.

The PSA unit produces an offgas stream that can be used by the SMR as the primary fuel source. In addition, the increase in product purity from the PSA unit has potential benefits in downstream units. For example, the higher purity hydrogen makeup to a hydrotreater increases reactor hydrogen partial pressure, lowers the recycle flow, and potentially reduces compression costs, and/or increases hydrotreater performance and catalyst run life. Figure 24.9 shows a typical layout for a Modern hydrogen plant.

24.3 Design Parameters for SMRs

Steam reformers are used in hydrogen generation plants throughout the refining and petrochemical industries and are expected to remain the most cost-effective approach for on-purpose hydrogen production. The steam reformer for hydrogen plants consists of a fired heater containing catalyst-filled tubes. This article discusses process design considerations for a modern reformer of this type.

24.3.1 Function

The primary function of a steam reformer is to produce hydrogen. Hydrocarbon feed gas is mixed with steam and passed through catalyst-filled tubes. Hydrogen and

carbon oxides are produced by the following reactions.

The first reaction is the reforming reaction, and the second is the shift reaction. Both reactions produce hydrogen. Both reactions are limited by thermodynamic equilibrium. The net reaction is endothermic. These reactions take place under carefully controlled external firing, with heat transfer from the combustion gas in

the firebox to the process gas within the catalyst-filled tubes.

The carbon monoxide in the above product gas is subsequently shifted almost completely to hydrogen in a downstream catalytic reactor by further utilization of (24.5).

24.3.2 Feedstocks

Typical hydrocarbon feedstocks for the reformer include natural gas, refinery gas, propane, LPG, and butane. Naphtha feedstocks with final boiling points up to about 430 °F (220 °C) can also be processed.

24.3.3 Fuels

Typical fuels for the reformer are light hydrocarbons such as natural gas and refinery gas, although distillate fuels are sometimes used. Residual fuels are not utilized since trace metals in the fuel oil can damage the reformer tubes.

In most hydrogen plants, a pressure swing adsorption (PSA) system is used for hydrogen purification. In such plants, a major portion of the reformer fuel is PSA offgas, with the makeup fuel being a hydrocarbon stream as discussed above.

24.3.4 Design

Reformers are fired to maintain a required process gas outlet temperature. Most modern reformers are top-fired. In this design, the burners are located in the top of the furnace, and fire downward. The process gas flows downward through the catalyst-filled tubes in the same direction.

Accordingly, the top-fired design features co-current flow of process gas and flue gas. The co-current flow permits use of (1) the highest flue gas temperature when the in-tube process gas temperature is lowest, and (2) the lowest flue gas temperature when the in-tube process gas temperature is highest. This in turn provides tube-wall temperatures that are quite uniform over the length of the tube. Because of this uniformity, the average tube-wall temperature is lower. And lower tube-wall temperatures reduce tube cost and increase tube life.

Another advantage of co-current flow is that as the flue gas cools, it sinks in the same direction as its normal flow. This provides an inherently stable furnace operation. In particular, it avoids flue gas back-mixing that inherently occurs in alternative designs. Since there is no back-mixing, the flue gas outlet temperature tends to more closely approach the process gas outlet temperature than in alternative designs. This improves the furnace efficiency.

Note that the highest tube-wall temperature occurs at the outlet, which is quite common for this type of furnace. Also note that at the tube outlet, the tube-wall temperature is very close to the required process gas outlet temperature. This is because the heat flux at the outlet is quite low, having fallen steadily for the last two-thirds of the tube.

Therefore, the tube-wall temperature is minimized for the required process gas outlet temperature, which in turn minimizes the required tube-wall thickness.

In addition, note that the flue gas temperature falls off steadily for the last two-thirds of the tube, and is at a minimum at the tube outlet. Since the furnace must be fired to provide the necessary flue gas outlet temperature, the fact that the flue gas outlet temperature is relatively low means that the fuel requirement is minimized.

The burners are housed at the top of the reformer by an enclosure commonly referred to as a penthouse. This housing provides a convenient shelter for the burners and for the inlet piping and valving.

The flue gas is collected at the bottom of the reformer in horizontal fire-brick ducts, often referred to as *tunnels*. The flue gas then exits horizontally into a waste heat recovery (WHR) unit. The combustion gas is drawn through the WHR unit by an induced draft fan and the gas is then discharged to the atmosphere through a stack. The WHR unit and fan are essentially at grade, which facilitates operation and maintenance.

When the above features of the top-fired design are considered and weighed against alternative arrangements, the consensus of the industry favors the top-fired design.

The remainder of this section will therefore focus on the top-fired design.

The process considerations discussed below focus on steam reformer parameters specifically related to hydrogen plant design. However, many of these parameters also apply to steam reformers for other types of plants (such as syngas, ammonia, and methanol plants).

24.3.5 Pressure

The shift reaction equilibrium is independent of pressure. However, the reforming reaction equilibrium is favored by low pressure. Therefore, for the overall reaction, the lower the pressure, the higher the conversion of hydrocarbon to hydrogen. Accordingly, from the reaction standpoint, it is best to operate at low pressure.

However, there are other considerations. For example, modern hydrogen plants typically use a pressure swing adsorption (PSA) unit for hydrogen purification. PSA units are more efficient at higher pressure. The

minimum pressure for acceptable operation is typically 150–200 psig (≈ 10 –14 bar). The optimum pressure may be 300–450 psig (≈ 20 –30 bar). Therefore, to accommodate the PSA unit, the reformer pressure will need to be adjusted accordingly.

Another consideration is product hydrogen pressure requirements. In many applications, the hydrogen product from the hydrogen plant requires subsequent compression to a much higher pressure, for example for refinery hydrotreating applications. In such cases, the compression cost can be reduced considerably if the hydrogen from the hydrogen plant is produced at a higher pressure.

As discussed below, hydrogen plant reformers typically operate at process gas outlet temperatures up to 1700 °F (≈ 930 °C). At these temperatures, metallurgical considerations for the outlet piping typically limit the reformer outlet pressure to about 550 psig (≈ 38 bar). This corresponds to a hydrogen product pressure of about 500 psig (≈ 35 bar).

Many hydrogen plant reformers are designed consistent with a hydrogen product pressure of about 300–350 psig (≈ 20 –24 bar). Although this decreases the reforming reaction conversion, the overall plant economics often favors the higher pressure.

Conversely, if the product pressure requirement is low, then the PSA unit will typically determine the minimum pressure.

Therefore, for hydrogen plants, the reformer outlet pressure typically runs between 150–550 psig (≈ 10 –38 bar).

24.3.6 Exit Temperature

The reforming reaction equilibrium is favored by high temperature. At the pressure levels used in hydrogen plants, the reformer process gas exit temperature typically runs between 1500 and 1700 °F (≈ 815 –930 °C). Lower temperatures give insufficient conversion. Higher temperatures increase metallurgical requirements, tube-wall thickness, and fuel consumption.

24.3.7 Inlet Temperature

The reforming reaction rate becomes significant at about 1000 °F (≈ 540 °C), so it is usually advantageous to design for an inlet temperature near this value. This is typically achieved by preheating the reformer feed against the hot flue gas in the WHR section of the reformer.

A higher reformer inlet temperature decreases the absorbed duty requirement and therefore decreases the number of tubes, the size of the furnace, and the fuel re-

quirement. It also decreases the steam generation from the waste heat recovery unit.

If steam has a high value relative to fuel, it may be economical to reduce the reformer inlet temperature somewhat in order to maximize steam generation. In many such cases, the optimum inlet temperature is about 1050 °F (≈ 565 °C). This is low enough to maximize steam generation, but high enough to keep the furnace size down.

If steam does not have a high value, the optimum reformer inlet temperature is often about 1100 °F (≈ 590 °C). Above this, metallurgical considerations with the inlet piping become a factor.

Up to 1050 °F (≈ 565 °C), 2-1/4 Cr-1 Mo material is satisfactory for the inlet piping. At higher temperatures, stainless steel would ordinarily be used, but stainless steel is generally considered unacceptable because of the possibility of chloride stress cracking. Such cracking can occur if the steam in the feed has chloride-containing water droplets carried over from the steam drum. Incoloy is considered the next step up in metallurgy and is not subject to chloride stress cracking, but its cost typically prohibits its use. Accordingly, for metallurgical reasons the maximum inlet temperature should remain at about 1050 °F (≈ 565 °C).

24.3.8 Steam/Carbon Ratio

The feed must contain sufficient steam to eliminate carbon formation. The relationship between steam and hydrocarbon is typically expressed as the steam-to-carbon ratio. This corresponds to the moles of steam per mol of carbon in the hydrocarbon. The design steam-to-carbon ratio is typically about 3.0 for all hydrocarbon feedstocks. Lower values (down to about 2.5) can be used for some feedstocks, but there is a higher risk from potential operating upsets that might occur which could drop the ratio down to where carbon formation could occur.

For heavier feedstocks, carbon formation is more likely, and an alkali-based catalyst must be used to suppress carbon formation. Such catalysts are readily available, and it is understood that the 3.0 steam-to-carbon is applicable only if the proper catalyst is chosen. Otherwise, higher steam-to-carbon ratios are required.

24.3.9 Heat Flux

The reformer heat flux is typically defined as the heat input per unit of time per area of inside tube surface. For a given absorbed duty, the heat flux is therefore determined by the amount of tube surface.

A low heat flux provides extra catalyst volume and lower tube-wall temperatures. This provides sev-

eral advantages: The extra catalyst volume increases the reforming reaction conversion. The lower tube-wall temperature reduces the tube-wall thickness, which in turn reduces the cost per tube and increases the tube life. The lower tube-wall temperature also reduces the fuel requirement.

A high heat flux has the opposite effect, but has the advantage of reducing the number of tubes.

Because of these trade-offs, commercial heat fluxes typically vary from about 20 000 to 28 000 Btu hr⁻¹ ft⁻² (63 000–88 000 W/m²). A conservative design will typically run from 20 000 to about 25 000 Btu hr⁻¹ ft⁻² (63 000 to about 79 000 W/m²).

The above fluxes are average values for the entire furnace. The point flux is highest in the zone of maximum heat release, and then falls off to a relatively low value at the tube outlet. The maximum point flux is often 35 000–40 000 Btu hr⁻¹ ft⁻² (110 000–126 000 W/m²).

24.3.10 Pressure Drop

The reformer pressure drop depends primarily on the number of tubes, the tube diameter, and the catalyst selection. Typically, the overall design pressure drop will range from 40–60 psi.

24.3.11 Catalyst

Reforming catalysts are typically manufactured in a ring or a modified ring form. The modified ring forms have increased surface area and a higher activity for about the same pressure drop, but they cost more.

Reforming catalysts use nickel as the principal catalytic agent. For heavier feedstocks, an alkali promoter is typically used to suppress carbon formation. For heat fluxes above about 25 000 Btu hr⁻¹ ft⁻², modified ring shapes are needed to maintain the reforming reaction conversion.

The reaction conversion is typically measured in terms of *approach to equilibrium*. A typical design approach to reforming equilibrium is 20 °F (≈ -7 °C). This means that the reforming reaction (24.1) is at equilibrium corresponding to a temperature 20 °F (≈ -7 °C) lower than the actual temperature. This corresponds to a typical end-of-life catalyst condition. Fresh catalyst typically runs at essentially a 0 °F (≈ -18 °C) approach to reforming equilibrium (that is, for fresh catalyst the reforming reaction is essentially at equilibrium at the actual temperature). The shift reaction (24.3) is rapid and is considered in equilibrium at all times.

Typical catalyst life is 4–5 yr. To obtain the performance discussed above over this time frame, the

appropriate catalyst must be selected, consistent with the design heat flux and allowable pressure drop.

For higher flux reformers, a dual charge of catalyst is typically used. The top half of the tube is loaded with a high activity catalyst that prevents carbon formation in the zone of maximum flux. The bottom half of the tube can be a more conventional, less expensive catalyst.

Catalyst pressure drop is also an important consideration. Fortunately, the modified ring catalysts, with high void space, can provide higher activity for about the same pressure drop. If significantly higher activity is needed, a higher pressure drop must be accepted.

24.3.12 Tubes

Reformer tubes typically operate at maximum temperatures of 1600–1700 °F (≈ 870–930 °C) and are designed for a minimum stress-to-rupture life of 100 000 operating hours. Today's preferred metallurgy is a 35/25 Ni/Cr alloy modified with niobium and microalloyed with trace elements including titanium and zirconium.

Smaller tube diameters provide better in-tube heat transfer and cooler walls. The cooler walls reduce tube-wall thickness, which reduces tube cost and increases tube life. The cooler walls also decrease fuel consumption. However, more tubes are required and the pressure drop is higher. On the basis of these parameters, the optimum inside tube diameter is typically 4–5 inches (≈ 10–13 cm).

Thin walls increase tube life because secondary stresses are minimized during thermal cycling on startups, shutdowns, and upsets. Accordingly, the tube-wall thickness should be minimized consistent with meeting the tensile strength requirement. For many applications, the minimum sound wall (MSW) can be as low as 0.25 inches (≈ 0.6 cm).

Longer tubes provide a longer co-current heat transfer path in the reformer, and thereby reduce the flue gas exit temperature, which conserves fuel. Longer tubes also reduce the number of tubes. However, the pressure drop is higher. The optimum tube length is typically 40–45 feet (≈ 12–14 m).

Increasing the tube pitch (the center-to-center spacing) reduces the shielding effect between tubes and lowers the peak temperature around the tube circumference. This improvement is significant for short tube pitches, but falls off at longer pitches.

If the pitch is too short, the design must be modified to avoid overlapping the tube inlet flanges. The optimum pitch is typically 2–3 tube diameters.

The lane spacing between tube rows must be sufficient to avoid flame impingement from the burners. Typical spacing ranges from 6 to 8 feet (≈ 1.8–2.4 m).

24.3.13 Burners

The burners are located between the tube rows. Increasing the number of burners reduces the heat release per burner, which permits a smaller flame diameter and reduced lane spacing. The number of burners varies with the design, but a ratio of one burner for every 2–2.5 tubes will provide a very uniform heat release pattern and is considered good design practice.

For most hydrogen plants, the burners are a dual-fired design, which will fire both PSA offgas and the supplemental makeup gas. Lo-NO_x burners are typically used to meet modern environmental requirements. In some burner designs, the makeup gas is used to induce flue gas into the flame, thereby reducing the flame temperature and the NO_x level. With a properly designed burner, NO_x levels of as low as 0.025 lbs/MM Btu LHV (0.011 kg/GJ) of heat release can be expected.

24.3.14 Flow Distribution

It is important to obtain good flow distribution for all reformer streams. The piping should be designed such that the variation in gas flow to the reformer tubes and to the burners does not exceed $\pm 2.5\%$. Otherwise, the tube-wall temperatures may not be sufficiently uniform.

Special consideration must be given to the PSA offgas flow since it is typically available to the burners at only about 3 psig. Even greater consideration must be given for preheated combustion air (if used), since the differential air pressure across each burner is typically no more than 2 inches (≈ 5 cm) H₂O.

To help ensure good distribution, the piping should be as symmetrical as possible, and detailed pressure drop computations should be made and analyzed.

It is especially important that the flue gas tunnels be properly designed. The tunnels are rectangular fire-

brick structures located at the bottom of the reformer which serve as horizontal ducts for flue gas removal. Selected bricks are removed along the bottom of the tunnels to provide openings for the flue gas. To ensure plug flow of flue gas down the box, these openings must be designed for uniform flow distribution of the flue gas from the box into the tunnels. To ensure proper design, detailed hydraulic calculations should be made and analyzed.

24.3.15 Heat Recovery

The flue gas typically exits the radiant box at 1800–1900 °F (≈ 980 – 1040 °C). A waste heat recovery (WHR) unit is provided to recover heat from this gas. Typically, this consists of a package unit containing a reformer feed preheat coil, followed by a steam superheat coil (if applicable), followed by a steam generation coil, followed by a boiler feedwater preheat coil. If combustion air preheat is used, the air preheat unit typically replaces the boiler feedwater coil. The flue gas typically exits the WHR unit at about 300 °F (≈ 150 °C).

On this basis, and with a typical heat loss of 3% of the absorbed duty, the overall efficiency of the reformer (radiant plus WHR) is about 91% on an LHV basis.

Steam is also generated in a process steam generator, which extracts heat from the reformer outlet process gas. The WHR unit and the process steam generator typically share a common steam drum.

Steam generation pressure must be sufficient to provide steam to the reformer. Typically, the minimum required pressure is 100–150 psig above the hydrogen product pressure, depending on the plant pressure drop. Significantly higher steam pressures can easily be accommodated, and reformers generating 1500 psig steam are not uncommon in some industries.

24.4 Environmental Issues

The federal government's passage of the Clean Air Act in 1970 set national limits on industrial emissions to reduce air pollution and acid rain. Since 1970, the Clean Air Act has been amended and some states, such as California, have set even stricter limits on several of these emissions. Therefore, a major point of emphasis when designing a hydrogen plant is the reduction of plant emissions. A typical hydrogen plant has three sources of emissions:

- Flue gas from the combustion chamber of the reformer

- Condensate from the process
- Wastewater from the steam generation system.

24.4.1 Flue Gas Emissions

There are five primary pollutants found in the flue gas: nitrogen oxides, carbon monoxide, sulfur oxides, unburned hydrocarbons, and particulates. These components are formed during the combustion process.

The majority of the flue gas emissions consist of the nitrogen oxides (NO_x). NO_x is an environmental concern because it can cause photochemical smog and

acid rain. The nitrogen oxides from a hydrogen plant primarily consist of nitrogen oxide (NO) and nitrogen dioxide (NO₂). There are three types of NO_x formation: prompt NO_x, fuel NO_x, and thermal NO_x. Prompt NO_x is formed when fragments of hydrocarbons in the fuel combine with nitrogen in the combustion air. This form of NO_x is considered to be negligible as compared to thermal NO_x in hydrogen plant applications. Fuel NO_x is formed when nitrogen-containing hydrocarbons in the fuel are burned. However, this is typically not a concern for hydrogen plants because the makeup fuel is usually natural gas. Thermally produced NO_x represents the largest contributor to NO_x formation in a hydrogen plant. Thermal NO_x is produced by N₂ and O₂ in the combustion air reacting in the hottest part of the burner flame. The rate of thermal NO_x formation is based on the burner flame temperature, the amount of combustion air, and residence time. As the flame temperature increases, the amount of NO_x formed increases. Issues such as type of fuel gas, amount of excess air and combustion air temperature affect the amount of thermal NO_x formation. Therefore, to reduce the flame temperature, many burner manufacturers have developed burner designs that incorporate staged combustion and flue gas recirculation. The recirculation of the flue gas cools the flame thus lowering the amount of thermal NO_x formation. The recirculation will also lower the amount of CO exiting the burner, as a portion of it will be recycled and combusted.

A NO_x removal system may be required to meet a site's emission requirements. The typical system used for this case is a Selective Catalytic Reduction unit (SCR). The SCR unit reduces NO_x by reacting ammonia with the flue gas over a catalyst, which yields nitrogen and water vapor. An SCR unit can reduce the NO_x emission from a hydrogen plant by approximately 90%. There is a small slipstream of ammonia, approximately 10 ppmv that will exit with the flue gas. This unit adds additional capital costs as well as operating costs and ammonia handling issues but is sometimes required as the best available control technology (BACT) for NO_x removal.

The CO, combustion-produced particulates, and the unburned hydrocarbons are all related to the amount of excess air, type of fuel, and the amount of mixing of the

fuels within the burner. Insufficient air and inadequate mixing can result in incomplete combustion thus raising the amount of CO and unburned hydrocarbons in the flue gas. Particulates formed in the combustion process are very low for gaseous fuels but will increase with the use of liquid fuels.

The sulfur oxides that are formed are directly related to the amount of sulfur found in the fuel. These emissions are typically low when PSA offgas is burned with natural gas. The PSA offgas is sulfur-free due to feedstock pretreatment to protect catalyst beds within the hydrogen plant. Natural gas also typically contains very low levels of sulfur. However, if refinery fuel gases are used as a makeup fuel to the reformer, then the sulfur emissions can increase dramatically as these streams often contain large amounts of sulfur.

Burner manufacturers will have typical values of these emissions for their burners based on actual tests of their burner design. The emission limits of the CO, sulfur oxides, unburned hydrocarbons, and particulates are generally met since light gaseous fuels are typically used as the fuels for the reformer. Table 24.9 below contains some typical emission values for a standard hydrogen plant utilizing Low-NO_x burners when burning PSA offgas with natural gas.

24.4.2 Process Condensate (Methanol and Ammonia)

The process condensate from a standard hydrogen plant contains impurities such as dissolved gases, ammonia, methanol, and traces of other organic compounds. The dissolved gases that are found in the process condensate consist of the components in the syngas (CO, CO₂, H₂, CH₄, and N₂). Henry's Law can be used to calculate the amounts of these gases that are in the condensate

$$P = Hx, \quad (24.6)$$

where P is partial pressure of a component, H is Henry's Law constant, x is mole fraction of component in solution.

The CO₂ represents the largest amount of dissolved gas in the condensate, typically in the range of several 1000 ppmw. The dissolved H₂, CO, and CH₄ are typ-

Table 24.9 Typical emission values for a standard hydrogen plant

Emission	Units	Value
NO _x	lb/(MMBtu LHV)	0.03
	kg/GJ LHV	0.013
CO	ppmv (3% O ₂ dry basis)	25
Unburned hydrocarbons	ppmv (3% O ₂ dry basis)	5
Particulates	lb/MMBtu LHV	0.005
	kg/GJ LHV	0.002

ically in lower concentrations of less than a hundred ppmw each.

In a hydrogen plant, ammonia is produced in the reformer. The steam methane reformer's operating conditions are similar to that of an ammonia synthesis reactor. The amount of ammonia produced is based on the amount of nitrogen in the feed. Feedstocks with negligible amounts of nitrogen will not produce an appreciable amount of ammonia. Ammonia formation depends on the reaction equilibrium and the residence time inside the reformer. The ammonia equilibrium reaction is given below.

$$[\text{NH}_3] = K_{\text{PNH}_3} [\text{N}_2]^{0.5} [\text{H}_2]^{1.5} P_T, \quad (24.7)$$

where [] is mole fractions, K_{PNH_3} – Equilibrium constant, P_T – Total pressure (atm).

Ammonia formation is lessened due to the fact that the residence time of the steam methane reformer is designed for hydrogen production not ammonia production with recycle. In an NH_3 plant, the ammonia is considered to be at equilibrium in a secondary reformer that is operating approximately 300–500 °F (≈ 140 –260 °C) higher than a traditional steam methane reformer. Therefore for calculations, the worst case for ammonia production in a hydrogen plant can be assumed to be equilibrium at the reformer outlet temperature plus an additional 300 °F (≈ 140 °C).

Methanol is produced as a by-product in the shift converters within the hydrogen plant. In High-Temperature Shift Converters (HTSC), the formation of methanol is an equilibrium reaction similar to that of ammonia formation in the reformer. The equilibrium reaction for methanol is given below.

$$[\text{CH}_3\text{OH}] = \frac{K_{\text{PCH}_3\text{OH}} [\text{CO}_2] [\text{H}_2]^3 P_T^2}{[\text{H}_2\text{O}]}, \quad (24.8)$$

where [] is mole fractions, $K_{\text{PCH}_3\text{OH}}$ – Equilibrium constant, P_T – Total pressure (atm).

The typical concentrations of methanol in an HTSC application are approximately 100–300 ppmw. In a Low-Temperature Shift Converter (LTSC) application, the methanol production is greater than that of an HTSC application. The formation of methanol is not just related to equilibrium for an LTSC but also to the catalyst characteristics and kinetics. Therefore, the catalyst vendor should be contacted in reference to calculating the expected amount of methanol from an LTSC application.

In the majority of hydrogen plants today, the process condensate is used as makeup water to the steam generation system of the plant. Typically, boiler feedwater makeup is mixed with the process condensate and

sent to a deaerator. The deaerator uses steam to strip the dissolved gases, namely O_2 and CO_2 , and the other contaminants from the boiler feedwater. These contaminants can be harmful to downstream equipment and boiler operation. These contaminants are then emitted to the atmosphere. Since there are large amounts of CO_2 , the type of deaerator for hydrogen plant use typically has a vertical stripping section consisting of either trays or packing located on top of the deaerator. To calculate the amount of each contaminant leaving the deaerator's stripping section, one can use the equations below.

Mole Fraction Remaining

$$\frac{(Lx_{\text{OUT}})}{(Lx_{\text{IN}})} = \frac{(S-1)}{(S^{n+1}-1)} \quad (24.9)$$

and Mole Fraction Stripped

$$\frac{(Gy_{\text{OUT}})}{(Lx_{\text{IN}})} = \frac{S(S^n-1)}{(S^{n+1}-1)}, \quad (24.10)$$

where G & L are Molar Flow Rates, S – Stripping Factor (KG/L), n – Number of Equilibrium Stages, K – Vapor-liquid distribution coefficient, ($y/x = H/P_T$).

As methanol emissions continue to be monitored more closely, there are some methods for reducing the methanol in the deaerator vent. The vent stream could be condensed and sent to the reformer or the steam system. Catalytic combustion could be used to reduce the methanol. A scrubber system could be added to remove the methanol. In some instances a condensate stripper is added instead of the deaerator to remove the ammonia, methanol, and other contaminants from the condensate. This system recycles the vent stream to the reformer as process steam and the bottoms are mixed with the incoming boiler feedwater makeup. However, this system adds considerable capital cost to a project.

24.4.3 Wastewater

The wastewater from a hydrogen plant typically consists of only the blowdown from the boiler system. The boiler feedwater that feeds the steam generation system has small amounts of impurities such as sodium, chlorides, silica, and organic carbons. These impurities will accumulate within the boiler system and create sludge, scaling of the boiler tubes, and possible carryover of solids into the process steam. Blowdown of the boiler water is performed to prevent these issues from affecting the operation of the steam system. The blowdown is typically sent to the sewer or the on-site waste treatment plant for treatment and disposal.

24.5 Monitoring Plant Performance

There are several areas of focus when monitoring the performance of a hydrogen plant. The first area of focus is the performance of the catalyst beds employed in the hydrogen plant. The Hydrotreater, which converts sulfur compounds to H_2S , should be checked periodically for pressure drop through the bed. The hydrotreating catalyst life is approximately 3 yr. If the catalyst bed's pressure drop exceeds design then it may be time to change the catalyst out due to catalyst degradation and activity loss.

The next typical catalyst bed in a hydrogen plant is the desulfurizer bed. The desulfurizer uses zinc oxide to remove traces of H_2S from the feed gas. The desulfurizer catalyst bed design is based on the loading of the sulfur compounds. Therefore, the gas exiting from the desulfurizer bed should be checked to ensure that the sulfur levels are below 0.1 ppmv. If the original design life of the catalyst bed is known, then periodic feedstock analysis can be used to forecast when the bed may require change out.

Since the reforming reaction constitutes the majority of the hydrogen production in the plant, it is important to monitor the reforming catalyst. The reforming catalyst is typically designed for a 5 yr life. Pressure drop measurements should be taken across the catalyst-filled tubes in the reformer. If the pressure drop increases as time goes by, this could be an indication that catalyst attrition or possible carbon formation on the catalyst could be taking place. The activity of the catalyst can be checked by comparing the outlet composition of the reformer to the expected composition at the design approach to equilibrium conditions. If the pressure drop increases or the activity has decreased, then it is probably time to change out the reforming catalyst.

The examination of the high-temperature shift catalyst is similar to that of the reforming catalyst. The catalyst life for the high-temperature shift catalyst is approximately 5 yr. Pressure drop readings should be taken to check for possible catalyst attrition. The outlet composition should be validated with the expected composition with the design approach to equilibrium conditions.

The pressure swing adsorption (PSA) system has a catalyst life of approximately 20 yr or equal to the expected plant life. However, hydrogen purity and recovery should be recorded periodically to watch for possible catalyst poisoning. The amount of nitrogen in the feedstock also has an effect on these two operating parameters and should be checked. A higher nitrogen content in the feed gas than design could lower the hydrogen recovery in the PSA unit.

The reformer tubes are one of the most important pieces of equipment in a hydrogen plant. These tubes are built from microalloyed materials in order to handle the extreme environment to which they are exposed. The industry standard for reformer tube design is for 100 000 h life. To ensure that the tubes will last the designed 100 000 h life, the reformer tube-wall temperature readings should be taken on a regular basis. An optical pyrometer is the instrument of choice for this task. In order to obtain the correct tube-wall temperature reading, the tube-wall and the furnace background should be measured for each tube reading. The background temperature is required to correct for background radiation. The equation below can be used to correct the tube-wall temperature readings (Please note that the temperature scale is Rankine). The emissivity on the pyrometer should be set to 1 before taking the readings.

$$T_t = \left[\frac{(T_{MT}^4 - (1 - e)T_{MB}^4)}{e} \right]^{1/4}, \quad (24.11)$$

where T_t is True Tube Temperature ($^{\circ}R$), T_{MT} is Measured Tube Temperature ($^{\circ}R$), T_{MB} is Measured Background Temperature ($^{\circ}R$), e is average furnace emissivity (typical = 0.82).

The maximum allowable tube stress will need to be calculated in order to calculate the actual reformer tube life. This is accomplished by using the Mean Diameter Formula given below.

$$S = \frac{PD_M}{2t_{MIN}}, \quad (24.12)$$

where S is tube stress (psi max), P is tube inlet pressure (psig), D_M is tube mean diameter = $(D_O + D_I)/2$, D_O is tube OD, as cast (in), D_I is tube ID = $D_O - 2t_{MIN} - 2CA$, CA is casting allowance (typically 1/32 in on outside wall, 0 in on inside wall), t_{MIN} is minimum sound wall (in).

The Larson–Miller equation correlates the stress-temperature to life of the tubes. The equations below are for Manaurite XM material tubes.

$$S = 0.145B \times 10^{(-0.0062P^2 + 0.2955P - 1.5426)} \quad (24.13)$$

$$P = T[22.96 + \log(t)] \times 10^{-3} \quad (24.14)$$

where S is minimum stress to rupture (ksi), B is ratio of minimum to average stress (typical temperature range, $B = 0.85$), P is Larson-Miller parameter (dimensionless), T is tube-wall temperature (K), t is tube life (hours).

If the measured temperature is less than design, then the reformer tubes should last their expected life. However, if the measured temperature is greater than the design temperature, then the reformer tube life will be shortened. If the actual life of the reformer tubes is below the expected life, then the operating conditions of the reformer should be further investigated.

The steam system is an area that requires constant attention to ensure proper operation of the hydrogen plant. If the steam quality decreases, it can lead to solids carryover from the steam drum. These solids will plate out in the feed preheat coil of the convection section and subsequently lead to an equipment failure and plant shutdown. To reduce the probability of an upset, the steam drum should be manually blown down on a regular basis to reduce the amount of dissolved solids and other impurities in the steam drum. Next, the boiler feedwater should be analyzed on a regular basis to ensure that the treatment it is receiving is adequate for the desired steam generation conditions.

Cooling water is generally used for the final trim cooling of the process gas before the hydrogen purification step. In most instances, the cooling water is considered to be a dirty medium. Therefore, it is recommended to develop a temperature profile of the cooling water side of the exchanger based on design data. Ad-

ditional temperature profiles should be developed based on data from the operation of the plant and compared to the original profile. This data can be used as a means to check for fouling of the cooling water side of the exchanger and improper heat transfer through the exchanger.

Another means of monitoring the performance of the hydrogen plant is to check the pressure drop through the entire plant. If the pressure drop is higher than design, then individual pieces of equipment should be checked for excess pressure drop. This may signify several things such as catalyst attrition, excessive exchanger fouling, or equipment failure.

The final method of checking the performance of the unit is to calculate the overall utility consumption of the plant and compare it to the design summary or previous summaries. The feed and fuel flows are typically converted to energy since their utility cost are typically on an energy basis (for example: MM Btu/hr LHV). These numbers as well as the other utility quantities are divided by the hydrogen product flow. This method allows for calculating the total price of hydrogen on a US\$/M SCF H₂ basis. Once the summary has been created, comparisons to earlier summaries and analysis of major cost areas can be investigated. The effects of process improvements can be evaluated on this basis.

24.6 Plant Performance Improvements

The most common method of improving plant profitability is to increase the capacity of the hydrogen plant. The plant design should be evaluated as to its capability to handle an increased load before this is attempted. The process design specifications should be retrieved on all of the relevant plant equipment and compared to the vendor's design specifications. If there are any significant differences between the two sets of specifications, investigation into the cause of the difference is warranted. From this comparison, a final set of equipment design data should be developed for each piece of equipment.

The operating data of the equipment should then be compared to the design capabilities of the equipment in order to set the available capacity increase for each piece of equipment. Compressors should be checked for capacity versus design flow, spillback design, inspection of valves, and motor requirements. The fans should be checked for operating versus design capacity, vane inspection, and motor requirements. The pumps should be checked for operating versus design capacity, inspection of screens and impellers, and motor requirements.

The next area of evaluation consists of the pressure profile of the plant. The operating pressure profile should be compared to the design pressure profile. Any significant differences should be investigated and possibly corrected. An acceptable capacity increase for the equipment should be used to set a proposed capacity increase for the plant. The pressure drop for this raised capacity case should be calculated and compared to design pressure profile. Depending on the results of this calculation, investigation into the available feed pressure may be warranted. Relief settings for the raised capacity case should be evaluated to ensure proper operation. Some pieces of equipment may have to be checked to determine if they can be re-rated for a higher operating pressure than design.

The reformer tubes will need to be evaluated as to their capability of handling an increase in capacity. Temperature readings should be taken at several plant capacity increments (50%, 75%, 100%). This data should be compared with the maximum design tube-wall temperature. If the tube-wall temperature is approaching the maximum design tube-wall temperature, there are several things that can be considered.

The catalyst vendor should be contacted about the possibility of a more active reforming catalyst. The burners could be revamped or replaced. The burner pressure drop should be monitored and compared to design data. The excess air used for the combustion should be checked to ensure proper operation. If the burners were to be replaced, it would affect firing capacity, flame pattern, and NO_x emissions. The reformer tube metallurgy should be checked to see if it could be upgraded. An upgrade in tube metallurgy would affect the tube ID and the design tube-wall temperature.

Most hydrogen plants utilize a PSA system for their hydrogen purification. This system should be checked for H_2 purity, and a corresponding H_2 recovery should be calculated. This data should be compared to the original design data of the unit. The cycle times should be compared to the design cycle time. To check the available capacity increase for the PSA unit, the adsorption time should be increased in small increments until the maximum permissible impurity breakthrough occurs. The cycle time should be adjusted and the H_2 recovery calculated. The purge time in this cycle should be compared with the design purge time. The additional purge time is a measure of the additional capacity that is available in the PSA unit. If the PSA unit is capacity limiting, then the following options should be considered: reduction of offgas drum back pressure, improvement of feed conditions, relaxation of purity specifications, setting unit on automatic purity control, change cycle (equalizations), adsorbent change out, or addition of additional vessels.

The reduction of the utility consumption of the plant is another method of improving plant performance. It is important to make certain that the plant is not using an excessive amount of utilities. The reformer is a key target area for this investigation. The burners should be checked to ensure that they are using the correct amount of excess air (typically 10%, 20% for heavier fuels). For example, if the burners were using 20% versus 10% excess air, this would translate to an approximate increase in reformer firing of 10%. Therefore, using the correct amount of excess air does not waste fuel. The bridge-wall temperature should also be checked. For every 20°F ($\approx 7^\circ\text{C}$) above the required bridge-wall temperature, there is a 1.5% increase in reformer firing. The bridge-wall temperature should be set at the temperature required to obtain the process outlet temperature that yields the proper CH_4 slip through the reformer. As discussed above, the PSA recovery should be maximized. For every 1% increase in recovery, there is an approximate saving of 0.5% of feed and fuel. The deaerator vent and steam system blowdowns should be checked. Excessive blowdown adds additional treating chemicals and boiler feedwater flow while reducing the export steam quantity.

Another option is to debottleneck an existing hydrogen plant by revamping or upgrading portions of it. However, these cases should be evaluated on a case-by-case basis as different sites have different utility and/or plot considerations. Some of the upgrades are discussed in Sect. 24.7.

24.7 Economics of Hydrogen Production

There is a growing focus in the refining industry on hydrogen capacity. Hydrogen is generally required for deep sulfur removal from hydrocarbon products. As sulfur restrictions on gasoline and diesel become increasingly stringent, the refining demand for hydrogen continues to grow.

By evaluating the hydrogen utilization in their facilities, refiners are coming to the realization that they need additional hydrogen supply. There are a number of options available to address this need. Refiners may be able to meet the increased demand by improving operations of their existing hydrogen plants. They may choose to separate hydrogen from waste or offgas streams or even purchase hydrogen from third parties. As an alternative, after careful technical and economic evaluation, they may conclude that the best solution to optimize the economic benefit to them over the longer term is to build a new hydrogen plant.

In recent years, many advances have been made in hydrogen plant technology. Substantial improvements have been incorporated into hydrogen plant design to significantly improve overall life cycle costs. On the basis of experience with hydrogen plant benchmarking, it has become clear that the optimum economic solution in some cases may be to replace an existing hydrogen plant with a new modern hydrogen plant.

There are a number of options available to refiners to meet the increase in hydrogen demand. Before deciding to proceed with any option, refiners should conduct a comprehensive technical and economic evaluation of their existing operations and evaluate the technical and economic benefits of the options available to them. The option that provides the optimum economic and operations benefits will be different for each situation and will depend on such things as the existing steam balance, the cost and availability of utilities,

plot limitations, and the condition of existing hydrogen plants.

The first option for refiners who are operating Old Style (Sect. 24.2.4) hydrogen plants is to consider ways to increase the capacity of these plants. Following an evaluation of the condition and efficiency of the existing plant, they may be able to effectively increase the capacity by either tightening up on operations or selectively upgrading portions of the old plant.

In many refineries, hydrogen is treated like a utility. There may not be much of a focus on the details of the actual production and the plants are sometimes operated *loose*. In this case, simple operational changes could significantly increase production and efficiency. Refiners could also debottleneck an existing hydrogen plant by revamping or upgrading portions of it. Debottlenecking options can also have a positive efficiency impact. Some of these potential upgrades may include:

- Replacing reformer tubes with upgraded metallurgy and thinner walls will allow for more throughput and a higher heat flux, which would increase capacity.
- Adding a Preformer would unload the primary reformer so capacity can be increased.
- Adding a Secondary Reformer would increase methane conversion, which increases capacity.
- Adding Combustion Air Preheat would lower the fuel requirement and potentially unload the waste heat recovery unit and fluegas fan, resulting in a capacity increase.
- Upgrading the CO₂ removal unit would minimize hydrogen loss in the Methanator, resulting in a potential capacity increase.
- Adding a PSA unit would decrease hydrogen production, but would typically produce more cost effective and higher purity hydrogen.

A second option is to separate hydrogen from a waste stream or an offgas stream that is currently being sent to fuel. This would typically require the addition of separation equipment and possibly some compression. In addition, separating hydrogen out of the fuel system will usually result in additional makeup fuel. This could change the heating value of the refinery fuel system and possibly have an impact on other fuel-burning equipment.

A third option is to buy hydrogen from a third party. Various industrial gas suppliers are willing to sell hydrogen to refiners either by pipeline or, depending on location, by a stand-alone plant. This option requires a minimal capital investment by the refiner but the delivered hydrogen will probably be more expensive per unit than if self-produced.

The last option is to build a new hydrogen plant. Building a Modern hydrogen plant is typically the most capital intensive of the options available. However, the capital investment could pay off if there is a significant gain in efficiency. Below we will analyze and compare the typical overall production cost of hydrogen between a Modern and an Old Style hydrogen plant.

24.7.1 Overall Hydrogen Production Cost

The most significant economic factor in evaluating options to increase hydrogen capacity is the overall production cost of hydrogen. The overall production cost can be estimated over the life of the hydrogen plant by using the different cost parameters of constructing, operating, and maintaining the hydrogen plant. This overall production cost reflects a complete picture of the hydrogen plant economics over the life of the plant.

The efficiency of producing hydrogen and by-products are very important in minimizing the production cost of hydrogen. Utility costs are the major operating cost in hydrogen production. Utilities typically include usage of feed, fuel, boiler feed water, power, and cooling water, and generation of export steam (steam is typically a by-product of the hydrogen production process). Of these, feed and fuel make up the largest portion of the utility costs. In addition, the credit for export steam can have a significant impact on utility costs, especially when refinery utility costs are favorable for steam production. The remainder of the utilities combined typically make up less than 10% of the total operating cost.

These utility costs, together with other economic parameters applicable to the plant being evaluated, can be incorporated into a cash flow model and the overall production costs of hydrogen can be evaluated. The other economic parameters include such things as capital cost, start-up cost, other operating costs (including catalyst replacement and tube replacement), and maintenance costs. From this model, the internal rate of return (IRR), net present value (NPV) at various rates of return, net cash flow, and a generated income statement can also be developed.

24.7.2 Overall Production Cost Comparisons

Building a new hydrogen plant is typically not the most appealing alternative to refiners. A new hydrogen plant requires a significant capital investment, and although hydrogen is required to support many of the refinery unit operations, it is generally not viewed as a direct *money maker*. However, once all factors are taken into account and a total production cost of hydrogen over the life of the plant is determined, the best economic solu-

tion may be replacing an Old Style hydrogen plant with a new Modern hydrogen plant. The following evaluation illustrates this potential.

24.7.3 Evaluation Basis

To demonstrate the economics of building a Modern hydrogen plant versus continuing to operate an Old Style plant, two representative plants each producing 90 MMSCFD of contained hydrogen from a natural gas feed will be compared. Natural gas will also be used for fuel, and both plants will export 600 psig superheated steam. The Old Style plant will consist of the major processing units described above and will produce hydrogen with a purity of 95%. Other parameters for the Old Style plant will be based on typical observed values. The Modern plant will consist of the major processing units described above and will produce hydrogen with a purity of 99.99%. The Modern plant design will be based on producing maximum export steam.

This evaluation could be done based on a variety of other plant configurations, but for demonstration purposes, this evaluation is limited to the plant types described. For comparison purposes, the cost of utilities will be based on the following:

- Natural Gas US\$4.00 per MMBtu (US\$3.79 per GJ)
- High pressure (HP) Steam US\$5.00 per 1000 lbs (US\$11.02 per ton)
- Boiler Feedwater US\$0.50 per 1000 lbs (US\$1.10 per ton)
- Power US\$0.05 per kWh
- Cooling Water US\$0.10 per 1000 gals (US\$0.026 per m³).

24.7.4 Utilities

As previously discussed, the utility costs of a hydrogen plant are among the most important economic factors in determining the overall production cost of hydrogen. Simulation models were built for both the Old Style and Modern plants to calculate utility costs. The Old Style plant utilities are based on a simulation model built to reflect typical plant performance. The Modern plant utilities are based on a simulation model for the design of a typical new plant. Table 24.10 shows the utilities and utility cost of hydrogen for each plant.

Table 24.10 clearly illustrates a lower total utility cost for producing hydrogen in the Modern Plant than in the Old Style plant. The Modern plant produces hydrogen at a rate of US\$1.409 per MSCF of contained hydrogen, while the Old Style plant produces at a rate of US\$1.908 per MSCF of contained hydrogen. For

a plant producing 90 MMSCFD of contained hydrogen, this difference results in annual utility savings for a Modern plant of US\$16.4 MM. Of course, the utility cost alone does not complete the picture of the overall production cost of hydrogen. We must also evaluate a number of other economic and operating factors.

24.7.5 Capital Cost

Capital must be invested to build the new plant in order to capture the utility savings of the Modern plant. A total capital investment of about US\$55 MM would be expected for a new typical 90 MM SCFD hydrogen plant. This approximate installed sales price is based on inside battery limits, natural gas feed, no compression, no buildings, no water treatment units, no SCRs or MCCs, industry engineering standards, and delivery to the US gulf coast. For purposes of comparison, no capital investment is considered for the Old Style plant.

24.7.6 Life of the Plant Economics

A cash flow economic model can be generated using the utility costs developed for each plant, the capital cost required for the Modern plant, as well as a number of other economic factors. These other economic factors, along with their associated values are listed below:

- New Plant construction time – 2 years
- Escalation Rate 1.5% for all feed, product, and utilities
- Labor – two operators per shift
- Overhead – 50% of labor
- Maintenance – 2% of plant cost per year
- Other Misc – 1% of plant cost per year
- Catalyst costs accrued in year of change out
- Reformer tube replacement – every 10 years
- On Stream Time – 98.5%
- Working Capital – 45 days
- Debt Level – Borrow 75% for New Plant
- Cost of Capital – 8%
- Debt Length – 7 years
- Depreciation Life (of Capital Cost) – 10 years
- Tax Rate – 34%
- Project Life – 25 years (includes 2 years of construction)
- Internal Rate of Return – 0% to obtain actual cost of hydrogen production.

The resulting average overall production cost of hydrogen, calculated for the life of the plant, is shown in Table 24.11.

The evaluation shows that taking all relevant economic factors into consideration, the overall production

Table 24.10 Utility cost of hydrogen production

Utilities per 1000 SCF contained hydrogen		
	Old Style	Modern
Natural gas feed (MMBtu LHV)	0.275	0.317
Natural gas fuel (MMBtu LHV)	0.200	0.126
Total feed + fuel (MMBtu LHV)	0.475	0.443
HP export steam (lbs)	20	90
Boiler feedwater (lbs)	45	120
Power (kWh)	0.65	0.52
Cooling water (gal)	530	8
Cost (US\$) per 1000 SCF contained hydrogen		
	Old Style	Modern
Natural gas feed (MMBtu LHV)	1.100	1.268
Natural gas fuel (MMBtu LHV)	0.800	0.504
Total feed + fuel (MMBtu LHV)	1.900	1.772
HP export steam (lbs)	− 0.100	− 0.450
Boiler feedwater (lbs)	0.023	0.060
Power (kWh)	0.033	0.026
Cooling water (gal)	0.053	0.001
Total utility cost (US\$)	1.908	1.409
Utilities per 1000 NCM contained hydrogen		
	Old Style	Modern
Natural gas feed (GJ LHV)	10.83	12.48
Natural gas fuel (GJ LHV)	7.87	4.96
Total feed + fuel (GJ LHV)	18.70	17.44
HP export steam (kg)	338.87	1524.90
Boiler feedwater (kg)	762.45	2033.19
Power (kWh)	24.26	19.41
Cooling water (m ³)	74.88	1.13
Cost (US\$) per 1000 NCM contained hydrogen		
	Old Style	Modern
Natural gas feed @ US\$3.79/GJ LHV	41.05	47.32
Natural gas fuel @ US\$3.79/GJ LHV	29.86	18.81
Total feed + fuel @ US\$3.79/GJ LHV	70.91	66.13
HP export steam @ −US\$11.02/tonne	− 3.74	− 16.81
Boiler feedwater @ US\$1.10/tonne	0.84	2.24
Power @ US\$0.05/kWh	1.21	0.97
Cooling water @ US\$0.0264/m ²	1.98	0.03
Total utility cost (US\$)	71.204	52.563

Table 24.11 Overall production cost of hydrogen

	Old Style	Modern
Plant capacity (MM SCFD) contained	90	90
Plant capacity (NCMH) contained	100 482	100 482
Capital cost (MM US\$)	–	55
Average H ₂ production cost (US\$/1000 SCF)	1.996	1.602
Average H ₂ production cost (US\$/1000 NCM)	74.491	59.787
Average H ₂ production cost (US\$/yr)	65 568 600	52 625 700
Average annual production cost savings (US\$)	–	12 942 900

cost of hydrogen is lower for the Modern plant. The Modern plant produces hydrogen at a rate of US\$1.602 per M SCF of contained hydrogen while the Old Style plant produces hydrogen at US\$1.996 per M SCF of contained hydrogen. This lower overall production cost

results in an annual savings for the Modern plant of about US\$12.9 MM per year. This evaluation proves that for the cases analyzed, it is economically feasible and potentially advantageous to build a new, more efficient hydrogen plant.

24.7.7 Sensitivity to Economic Variables

Economic parameters for each refinery are different. The major parameters that can significantly alter these results are the efficiency of the existing plant, the feed and fuel price, and the export steam credit. The efficiency of the existing plant can span a wide range and is specific to each plant. For the remaining evaluations, the Old Style plant utilities will be held constant. The overall production cost of hydrogen will be analyzed as a function of the other two major factors, feed and fuel price and export steam credit.

24.7.8 Feed and Fuel Price

The cost of feed and fuel is typically the largest component of the overall production cost of hydrogen. Feed and fuel usually account for more than 80% of the total before the steam credit is taken. The overall operating cost changes significantly as the natural gas price varies. Figure 24.10 shows the effect of varying the natural gas price

price. For this evaluation, the export steam credit to natural gas price ratio was held constant.

As the price of natural gas increases, the Modern plant becomes more favorable. This is due to the overall feed and fuel efficiency advantage of the Modern plant. For example, if the natural gas price were changed from US\$4 to US\$8 per MMBtu (double the base case credit), the overall production cost would increase by US\$1.326 per MSCF of hydrogen for the Modern plant and US\$1.804 for the Old Style plant. The higher natural gas price would increase the average annual savings for the Modern plant from US\$12.9 MM to US\$28.6 MM.

24.7.9 Export Steam Credit

The export steam credit also has a significant effect on the overall production cost. The value a refinery places on steam depends on utility factors and the existing steam balance in the refinery. For example, during the winter, steam tracing is generally used more heavily

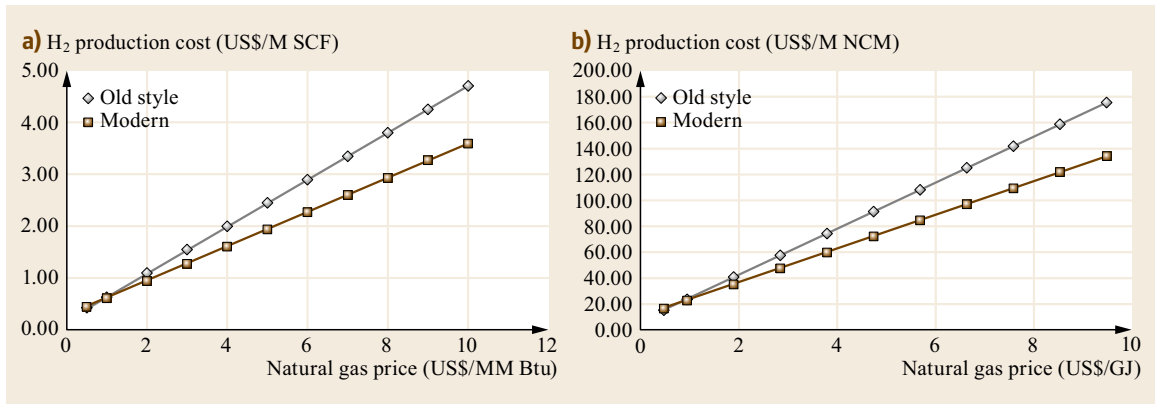

Fig. 24.10a,b H₂ production versus natural gas price

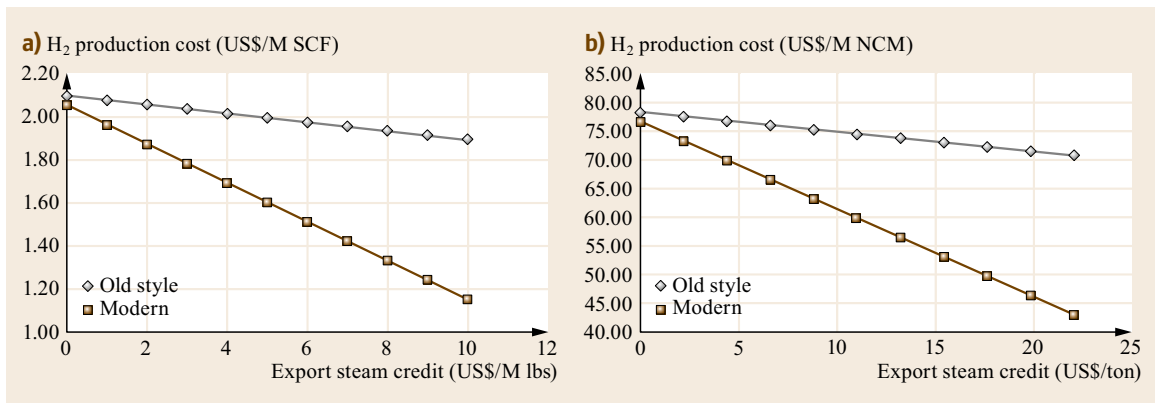

Fig. 24.11a,b H₂ production cost versus steam credit

and the value of steam could be higher than average. Conversely, in the summer, when less steam tracing may be utilized, steam may have a lower than average value. Modern hydrogen plants typically export much more steam due to the fact that they are more efficient and have a CO₂ removal regeneration requirement. Figure 24.11 shows the effect of varying the export steam credit. For this evaluation, the natural gas price remained the same.

24.8 Conclusion

Refiners have a number of different options to consider in addressing the demand for additional hydrogen. A comprehensive technical and economic evaluation of existing operations is required to determine the optimum solution for each specific application. The optimum solution for each refinery will be different due to site-specific items such as the cost and availability of utilities, plot limitations, refinery steam balance, emission requirements, and the condition of any existing hydrogen plants. The rising cost of utilities, and particularly natural gas, has placed a premium on the overall

As the export steam credit increases, the economics for the Modern plant become more favorable. For example, if the export steam credit were changed from US\$5 to US\$10 per Mlbs (double the base case credit), the overall production cost would drop by US\$0.450 per MSCF of hydrogen for the Modern plant and US\$0.100 for the Old Style plant. The higher steam credit would increase the average annual savings for the Modern plant from US\$12.9 MM to US\$24.4 MM.

plant efficiency. Therefore, the overall plant efficiency has not only become a key factor in determining the economics of what option to pursue, but also in the performance enhancement of existing hydrogen plants.

Today's Modern hydrogen plants take advantage of numerous technological improvements and offer a much more efficient plant with a lower overall life cycle cost. Once technical and economic evaluations are performed, it should not be surprising that the most economically attractive and most feasible approach may be to build a new hydrogen plant.

Hydrogen Ne

25. Hydrogen Network Optimization

Nick Hallale, Ian Moore, Dennis Vauk, Paul R. Robinson

Plantwide systems impact every process unit in a petroleum refinery. All units require electrical power, water, steam and instrument air. Units with fired heaters burn fuel oil or fuel gas from a common pool. Many units require hydrogen and most produce offgas streams, which are collected and treated in common facilities. In addition to methane and other light hydrocarbons, offgas may contain H₂ and toxic H₂S. Most modern refineries can benefit from hydrogen recovery and purification. Keeping hydrogen out of fuel gas is beneficial for many reasons. Recovery decreases the required amount of on-purpose hydrogen. Hydrogen burns hotter than other gases, so it raises the temperature of fuel gas combustion, which can limit fired heaters constrained by tube temperature limits. Hydrogen network optimization is more complex than other utility optimization efforts, because in addition to flow and pressure, one must consider the impact of gas composition on the units to which hydrogen gas might be sent. The benefits of hydrogen network optimization with the technology described in this chapter range from US\$ 1 mil-

lion per year for low- or no-cost recovery and purification projects to more than US\$ 15 million per year for modest-investment projects, with payback times measured in months.

25.1 Background

Plantwide systems impact every process unit in a petroleum refinery. To one extent or another, all units require electrical power, water and steam. Units with fired heaters burn fuel oil or fuel gas from a common pool. Many require hydrogen and most produce offgas streams, which are collected and treated in common facilities. Optimizing plantwide hydrogen networks can provide considerable benefits, ranging from US\$ 1 million per year for low- or no-cost recovery and purification projects [25.1, 2] to more than US\$ 15 million per year for modest-investment projects with paybacks measured in months [25.3].

These days, you can't be involved in the oil refining industry without coming across something on hydrogen management. However, most articles and presentations follow the same route, namely discussing

stricter sulfur and aromatics specifications, such as Euro V and perhaps the need to upgrade heavier oil. They then move on to say that more hydroconversion will be required. The conclusion? Refineries are going to need more hydrogen. But are they telling the refiners anything they didn't already know? An obvious option, of course, is to build or revamp a hydrogen plant, or buy more hydrogen from an offsite supplier in the future.

This chapter aims to be different. Instead of focusing on the problems, we will look at the opportunities. The intention is to get refiners thinking of their hydrogen as an asset not a liability.

Before proceeding, here is some background information on hydrogen production, purification and consumption in the petroleum processing industry.

25.1.1 Hydrogen Production

- *Catalytic reforming* converts treated heavy naphtha into aromatics while generating hydrogen. Hydrogen purities range from 75–90 vol. %.
- *Steam-methane reforming* (SMR) converts mixtures of steam and light hydrocarbon gases into hydrogen and CO₂ via the water-gas shift reaction. Product hydrogen may contain traces of CO and, depending on the process, 0.0001–4 vol. % CH₄.
- *Partial oxidation* (POX) produces CO and H₂ from natural gas or heavier feeds, such as vacuum residue or coal. POX does not require a catalyst or external steam. Design and operation can be varied to maximize production of hydrogen or synthesis gas. Chemicals are manufactured from the latter. Co-generation (*co-gen*) POX plants also generate steam for power production.
- *Olefin production plants*, also known as steam crackers, convert a wide variety of feeds, ranging from ethane to unconverted oil from hydrocrackers, into ethylene, propylene, higher olefins and aromatics. Hydrogen is a by-product, which can be consumed in the plant or exported. The hydrogen stream may contain around 4% CH₄.
- *Chlorine plants* generate hydrogen and chlorine from aqueous hydrochloric acid. The hydrogen may contain unwieldy amounts of Cl₂, which must be removed before the hydrogen is exported.
- *Lean oil recovery* (LOR) recovers C₃–C₆ hydrocarbons, mostly C₃–C₄, from offgas streams. The hydrocarbon-rich oil goes to a stripper, where the hydrocarbons are covered. LOR is one of the most cost-effective hydrogen purification units.
- *Pressure-swing adsorption* (PSA) prepares hydrogen with 99.99% purity, recovering 75–90% of the hydrogen in the feed gas. Modern SMR units include a PSA. In newer units, pressure-swing adsorption removes nearly all contaminants, yielding a product containing 99.99% hydrogen. A PSA unit employs a collection of solid adsorbents – molecular sieves, activated carbons, silica gels and activated aluminas. For carbon, silica and alumina, separation is due to their differential tendency to adsorb different gases. PSA cycles include pressurization, depressurization and purging. The rejected gas, a low-Btu mixture containing methane, CO and CO₂, is burned to provide some preheat duty.
- *Membrane units* employ semipermeable membranes to purify hydrogen, providing hydrogen with 85–98% purity, typically 95%. H₂ recovery ranges from 80 to 99%, typically 90%. The driving force is pressure differential across the membrane. There is a tradeoff between H₂ recovery and product purity. Higher recovery is associated with lower purity and vice versa.
- *Cold box* units can be designed to separate H₂ and CH₄ from other gases, to separate H₂ and N₂ from CO, etc., at cryogenic temperatures.

25.1.2 Other Hydrogen Sources

- *Purge streams from hydrogen consumers* often contain recoverable hydrogen. Hydrogen may be purged to manage the purity of recycle gas, or improve operability, or occasionally for pressure control.
- *Wet gas from cracking units* contains significant amounts of hydrogen. In a few studies, we saw that the fluid catalytic cracking (FCC) produced nearly as much hydrogen as the catalytic reformer. But the economics of hydrogen recovery were poor, due to the low pressure of the stream – recovery would have required an expensive compressor – and contaminants such as olefins and H₂S.

25.1.3 Hydrogen Purification and Recovery

- *Amine units (scrubbers)* remove H₂S (and in certain instances CO₂) from offgas streams and transport the H₂S to a sulfur recovery plant. Scrubbed gases often contain recoverable hydrogen. Hydrogen may be purged to manage the purity of recycle

- gas, or improve operability, or occasionally for pressure control. Scrubbed gas contains < 20 ppm H₂S.

Table 25.1 provides a rough comparison between PSA, membrane and cold-box technology for hydrogen purification.

25.1.4 Hydrogen Consumption and Losses

- *Hydroprocessing* units – hydrotreaters and hydrocrackers – consume hydrogen chemically.
- *Isomerization* units consume less hydrogen – just enough to keep the catalysts clean.
- *Entrainment and dissolution* losses occur in flash drums, which reduce the pressure of process fluids. Flash-drum overhead vapors are recycled and/or cooled and flashed again. Flash-drum liquids contain dissolved or entrained hydrogen, which eventually is stripped away at low pressure. Stripper hydrogen usually ends up in the fuel gas system.
- *Purging to fuel gas* accounts for most of the hydrogen lost in refineries. Purging can be intentional or unintentional. Unintentional purging can be surprisingly significant.

Table 25.1 Comparison of common hydrogen purification processes

Variable	PSA	Membrane	Cold box
H ₂ product purity	> 99.9%	85–95%	90–99%
H ₂ recovery	75–90%	80–90%	98–99%
H ₂ product pressure	10 psi less than feed	200–1400 psi less than feed	Design variable
Feed H ₂ content	> 40 vol. %	> 30 vol. %	> 20 vol. %
Feed pressure	250–900 psig	Up to 2500 psig	Design variable
Pretreatment	Liquids removal	Liquids removal	H ₂ O, H ₂ S, CO ₂ removal
Modular?	Yes	Yes	No

Speaking of losses: during hydrogen network optimization studies, we talked with people who believed that hydrogen leaks are common, significant and undetectable. This is simply not true. The auto-ignition range

for hydrogen in air is wide – from 18.3 to 59 vol. % at standard conditions – wider by far than the range for any other pure substance. Hydrogen leaks – even small leaks – cause fires.

25.2 Assets and Liabilities

As we will show, refiners will never get the most value from their hydrogen unless they have the correct view of it. For the most part, refiners tend to view hydrogen as a necessary evil – often expensive – that has to be supplied in order for them to operate, just like fuel, electricity and water. In other words, it is a liability.

Hydrogen – if properly managed – can be an asset, something that *makes* money for the refinery. Just as there are good and bad investments, there are good and bad ways to use hydrogen in a refinery. The secret is in finding the good ways. To do this requires a willingness to question conventional wisdom and to take a wider view of the issues. This chapter will discuss some of the important tools that will help to do this. It will also discuss some of the lessons learned from studies and industrial projects conducted by AspenTech and Air Liquide as part of their alliance called PRO-EN Services [25.4].

Refineries generally fit into one of three situations with respect to hydrogen:

Type 1: Hydrogen long: The refinery has an excess of hydrogen, which is routed to the fuel gas system. Refinery operations are not constrained by hydrogen. The price of hydrogen is based on its fuel gas value. Direct pressure-control let-downs to fuel gas have no economic penalty. In process units, high-pressure purge rates can be increased to increase hydrogen partial pressure in reactors without penalty. In some cases, catalytic reformer hydrogen is the only source of hydrogen supply.

Type 2: Hydrogen short: The refinery often needs more hydrogen. In locales where diesel is preferred over gasoline, the catalytic reformer acts as the *swing* hydrogen producer. Refinery operations and profitability are constrained by hydrogen. Key process units *compete* for hydrogen, which is priced in the refinery linear pro-

gram (LP) model based on plantwide profitability (e.g., gasoline over-production). Direct pressure-control let-downs have a high economic penalty. In process units, high-pressure purges are minimized, reducing hydrogen partial pressure in the reactors. In these cases, catalytic reformer hydrogen may still be the only source of hydrogen supply, although Type 2 also applies when on-purpose generation or import capacity is limited and operating at maximum.

Type 3: Hydrogen available on demand: The refinery can meet changes in hydrogen demand through *on-purpose* hydrogen production (e.g., with an SMR) or through external import. These are the refinery *swing* hydrogen producers. Refinery operations are not constrained by hydrogen. Hydrogen is priced based on its marginal production cost or import value. Direct pressure control letdowns have an economic penalty based on the value of hydrogen as a reactant in process units relative to its value as fuel. In process units, high-pressure purge rates are optimized to balance the value of higher hydrogen partial pressures (better yields, increased capacity, longer catalyst life) against the cost of purge losses. The value of hydrogen depends on whether or not the cost of capital is included in the price. For a refinery that has pre-invested in a hydrogen plant, the marginal production cost could be 500 €/t (2003 prices, which were considerably higher than present prices in most locales). If hydrogen is imported from an external supplier, the cost is more likely to approach 900 €/t.

Most refiners have completed the journey from type 1 to type 2. Larger and more profitable refineries are developing and implementing plans that take them to type 3, while a small number may choose to stay within type 2 because major new investment simply cannot be justified.

25.3 It's All About Balance

Accountants talk about balance sheets. Chemical engineers talk about mass balances. The principle is the same: what goes in must be accounted for. When we are dealing with hydrogen systems, the total amount of hydrogen produced and/or supplied must equal the total hydrogen that is chemically consumed, exported, burned as fuel or flared. Unfortunately, it is very rare to find a refinery where all hydrogen is accounted for. There is usually a poor hydrogen balance – poor not in reality but on paper – to begin with. Streams, flow rates and compositions are often not measured, and when they are the data may contain significant inconsistencies. In many cases, large imbalances are often accepted and attributed to *leaks*, *distribution losses*, *meter error* and *unaccounted flow*. If actual currency were involved, the accountants would probably use less euphemistic terms, such as *embezzlement*, *fraud*, *misappropriation* and *theft*. If we take the view that hydrogen is a valuable asset, not having a decent hydrogen balance is tantamount to throwing money away or letting someone steal it. It has been our experience that significant benefits – hundreds of thousands of dollars or more per year – can be achieved by examining the hydrogen balance and finding no-cost *housekeeping* improvements.

Simple as this may sound, it can only be realized by understanding the overall hydrogen system and this in turn needs systematic analysis and modeling capabilities.

To give an example, we performed a hydrogen system study for a US refinery, in which the hydrogen generated by its two catalytic reformers is supplemented with purchased hydrogen. Flow rate and composition data were collected from the refinery and used to set up a flow sheet balance with surprising results. We found that hydrogen worth \$2 million per year was being lost to flare and fuel gas through three specific areas, one of which was a leaky valve. We also found other opportunities, including reducing the amount of hydrogen purged for pressure control and avoiding the needless recompression of rather large gas streams.

So what is needed to set up a hydrogen balance? Firstly, flow rates, compositions and pressures must be determined at certain key points in the hydrogen system. Flow diagrams of the hydrogen-consuming processes are also needed so that reactor and separator configurations as well as recycle locations can be determined.

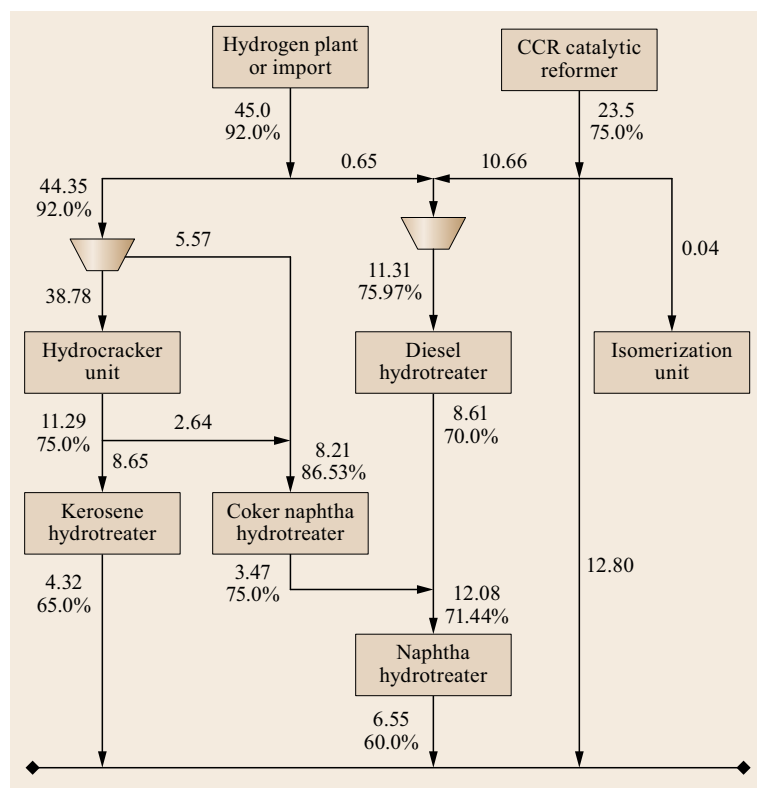

Fig. 25.1 A typical refinery H₂ balance (flows in million standard cubic feet per day (MMSCFD), H₂ purity in mol%)

Secondly, models of the consumers are required. These models need not be totally rigorous ones because configuring the models might take far too long in the early stages of a project. However, they should be sufficiently detailed to capture the important operating features of the units as well as to predict their performance. AspenTech developed such models using software that generates fit-for-purpose simplified models for reactors, flash drums and separation columns, which can be used as building blocks for the entire hydrogen network.

Thirdly, data correction and reconciliation tools are required. During this process, many refiners are surprised to discover that their hydrogen-system flow meter readings, if properly corrected, aren't so bad after all. Think of currency exchange rates. No semidecent accountant would try to convert South African rands into US dollars at the exchange rate used in the 1970s. However, it is surprising to see how often people are happy to trust flow meters calibrated with molecular weights that are now quite different from present op-

eration. Because the molecular weight of hydrogen is so low, small changes in stream composition can affect the stream molecular weight significantly. For example, a mixture consisting of 99% hydrogen and only 1% ethane has a molecular weight 14% greater than that of pure hydrogen. Refiners typically correct flow meter readings for temperature and pressure, but not for composition. In other words, if hydrogen were currency, they would be using outdated exchange rates. The software mentioned above can automatically correct measured stream flow rates for deviations from the calibration point. It can also carry out a data reconciliation whereby the user can enter whatever data are available and then specify how much confidence he or she has in each value. For example, a flow rate can be an accurate measurement (within 5%), an accurate estimate (within 20%), a rough estimate (within 50%) or a guess (within 500%). The software will then reconcile the values to achieve a balance while staying within the confidence bounds. Figure 25.1 shows what a completed hydrogen system balance might look like.

25.4 Put Needs Ahead of Wants

We believe that refiners should question whether certain units actually need to be fed with hydrogen of very high purity. If there is a supply of hydrogen at 99% purity available, chances are that engineers or operators will claim that their unit *needs* to have 99% pure hydrogen. It is this mindset that needs to be challenged. Once we break away from this, the scope for reusing and recycling hydrogen becomes a lot greater and benefits can be substantial.

One European refinery used a significant flow rate of very pure hydrogen for drying purposes. When questioned about this, the refinery engineers replied that this was the way it had always been done. That made sense because until recently, the refinery had a large surplus of hydrogen. Then, however, that hydrogen was worth several hundred thousand dollars per year. It would be far more sensible to use the offgas from another consumer, accomplishing the same job for free!

Admittedly, most refineries do not have such obvious savings. Most hydrogen consumers require a certain flow rate of gas and hydrogen purity in order to operate properly. The flow rate is needed to maintain a gas to oil ratio high enough to prevent coking, while the purity is required to maintain the required hydrogen partial pressure for effective kinetics. With fixed flow rate and purity demands, it may not look like there is any scope for improvement. However, the opportunities are still there if we know where to look for them.

The secret is simple: look at reactor inlets, not makeup streams. Figures 25.2 and 25.3 illustrate this point. Figure 25.2 is a diagram of a hydrogen consumer showing the makeup hydrogen and the high pressure and low pressure purges. Looking at it in this way, it is very easy to be misled into thinking that the unit requires 10 000 sm³/h of hydrogen at 99% purity. However, this is wrong. In order to find the real requirement, one needs to look at the internal workings of the consumer as shown in Fig. 25.3.

As can be seen, the hydrogen makeup stream is mixed with hydrogen recycle before being fed to the reactor inlet. Therefore, the purity that the reactor actually sees is only 83%. Recognizing this immediately opens

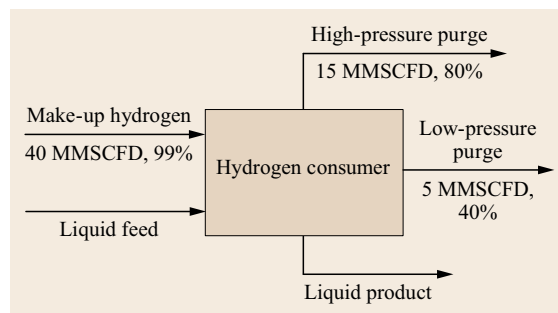

Fig. 25.2 A black-box view can mislead us to think the consumer needs 99% pure hydrogen

up the scope for reusing other gases in the makeup stream and using less of the 99% hydrogen. As long as the flow rate and purity of the hydrogen going into the reactor do not change, the makeup purity is not that important. Put another way, the consumer may *want* 99% purity in the makeup, but it really needs 83% purity at the reactor inlet.

A simple example is shown in Figs. 25.4 and 25.5. Two hydrogen consumers are both taking makeup hydrogen from an external supplier at 99% purity, with a total demand of 20 000 sm^3/h . If we make the mistake of saying that the makeup purity must be fixed, there is clearly no scope at all for reusing hydrogen (Fig. 25.4).

However, if we do the correct thing and focus on the reactor inlet, Fig. 25.5 shows that it is possible to reuse the purge from Consumer A as part of the makeup of Consumer B. This allows the demand from the external supplier to be reduced by 1710 sm^3/h or 8.7%. With typical hydrogen costs, this could be worth between half a million and a million US dollars per year. The flow rates being compressed by B's makeup and recycle compressors are lower, giving power-cost savings too. Pretty good value for the cost of a pipe! Notice that consumer B still has exactly the same flow rate and hydrogen purity at the reactor inlet as before. All that has changed are the makeup and recycle flow rates.

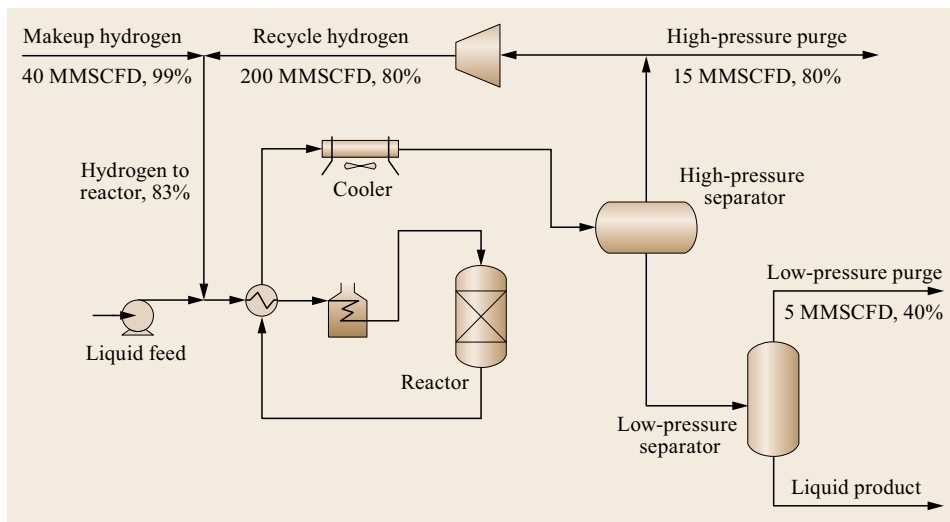

Fig. 25.3 The true reactor inlet purity requirement is only 83%

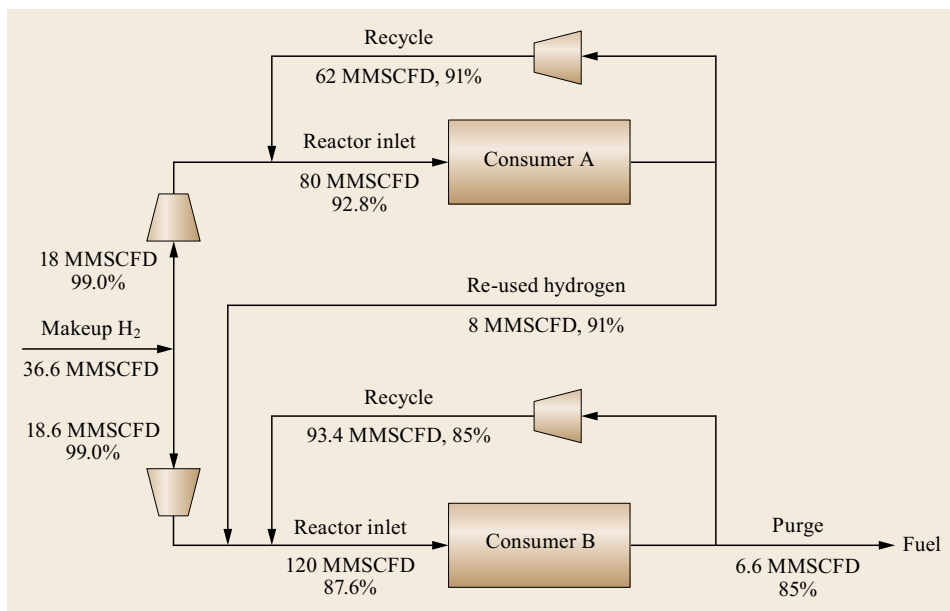

Fig. 25.4 If the makeup purities are fixed, there is no way to reduce the makeup flow rate

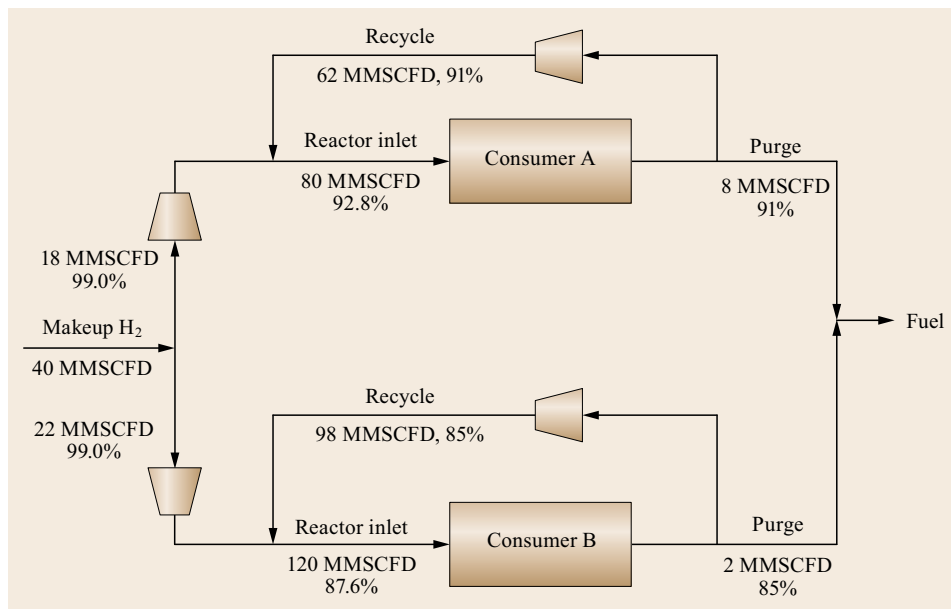

Fig. 25.5 Focusing on reactor purity allows about 87.6% at constant reactor inlet purity

Real refineries have to consider a lot more than two units at once. Should we use hydrocracker offgas to feed the diesel hydrotreater, or should we send it to the naphtha hydrotreater? Maybe we should use cat reformer hydrogen instead of imported hydrogen, but should we use it directly or blend it with hydrogen from elsewhere? Maybe that hydrocracker offgas should be used as fuel instead? Or maybe we could purify it in a PSA. Or why not a membrane? Since we're thinking of PSAs and membranes, maybe we should purify the naphtha hydrotreater offgas as well? Where should we send the purified product?

Hydrogen pinch analysis is a quick and systematic way of knowing immediately what the maximum hydrogen recovery achievable is. The method is similar to the well-known energy pinch analysis used for designing heat exchanger networks [25.5]. Instead of looking at enthalpy and temperature, though, we concern ourselves with gas flow rate and hydrogen purity. The method in its original form aims at maximizing the in-plant reuse and recycling of hydrogen to minimize *on-purpose* or *utility* hydrogen production [25.6]. Later in this article we will discuss whether this is, in fact, the correct thing to do in all cases.

The first step in the pinch analysis is to plot hydrogen composite curves (Fig. 25.6). These are plots of hydrogen purity versus flow rate for all the sources and all the demands for hydrogen in the refinery. Sources are streams containing hydrogen that potentially could be used. They include catalytic reformer hydrogen, *on-purpose* hydrogen as well as the overhead gases from high and low pressure separators in the various consum-

Fig. 25.6 Composite curve showing hydrogen flow and purity

ing units. When plotting hydrogen demands, remember the lesson on needs versus wants. Don't base your calculations on makeup purities!

By plotting hydrogen purity versus the area enclosed between the source and sink composites, a hydrogen surplus diagram is constructed (Fig. 25.7). This diagram is analogous to the grand composite curve in heat exchanger network synthesis and shows the excess surplus hydrogen available at each purity level. If the hydrogen surplus is positive throughout the diagram, there is some slack in the system.

The hydrogen generation flow rate can be reduced until the surplus is zero (Fig. 25.8). The purity at which

Fig. 25.7 Hydrogen surplus diagram

Fig. 25.8 Hydrogen surplus diagram showing pinch point

Fig. 25.9 Three ways of placing a purification unit relative to the pinch

this occurs is termed the *hydrogen pinch* and it is the theoretical limit on how much hydrogen can be recovered from the sources into the sinks. It is analogous to the heat recovery pinch [25.7]. The on-purpose hydrogen flow rate that produces a pinch is the minimum target and is determined *before* any network design analysis. With the appropriate software, a task that would have taken days, weeks or months can be accomplished in hours. If the gap between the target and the current use is large, it is worthwhile spending time reconfiguring the hydrogen network. The key is to avoid cross-pinch hydrogen transfer and to be especially careful about the above-pinch purity, as this is the region that is most tightly constrained. Hydrogen streams with purities greater than the pinch purity should not be used to feed consumers that can use hydrogen below the pinch purity. Also, hydrogen streams above the pinch purity should not be sent to the fuel system or flared. If the

gap is not large, your time would be better spent looking at other improvement options, such as purification.

There are three main options for purification. In case you are wondering, these are *not* PSAs, membranes and cryogenic systems. Those processes all do fundamentally the same thing, which is to split a feed stream into a product stream with a high purity and residue stream with a low hydrogen purity. The options we are talking about relate to the placement of the purifier relative to the pinch. As Fig. 25.9 shows, there are three possible placements: above the pinch, below the pinch and across the pinch.

Placing the purifier below the pinch is not a wise idea. This simply takes hydrogen from a region where it is in excess and purifies it before sending it back to the same region. In essence, you would be buying an expensive unit to purify hydrogen for burning!

The best option is to place the purifier across the pinch. This moves hydrogen from a region of excess to a region that is tightly constrained on hydrogen. It

freed up hydrogen from *on-purpose* sources and any hydrogen lost to residue would have ended up in the fuel system anyway.

25.5 Beyond Pinch

The pinch analysis approach discussed above is good for getting an immediate overview of the system, setting targets and even doing some initial screening of ideas. However, in our project work, we have found a number of limitations.

Firstly, it does not fully cope with all the complexities of network design. The two-dimensional representation only considers flow rate and purity, but does not incorporate other important practical constraints such as pressure, layout, safety, piping, operability and of course capital cost.

One of the more important constraints is stream pressure. The targeting method assumes that any stream containing hydrogen can be sent to any consumer, regardless of the stream pressure. In reality, this is only true if the stream has a sufficiently high pressure. Thus, pinch analysis targets usually are too optimistic. They can encourage refiners to waste time developing projects that are infeasible or far too expensive due to the need to install compressors. Compressors are among the most expensive capital items in any chemical or refining process. Therefore, a sound retrofit design should make best use of existing compression equipment. Often, the economic feasibility of a hydrogen recovery project is determined by bottlenecks in existing compressors and not by purity and flow rate constraints alone.

Obviously, direct reuse of hydrogen between consumers is only possible if the pressure is sufficient. However, it is certainly possible to reuse a low-pressure hydrogen stream indirectly, i. e., by routing it through an existing compressor, if certain conditions are met. Firstly, there has to be sufficient capacity in a compressor to accommodate the stream; reusing hydrogen will change the makeup and recycle flow rates throughout the system, so capacity might be available in one or more other compressors. Also, the pressure of the reused stream must satisfy the inlet-pressure requirements of the target compressor. In addition, the discharge pressure of the compressor should be high enough for use in the target consumer.

To account for pressure and other important constraints, a mathematical programming or optimization approach is required. Work on this was started at the University of Manchester Institute of Science and Technology (UMIST) and AspenTech took the lead in further development [25.8].

25.5.1 Multicomponent Methodology

At this point we should be able to begin process engineering of the proposed reuse project. However, if we were to do so we would find that the simulated benefits are very much lower than those predicted by the optimizer. This is due to another major limitation of the hydrogen pinch approach: its assumption of a binary mixture.

Consider two hydrogen streams, each of 85 mol% purity. The first is ethylene plant export, containing almost 15% methane. The second is catalytic reformer export, containing roughly equal amounts of methane, ethane and propane, plus small amounts of heavier material. Hydrogen pinch techniques cannot differentiate between these streams and would identify no penalty or benefit from switching between them as a source of makeup gas. Yet in reality the ethylene plant gas would require operation with a much higher purge rate, due to the tendency of methane to buildup in recycle loops. In fact, in certain circumstances it is more efficient to substitute a makeup supply with a lower purity hydrogen source (but lower methane content), while the hydrogen pinch methodology would lead you to do the opposite.

To meet this challenge, we developed a multiple-component optimization methodology that fully accounts for the behavior of individual components within the process reactors, separators and the recycle gas loop. While in the binary pinch approach the composition and flows of reactor feed and separator gas are fixed, our multiple-component approach allows these compositions to float, so long as constraints such as minimum hydrogen partial pressure and minimum gas-to-oil ratio are met. Simulation models for reactors, and high-pressure and low-pressure separators are used to correctly model overall process behavior. We also developed a network simulation tool based on AspenTech's Aspen Custom Modeler (ACM) software.

By extending our analysis to include components other than hydrogen, we can simultaneously optimize downstream amine scrubbers, liquefied petroleum gas (LPG) recovery systems and the entire fuel gas system. Our project experience shows that the benefits from increased LPG recovery can outweigh the value of hydrogen savings.

25.5.2 Hydrogen Network Optimization

In addition to methane and other light hydrocarbons, offgas hydrogen may contain toxic hydrogen sulfide (H_2S). H_2S is adsorbed in amine units, which usually are integrated in some way with the plantwide amine system; the amine system transfers the H_2S to a sulfur recovery plant. The H_2S -free offgases become refinery fuel gas for general use throughout the plant.

Keeping hydrogen out of fuel gas is beneficial for many reasons. Recovering hydrogen decreases the required amount of on-purpose hydrogen. Because hydrogen increases flame temperatures in fired heaters, it can limit heaters with tube temperature constraints.

Hydrogen network optimization identifies possible investment options and changes to operation, which recover and purify hydrogen before it reaches the fuel gas system. This activity is more complex than other utility optimization techniques, because in addition to consid-

ering flow and pressure, one must consider purity and the impact of composition.

While preparing the optimization software, we first set up a superstructure that connects every sink with every source, provided that the source pressure is greater than or equal to the sink pressure. Compressors are included as both sources and sinks. We formulate basic constraints such as balances on total flow rate and hydrogen flow rate, as well as any compressor limitations such as maximum power or maximum throughput. A whole host of other constraints can also be incorporated, such as limited space, no new compressors allowed and the old favorite: *I don't want to spend any capital!*

Next, we subjected the superstructure to mathematical programming that eliminates undesirable features while satisfying an objective function, which could be minimum hydrogen generation. There is actually no need to limit ourselves to minimizing hydrogen gen-

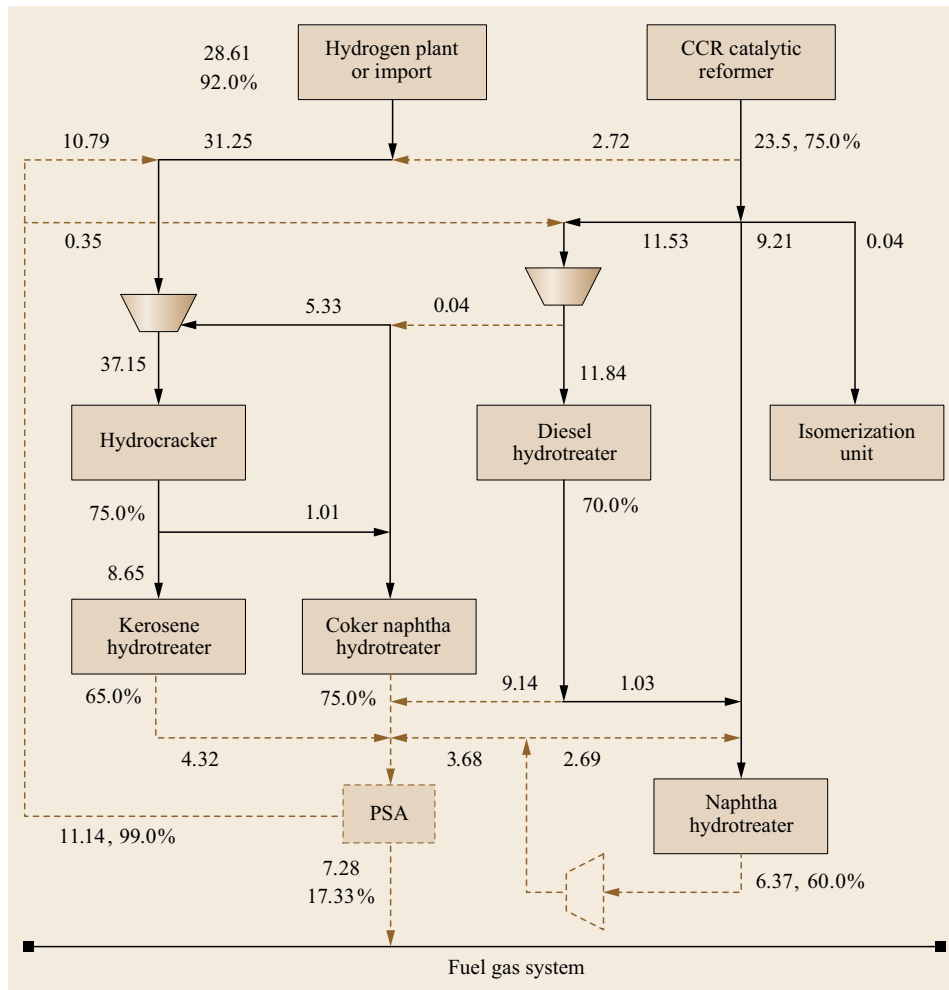

Fig. 25.10 Retrofit: Addition of PSA. New equipment shown with dotted lines

eration. For example, we could choose to minimize operating cost or total annual cost. All relevant costs can be considered, including hydrogen cost, compressor power cost, fuel gas credit and capital cost of new equipment. We will not bore you with all the details, as these can be provided by your front-end engineering contractor. Suffice it to say that the optimization tool uses a combination of linear and nonlinear programming.

The ability to add constraints at will means that all practical considerations can be built in. The cost of adding a constraint can also be determined. For example, an engineer may say he or she doesn't like the idea of running a long pipe across a road to connect two units. This option can be banned and the optimization carried out again. The difference in cost between the two solutions indicates how much his or her *not liking* the connection will cost. If it costs a million dollars per year, the engineer may decide that he or she doesn't actually mind it *that* much after all!

The other major limitation of pinch analysis is that it gives fundamental guidelines about purification placement, but does not always help with selecting which streams to purify or whether to use a PSA, membrane, cryogenic or other purification process. This is where know-how becomes vital. Purifier experts can rapidly assess different technologies for candidate feed streams, simulate their performance and give quick cost estimates. These experts can weigh the benefits of different options, recognizing that each application will be unique. For example, in a recent European study, a refinery was facing a large increase in hydrogen demand to meet upcoming sulfur-in-fuel specifications. In this case, hydrogen recovery was more important than product purity, so Air Liquide experts determined that, for a certain stream, a membrane would be a better choice than a PSA unit.

Another issue with purifiers is that different technologies have very different pressure requirements. A PSA unit gives a product pressure very close to the

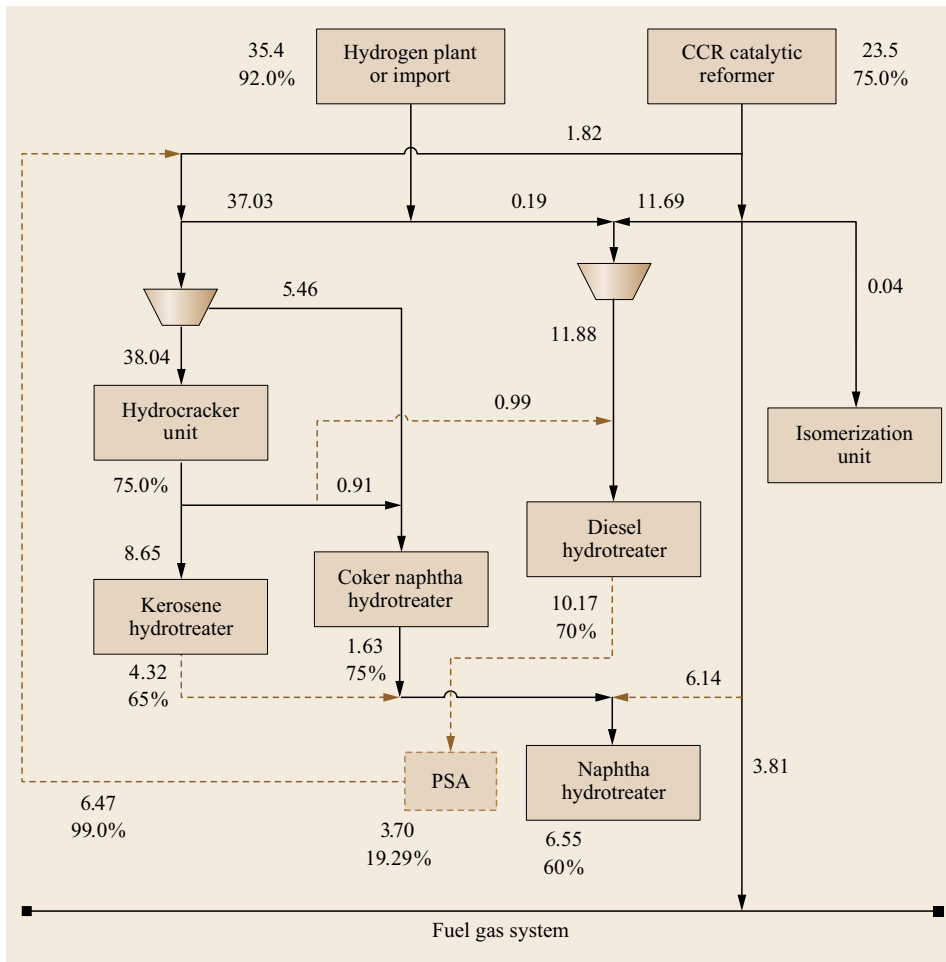

Fig. 25.11 Recommended changes if capital expenditure is limited to US\$ 5 million

feed pressure, but the PSA residue pressure is extremely low. On the other hand, a membrane requires a large pressure drop in order to perform properly, the product pressure is much lower than the feed pressure, and the residue pressure is almost the same as the feed pressure. These issues need to be considered in the specific context of the refinery and can be handled easily using the approach described above. Ultimately, economics should determine the optimum tradeoff between product purity, product pressure and hydrogen recovery.

Purification expertise also saves time. Hydrogen network analysis experts work in parallel with purification experts to rapidly assess options and develop a project flow sheet. This is much more time-effective than having one company generate a small number of options using pinch analysis and then sending the options to another company for cost quotes. With the parallel approach, more options are in less time and both the network analysis engineers and the purification engineers see the entire picture.

The following case study is representative of a real refinery system, but certain data have been disguised to maintain customer confidentiality. The existing hydrogen system is shown in Fig. 25.10. The objective of the study was to retrofit the network to minimize operating costs. Process and cost data are given elsewhere [25.9].

Several constraints were imposed by the refinery:

1. The existing compressors have 5% spare capacity
2. There is only space on the site for one new compressor and one new purification unit

3. A payback of more than two years will not be acceptable.

The network retrofit was designed by setting the objective function to be minimum operating cost while constraining the payback time (capital cost divided by annual operating cost savings) to be two years or less. Figure 25.10 shows the resulting design. Dotted lines indicate new equipment.

In the recommended project, both a new compressor and a PSA are used and substantial repiping is required. Notice that the new compressor accommodates the increased recycle requirement for the naphtha hydrotreater (NHT) as well as the need to compress one of the feeds to the PSA so that its product can be used in the hydrocracker.

The total capital investment of the retrofit is \$9.8 million and the operating-cost savings are \$6 million per year. The payback period is therefore 1.6 years, which is better than required.

Now, refineries often have limited capital budgets, so even modification with a good payback might be too expensive. It would be valuable to know the maximum savings achievable with a fixed capital budget, say US\$5 million. Adding capital expenditure as an additional constraint and re-optimizing gives the solution shown in Fig. 25.11. The best investment is a PSA unit requiring no new compressor. Notice too that fewer new pipes are installed. The operating cost savings are smaller (only \$3.5 million per year) but this is to be expected.

25.6 Investing versus Saving

Up to now, this article has addressed the issue of minimizing hydrogen supply, in other words, saving hydrogen. This is certainly a very real problem for refiners and many of our clients have specified this as their objective. After all, hydrogen is expensive and a few percent saved can mean millions of dollars per year. However, this is often not the most profitable course of action.

Let's go a step further and look at hydrogen consumers as investments. Instead of merely *saving* hydrogen, why not consider re-investing it where it will *make* money for you?

How do we re-invest hydrogen? By feeding more and/or purer hydrogen into the appropriate reactors. For example, the hydrogen freed up using the network design methods can be used to process cheaper feed stocks. It could also be used to boost partial pressures to enhance conversion, throughput, yields and catalyst life.

The important question is how do we know which units will be the most profitable ones to invest hydrogen in? When analyzing money investments, there are certain techniques that wise investors use. These include performing a due diligence and analyzing the financial statements and cash flows of the investment. A good return on investment is the goal. Nobody wants an investment that loses money and likewise a refiner should use hydrogen where it will provide a better return than simply saving it would give. We have our own techniques for analyzing hydrogen investments. They are reactor modeling and refinery LP modeling.

Rigorous kinetic modeling is used to obtain a good understanding of process operation under different feed hydrogen conditions. AspenTech has developed rigorous tools for modeling fixed-bed hydroprocessing units, such as hydrocrackers, reformers, FCC pretreaters and desulfurization units. They model kinetics for denitro-

genation, desulfurization, saturation and cracking and are capable of accurately predicting yields, hydrogen consumption and product properties for widely different feeds and operating conditions. These reactor models can easily be connected to rigorous fractionation models, creating a fully integrated model of the entire hydrotreater, reformer or hydrocracker complex.

The reactor models include a unique catalyst deactivation tool, which allows refiners to minimize catalyst life giveaway and to calculate future conversions, yields and product properties. Hydrocracking models can be used to optimize tradeoffs between feed rate, conversion, catalyst cycle life, feedstock severity, operating conditions and costs. For recycle hydrocracking units, there are tradeoffs between fresh feed rate and conversion-per-pass in single-stage units, or between first stage and second stage conversion in two-stage units.

It is not necessary to model every reactor and determine the benefits in a trial-and-error way. A combination of the LP model, understanding of current process operations and constraints and hydrogen network analysis can be used to develop a shortlist of key processes and potential changes to those processes. For example, the LP model will show the bottlenecks to increasing refinery profit. If increasing hydrogen partial pressure can eliminate one of these bottlenecks, then this unit will be a candidate for applying rigorous reactor modeling and subsequent process analysis.

Hydrogen network analysis can also give insights into process operations. Above a threshold hydrogen purity, hydrotreater operation is insensitive to hydrogen purity. If reducing the hydrogen partial pressure to a hydrotreating reactor gives a large saving in the overall refinery hydrogen target, this unit can be also be selected for rigorous modeling to determine the true impact on reactor operation.

All process changes need to be modeled, the impact on the hydrogen network evaluated and the final benefit established through the LP model. The reactor models can be linked to Aspen PIMS, a leading PC-based LP software package used by the petroleum and petrochemical industries. By providing automatic updates to Aspen PIMS vectors, the models can enhance detailed operations planning, economic evaluation and scheduling activities. In particular, they can help a refiner decide how best to apportion intermediate heavy distillate streams between different conversion units.

As an illustration, Fig. 25.12 shows case-study results from a rigorous model for a two-reactor hydrocracker with partial recycle of unconverted oil [25.9]. The unit runs at about 60% conversion-per-pass. A fixed flow of unconverted bottoms is recycled. The remainder

is exported to the FCC unit for heavy diesel blending. At present, the *export* comprises about half of the total unconverted oil.

For the case study, the purity of the makeup hydrogen was varied from the current value (89–100%). The feed rate, recycle oil flow rate and weighted average reactor temperature (WART) for both reactors was held constant. Under these conditions, the following effects were noted:

1. Full-range distillate yield increases from 52.8 to 54.6%
2. Heavy naphtha yield increases from 16.6 to 19.4%
3. Exported bottoms decreases from 17.8 to 11.3%.

According to the model, the net benefits of increasing the makeup-gas purity from 89–100% were on the order of \$2 million per year. But how much would it cost to make available the extra hydrogen needed? Using a simple marginal cost of hydrogen is not the way to answer this.

Figure 25.13 shows how our network design and analysis tools can fit into an overall profit optimization study. They identify quickly how much additional hydrogen can be made available for certain levels of cost. Typically, a few percent more hydrogen can be squeezed out with simple modifications requiring low or no cost, for example piping modifications. Then there will be a step-change where getting any more hydrogen will require a purification system. Finally, there will be another step-change where purification reaches its limit and any more hydrogen will have to be supplied from external sources, such as imports or a hydrogen plant. Knowing the true cost of providing additional hydrogen makes it easy to weigh it against the benefits that are suggested by process modeling and LP optimization.

Fig. 25.12 Hydrocracker performance improves with increased hydrogen purity

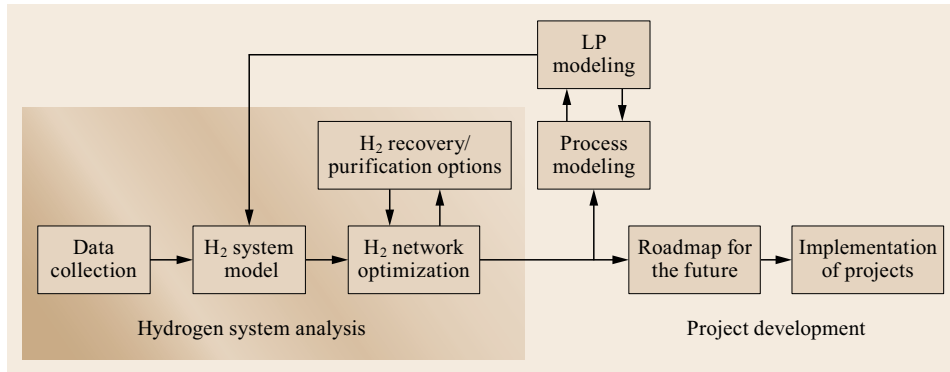

Fig. 25.13 Network design tools compare costs and benefits for project options

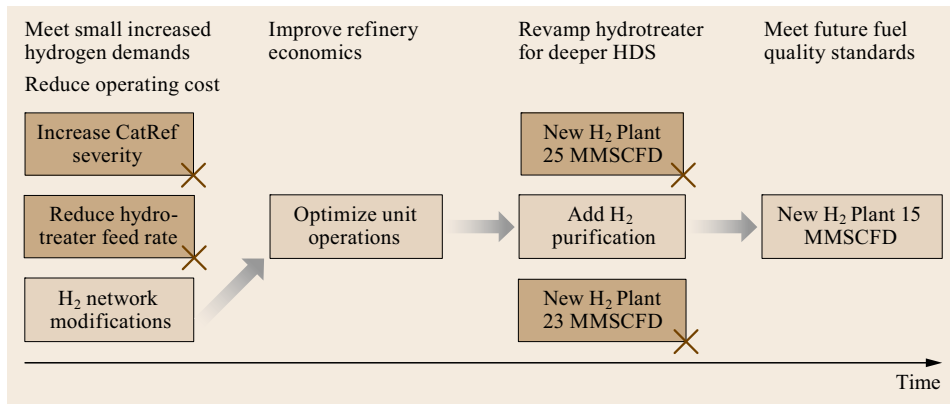

Fig. 25.14 Systematic tools are used to construct a roadmap for the future

Figure 25.14 shows a typical roadmap that can be drawn up, showing where the refinery is now and where it wants to be at different points in the future (e.g., in one year, five years, ten years). All of the tools described in this article give the refiner an eas-

ier job of planning how to tackle the future. They are used to systematically choose the best set of projects that achieve immediate objectives but also fit in with long-term goals. This avoids the *regret capital syndrome*.

25.7 Conclusion

In conclusion, several hidden opportunities typically are not addressed by refiners when developing plans for clean fuels. In our experience:

- Time spent in investigating the current balance pays back. This can identify substantial operating savings and it eliminates *unconscious over-design* in future investments.
- Make the best use of hydrogen purity. There is scope to reduce both capital investment and future operating costs by maximizing the benefits from high-purity hydrogen sources. Reactor modeling is an important part of evaluating these benefits and optimizing hydrogen use.
- Hydrogen is not the only consideration. A proper methodology for optimization must extend beyond the hydrogen system to include low-pressure purges, amine treating, LPG recovery and the fuel gas system. Purification upstream of LPG recovery units can debottleneck those units and increase their overall recovery efficiency, adding significantly to the value of the hydrogen-recovery project. Reducing hydrogen loss to fuel can have both positive implications (improved calorific value) and negative implications (increased fuel oil firing and hence increased SO_x emissions).
- New model-based network optimization methodologies allow the identification of no- and low-

capital-expenditure projects to improve current operations, particularly for refineries of types 2 and 3. As mentioned, these savings are often in excess of 1 million €/year, with payback times measured in months [25.2].

- If there is one conclusion you should take away with you, it should be that hydrogen is money. Stop thinking about it as merely an unglamorous utility and start looking at ways to make more money from it.

26. Model-Predictive Control Fundamentals

Paul R. Robinson, Dennis Cima

Model-predictive control (MPC) improves the capability of process units by stabilizing operation, increasing throughput, improving fractionator performance, decreasing product quality giveaway, and reducing utility consumption. MPC provides real-time information to higher-level applications, such as planning models and process optimizers. MPC input comes from the distributed control system (DCS), advanced regulatory controllers (ARCs), and laboratory data. A well-implemented MPC controller responds once per minute – or in some cases more frequently – to changes in feedstock, ambient temperature, and so on, by moving several variables simultaneously. For major process units, returns on investment for

	References	839

MPC can exceed \$0.50 per barrel, not including collateral benefits, such as improving the efficiency of operators and engineers, and improving process safety.

At relatively low cost, model-predictive control (MPC) improves the capability of process units by stabilizing operation, increasing throughput, improving fractionator performance, decreasing product quality giveaway, and reducing utility consumption.

It is said that a well-implemented MPC application is like having your best operator on the control board 24/7. Operators are indispensable, certainly at critical times such as startup, shutdown and emergencies, but during normal operation, MPC can be more capable than any human.

Major process units are complex. A single change affects dozens of other variables, to one extent or another. For each variable, the response time is different. Constraints must be honored. Violating constraints can ruin products, damage equipment, and lead to loss of containment. In all hydrocarbon industries – gas processing, chemicals manufacturing, and every phase of petroleum production, transportation and processing – loss of containment can cause fires, damage the environment, and cause injuries and fatalities. Therefore, it's no surprise that during manual operation, human operators keep process variables in a comfort zone, well away from limits, leaving plenty of time to react if something changes.

In response to a change in the unit or process objectives, an operator makes small adjustments to one setting (or one group of settings) then waits until the process is steady before making subsequent changes. In contrast, MPC makes appropriate adjustments every minute – even more frequently in some cases – in response to multiple changes, all without violating operational, equipment, or product quality constraints.

A colleague cites a typical example to illustrate the benefits of MPC versus manual operation. On the US Gulf Coast, many units are limited on hot, humid days by air-cooler capacity. A sudden thunder storm can cool the ambient temperature by 10 °C within a few minutes. Under manual control, an operator might not respond at all, but MPC applications respond immediately, increasing feed rate and manipulating other variables to maintain conversion and product quality. As the storm passes and the heat and humidity return, the MPC adjusts to maximize production rates. For a 100 000 FCC unit, the incremental production could be 500 barrels – say, 125 barrels per hour for four hours – which could be worth \$10 000.

An MPC application gets input from the distributed control system (DCS), advanced regulatory control

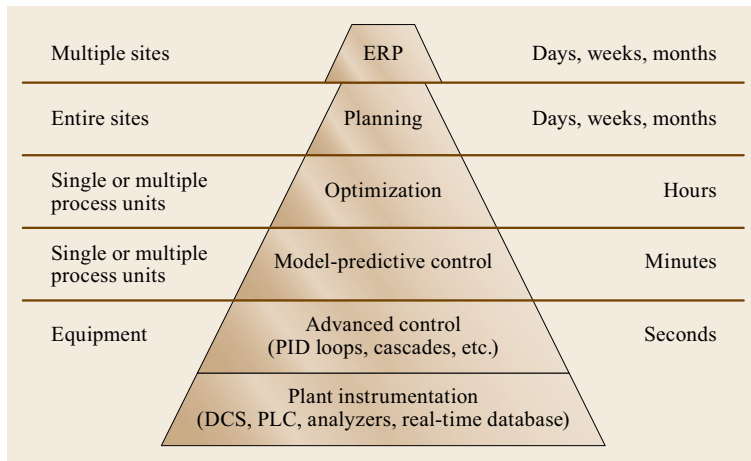

Fig. 26.1 Overview of computer control applications. ERP stands for enterprise resource planning, a software solution that integrates planning, manufacturing, sales, and marketing

(ARC), and laboratory data. It provides information to higher-level applications, such as planning models and process optimizers. For major process units, returns on investment for MPC can exceed \$0.50 per barrel, not including collateral benefits, such as improving the

efficiency of operators and engineers, and improving process safety.

Figure 26.1 presents an overview of refinery software applications and the frequency at which they typically run.

26.1 Useful Definitions

A *proportional-integral-derivative (PID)* controller is a feedback device. A *process value (PV)* is measured by a field transmitter. A controller compares the PV to its *setpoint (SP)* and calculates the required change – for example, a new *valve opening position (OP)*, expressed as a percentage – to bring the PV closer to the SP. The required change is calculated with a PID algorithm. In practice, proportional, integral, and derivative constants are parameters used for tuning.

Advanced process control (APC) and *advanced regulatory control (ARC)* applications employ control algorithms to improve process control compared to regulatory PID controllers. APC and ARC include loops or cascades, such as cascading a temperature controller to the fuel gas valve of a fired heater. They incorporate advanced control algorithms combined with regulatory control functions (i. e., lead/lag, ratio, high/low selectors, etc.) to implement a control strategy.

A *programmable logic controller (PLC)* is a small computer used to automate real-world processes. A PLC receives input from various sensors and responds to changes by manipulating actuator valves according to preprogrammed logic stored in the memory of the PLC.

A *distributed control system (DCS)* serves as the foundation of modern computer control. In a DCS, pro-

cess measurements and control functions, such as PID loops, and APC and ARC applications, are connected to processors, which are networked throughout the plant. A *graphical user interface (GUI)* makes it easier for operators to view data, create plots, change setpoints, and respond to alarms. In addition to process control, modern DCS software includes sophisticated trending and data storage.

A *real-time database* adds considerable capability to a DCS system. As the name implies, it stores historical data, but it does much more than that. It includes sophisticated graphics and real-time data trending, and it can be linked to external software, such as Microsoft Excel, planning software, or process optimizers.

Model predictive control (MPC) applications use multiple independent variables to control multiple dependent variables. If a variable is truly independent, its value is not affected by other process variables. There are two types of independent variables. *Manipulated variables (MVs)* can be changed by an operator to control the process. These include setpoints for regulatory PID controllers and valve positions. *Feed-forward (FF)* and *disturbance variables (DV)* affect the process but can't be manipulated. These include ambient temperature, the quality of an external feed, or the composition of fuel gas used by fired heaters.

The value of a dependent variable can be calculated using the values of independent variables and an appropriate dynamic model. *Controlled variables (CVs)* are maintained at a desired steady-state target. *Constraint variables* are maintained between high and low limits. Many variables are dependent, but not all dependent variables are important enough to be included in the MPC application.

MPC derives dynamic process models from past process behavior to predict future process behavior [26.1]. The dynamic models can be obtained during a series of manual step tests. Modern step tests are au-

tomated and/or rely on natural process variation. The predictions are used to control process units dynamically at optimum steady-state targets. MPC applications may also include the use of predicted product properties (*inferential analyzers*) and certain process calculations. Model-predictive controllers almost always include several independent variables, often several dozen.

In this chapter, when we say *APC (advanced process control)* we mean nonpredicting collections of cascades and control loops. In practice, *APC* and *MPC* are used interchangeably.

26.2 Overview of Economics

Table 26.1 presents typical benefits for applying model-predictive control to refinery units [26.2]. It is important to say that the benefits are not additive. For a combined MPC/optimization project, the costs are always lower and the benefits might be higher than if the projects are implemented separately. Conversely, the

advertised benefits of DCS and real-time database technology depend entirely on the applications for which they serve as platforms. Stabilizing a crude distillation unit with MPC will stabilize the feed to all downstream units, which decreases the impact of MPC on the other units.

Table 26.1 Typical benefits of multivariable model-predictive control

Process unit	Typical benefits (\$US/bbl)	Source(s)
Crude distillation	0.015–0.03	Higher feed rate Reduced product quality giveaway ^a Increased energy efficiency
Fluid catalytic cracking	0.15–0.30	Higher feed rate Reduced ΔP across slide valves Reduced product quality giveaway ^a Increased energy efficiency
Catalytic reformer	0.10–0.20	Higher feed rate Optimum coke on catalyst (CCR units) Reduced product quality giveaway ^a Increased energy efficiency
Hydrocracker	0.10–0.20	Improved safety Higher feed rate Increased stability Better conversion control Improved control of temperature profiles Better control of recycle gas purity Reduced product quality giveaway ^a Increased energy efficiency
Gas oil hydrotreater	0.02–0.10	Higher feed rate Increased stability Reduced product quality giveaway ^a Better control of recycle gas purity
Gas plant	0.05–0.10	Higher feed rate Reduced product quality giveaway ^a Increased energy efficiency
Product blending	0.10–0.20	Reduced product quality giveaway ^a

^a Equivalent to increased production of desired products

After installation of the requisite infrastructure – DCS, analyzers, real-time database software, operator terminals, process computer(s) – MPC projects on major petroleum refinery or chemical manufacturing units can be completed within 2–4 months. The return on investment is quite high; typical payback times usually are 4–12 months. For relatively simple gas processing plants, the costs are lower and the payback time can be shorter.

The applications that benefit most from model-predictive control have one or more of the following characteristics:

- High production capacity
- Competing control objectives
- Highly interactive processes

26.3 Sources of Benefits

The benefits of APC and model-predictive control come from one or more of the following:

- Reduced process variability
- Maximizing throughput against multiple process constraints
- Increased yield of high-value products
- Reduced product quality giveaway
- Reduced production losses [26.4].

Variability is a characteristic of all continuous processes. As shown in Fig. 26.2, simply reducing variability provides little (if any) benefit. Benefits start to accumulate when operators run the plant closer to true process constraints.

For example, if a hydrotreater must produce ultralow-sulfur diesel (ULSD) with ≤ 10 wppm sulfur

- Unusual dynamic behavior
- Day/night or seasonal variation
- A need to operate close to constraints
- A need to closely track optimization system targets
- A need to transition smoothly from one set of targets to another.

In refineries, the largest benefits of model-predictive control come from crude distillation units and gasoline blenders, for which the throughput is high, and from fluid catalytic cracking (FCC) and other conversion units, for which the difference in value between feeds and products usually is high. In all cases, benefits accrue from reduced product quality giveaway. In hydrocracking, MPC in conjunction with ARC can improve safety [26.3].

to meet product specifications, and if there is a severe economic penalty for exceeding the specification, the refiner may set a process target of 5 wppm to ensure that the plant never exceeds the limit. In this case, the difference between the target and the limit – i. e., the cushion – is 5 wppm. A cushion of this size is not atypical for coastal refineries where feed quality and/or hydrogen composition can change significantly from one day to the next, and where there is limited ability to correct a specification violation with blending. But a 50% cushion is expensive, resulting in higher operating cost and accelerated catalyst deactivation. If increased stability allows the process target to be raised from 5 to 8 wppm, hydrogen consumption will decrease, heater firing will decrease and catalyst cycle life will increase significantly. To achieve maximum bene-

Fig. 26.2 Reducing variability with APC allows MPC to operate the process closer to a product quality limit

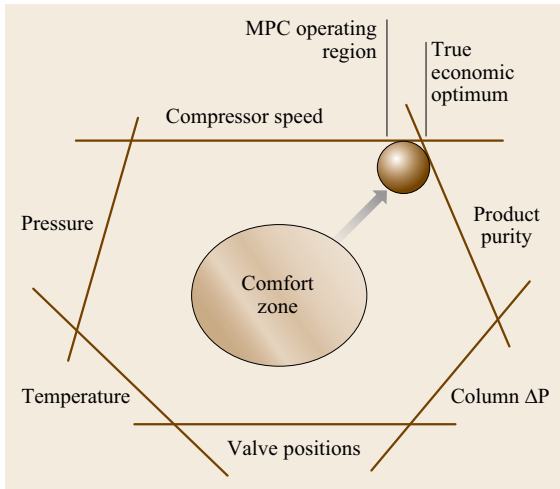

Fig. 26.3 Operating near the right constraints: a major source of MPC benefits

fits, automation requires good and timely information. Hydrotreaters equipped with online analyzers on both feed and product streams are in a much better position than those which rely on thrice daily laboratory measurements.

Speaking of measurements: Operating companies are always looking for ways to cut costs. In the recent past and even today, companies are reducing safety training budgets and analytical costs – with justification. Technology is improving the quality of training while allowing personnel to train when it’s most convenient. Automated training includes testing, which provides some assurance that an employee actually learned something. Automation of laboratories is improving the reliability of test results. Unfortunately, cutting tends to go too far. Deprived of laboratory information, inferential analyzers tend to degrade, sometimes so much that they become useless.

26.4 Implementation

The implementation of MPC requires four main steps – plant response testing, model analysis, commissioning, and training.

During plant response testing, independent variables are moved and dependent-variable responses are captured electronically. Obtaining good plant test data from which accurate models can be regressed is the key to a successful MPC project. For this reason, special care must be taken to ensure that the underlying instrumentation – meters, analyzers, and PID controllers – are properly tuned and calibrated. Traditionally, independent variables were moved manually and one at a time

Fig. 26.4 Response to a disturbance: comparison between manual (red), PID (blue) and MPC (green) control

Figure 26.3 illustrates how model-predictive control can achieve additional benefits by pushing against process constraints, such as safe compressor speed, product purity specifications, temperature, pressure, and pressure drop across a column. A well-tuned model-predictive control application can move a unit out of the comfort zone of manual operation into more profitable operation, by pushing simultaneously against multiple process constraints. Special techniques, such as move suppression, are used to prevent the plant from moving too far too fast.

Model-predictive control diminishes the impact of disturbances and quickly returns the process to the desired setpoint. Figure 26.4 compares how response to a disturbance might differ between manual control versus feedback (PID) control versus model-predictive control (MPC). The red line shows open-loop (manual) response. The dotted line shows better response with a PID controller. The green line shows that MPC (1) detected the disturbance in advance and took immediate remedial action, and (2) was the first to return to stable operation at the setpoint.

during the plant response test, but with recently developed software, an engineer can obtain equivalent plant test data using closed loop testing methods. Proprietary identification software converts the data into dynamic models for the plant. Response-test models can be used to predict future plant behavior with the following control equation

$$\delta \mathbf{CV} = \mathbf{A} \times \Delta \mathbf{I}, \quad (26.1)$$

where $\delta \mathbf{CV}$ is the predicted change in a given $\mathbf{CV}(i, j)$, \mathbf{A} is the gain matrix obtained during the model analysis phase, and $\Delta \mathbf{I}$ is a matrix of independent variable.

Fig. 26.5 Example of the control equation in matrix form, where the predicted result is the product of the dynamic response gain matrix **A** and a matrix of independent variable changes $\Delta \mathbf{I}$ ▶

Figure 26.5 shows an example of the control equation in matrix form.

Model predictions are used to control the plant against constraints, as shown in Fig. 26.3. This is not a trivial matter, because the application must cope successfully with the following:

- Plant/model mismatch
- Instrument failure
- Unmeasured disturbances
- Input data error
- Diverse process dynamics
- Changing process objectives.

$$\delta \mathbf{CV} = \mathbf{A} \times \Delta \mathbf{I}$$

$$\begin{bmatrix} \delta CV_1 \\ \delta CV_2 \\ \delta CV_3 \\ \delta CV_4 \\ \delta CV_5 \\ \delta CV_6 \\ \delta CV_7 \end{bmatrix} = \begin{bmatrix} 1 & & & & & & \\ 4 & 1 & & & & & \\ 6 & 4 & 1 & & & & \\ 7 & 6 & 4 & & & & \\ 7 & 7 & 6 & & & & \\ 7 & 7 & 7 & & & & \\ 7 & 7 & 7 & & & & \end{bmatrix} \times \begin{bmatrix} \Delta I_1 \\ \Delta I_2 \\ \Delta I_3 \end{bmatrix} = \begin{bmatrix} 1 \\ 4 \\ 4 \\ -1 \\ -5 \\ -7 \\ -7 \end{bmatrix}$$

Despite these challenges, when implemented by qualified personnel, MPC applications provide considerable value for manufacturing plants throughout the world.

26.5 Costs versus Benefits

Figure 26.6 illustrates the infrastructure required for computer control. APC and model-predictive control software usually run on a separate process computer, which uses a *data highway* to communicate with the

Modeling Refining Processes

Teh C. Ho

Conversion of petroleum fractions and crude oils involves a vast number of chemical species. Modeling of such large reaction systems has been and will continue to be an active research area. There has been an array of approaches bearing on the subject scattered throughout the literature in different contexts. This chapter provides a brief, coherent overview of several selected approaches. The emphasis is on model simplification and mechanism reduction via heuristic concepts and formal mathematical techniques. Among the topics discussed are: top-down and bottom-up kinetic modeling, graph/matrix representation of chemical reactions, mechanistic versus pathways models, quantitative structure–reactivity relationships, asymptotic and optimization methods of dimension reduction, tradeoff between kinetics and hydrodynamics, continuum approximation, collective behavior, and overall kinetics of a large number of reactions. Some common features of dimension reduction approaches are discussed. The areas requiring further investigation are suggested.

Petroleum refining is under increasing pressure to produce ultra-clean and high-value products with minimum capital outlays. A low-cost approach to meet this challenge is to develop robust process models capable of predicting how product quality is affected by feedstock composition, operating conditions, catalyst properties, and hardware configuration. Such models allow refiners to take full advantage of recent advances in analytical chemistry, computing, control, and optimization. This chapter provides an overview of modeling of petroleum refining.

Oil-refining processes are characterized by an astronomically large number of reacting species, each generating a complex reaction network. Traditionally, most kinetic models for oil refining have been developed along two lines. One is to divide a petroleum feedstock into a small number of kinetic lumps (or

pseudo-components) and the reactions among them are tracked. An example is the early 10-lump kinetic model for fluid catalytic cracking (FCC) of vacuum gas oil (VGO) [27.1]. Another is to lump all reactants into a single pseudospecies and determine the overall kinetic behavior of the feedstock as a whole. For instance, in hydrodesulfurization (HDS), only the reduction of total sulfur matters, not individual sulfur species. These two approaches may be called partition-based lumping and total lumping, respectively.

Recent developments in analytical chemistry and computing have made it possible to perform molecular speciation analyses on petroleum feedstocks and follow the reactions of a vast number of species computationally. Enormous efforts have been expended in developing detailed chemical kinetics for petroleum refining. To manage diverse refinery streams at a molec-

ular level calls for a bottom-up approach to kinetic modeling. The view is that it is the microscopic interactions at the molecular level that govern the macroscopic behaviors of petroleum fractions at the process scale. Thus, kinetic modeling starts with examining the feedstock at the molecular level, identifying mechanisms and pathways of individual reactions according to established reaction rules, and then working all the way up to the refinery level. To battle with the *curse of dimensionality*, one must sacrifice some exactness by judicious consolidation and pruning. The strategy is to develop high-fidelity, low-dimensional composition-based models through projection onto a subspace of the entire composition space.

Much progress has been made on using a multi-phase computational fluid dynamics (CFD) approach for modeling of hydrodynamically complex reactors. The problems needed to be solved become multidimensional and highly nonlinear. The result is that even with today's prodigious computing power, CFD-based process models can only accommodate rather simple

kinetics, thus, precluding the possibility of managing refinery streams at the molecular level. At the other end of the spectrum are composition-based models, which can accommodate a huge number of reactions but cannot portray the complexities of hydrodynamic effects. This state of affairs underlines the need for a hybrid approach aimed at striking a delicate balance between the kinetics-dominated and hydrodynamics-dominated approaches.

This chapter consists of six sections. The first is a brief account of the traditional top-down, partition-based lumping technique. Next is a discussion of some key features of the bottom-up, compositional modeling approach. Following this is a quick survey of mathematical techniques aimed at exorcising the curse of dimensionality. Then, the tradeoff between kinetics and hydrodynamics in process modeling is discussed using FCC as an illustrative example. The fifth section addresses total lumping. The concluding section points out some potentially fruitful areas for further research. Literature citations are illustrative rather than comprehensive.

27.1 Partition-Based Lumping

It has been a tradition to characterize petroleum feedstocks in terms of specific gravity, average molecular weight, boiling range, and solubility classes, rather than, say distinct individual gasoline molecules. For instance, the early paraffins, olefins, naphthenes, and aromatics (PONA) analysis divides countless number of molecules into just four lumps: paraffins, olefins, naphthenes, and aromatics. The literature abounds with kinetic and reactor models in terms of a small number of coarse lumps. These lumps, satisfying the conservation law and stoichiometric constraints, are usually selected based on measurability and gross properties (e.g., boiling range and solubility). For example, Fig. 27.1 shows an FCC four-lump kinetic model consisting of VGO, gasoline, gases, and coke [27.2].

Highly lumped models have also been developed based on functional groups (or structural moieties). An example is a three-lump model for the kinetics of heat release in hydroprocessing reactors [27.3, 4]. The extent of heat release is governed by three types of

Fig. 27.1 Boiling point based-lump model for FCC; k_i 's are rate constants. (After [27.2])

carbon-carbon bonds: σ -paraffinic, π -aromatic, and π -olefinic.

Residual oils are commonly partitioned into solubility lumps. Figure 27.2 shows a simple lumped model for thermal cracking of residual oils [27.5]. Here, M and A are maltenes (n -heptane soluble) and asphaltenes (toluene soluble/ n -heptane insoluble) in the feed, \bar{M} and \bar{A} are maltene and asphaltene cores, respectively (pyrolysis products), and V is volatiles. All the reactions are first order. The model needs to account for an induction time for coke formation, arising from the separation of a second liquid phase formed from partially converted asphaltene cores. The maximum cracked asphaltene concentration in the solution, $\bar{A}_{\max} = S_L(M + \bar{M})$, is dictated by the solubility limit S_L , which is a fraction of total maltenes. When the excess asphaltene becomes positive, $\bar{A}_{\text{ex}} = \bar{A} - \bar{A}_{\max} > 0$ coke (toluene insoluble) forms instantaneously and separates out as a second

Fig. 27.2 Solubility-based lumped kinetic model for residua pyrolysis: M and A are maltenes and asphaltenes; \bar{M} and \bar{A} are maltene and asphaltene cores; V is volatiles. (After [27.5])

phase. With a single set of stoichiometric coefficients, the model predicts the observed induction period and product slates for pyrolysis of both maltenes and whole resid. This simple model can be used for modeling residuum coking process.

27.2 Composition-Based Modeling

There is a limit to what can be gained by pursuing the top-down lumping approach. For one, the lack of sufficient molecular details makes it very difficult to predict the effects of feedstock composition over a wide range of conditions. A more challenging task is to predict subtle changes in product qualities [27.7]. Against this backdrop, a bottom-up, compositional modeling approach has emerged, which tracks interactions among a huge number of individual reactions. This approach also requires considerable pruning and lumping to fold microscopic events into meso- or macroscopic models. Global lumping is done in the end to predict overall product quality from molecular composition [27.7]. The following sections briefly describe some key aspects of this approach.

27.2.1 Matrix Representation of Chemical Reactions

Individual hydrocarbon species, while enormous in numbers in any boiling cut, belong to a limited set of compound classes (e.g., paraffins, aromatics, and olefins) and structural moieties (e.g., sulfur-, nitrogen-, and oxygen-containing heterocycles). They give rise to a far smaller number of reaction families than that of species or reactions. This fortunate characteristic offers at least two benefits. First, it holds out the prospect for

Besides the solubility-based lumping, residua have also been lumped into several boiling point cuts. For instance, the thermal cracking of a heavy Arabian vacuum residuum in FCC is described by a six-lump model [27.6].

developing structure–reactivity relationships capable of grouping reactions of the same family involving similar transition states. Second, the bookkeeping and transformation of these species, involving breaking and forming bonds, can be automatically and algorithmically tracked by matrix operations.

In a structure-oriented-lumping (SOL) approach [27.8, 9], a hydrocarbon molecule is described by a vector whose components, referred to as structural increments, represent the number of specific structural features. These increments are building blocks for constructing molecules. For example, A6 represents a six-carbon aromatic ring present in all aromatics, whereas A4, a four-carbon aromatic ring, is an incremental structure that must be fused to an A6 or another A4. Figure 27.3 shows the structure vector and its 22 structural increments that comprise three aromatic (A6, A4, and A2) and six naphthenic (N6–N1) ring structures, a $-\text{CH}_2-$ group (R) to specify the carbon number of alkyl chains or paraffins, the number of branches in a chain (br), the number of methyl substituents (me) on rings, bridging between rings (AA), hydrogen deficiency (H), and heteroatom groups. Each group in the vector has carbon, hydrogen, sulfur, nitrogen, and oxygen stoichiometry and hence molecular weight. Also shown in Fig. 27.3 are examples of molecules represented by this type of vectors. The vector components

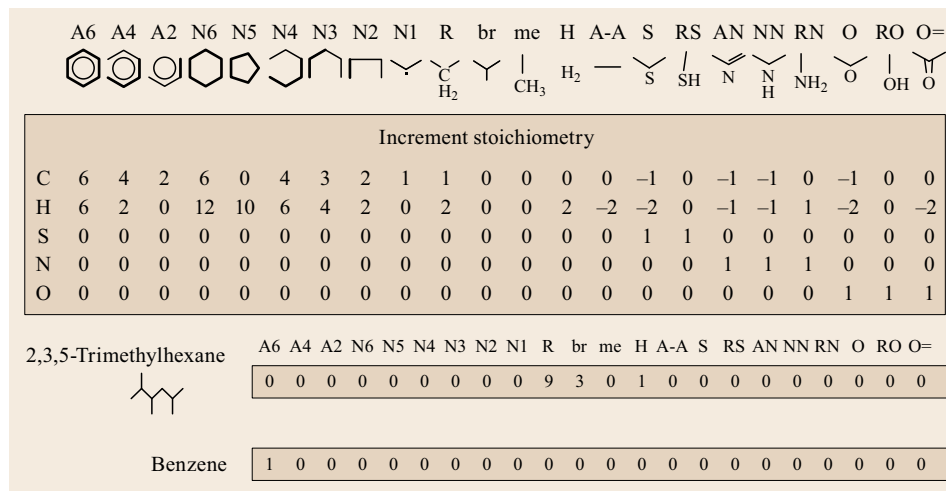

Fig. 27.3 Structure vectors and 22 structural increments defined in the structure-oriented lumping approach. Also shown are examples of SOL molecules. (After [27.8, 9])

indicate the number of increments in each group. Thus, benzene is represented by A6, with the first component of the vector having a value of one and all others zero. A homologous series is a set of vectors having identical structure increments except for the alkyl chain length and possibly the branching and methyl substituent indicators.

Graph theoretic concepts have been exploited to generate a reaction network by *Klein* and coworkers [27.10–12]. A molecule is represented by a graph whose nodes and edges are the atoms and bonds, respectively. This information can be contained in the associated connectivity matrix for a molecule, the numbers denoting the bond order for a bond between two atoms and the diagonal elements denoting an unpaired electron or ion associated with a particular molecule. Figure 27.4 shows an HDS reaction [27.13].

Hydrocarbons have also been represented by Boolean relation matrices [27.14, 15]. The matrix element on the *i*-th row and *j*-th column is *true* if there is

a bond between carbon atoms *i* and *j* in the molecule. Otherwise, a value of *false* is assigned. The number of ones on a row indicates whether a carbon atom is primary, secondary, tertiary, or quaternary. The presence and position of double bonds and a positive charge are provided by arrays. This scheme is illustrated in Fig. 27.5 for shifting methyl from the 2-methyl-3-heptyl carbenium ion to the 3-methyl-2-heptyl carbenium ion. The program searches all neighbors of the positively charged carbon atom and checks if they are linked to any methyl group. If so, the bond between the neighbor and the methyl group is broken and a bond between the methyl group and the positively charged carbon atom is formed.

With bookkeeping algorithms, reaction networks can be automatically generated by a computer based on known reaction rules. Such rules are generally obtained from experiments and sometimes from thermochemical considerations and/or computational chemistry.

27.2.2 Splitting and Lumping

To split a complex mixture, one can take a mechanistic approach that describes reaction networks in terms of elementary steps, including transient intermediates such as adsorbed ions or free radicals in the bulk phase. If this splitting is not fine enough, each elementary step may be decomposed into single events to account for reaction path degeneracy [27.16]. An alternative approach is a pathways-level description that does not consider ions or radicals, as in Sect. 27.2.4.

Whenever possible, the rate and equilibrium constants are estimated from a variety of sources, such as analogies with liquid- and gas-phase reactions, transition state theory, semiempirical techniques, first principle quantum chemical calculations, statistical mechanics, empirical correlations, existing databases, and so on. Various conventional and quantum chemical methods for estimating thermochemical and reaction rate coefficients have been reviewed [27.17, 18]. Most theoretical methods of estimating rate parameters have been applied to homogeneous gas-phase reactions of relatively small molecules at low pressures. However, the majority of oil-refining reactions involve mixtures of large hydrocarbon molecules in the liquid phase at moderate or high pressures and temperatures lower than those used in combustion.

For manageability, the step following the splitting is the preprocessing of the huge number of reactions, which involves simplification and consolidation of the networks of elementary reactions or single events. That is, splitting and mechanism reduction work in tandem.

Mechanism Reduction

Kineticists have long used various mechanism reduction techniques [27.19–21] to simplify problems until they become manageable while capturing salient features of the underlying system. Examples of such techniques are as follows:

- Rate-determining step
- Irreversible step approximation
- Relative abundance of catalyst-containing species
- Quasi-equilibrium approximation (QEA)
- Quasi-steady-state approximation (QSSA)
- Long-chain approximation [27.22]
- Large activation energy [27.23]
- Sensitivity analysis [27.24]
- Principal component analysis [27.24]
- Reaction shortsightedness [27.20]
- Analogies with electrical circuits [27.25]
- Thermodynamic constraints and consistencies [27.26, 27].

Some of the above approaches at their core are based on the notion of time scale separation.

A laudable outcome of applying mechanism-reduction techniques is that a set of elementary reactions can be lumped into an overall rate expression capturing the essence of the underlying microscopic events. As an example, consider alkane pyrolysis with free radicals as intermediates. The essential features of this class of chain reactions can be explained by the Rice–Herzfeld mechanism [27.28]. The following elementary reactions are paradigmatic of hydrocarbon pyrolysis

Here, P and P[•] are the parent alkane and parent radicals, respectively, R[•] and RH are lower alkyl radicals and the corresponding alkanes, respectively, and L represents olefins. The hydrogen abstraction and β-scission reactions are the chain-propagation steps. Alkylaromatics and cyclic saturated compounds follow similar pathways, whether the reaction medium is vapor or liquid [27.29]. Invoking the QSSA, one finds that the overall disappearance rate $\bar{\tau}_P$ of the parent molecule obeys an *n*-th-order law

$$\bar{\tau}_P = \bar{k} c_P^n, \quad (27.5)$$

where c_P is the concentration of the parent molecule and $n = 0, 1/2, 1, 3/2, \text{ or } 2$, depending on the nature of the initiating and termination steps [27.28].

Sensitivity and Principal Component Analyses

A complex kinetic model generally has a multitude of interacting dependent variables and rate parameters. The effects of these rate parameters on a given measured dependent variable (concentration, overall rate, selectivity, etc.) vary greatly as the reaction proceeds. Sensitivity analysis can reduce the model by identifying which rate parameters can be lumped or removed from the model in different regions of the composition space [27.30, 31]. It also helps to explore correlations among model parameters and design critical experiments. Before formally eliminating any rate constant from a part of the reaction network, one needs to check if the reduced model retains the structural features of

the original model. For instance, if a branch of the reaction network is equilibrium controlled, the sensitivity coefficients for the forward and backward rate coefficients are small. However, removing this branch may not be desirable.

Using the principal component analysis (PCA) can vastly simplify the analysis of the mass of numerical information generated from the sensitivity analysis [27.32]. It identifies the dominant reactions and the interactions among constituent reactions. There are many examples of using the sensitivity analysis for contracting reaction networks. For catalytic cracking of isobutene, only 31 out of 367 steps are kinetically significant [27.33]. A 10-lump FCC model can be contracted to five coarser lumps [27.34]. Combining sensitivity analysis and PCA allows 46 elementary water–gas shift reactions on Pt to be lumped into an overall, one-step rate expression covering both the kinetics- and equilibrium-controlled regimes [27.24]. This one-step rate model is needed for a CFD-based reactor model. The success of the final reactor model crucially depends on how credible the overall, reduced kinetic model is.

Quantitative Structure–Reactivity Relationship

The size of the reduced model obtained from application of the above techniques may still be undesirably large, necessitating further reduction and parameterizations. This is usually accomplished by finding quantitative structure–reactivity relationships (QSRRs) for various reaction families. The term QSRR broadly means a correlation that quantitatively relates the response (e.g., reactivity and adsorptivity) of a group of chemical species to changes in certain common physicochemical characteristics (descriptors) of the constituent species. The behavior of the entire family is describable by a small set of parameters determined experimentally or theoretically. For instance, the hydrogenation of alkylbenzenes is a reaction family in which all member compounds share the same chemical moiety and undergo the same reaction. The reactivity varies systematically with the moiety's electronic density governed by the substituents.

A simple QSRR example is the semiempirical linear free energy relationship (LFER), which may take the simple form $\ln k_i = a + bz_i$, where k_i and z_i are the rate constant and descriptor value for molecule i , respectively [27.10]. The choice of descriptor z_i reflects the controlling mechanism of the reaction, such as the aromatics' electronic properties in hydrogenation, carbocation stability in catalytic cracking, or reaction enthalpy in pyrolysis. Once the constants a and b are known, which are experimentally determined in most cases, the rate constants for all members of the reaction family can be calculated from z_i . A complex system

may need multiple descriptors, which can be measured or computed.

The LFER approximation has been known for some time [27.35–37]. It is an essential tool for modeling oil-refining reactions. Typically, the number of independent rate constants for modeling individual gas oil reactions is of the order 10^4 [27.4], whereas that of LFER parameters is of the order 10 [27.38, 39]. Most QSRRs have been developed by means of theoretical or experimental methods. For instance, using the group contribution method can reduce the problem of establishing FCC kinetics for hundreds of species to one of determining two dozen parameters experimentally [27.40, 41]. Adsorption equilibrium constants have been estimated from an integrated form of Van 't Hoff's equation [27.42, 43]. Density-functional theory (DFT) calculations have shown that the hydrodenitrogenation (HDN) reactivities of cyclohexylamines and alkylpiperidines correlated with the negative Mulliken charges on the nitrogen atom [27.44].

For a simple homologous reaction family, one could probably identify what would be the dominant descriptors on intuitive grounds. For instance, it is reasonable to expect that chain length should be the most relevant descriptor when a linear paraffin's overall cracking rate is of primary concern. Indeed, the catalytic cracking rate scales as $N_c(N_c - 5)$, where N_c is number of carbon atoms in the chain [27.45]. The rate constants for olefin oligomerization on the ZSM-5 catalyst decrease with increasing N_c , based on diffusion considerations [27.46].

For more complex systems involving a large descriptor space, one faces the question of which descriptors from a long list of candidates are most relevant. There are many different types of descriptors. Some examples are as follows: constitutional (derived from atomic composition of compounds, e.g., counts of atoms and bonds), geometric (derived from three-dimensional atomic coordinates, e.g., molecular volume), topological (e.g., molecular connectivity), electrostatic (e.g., polarity indices), and quantum-chemical (e.g., bond orders). Some quantum-chemical descriptors can be calculated from available software (e.g., MOPAC and AMPAC). The following is an example of building a practical QSRR from a set of descriptors.

Organonitrogen species and polynuclear aromatic compounds are known to poison FCC catalysts through competitive adsorption. There are many different structural types of nitrogen compounds and aromatics. Candidate descriptors may include pK_a , proton affinity (PA), electron density around the nitrogen atom, various molecular connectivities, boiling point, molecular volume, to name a few [27.47]. In order not to miss any important descriptors, it pays to include all plausi-

ble descriptors at first, even though some of them show varying degrees of correlation. The result is a large descriptor space whose dimension must be drastically reduced for tractability and physical clarity. This is achieved by projecting the raw data onto a subspace with fewer orthogonal dimensions via the partial least squares (PLS) analysis [27.47–51]. The purposes are to eliminate data collinearity and gain insights into underlying fundamentals and therefore identify dominant descriptors. The thus-identified dominant descriptors are used to construct a compact correlation collapsing the data.

To illustrate, consider the poisoning effects of 32 nitrogen and aromatic compounds on FCC catalysts [27.47]. Let the poisoning power of the i -th poison (nitrogen or aromatic compounds) be y_i , a component of the vector \mathbf{Y} . For each poison, 24 descriptors are selected, hence the descriptor space is represented by a 32×24 matrix \mathbf{Z} . Each column contains the values of a particular descriptor for all 32 poison compounds, whereas each row contains all 24 descriptor values for a particular poison compound. If one uses conventional statistical regression methods (e.g., least squares) to find a linear correlation between \mathbf{Y} and \mathbf{Z} , the problem is ill-conditioned due to data collinearity. The resulting correlation would not be robust and has a large prediction variance. Using neural networks for constructing nonlinear models suffers from the same problem [27.52]. It is thus essential to eliminate data collinearity prior to model building. PLS achieves this by linearly combining all descriptors to form a new set of uncorrelated latent variables (LVs). The LVs are obtained in order of diminishing accountability: the first LV accounts for the largest amount of variation in \mathbf{Y} , the second LV explains the second largest amount of \mathbf{Y} variation, and so on. Dimension reduction is then accomplished by retaining only the first few LVs. Examining the major descriptors contributing to these dominant LVs helps reveal the physics of the system, which provide the basis for building a linear or nonlinear correlation in terms of these key descriptors. Such dominant descriptors are uncorrelated and their number is small [27.47–49]. The resultant correlation has clear physical meanings.

The PLS is more than just a tool for dimension reduction and model building, it should be used for gaining physical insights. For example, the PLS results indicate that of the 24 structural descriptors, the most influential one is molecular weight (MW) – followed by proton affinity. The best polynomial model is of the form [27.47]

$$y_i = 0.075 + 0.74(MW_i)^2(PA_i)^2 - 0.41(MW_i)^3, \quad (27.6)$$

Fig. 27.6 Contour plot of poisoning value y_i versus MW_i and PA_i . (After [27.47])

where MW_i and PA_i are normalized values. That molecular weight (or size) is more important than PA counters conventional wisdom, which has held that basicity is the key determinant of poisoning potency. Moreover, the correlation reveals a pore diffusion effect: At a constant PA, poisoning increases with MW, but only up to a certain point beyond which poisoning starts to decrease, as shown in Fig. 27.6. Here, y_i can be viewed as a proxy for the apparent adsorption equilibrium constant. Then, MW and PA play the roles of adsorption entropy and enthalpy, respectively. This example demonstrates that in many cases a hydrocarbon processing system, complex as it is, can actually be governed by a small number of dominant physicochemical events once it is distilled to its essence.

27.2.3 Mechanistic Modeling

We now highlight approaches for developing fundamental models that include such mechanistic details as adsorbed ions or free radicals. Microkinetic analysis of surface reaction mechanisms helps developing a kinetic model for a network of elementary surface reactions [27.53]. By judiciously selecting a probe reaction, the analysis provides insights into the underlying mechanisms for a reaction family over a given catalyst type. This approach also provides a sensitive tool for characterizing a catalyst family. *Yaluris* et al. gave illustrative examples for isobutane cracking over zeo-

lite Y-based FCC catalysts from 733 to 773 K [27.54, 55]. Pruning the reaction network is an integral part of the analysis. An Evans–Polanyi type of correlation is used to parameterize the observed activation energies E_a based on known thermodynamic properties of gas phase hydrocarbons and carbocations. In so doing, the number of fitting parameters can be substantially reduced.

The single-event theory proposed by *Froment* [27.16] in essence is a structure-oriented approach. Its basic idea is to link rate constant to molecular structure, thereby, reducing the number of rate coefficients. This is done by factoring out the structure effect from the change of standard entropy associated with the reactant-to-product transformation through a transition state. The standard entropy consists of translational, vibrational, and rotational contributions. The last one can be considered as representative for the structure and written as

$$S_{\text{rot}} = \hat{S}_{\text{rot}} - R \ln \sigma,$$

where \hat{S}_{rot} is an intrinsic term and σ relates to the symmetry number of the species. If chirality needs to be considered, a global symmetry number $\sigma_{\text{gl}} = \sigma/2^{\tilde{n}}$ is introduced, where \tilde{n} is the number of chiral centers in the species. The change in the standard entropy due to symmetry changes in going from reactant (superscript r) to the transition state is

$$\Delta S_{\text{symm}} = R \ln \frac{\sigma_{\text{gl}}^r}{\sigma_{\text{gl}}^{\ddagger}}. \quad (27.7)$$

One can factorize the rate constant k into two terms, namely,

$$\begin{aligned} k &= \left(\frac{\sigma_{\text{gl}}^r}{\sigma_{\text{gl}}^{\ddagger}} \right) \left[\left(\frac{k_B T}{h} \right) \exp \left(\frac{\Delta \hat{S}}{R} \right) \exp \left(-\frac{\Delta H^{\ddagger}}{RT} \right) \right] \\ &= n_e \hat{k}. \end{aligned} \quad (27.8)$$

Here, $n_e \equiv \sigma_{\text{gl}}^r / \sigma_{\text{gl}}^{\ddagger}$, the number of single events for the elementary step, accounts for the structural effect, whereas \hat{k} is the single-event rate coefficient that is structure invariant. To calculate n_e requires information on species structure, which may be obtained from available quantum chemical software. This approach vastly reduces the number of single event rate coefficients. There are many oil-refining kinetic models based on the single event approach, as exemplified by FCC of VGO to which a massive consolidation of reactions is

essential [27.56]. Modeling of catalyst coking was also attempted [27.57].

27.2.4 Pathways Modeling

Applying the mechanistic modeling approach to refining processes is no easy task because of the sheer size of the reaction network, the more so when the kinetics must be combined with reactor hydrodynamics and heat transfer in attacking practical problems. These issues motivated the development of a simpler approach by neglecting transient intermediates (e.g., carbocations or free radicals) and focusing on dominant reaction pathways.

An example of pathways modeling is the SOL approach, which describes a petroleum mixture as a large set of structure vectors of different concentrations (e.g., weight percentages), with each vector being a molecule or a collection of isomers [27.8, 9]. Collections of reaction rules are defined for the thousands of representative hydrocarbon components. Typically, petroleum process chemistry is defined by 20–30 reaction families resulting in more than 50 000 reactions. Each refining process (e.g., FCC and HDS) has its own reaction rules, although all petroleum mixtures have the same vector representation. The isomers of a molecular class for a given carbon number are assumed to have similar physical, chemical, and thermodynamic properties. Lumping is largely done through consolidation of reaction types by invoking, for instance, the equal reactivity assumption and QSSRs.

The SOL approach has led to a number of oil-refining process models. For FCC applications, the approach applies reaction rules to more than 30 000 reactions involving over 3000 species [27.58]. These species include representative molecules, isomeric lumps, micro-lumps, and so on. The model can predict both product yields and composition for a range of feeds and catalysts with a single set of kinetic parameters and QSRRs. A more compact FCC model [27.59] involving 450 species and 5500 reactions was developed, featuring a stochastic approach for constructing molecular structures of gas oil feedstock. The model reveals that a significant protolytic cracking rate defines much of the product distribution for light catalytic cycle oil, whereas significant hydride-abstraction defines the gasoline product distribution. A hybrid approach is used to develop a molecule-based model for catalytic reforming [27.60]. The acid catalytic chemistry is described at the mechanistic level, whereas the metal chemistry at the pathways level. The assumption is that some exactness can be sacrificed for the metal chemistry with impunity.

27.3 Mathematical Reduction of System Dimension

This section is a very brief account of mathematical techniques for dimension reduction. The interested reader should consult the original references for details. In broad terms, an underlying theme in many of the techniques is to obtain a low-dimensional model by truncating an asymptotic expansion. This entails transforming the state variable (e.g., the vector function \mathbf{c}) into a new set of pseudostate variables with more desirable properties. For instance, the system behavior is expressed as a weighted sum of optimally selected basis functions (e.g., eigenfunctions or eigenvectors) – in descending order of influence. That is, the first term is the most influential. There then follows the second, the third term, and so forth. A low-dimensional model is therefore obtained by keeping only the first few terms. In so doing, one focuses only on the most essential part of the problem. This approach is also referred to as order reduction.

Let us consider an isothermal system governed by the following mass balance equation for N_s reacting species represented by the $N_s \times 1$ concentration vector \mathbf{c}

$$\frac{d\mathbf{c}}{dt} = \mathbf{f}(\mathbf{c}), \quad \mathbf{c}(0) = \mathbf{c}_f, \quad (27.9)$$

where t is space time (plug-flow reactor) or time (batch reactor) and \mathbf{c}_f is the feed concentration vector. The goal is to find a low-dimensional system that can at least approximately portray the behavior of the underlying full system. For first-order reactions $\mathbf{f} = \mathbf{K}\mathbf{c}$, where \mathbf{K} is the matrix of rate constants k_{ij} . Reference [27.61] is a brief review of some mathematical methods of dimension reduction.

27.3.1 Time Scale Separation

Although kinetically complex systems often have a multitude of widely disparate time scales, seldom does the need for considering all of them during the course of the reaction arise. This characteristic lends itself to dimension reduction. Suppose that the time window of interest is $\underline{t} \leq t \leq \bar{t}$. Species reacting with time scales much shorter than \underline{t} may be considered relaxed. The state of these fast-reacting species can be treated as initial conditions. On the other hand, species reacting on time scales much longer than \bar{t} remain dormant; their concentrations are essentially frozen and may be treated as system parameters.

The mathematical techniques considered here are the perturbation method, modal analysis, and projective transformation. To put them in perspective and illustrate the interplay of physical and mathematical viewpoints

in model reduction, we consider the quasi-equilibrium system of first-order reactions as

Here, A_1 and A_2 quickly reach equilibrium after which the system becomes one-dimensional, for it is governed by the slow depletion of the equilibrium pool of $(A_1 + A_2)$ due to the *leakage* reaction with rate constant k_3 . The time scale disparity is gauged by $\varepsilon = k_3/k_1 \ll 1$. (Throughout this chapter, ε denotes a small positive number, with its physical meaning depending on the context.)

Let c_1 and c_2 be the concentrations of A_1 and A_2 , respectively. The initial conditions are $c_1(0) = c_{1f}$ and $c_2(0) = c_{2f}$. With $\tilde{c}_1 = c_1/c_{1f}$, $\tilde{c}_2 = c_2/c_{1f}$, the system dynamics is described by

$$\frac{d\tilde{\mathbf{c}}}{dt} = \begin{bmatrix} -k_1 & k_2 \\ k_1 & -(k_2 + k_3) \end{bmatrix} \begin{bmatrix} \tilde{c}_1 \\ \tilde{c}_2 \end{bmatrix} = \mathbf{K}\tilde{\mathbf{c}}. \quad (27.11)$$

For $k_1 = 1$, $k_2 = 0.6$, and $k_3 = 0.05$, the eigenvalues of \mathbf{K} are -0.0309 and -1.6191 , hence the system has two well-separated time scales: $| -1/0.0309 | = 32.36$ versus $| -1/1.6191 | = 0.62$. If the short initial transient is not of interest, the system can be projected onto a one-dimensional subspace. Referring to Fig. 27.7, the subspace is invariant in that *once you get in, you cannot get out*. Regardless of their starting points, all trajectories get attracted to the common subspace (solid line)

Fig. 27.7 A common invariant subspace (thick solid line) attracts reaction trajectories originated from different initial compositions for the reaction in (27.10); $k_1 = 1$, $k_2 = 0.6$, and $k_3 = 0.05$

after an exponentially fast transient. In this subspace, A_1 and A_2 are related to each other algebraically due to the quasi-equilibrium. The movement of the system toward equilibrium is governed by the slow motion within the invariant subspace, which is confined to a very small region of the composition space. Yet, it is this region that is of interest shortly after the startup of the reaction. In practice, process controllers are usually designed to operate a reactor around the invariant subspace.

27.3.2 Perturbation Analysis

To look at the system from a long-time perspective, we use a slow-time scale defined as $\tau = k_3 t$. Let $K = k_2/k_1$, (27.11) becomes

$$\varepsilon \frac{d\tilde{c}}{d\tau} = \begin{bmatrix} -1 & K \\ 1 & -(K + \varepsilon) \end{bmatrix} \begin{bmatrix} \tilde{c}_1 \\ \tilde{c}_2 \end{bmatrix}. \quad (27.12)$$

Given that $\varepsilon \ll 1$, one seeks the solution in the form $\tilde{c}_1 = \tilde{c}_{10}(\tau) + \varepsilon \tilde{c}_{11}(\tau) + O(\varepsilon^2)$ and $\tilde{c}_2 = \tilde{c}_{20}(\tau) + \varepsilon \tilde{c}_{21}(\tau) + O(\varepsilon^2)$. Substituting these series expansions into (27.12) and equating coefficients of like powers of ε , one obtains a set of equations for \tilde{c}_{1j} and \tilde{c}_{2j} ($j = 0, 1, 2, \dots$). For practical purposes, retaining only the leading-order terms (denoted by the subscript 0) of the expansion suffices because ε is sufficiently small. Then, the original problem is reduced to an algebraic equation coupled with a differential equation for a lumped species, namely

$$\tilde{c}_{10} = K\tilde{c}_{20} \quad (27.13)$$

$$\frac{d(\tilde{c}_{10} + \tilde{c}_{20})}{d\tau} = -\tilde{c}_{20}. \quad (27.14)$$

Thus, on the long-time scale, A_1 and A_2 are essentially in equilibrium (27.13) and move together as a lump (27.14). Solving (27.13) and (27.14) gives

$$\tilde{c}_{10} = Kb^* e^{-\tau/(1+K)}, \quad \tilde{c}_{20} = b^* e^{-\tau/(1+K)}, \quad (27.15)$$

where b^* is the yet-to-be-determined *initial* condition ($\tau = 0$) for the slow-time scale problem. Equation (27.15) describes the slow movement of the ($A_1 + A_2$) lump: It decays slowly with the time constant $(1 + K)/k_3 = 32$. The QEA is nothing but the leading-order term of the perturbation series, corresponding to the solution to the unperturbed problem ($\varepsilon = 0$).

The above reduced model, obtained from a long-time asymptotic analysis, is invalid over the initial

transient period. To examine the small- t dynamics requires a separate perturbation series on a short-time scale. Only when these two perturbation expansions are pieced together can one obtain a complete picture of the reaction trajectories for all t . This is done through matching in the regions of overlap between the small- t and large- t domains. This type of perturbation problems is called singular. A regular perturbation problem is easier to solve as it requires only one perturbation series for all t .

We now probe the short-time behavior (or the boundary-layer effect in perturbation parlance). To this end, we use a fast-time scale $\bar{\tau} = k_1 t$. The mass balances become $d\tilde{c}_1/d\bar{\tau} = -\tilde{c}_1 + K\tilde{c}_2$ and $d\tilde{c}_2/d\bar{\tau} = \tilde{c}_1 - (K + \varepsilon)\tilde{c}_2$ with $c_1(0) = c_1^*$ and $c_2(0) = c_2^*$, respectively. Adding these two equations yields $d(\tilde{c}_1 + \tilde{c}_2)/d\bar{\tau} = -\varepsilon\tilde{c}_2 \approx 0$, hence to leading order, $(\tilde{c}_1 + \tilde{c}_2) = \text{constant} = (c_1^* + c_2^*)$ over the initial period. This provides the needed initial condition for the large- t expansion; that is, setting $\tau = 0$ in (27.15) leads to $b^* = (c_1^* + c_2^*)/(1 + K)$, thus, completing the matching of the two expansions. Solving the unperturbed problem ($\varepsilon = 0$) reveals that during the initial period, A_1 and A_2 equilibrate at an exponentially fast rate, with a characteristic time scale of $1/[k_1(1 + K)] = 0.63$, to leading order.

The singular perturbation technique has often been used to attack nonlinear problems of high dimensionality [27.62]. Typically, the system in question is split into slow (subscript s) and fast (subscript f) subsystems in the following singularly perturbed form

$$\frac{dc_s}{dt} = f_s(c_s, c_f), \quad \varepsilon \frac{dc_f}{dt} = f_f(c_s, c_f), \quad (27.16)$$

where f_s and f_f are n_s -, n_f -dimensional vector functions, respectively, with $n_s + n_f = N_s$. The product $\varepsilon(dc_f/dt)$, symptomatic of a singular perturbation problem, cannot be dropped because dc_f/dt is sufficiently large (order of $1/\varepsilon$) for small t . In other words, the zeroth-order model $f_f(c_{s0}, c_{f0}) = \mathbf{0}$, obtained by setting $\varepsilon = 0$, cannot portray the rapidly changing behavior of c_f in the boundary-layer (small t) region of the composition space. So, the dc_f/dt term must be retained for small t by adopting a commensurately fast-time scale $t^* = t/\varepsilon$. An asymptotic solution for the small- t domain can be found through the expansion $c_f(t^*) = c_{f0} + \varepsilon c_{f1} + O(\varepsilon^2)$. A uniformly valid solution for all t can then be obtained by piecing together the short- and long- t expansions. This discussion is illustrative of an important tactic for dimensionality reduction: It is often necessary to divide the whole domain into several subdomains and develop a reduced model for each subdomain.

27.3.3 Modal Analysis

For linear systems represented by $d\mathbf{c}/dt = \mathbf{K}\mathbf{c}$, the approach is to decompose the original full system into dynamically independent modes. This is done through the decomposition $\mathbf{K} = \mathbf{X}^{-1}\mathbf{\Lambda}\mathbf{X}$, where $\mathbf{\Lambda}$ is the diagonal matrix of eigenvalues λ_i of \mathbf{K} . \mathbf{X} is taken as the modal matrix whose columns are the associated eigenvectors \mathbf{x}_i , and \mathbf{X}^{-1} is the inverse of \mathbf{X} . The modal system $\bar{\mathbf{c}}$ is obtained under the linear transformation

$$\bar{\mathbf{c}} = \mathbf{X}^{-1} \mathbf{c}, \quad (27.17)$$

which decouples the original system by virtue of the fact $d\bar{\mathbf{c}}/dt = \mathbf{\Lambda}\bar{\mathbf{c}}$ with $\bar{\mathbf{c}}(0) = \bar{\mathbf{c}}_f$. Hence, for $\bar{\mathbf{c}}(t) = \bar{\mathbf{c}}_f \exp(\mathbf{\Lambda}t)$, each mode \bar{c}_i moves independently with its own characteristic time scale $1/|\lambda_i|$. Back to the QEA case (27.10), the slow and fast eigenvalues are the roots of $\lambda^2 + (1+K+\varepsilon)\lambda + \varepsilon = 0$. Thus, $\lambda_s = -\varepsilon/(1+K) + O(\varepsilon^2) \approx -0.0313$ and $\lambda_f = -(1+K) + O(\varepsilon) \approx -1.6$. It follows that $\bar{c}_{s0} = \bar{c}_{10} + \bar{c}_{20} = \exp(-\lambda_s t) \approx \exp(-0.0313t)$ and $\bar{c}_{f0} = -\bar{c}_{10}/K + \bar{c}_{20} = \exp(-\lambda_f t) \approx \exp(-1.6t)$, reproducing the results from the perturbation method. The slow mode is the dominant one over much of the time period since the fast mode dies out rapidly during the transient period en route to the quasi-equilibrated state.

To recapitulate, suppose that λ_j 's are such that $|\lambda_1|, |\lambda_2|, \dots, |\lambda_k| \gg |\lambda_{k+1}|, |\lambda_{k+2}|, \dots, |\lambda_{N_s}|$ and we are interested only in events on time scales longer than $1/|\lambda_k|$. Then, dimensionality (or order) reduction is achieved by weeding out those fast, relaxed modes and projecting the system to a common $(N_s - k)$ dimensional subspace. This subspace, associated with slow time scales, is spanned by eigenvectors $\mathbf{x}_{k+1}, \mathbf{x}_{k+2}, \dots, \mathbf{x}_{N_s}$ as follows

$$\bar{\mathbf{c}} = \sum_{j=k+1}^{N_s} \bar{c}_{j,f} \exp(\lambda_j t) \mathbf{x}_j \quad t \gg \frac{1}{|\lambda_k|}. \quad (27.18)$$

Relaxing those fast modes provides algebraic relations among species, which can be substituted into the slow equations that govern the movement toward the equilibrium point. This linear analysis also forms the basis for attacking certain nonlinear systems through linearization and decoupling [27.62–64].

For more complicated situations, the system time scales vary with time. No clear distinction between fast and slow modes can be made. To circumvent the problem, a so-called computational singular perturbation (CSP) scheme has been developed [27.65]. The eigenvectors and associated adjoint eigenvectors are computed locally at any time. The CSP algorithm

then minimizes local mode coupling/mixing by deriving a progressively more *intelligent* set of basis vectors from any reasonable set of initial trial basis vectors. This is done on-the-fly as reactions proceed by using a recursive refinement procedure. The approach can distinguish fast and slow modes and account for the boundary-layer effect.

27.3.4 Projective Transformation

The approach here is to lump reacting species into a smaller number of pseudospecies through a linear transformation of the N_s -tuple vector \mathbf{c} into an \hat{N}_s -tuple vector $\hat{\mathbf{c}}$ ($\hat{N}_s < N_s$) with an $\hat{N}_s \times N_s$ constant matrix \mathbf{M} of the rank \hat{N}_s , that is,

$$\hat{\mathbf{c}} = \mathbf{M}\mathbf{c}. \quad (27.19)$$

Thus, the original N_s -dimensional space is projected onto a smaller \hat{N}_s -dimensional space. For first-order reaction system represented by $d\mathbf{c}/dt = \mathbf{K}\mathbf{c}$, the dynamics is dictated by the eigenvalues λ_i and eigenvectors \mathbf{x}_i of \mathbf{K} . The system is said to be exactly lumpable by the lumping matrix \mathbf{M} if an $\hat{N}_s \times \hat{N}_s$ matrix $\hat{\mathbf{K}}$ exists such that [27.66]

$$\frac{d\hat{\mathbf{c}}}{dt} = \hat{\mathbf{K}}\hat{\mathbf{c}}. \quad (27.20)$$

This is achievable if and only if

$$\mathbf{M}\mathbf{K} = \hat{\mathbf{K}}\mathbf{M}. \quad (27.21)$$

The consequence of the lumpability on the system's eigenspace is that the vector $\mathbf{M}\mathbf{x}_i$ either vanishes or is an eigenvector of $\hat{\mathbf{K}}$ with the same eigenvalue λ_i of \mathbf{K} , that is,

$$\mathbf{M}\mathbf{x}_i = \mathbf{0} \quad \text{or} \quad \hat{\mathbf{K}}(\mathbf{M}\mathbf{x}_i) = \lambda_i(\mathbf{M}\mathbf{x}_i). \quad (27.22)$$

The matrix $\hat{\mathbf{K}}$ has only \hat{N}_s eigenvectors derived from \mathbf{x}_i , $\hat{\mathbf{x}}_i = \mathbf{M}\mathbf{x}_i$. Thus, lumping amounts to crossing out some eigenvectors of \mathbf{K} , suggesting some degree of system decoupling. The fact that $\hat{N}_s < N_s$ means that we are solving an *underdetermined* problem. Finding $\hat{\mathbf{K}}$ from given \mathbf{M} and \mathbf{K} amounts to solving an optimization problem involving minimizing $\|\mathbf{M}\mathbf{K} - \hat{\mathbf{K}}\mathbf{M}\|^2$. A least-squares solution of (27.21) gives

$$\hat{\mathbf{K}} = \mathbf{M}\mathbf{K}\mathbf{M}^T (\mathbf{M}\mathbf{M}^T)^{-1}. \quad (27.23)$$

Determination of Lumping Matrices

\mathbf{K} defines the adjoint eigenvalue problem $\mathbf{K}^T \underline{x}_i = \lambda_i \underline{x}_i$. Transposing (27.21) gives

$$\mathbf{K}^T \mathbf{M}^T = \mathbf{M}^T \hat{\mathbf{K}}^T, \quad (27.24)$$

where \mathbf{M}^T and $\mathbf{M}^T \hat{\mathbf{K}}^T$ are both $N_s \times \hat{N}_s$ matrices. Equation (27.24) says that the mapping of \mathbf{K}^T on \mathbf{M}^T is to produce a matrix that still remains in the same vector space. The vector space represented by \mathbf{M}^T is said to be an invariant subspace of \mathbf{K}^T . The simplest \mathbf{K}^T -invariant subspace is the one-dimensional, straight line containing \underline{x}_1 : That $\mathbf{K}^T \underline{x}_1 = \lambda_1 \underline{x}_1$ means any vector $a \underline{x}_1$ (a , a constant) upon mapping by \mathbf{K}^T produces the vector $a \lambda_1 \underline{x}_1$ that remains on the same straight line. Thus, \mathbf{M} can be constructed from any of the invariant subspaces of \mathbf{K}^T . That is to say, \mathbf{M} can be determined from the modal matrix of \mathbf{K}^T , denoted by \mathbf{X} (i.e., $\mathbf{X}^{-1} \mathbf{K}^T \mathbf{X} = \Lambda$). Since $\mathbf{X}^{-1} = \mathbf{X}^T$, \mathbf{M} can also be determined from \mathbf{X}^{-1} . This says that lumping leverages optimization approaches to find the best invariant subspace capturing the essential features of the full system (more on this in Sect. 27.3.5).

Practitioners often perform lumping by summing up the concentrations of chemically similar species with equal weight. This direct sum is a special case of the so-called *proper lumping* [27.66], meaning that each column in \mathbf{M} is a canonical unit vector having a single nonzero entry of unity, for example,

$$\hat{c} = \mathbf{M}c = \begin{bmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} c. \quad (27.25)$$

For proper lumping, a *cluster analysis* can be used to determine $\hat{\mathbf{K}}$, which is based on an invariant response principle [27.67]. A mixture with innumerable components can be practically treated as a continuum (more on this later); the counterpart of (27.20) is available for continuous mixtures [27.68].

For perspective, let us return to the reaction system shown in (27.10) and (27.11). To leading orders, the eigenvectors of \mathbf{K}^T are $\underline{x}_{s0} [1, 1]^T$ and $\underline{x}_{f0} = [-1/K, 1]^T = [-1.67, 1]^T$. These approximate eigenvectors lead to the following lumping matrices: $\mathbf{M}_s = [1, 1]$ and $\mathbf{M}_f = [-1.67, 1]$, with the corresponding lumped species $\hat{c}_{s0} = c_1 + c_2$ and $\hat{c}_{f0} = -1.67c_1 + c_2$. The associated lumped rate constants can be calculated from (27.23). The resulting lumped models are

$$\frac{d\hat{c}_{s0}}{dt} = -0.031\hat{c}_{s0}, \quad \frac{d\hat{c}_{f0}}{dt} = -1.619\hat{c}_{f0}. \quad (27.26)$$

The trajectories in Fig. 27.8 are calculated from (27.26) for the same initial conditions as those for

Fig. 27.8 Reaction trajectories calculated from lumped and full model for the reaction in (27.10) with different initial compositions. $k_1 = 1$, $k_2 = 0.6$, and $k_3 = 0.05$

Fig. 27.7. After a fast transient (horizontal trajectories), the system moves along a common one-dimensional vertical line, which is an exponentially attracting invariance subspace. As expected, the projective transformation method automatically decouples the system into two independent modes.

It must be noted that the lumped state variable \hat{c} in general has no clear physical meaning. This is especially true of large-scale reaction systems. In certain situations, one probably can gain physical insights from the weights (or coefficients) of the linear combination for a lumped variable. One may also be able to attach some physical meaning to \hat{c} by imposing a priori constraints on the lumping matrix. The caveat is that the accuracy requirement for the lumped model may have to be relaxed.

An example of the projective transformation approach is the reduction of a 10-lump FCC model to a 5-lump model with virtually the same predictive power for the product slate [27.69]. If gasoline is the only unlumped species, then three lumps suffice. Another example has to do with *nonane reforming*; the number of lumps can be reduced from 14 to 7 or possibly to 5 [27.70].

Approximate Lumping

Approximate lumping aims to minimize some measures of inconsistencies between the lumped and full system dynamics. Defining a lumping error $e(t) = \mathbf{M}c(t) - \hat{c}(t)$, one obtains $de(t)/dt = \hat{\mathbf{K}}e - (\hat{\mathbf{K}}\mathbf{M} - \mathbf{M}\mathbf{K})c$ implying $de/dt = \hat{\mathbf{K}}e(t)$ if $\mathbf{M}\mathbf{K} = \hat{\mathbf{K}}\mathbf{M}$. Thus, if $\hat{c}(0) = \mathbf{M}c(0)$, then $e(t) = 0$ for all t . This means that the reaction

trajectories for all initial conditions, upon projection onto a common subspace, are bunched together to lie within the subspace for all t . On the other hand, if $\hat{c}(0) \neq \mathbf{M}\mathbf{c}(0)$, $\mathbf{e}(t)$ asymptotes rapidly to zero. In this case, exact lumping is achieved asymptotically. If $\mathbf{M}\mathbf{K} \neq \hat{\mathbf{K}}\mathbf{M}$, one may choose \mathbf{M} such that some components of \mathbf{e} are zero and the nonzero components vanish quickly.

For most practical applications, $\mathbf{M}\mathbf{K} \neq \hat{\mathbf{K}}\mathbf{M}$. It is thus important to develop approximate lumping schemes that make $\mathbf{e}(t)$ as close to $\mathbf{0}$ as possible for all t [27.71, 72]. The part of system dynamics not projected onto the invariant subspace can be characterized by the error matrix $\mathbf{E} = \mathbf{M}\mathbf{K} - \hat{\mathbf{K}}\mathbf{M}$. Upper bounds on the maximum error for all t among all \hat{c}_i have been developed [27.71].

Nonlinear Kinetics

Nonlinear processes can be notoriously sensitive to initial conditions. The system represented by (27.9) is exactly lumpable by \mathbf{M} if an \hat{N}_s -dimensional system of the form $d\hat{\mathbf{c}}/dt = \hat{\mathbf{f}}(\hat{\mathbf{c}})$ can be found [27.73–76]. To realize this, the system must have some degree of *partial linearity* related to the properties of the Jacobian matrix $\mathbf{J}(\mathbf{c})$. Specifically, exact lumping can be achieved for the whole N_s -dimensional composition space if $\mathbf{J}^T(\mathbf{c})$ has nontrivial fixed (\mathbf{c} independent) invariant subspaces represented by \mathbf{M} . If exact lumping is desired only for a subdomain Ω of the composition space, then an additional necessary and sufficient condition is needed, namely that for any \mathbf{c} in Ω , the corresponding eigenvalues for $\mathbf{J}^T(\mathbf{c})$ and $\mathbf{J}^T(\overline{\mathbf{M}}\mathbf{M}\mathbf{c})$ are equal. $\overline{\mathbf{M}}$ is one of the generalized inverses of \mathbf{M} satisfying $\overline{\mathbf{M}}\mathbf{M} = \mathbf{I}_{\hat{N}_s}$, the \hat{N}_s -dimensional identity matrix. And there exists at least one point \mathbf{c}_o in Ω such that $\mathbf{c}_o = \overline{\mathbf{M}}\mathbf{M}\mathbf{c}_o$. The invariance of the eigenvalues can also be represented by $\mathbf{M}\mathbf{J}(\mathbf{c}) = \mathbf{M}\mathbf{J}(\overline{\mathbf{M}}\mathbf{M}\mathbf{c})$. The lumped system corresponding to (27.9) is

$$\frac{d\hat{\mathbf{c}}}{dt} = \hat{\mathbf{f}}(\hat{\mathbf{c}}) = \mathbf{M}\mathbf{f}(\overline{\mathbf{M}}\hat{\mathbf{c}}). \quad (27.27)$$

Whether or not a system is exactly lumpable depends on \mathbf{f} and \mathbf{M} . The number of the invariant subspaces is finite, but the number of the lumping matrices is infinite. The nonuniqueness of the lumping matrix does not affect the form of the lumped models. With the exception of first-order reaction mixtures, not all of the $\mathbf{J}^T(\mathbf{c})$ -invariant subspaces can be used to construct \mathbf{M} . Some of the resultant lumped kinetic equations may have different forms than the full system. Discussions on the determination of lumping matrices and nonlinear projective transformation can be found elsewhere [27.77–79].

27.3.5 Mathematical Programming

This section is about a computational optimization approach, based on the very fact that dimension reduction is essentially a matter of optimally reducing the number of reactions, reacting species, or a combination of the two. What follows is an illustrative example of reducing the number of reactions for a full kinetic model with N_r reactions in an isothermal plug flow reactor (PFR) or a batch reactor. The objective is to obtain a reduced model having the fewest number of reactions while retaining the salient features of the full model. The approach centers on an *on-off* binary variable ψ_i that signifies the presence ($\psi_i = 1$) or absence ($\psi_i = 0$) of a particular reaction. In this framework, the dimension reduction is cast as the following integer optimization problem [27.80]

$$\min_{\psi \in \Lambda^{N_r}} \sum_{j=1}^{N_r} \psi_j, \quad (27.28)$$

subjected to the constraints of satisfying required mass conservation and accuracy (as measured by ε shown below), that is,

$$J = \left[\sum_i \int_0^t \left(\frac{c_i^{\text{reduced}}(t) - c_i^{\text{full}}(t)}{c_i^{\text{full}}} \right)^2 dt \right]^{1/2} \leq \varepsilon \quad (27.29)$$

and

$$\begin{aligned} \frac{dc_i}{dt} &= \sum_{j=1}^{N_r} \psi_j (\overleftarrow{v}_{ij} - \overrightarrow{v}_{ij}) \\ &\times \left(\overrightarrow{k}_j \prod_{i=1}^{N_s} c_i^{\overrightarrow{v}_{ij}} - \overleftarrow{k}_j \prod_{i=1}^{N_s} c_i^{\overleftarrow{v}_{ij}} \right), \\ i &= 1, \dots, N_s, \end{aligned} \quad (27.30)$$

where v_{ij} , N_s , and Λ^{N_r} are stoichiometric coefficients, number of species, and the set formed by all possible N_r 's, respectively. In the same vein, the problem can be formulated as that of reducing the number of species. Solving the species reduction problem is in principle less demanding computationally because $N_s < N_r$ in most situations of interest.

Equations (27.28)–(27.30) define a class of optimization-integer-decision problems, which can be solved by means of Branch and Bound algorithms [27.80] or genetic algorithm [27.81]. One must be mindful of the fact that the resulting reduced model may be valid over only a limited region of the com-

position space. Hence, what is needed is an in-situ adaptive approach that performs mechanism reduction over different domains of the composition space as needed [27.82, 83].

Mentions should be made of another computational technique for dimension contraction, the so-called in-

trinsic low dimensional manifold method [27.83, 84]. It computes the low dimensional manifolds on which the slow chemistry evolves in the composition space and then tabulates the computed results in a lookup table. The table is incorporated into a CFD code for reactor simulation.

27.4 Kinetics–Hydrodynamics Tradeoff

As mentioned earlier, process modeling requires balancing kinetics and hydrodynamics. In this section, we use FCC as an illustrative example. Recent developments in FCC modeling fall into two broad categories. One is the one-dimensional, homogeneous plug-flow model [27.1, 2, 85], which can accommodate a large number of reactions and hence make it possible to develop a composition-based model using, say, the SOL approach. Such kinetics-dominated models pay little attention to hydrodynamic effects that affect the reaction time and the local catalyst-to-oil (CTO) ratio. In other words, the momentum conservation equations are either simplistic or ignored. Another approach is

the CFD-based models [27.86–89], which involves numerical solution of partial differential equations for multi-dimensional flow systems. Here, the allowable number of chemical reactions is necessarily small even with today's powerful computers. The CFD-dominated models would not be able to portray the complexities and subtleties of the underlying chemistry and catalysis. Nor do they enable refiners to manage FCC feedstocks and products at a molecular level.

Recently, attempts have been made to develop a hybrid approach aimed at striking a proper balance between the two aforementioned *asymptotic* approaches [27.90–93]. The tactic is to develop a phe-

Fig. 27.9 FCC feed injection zone with four fan-shaped nozzles

nomenological model of momentum transfer without invoking the CFD. Also, there is a need to gain a predictive understanding of *entrance cracking* via the development of a quantitative treatment of the feed injection zone where temperature and catalyst activity/concentration are highest. These considerations led to the construction of one-dimensional heterogeneous riser models accounting for catalyst acceleration, catalyst–catalyst collision force, catalyst–gas interfacial force, and interactions of multiple feed injectors. What follows is an example.

A recent modeling study considers four symmetric, overlapping fan-shaped atomizing nozzles [27.93]. This type of nozzles provides a wide and fairly uniform feed coverage across the catalyst stream, thus, starting the vapor-phase cracking as early as possible [27.94, 95]. As Fig. 27.9 shows, a reactive, vaporizing spray will penetrate into the *territory* of another spray. The flows of gas and catalyst are accelerated by vaporization and cracking, both of which are driven by droplet–catalyst collision. The cracking reactions are described by the four-lump model shown in Fig. 27.1 because of the availability of commercial data [27.96].

Temperature and the CTO ratio are the dominant cracking intensity indicators and they behave similarly. The model divides the system into two zones: an entrance (feed injection) zone and a downstream fully developed riser zone. Inside the entrance zone, both indicators are very high and change rapidly, resulting in an immediate, sharp rise in VGO conversion. Outside the entrance zone, both indicators are low and become slowly varying, giving rise to a sluggish increase in VGO conversion. These two zones have very different physicochemical characteristics and need to be modeled separately. The behavior of the entrance zone sets the initial condition for the downstream zone. Here, an analogy may be loosely made with the boundary-layer theory in transport phenomena. The two-zone model

Fig. 27.10 Riser profiles of gasoline yield and VGO conversion, plant data versus model predictions. (After [27.93])

can accommodate a large number of reactions as each zone is described by a set of first-order ordinary differential equations.

The commercial data of *Derouin et al.* [27.96] indicate that the first 10% of the riser height accounts for more than 65% of the VGO conversion over the entire riser, signifying the dominance of *entrance cracking* and hence the need of predictive calculations for this region [27.97]. As detailed elsewhere [27.93], the two-zone model satisfactorily predicts both the VGO conversion and gasoline yield, as shown in Fig. 27.10.

In summary, the underlying chemistry and physics of the FCC process are such that the process has an inherent two-zone character. A key feature of the heterogeneous model is the consideration of catalyst–fluid interfacial momentum transfer. The model is computationally simple. As such, this model can be used for molecular management, on-line control, and real-time optimization. It is relevant to point out that the complexity of designing controller and the difficulty in its implementation scale with the complexity of the process model.

27.5 Total Lumping: Continuum Approximation

Total lumping is about determining the aggregate behavior and overall kinetics of a large number of reactions. As mentioned, in HDS, only the reduction of total sulfur really matters. The same is true of HDN and hydrodemetallation. FCC is designed primarily for the deep conversion of high-boiling ($> 340^\circ\text{C}$) to low-boiling ($< 340^\circ\text{C}$) fractions.

The problem of finding the aggregate behavior and overall, lumped kinetics of a large number of reactions can be stated as follows. Let $c_i(t)$ ($i = 1, 2, \dots, N \gg$

1) be the concentration of reactant i with rate constant k_i and $C(t) = \sum_i c_i$ be the total concentration of all reactants at time t . The concentration of reactant i in the feed is $c_{if} = c_i(0)$. Each reactant disappears at its own rate r_i . The aim is to predict the dependence of $C(t)$ on feed properties and reactor type. It is also of interest to know if an overall, lumped kinetics $\bar{r}(C)$ can be found for the large mixture as a whole [27.98]. Since petroleum feedstocks have an astronomically large number of species, a mathemati-

cally convenient approach is to treat the feedstock as a continuum [27.99–102]. That is, the sum \sum_i is replaced by an integral over a distribution function, which is parameterized by a small number of constants. In practice, the chemical–analytical characterization data for hydrocarbon mixtures can be obtained as a continuous function of such macroscopic properties as boiling point, molecular weight, molecular polarity, or hydrogen deficiency. Figure 27.11 shows the sulfur content of a gas oil over its boiling range [27.103]. In some refining processes, a feedstock’s reactivity is closely related to boiling point (or molecular size) and/or hydrogen deficiency.

Examples of continuum process models can be found elsewhere [27.104–106]. The continuum approach can also be used to solve an inverse problem: determining feedstock reactivity–composition spectra from the measured $C(t)$ [27.107]. When the total number of species N is very large, the total reactant concentration is approximated by the following integral [27.102]

$$C(t) = \int_0^{\infty} c(k, t) D(k) dk. \quad (27.31)$$

Here, each reactant is labeled by its reactivity k . The concentration of reactant k is $c(k, t)$. The slice $D(k)dk$ is the total number of reactant types with rate constant between k and $k + dk$. Thus, D is a reactant-type distribution function and acts as the Jacobian of the

Fig. 27.11 Feed sulfur concentration as a function of boiling point. (After [27.103])

discrete-to-continuous (i -to- k) coordinate transformation. The construction of $D(k)$ requires analytical measurements [27.108, 109] combined with kinetics experiments using representative model compounds [27.110, 111]. A power-law expression for $D(k)$ is used in hydrocracking [27.104].

27.5.1 Overall Lumped Kinetics

For first-order reactions in a PFR,

$$c(k, t) = c_f(k) \exp(-kt)$$

and

$$C(t) = \int_0^{\infty} h(k) \exp(-kt) dk,$$

where $h(k) = D(k)c_f(k)$. To describe a wide variety of feed properties with just two parameters, *Aris* used the gamma distribution [27.100]

$$h(k) = \frac{\gamma^\gamma (k/\bar{k})^{\gamma-1} \exp(-\gamma k/\bar{k})}{\bar{k} \Gamma(\gamma)}, \quad \gamma > 0, \quad (27.32)$$

where Γ is the gamma function and γ a feed quality index; the smaller the γ value, the more refractory the feed. Substituting (27.32) into (27.31) gives

$$C(t) = \frac{1}{(1 + \bar{k}t/\gamma)^\gamma}. \quad (27.33)$$

This implies that $dC/dt = -\bar{r}(C) = -\bar{k}C^{\bar{n}}$ an overall reaction order $\bar{n} = 1 + 1/\gamma > 1$ with a rate constant \bar{k} .

For the design and development of hydrocarbon conversion catalysts and processes, it is essential to determine $C(t)$ and $\bar{r}(C)$ a priori, which requires complete information on feed properties and reactivity spectra. In practice, however, practitioners do not usually have the luxury of fully characterizing hydrocarbon feedstocks. A pragmatic approach is to find $C(t)$ and $\bar{r}(C)$ at high conversions (or long time) for partially characterized feedstocks [27.112–115]. Such an asymptotic approach provides a simple, unifying framework for gaining insights into a mixture’s behavior and explaining many perplexing behaviors observed in hydrocarbon processing [27.98]. Developing long-time asymptotic kinetics is commensurate with the growing need of refiners to achieve deep conversions, which is mainly driven by the ever-increasing demand for ultra-clean fuels. For example, the diesel sulfur specifications in a few countries

Fig. 27.12 Reactor volumes and reactor volume ratio versus percent conversion for first-order and second-order reactions

are now set at 10–15 ppmw. More countries will certainly follow suit in the future. The sulfur content of middle distillates (200–370 °C boiling range) typically ranges between 1 and 3 wt%. Desulfurizing a distillate from 1 wt% sulfur to 10 ppmw means an HDS level of 99.9%. A similar situation exists in hydrocracking that requires ultra-deep HDN. This may incur huge capital outlays because reactor volume is extremely sensitive to conversion at high conversions. This is shown in Fig. 27.12 for the first- and second-order reactions in an isothermal plug-flow reactor. Also shown is the reactor volume ratio for the two reactions versus percent conversion, which illustrates the importance of knowing the deep-conversion kinetics. In exploring or developing new catalysts for hydroprocessing, competing catalysts should be evaluated at high conversions.

27.5.2 Long-Time Asymptotic Kinetics

Developing long-time asymptotic kinetics can mostly be done with partially characterized feedstocks. Intuitively, one may expect that the feedstock's long-time behavior is governed by the most refractory part of the feed. Hence, we expand $D(k)$ and $c_f(k)$ as $D(k) \sim d_o k^\mu$ and $c_f(k) \sim c_o k^\nu$ near $k = 0$. Alternatively, $h(k) \sim h_o k^{\gamma-1}$, where $h_o = c_o d_o$ and $\gamma \equiv \mu + \nu + 1$. For the irreversible first-order reactions, $C(t) \sim h_o \Gamma(\gamma) / t^\gamma$ at large t , yielding an asymptotic (subscript a) overall kinetics $\bar{r}_a = \gamma [h_o \Gamma(\gamma)]^{-1/\gamma} C^{\bar{n}_a}$, where the asymptotic reaction order $\bar{n}_a = 1 + 1/\gamma > 1$ [27.112, 113]. *Ho* and *White* [27.116] determined the asymptotic power-law kinetics for deep HDS of a light cycle oil over three different catalysts, with $\bar{n}_a = 2.5$. *Sie* found that $\bar{n}_a = 2$ for both gas oil and prehy-

drotreated gas oil over a sulfided CoMo/Al₂O₃ catalyst [27.117].

Hydroprocessing catalyst and process exploratory studies involve rapid evaluation of various experimental catalysts with simple overall kinetics. For such studies, the continuum approach developed if–then rules that allow researchers to explain and predict the kinetic behaviors of reaction mixtures with incomplete feed information. Some examples include the following:

- The overall reaction order for HDS is higher than that for HDN.
- High-activity catalysts give rise to lower overall reaction order than low-activity catalysts.
- Refractory feeds show higher overall order than reactive ones.
- The overall HDS order decreases with increasing temperature.
- The overall order for plug flow reactors is higher than that for stirred tank reactors.
- Reactors with and without recycle in general have different overall kinetics.

Useful as it may be, the long-time asymptotic analysis based on the continuum theory has its limitation in some situations [27.116]. Consider first-order reactions in a discrete mixture as an example. After a sufficiently long time, one expects that the mixture behaves as if there were only one surviving reactant decaying exponentially because the concentrations of all other species are exponentially smaller. However, the corresponding continuous mixture at large times ($t \rightarrow \infty$) decays asymptotically as a second-order reaction [27.112, 113]. This apparent paradox arises from the fact that the long-time asymptotic kinetics is valid only over an intermediate time frame – one in which time is large enough for the asymptotic kinetics to be valid (and the mixture's behavior no longer depends on the details of feed properties), but short enough for the mixture remaining to be sufficiently crowded (hence second-order kinetics) [27.116]. Such intermediate asymptotics are common in engineering science [27.118].

Thus, there is a need to determine the condition under which the continuum theory and its long-time limit are both valid. The issue then boils down to the reaction mixture's granularity. A sufficiently fine granularity ensures the validity of the continuum approximation at long times. For first-order reactions, the condition is $1/\kappa \ll t \ll 1/\Delta$, where κ is a characteristic rate constant for a moderately refractory species and Δ is the maximum difference between the rate constants for two species whose reactivities are adjacent to each other. In many situations of practical interest, the above condition is not stringent [27.116]. For nonfirst-order

reactions, the condition becomes [27.119]

$$\frac{1}{\kappa} \ll t \ll \left(\frac{\kappa}{\Delta}\right)^y \frac{1}{\kappa} \quad \text{or} \quad \left(\frac{\kappa}{\Delta}\right)^y \gg 1. \quad (27.34)$$

The exponent y depends on reaction kinetics and feed properties. For irreversible first-order reactions, reversible first-order reactions, and bimolecular second-order reactions, $y = 1, 2,$ and $3,$ respectively.

For high-order reactions, the continuum approximation can be valid for arbitrarily long time. The large- t behavior of a reaction mixture with power-law kinetics is not necessarily dominated by the most refractory species. It can be dominated by species of intermediate reactivity, moderately refractory species, or all species. Zeroth- and certain fractional-order reactions are incompatible with continuum description [27.119]. The overall kinetics obtained from a PFR cannot be carried over to a continuous stirred tank reactor (CSTR). In general, backmixing widens the range of validity [27.120].

27.5.3 Reactions in CSTR

An advantage of the asymptotic analysis is that in many cases one needs only local information ($k \approx 0$) to determine the overall rate in a PFR. This is not necessarily true for reactions taking place in a CSTR. For first-order reactions in a CSTR, $c(k, t) = c_f(k)/(1+kt)$, hence $c(k, t) = O(1/t)$ at large t . $C(t)$ is of the form

$$C(t) = \int_0^{\infty} \frac{h(k)dk}{1+kt}. \quad (27.35)$$

Compared to the PFR, the system is more complex because for each reactant, there is an exponential distribution of residence times among all the molecules of that reactant. In this situation, the overall kinetics $\bar{\tau}_a(C)$ admits three possibilities [27.115]. The case $\gamma < 1$ (refractory feeds) is similar to the PFR in that the mixture's long-time behavior is dominated by the most refractory species and follows a power law: $C = O(1/t^\gamma)$ and $\bar{\tau}_a(C) \sim C^{1/\gamma}$ at large t . For $\gamma > 1$, the feed comprises primarily reactive species. Then, $\bar{n}_a = 1$ and $C \sim I/t$ at large t , with $I \equiv \int k^{-1}h(k)dk$. Hence, the mixture's long-time behavior is governed by all species.

The situation is very different for the transition case $\gamma = 1$, which gives rise to $C \propto \ln t/t$. Hence, the decay of C , although governed by the refractory species, is accelerated by the reactive species. The instantaneous asymptotic order $\bar{n}_a = d \ln \bar{\tau}_a / d \ln C$ decreases slowly with conversion, consistent with the experiment [27.121]. At high conversions, $1 < \bar{n}_a =$

Table 27.1 Asymptotic kinetics for PFR and CSTR

	PFR		CSTR	
	$\gamma > 0$	$\gamma > 1$	$\gamma < 1$	$\gamma = 1$
$\bar{\tau}_a(C) \sim$	$C^{1+1/\gamma}$	C	$C^{1/\gamma}$	$\frac{C}{ \ln C }$

$1 + 1/|\ln C| < 2$. Finally, \bar{n}_a for the PFR is always higher than that for the CSTR. The CSTR's size is larger than PFR's size at constant conversion [27.115].

The overall kinetics represents an averaging over the reactivity and composition spectra. Such averaging should be different in reactors with different residence time distributions. In consequence, the overall kinetics obtained from the PFR may not be directly carried over to the CSTR. It is therefore important to develop if-then guidelines for translating data from one reactor type to another. Table 27.1 is one such example. The asymptotic overall order for the PFR is higher than that for the CSTR.

Summarizing, the effect of lumping greatly manifests itself for the CSTR through the interactions between the reactivity/concentration spectra and the exponential residence time distribution. Although all reactants are slowed down compared to those in the PFR case, the fast-reacting ones are hampered more than the slow-reacting ones. Consequently, the disparities among the species become smaller, making the mixture more homogeneous. A relatively homogeneous feed (high γ) can be further homogenized in the CSTR to such an extent that its long-time behavior approaches that of a single reactant.

It has been observed experimentally that the overall kinetics of HDS, HDN, and hydrocracking of a coker gas oil are all first order in the CSTR free of mass transfer effects [27.122]. An overall order greater than one has been reported for HDS in a CSTR [27.123]. In the hydrodemetallization of a heavy residual oil that can be described by the gamma distribution with $\gamma = 1$, an overall order of two was observed with the PFR. For the CSTR, $C(t) = \exp(1/t)E_i(1/t)/t$, where E_i is the exponential integral, which can be fitted by a 1.5-order power law over the 20–80% conversion range [27.124].

27.5.4 Summary of Asymptotic Analysis

It is helpful at this point to wrap up the results of the asymptotic analysis. The preceding sections show that the asymptotic kinetics can be quite complex (e.g., 21 possibilities for reversible first-order reactions in a CSTR). Yet, the decay of $C(t)$ at suitably large t , for a variety of kinetics (n -th order, Langmuir-Hinshelwood, bimolecular reactions, etc.) and regardless of reactor type (PFR and CSTR), takes one of

following forms [27.114, 115, 118]

$$C(t) \sim \frac{1}{t^z}, \quad C(t) \sim \frac{\ln t}{t^z},$$

$$\text{or } C(t) \sim \frac{\exp(-\beta t)}{t^z} \quad \text{at large } t. \quad (27.36)$$

The most common behavior by far is the simple power law $C = O(1/t^z)$ for large t . The occurrence of $C = O(e^{-\beta t}/t^z)$ is restricted to first-order reversible reactions in a PFR. The parameters z and β are determined by (i) the most refractory species, (ii) all species, or (iii) species of intermediate reactivity.

27.5.5 One-Parameter Model

The foregoing asymptotic analysis indicates that in most cases $C(t) \sim \sigma/t^z$ at large t . This behavior gives rise to a one-parameter model that exactly calculates or estimates $C(t)$ for all t . The model is of the form [27.125]

$$C_q(t) = \frac{1}{(1 + t^z q / \sigma^q)^{1/q}} \quad q > 0, \quad (27.37)$$

where q is the model parameter determined experimentally at an intermediate time (say, between 45% and 60% conversions). The best result is obtained by measuring C at $t = t^* = \sigma^{1/z}$. Once $C(t^*)$ is known, then $q = -\ln 2 / [\ln C(t^*)]$. When $C(t^*)$ is not known, one may find q by nonlinear regression over a range of intermediate conversions. Numerical experiments show that

27.6 Conclusions

The past three decades have seen much progress on modeling of large-scale reaction systems. This is especially true for petroleum-refining processes. The molecule-based, bottom-up modeling approach is becoming increasingly important. Various useful QSSRs have been developed, some of which are based on computational chemistry. The continuum approximation has produced many useful results and guidelines. A recent development has been the application of mathematical programming to model reduction. It holds the promise of implementing in-situ adaptive algorithms for dimension reduction in different subdomains of the composition space.

Much remains to be done, however. One of the most challenging areas is to incorporate catalyst properties into kinetic models. For crystalline catalysts with well-characterized structures (e.g., zeolites), some limited progress has been made, but this is far from being the

the model has a remarkable ability to mimic the mixture behavior. In fact, if the overall kinetics are inherently of a power-law structure (e.g., gamma feeds with first-order reactions in a PFR), (27.37) mirrors $C(t)$ exactly by simply setting $q = 1/z$.

If the overall kinetics do not have an inherent power-law structure, it still pays to let $q = 1/z$: It results in a tight upper bound on C , or C_u , for all t ,

$$C(t) \leq C_u(t) \equiv \frac{1}{(1 + t/\sigma^{1/z})^z}. \quad (27.38)$$

C_u itself satisfies the power law

$$\frac{dC_u}{dt} = -z\sigma^{-1/z} C_u^{1+1/z} \quad (27.39)$$

and can be used as a tight, conservative estimate of $C(t)$. An accurate prediction needs an additional data point on $C(t)$ at an intermediate conversion by virtue of (27.37). Equation (27.38) suggests that $\bar{r}_a(C)$ in most practical situations can be described by a power law for nongamma feeds.

Both z and σ can be determined from information on the most refractory fraction of the feed. Thus, in developing process kinetics, in many cases, it is not necessary to characterize the whole feed. Instead, characterizing only the most refractory fraction and running the reaction at an intermediate conversion may suffice. In practice, it is easier to characterize the refractory species. After all, these species survive the reaction.

case for structurally complex catalysts such as highly disordered metal sulfides.

Extending catalyst life is an integral part of improving existing and developing new refining technologies. It is imperative to develop fundamentals-based model of coke formation, thereby, helping design mitigation means through control of feedstock composition and operating conditions. Coke on catalyst not only decreases activity, but also greatly affects selectivity. To complicate matters, there are many types of coke for a given process chemistry (e.g., FCC and coking). Catalyst deactivation caused by metal sintering or poisoning is also an issue of great concern. Reactor fouling caused by carbonaceous deposit remains an important operation issue in many cases. All these areas are fertile grounds for further modeling research.

The tradeoff between kinetics and hydrodynamics for hydrodynamically complex systems continues

to be a challenge. For instance, to address problems of fluid maldistribution in trickle bed reactors or the feed injection zone at the base of an FCC riser, one is compelled to sacrifice chemistry details. The same is true when one needs to solve control and optimization problems.

To make discovery and development faster and cheaper, many research laboratories have been engaged in developing high-throughput experimentation (HTE)

methodologies. Much effort has been focused on the design and development of parallel miniaturized reactors to which complex reaction mixtures are fed. If the results obtained from miniature-scale apparatus are not scalable, the HTE approach may well create a bottleneck. In order to reap the full benefit of HTE platforms, it is important to develop robust models from HTE units, aiming at extracting fundamental, scale-invariant information.

Refinery-Wide

28. Refinery-Wide Optimization

Dale R. Mudt, Clifford C. Pedersen, Maurice D. Jett, Sriganesh Karur, Blaine McIntyre, Paul R. Robinson

Refinery-wide optimization (RWO) requires integration of several systems – regulatory control, the distributed control system (DCS), the laboratory information management system (LIMS), model-predictive control, online optimization based on rigorous models of individual units and process areas, and refinery planning linear program (LP) software. Project implementation requires communication between refinery personnel – managers, engineers, and operators – and outside modeling experts.

Starting in 1998, refinery-wide optimization was implemented at the Suncor refinery in Sarnia, Ontario, Canada. The model-predictive control system was DMCplus. The rigorous models were developed by Aspen Technology, Inc., using Aspen RT-Opt for conventional equipment, a rigorous hydrocracker model developed jointly by Sun Oil and

AspenTech, and reactor models developed by AspenTech for the Houdry cracking unit (HCC) and a catalytic reformer. Benefits from implementation of an early version of the hydrocracker rigorous model exceeded US\$ 3000 per day.

One reason for writing this chapter is to report on the success of real-time, online refinery-wide optimization (RWO) at Suncor-Sarnia using rigorous process models. Another reason is to show how the same rigorous

models can be used offline to quantify key nonlinear relationships during the evaluation of project ideas, especially those related to the production of clean fuels.

28.1 Overview of Suncor

Suncor operates a 70 000 barrel/day refinery at Sarnia, Ontario, Canada. The refinery processes feeds from the following sources:

- Synthetic crude oil from Suncor's oils sands processing plant at Fort McMurray, Alberta
- Conventional crude oil
- Condensate
- Vacuum gas oil (VGO).

Figure 28.1 presents an outline of the plant, which started operation in 1953. Synthetic crude and conventional crude oil come to the refinery through the inter-provincial pipeline, which runs from Edmonton, Alberta to Sarnia, Ontario. The transit time is about one month. Other crudes are also available from nearby facilities.

The refinery includes the following major process units:

- Crude distillation (CDU) – 2 units
- Vacuum distillation (VDU)
- Houdry catalytic cracking unit (HCC)
- Catalytic reforming (CRU) – 2 units
- Alkylation unit
- Aromatics recovery unit
- Unsaturated gas plant
- Saturated gas plant
- Naphtha hydrotreater
- Diesel/gas oil hydrotreater
- Hydrocracker complex.

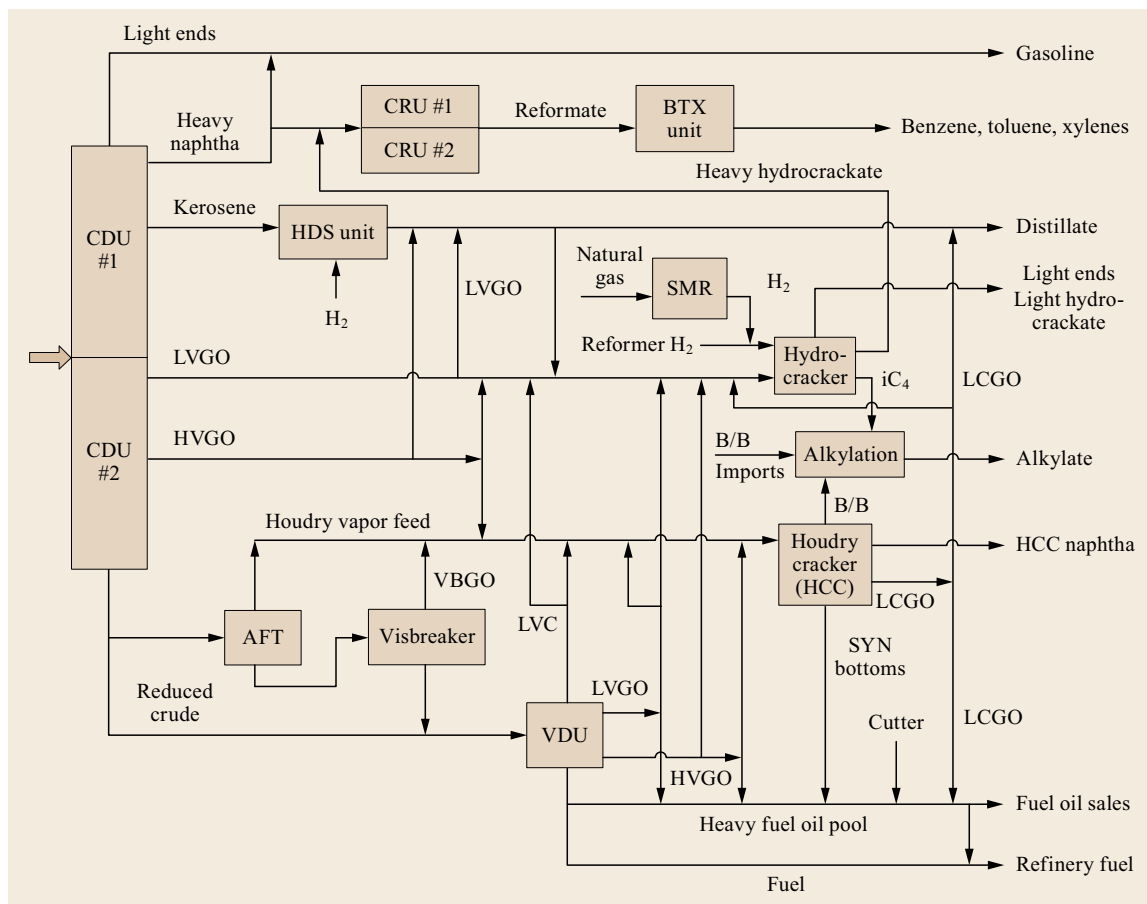

Fig. 28.1 Overview of the Suncor refinery in Sarnia, Ontario

28.2 Refinery-Wide Optimization (RWO)

The refinery-wide optimization (RWO) initiative began in July 1998. Three phases were defined for the project:

- Phase 1: Build a solid and sustainable advanced control and optimization foundation.
- Phase 2: Ensure model consistency between planning, scheduling, and real-time optimization.
- Phase 3: Integrate planning, scheduling, and real-time optimization by linking the optimization models to the refinery LP.

Expected benefits from the RWO initiative included:

- Increased refinery throughput
- Improved refinery yields
- Improved gas oil management

- Improved hydrogen management
- Optimum product recoveries
- Reduced energy costs
- Increased ability to respond to market changes.

Rigorous models for stand-alone units can also provide significant benefits. Previously [28.1], we reported benefits of US\$ 3000 per day (US\$ 0.15 per barrel) for the initial optimizer on the hydrocracking complex; these benefits were in addition to those provided by model-predictive DMC control. For RWO, a revised model based on Aspen Hydrocracker (AHYC) was developed. It included a catalyst deactivation block, which enhanced maintenance turnaround planning by predicting future catalyst activity, product yields and product properties for a variety of assumed feeds and specified operating conditions. This information

Table 28.1 Scope of refinery-wide optimization applications

Plant 1	Scope
Crude and HCC	Preheat train, crude heaters, crude tower, atmospheric flash tower, syn tower, HCC heaters, reactor, kiln, steam coils, air blower, cyclone, main fractionator, unsaturated gas plant
Plant 2	
Crude and vacuum reformer 2 and aromatics	Preheat train, heaters, atmospheric tower, vacuum tower heaters, compressors, pretreater, reactors, flash drums, depropanizer, naphtha splitter, absorber/deethanizer, aromatics complex
Plant 3	
Steam methane reforming (SMR), HYC, gas plant	H ₂ Plant, hydrocracker reactor section, preflash, main tower, absorber/stripper, debutanizer, jet tower, diesel tower, saturated gas plant

Table 28.2 Hardware and software for RWO

Item	Vendor
DCS systems	Honeywell TDC 2000/3000, Foxboro I/A
Online computers	DEC alpha with VMS software
Offline computers	Compaq (Windows NT)
Real-time database	Aspen infoplus, Honeywell PHD
Control software	DMCplus, Aspen IQ
Optimization software	Aspen RT-opt
Refinery LP	Haverly GRTMPS

is also used to impose constraints on daily operation.

The RWO initiative was driven in part by the need to upgrade or replace software applications that were not Y2K compliant. In addition, the project reduced application maintenance costs because the same software versions were used throughout the plant, and because modern control and optimization software is more user-friendly than it was in the 1980s, when Suncor first began implementing model-predictive control and online optimization.

Table 28.1 summarizes the scope of the major RWO applications. A large DMCplus application – 64 manipulated variables (MV) × 16 feed-forward variables (FF) × 168 controlled variables (CV) – controls Plant 1. For Plant 1, the process scope of the controller is equivalent to that of the optimizer, which sends 34 targets to the controller. In Plant 3, separate controllers are used for the hydrogen plant, the hydrocracker (HYC), the HYC gas plant, and low-sulfur diesel (LSD) tower, but a single optimizer sends targets to these controllers.

Table 28.4 Key integration points

Plants 2 (H ₂ from reformer) ⇒ Plant 3 (HYC)
Plants 1, 2, and 3 (reformates and HYC light naphtha) ⇒ Gasoline blender
Plant 3 (HYC heavy naphtha) ⇒ Plant 2 (Reformer 2)
Plant 3 (isobutane) ⇒ Plant 1 (alky feed)

Table 28.3 Integration point categories

Type of integration point	Time scale
Feed-forward information required by the model predictive controllers	Minutes
Steady-state information (inputs to and outputs from) the online optimizers	Hours
Higher level information (inputs to and outputs from) the refinery LP	Daily

The RWO initiative used the hardware and software listed in Table 28.2.

Each optimizer includes an offline version, which is periodically updated with live plant data. Offline models are used to tune and monitor the performance of the optimizers. They can also be used for maintenance planning and design studies.

The success of RWO depended heavily upon proper integration of the separate applications. Integration points fell into three categories (Table 28.3). Intermediate tanks presented special problems in part because they tend to stratify, but mostly because they complicate time-scale issues. For several critical tanks, open-equation models calculate tank compositions on a regular basis – about every 5 min – to provide feed-forward inputs to other optimizers or possibly DMCplus controllers. Special logic is used to compensate for stratification. To date, these tank composition models are performing well.

Other key integration points are shown in Table 28.4.

Integrating the real-time optimizers into Suncor's planning and scheduling methodology will require con-

sistency between the optimizers and the refinery LP in the following areas:

- Yields and product qualities
- Degrees of freedom
- Constraints.

Initially, data were transferred manually between the LP and the optimizers. This was beneficial because

28.3 Rigorous Models for Clean Fuels

As mentioned above, one purpose of this paper is to show how rigorous models can be used offline to quantify key nonlinear process relationships, including those related to manufacturing clean fuels.

At most North American refineries, including Suncor-Sarnia, most of the sulfur in the gasoline pool comes from a catalytic cracking unit. To make low-sulfur gasoline, an Axens Prime-G unit was installed to desulfurize gasoline from the Houdry catalytic cracker (HCC) and visbreaker units. Another option would have been to pretreat all of the HCC feed [28.3].

To summarize, our RWO experience has demonstrated the following:

- Rigorous optimizers provide significant economic benefits.
- Open-equation optimizers can be linked, and linked optimizers can successfully represent nonlinear interactions between process units.
- Aspen FCC (AFCC) (modified) and AHYC provide high-fidelity representations of Suncor's HCC and hydrocracker, respectively. We can conclude that linking AHYC with AFCC will enhance the industry's understanding of FCC feed pretreating, and eventually lead to the operation of FCC-plus-pretreater installations as a single, optimized complex.

28.3.1 Feedstock and Product Characterization

For any rigorous model, success requires detailed, accurate feedstock and product characterizations. For the HCC and hydrocracker, GC/MS, ^1H NMR, ^{13}C NMR, HPLC, and standard American Society for Testing and Measurement (ASTM) methods were used to analyze a battery of feedstock and product samples. The analytical results were used to generate base-case distributions for the components used in the models and to tune reaction kinetics.

In the real world, feedstock properties and product slates are changing continually. In AFCC and AHYC,

the models allowed us to increase the accuracy of LP shift vectors. A recent publication [28.2] describes the benefits of running steady-state models in recursion with Aspen PIMS, a widely used LP program. This method may offer the best of both worlds – the practicality of LP technology augmented by the rigor of nonlinear, unit-specific models.

It was expected that during RWO Phase 3, the transfer of data would be automated.

proprietary feed-adjust models skew the base-case component distribution to match the measured properties of feeds and products.

28.3.2 Aspen FCC Overview

Aspen FCC (AFCC) is an open-equation, flowsheet-based model designed for both online and offline applications. The model is constructed from individual blocks that represent the separate pieces of equipment – riser, standpipe, slide valve, cyclone, transfer line, etc. – found in commercial FCC units. Each building block is generic and can be configured with dimensions corresponding to a given commercial unit (Table 28.5).

A typical FCC unit configuration is presented in Fig. 28.2. The diagram shows a simple version of the actual blocks used to model the feed, feed adjust and preheat systems.

In the riser model, detailed hydraulics and heat effects are captured by linking flow equations to kinetics. The riser model can be configured vertically, horizontally, or at any angle of inclination. Multiple risers can be used. The individual risers can process different feeds or the same feed. In essence, any commercial riser/reactor configuration can be simulated with the modular components of AFCC.

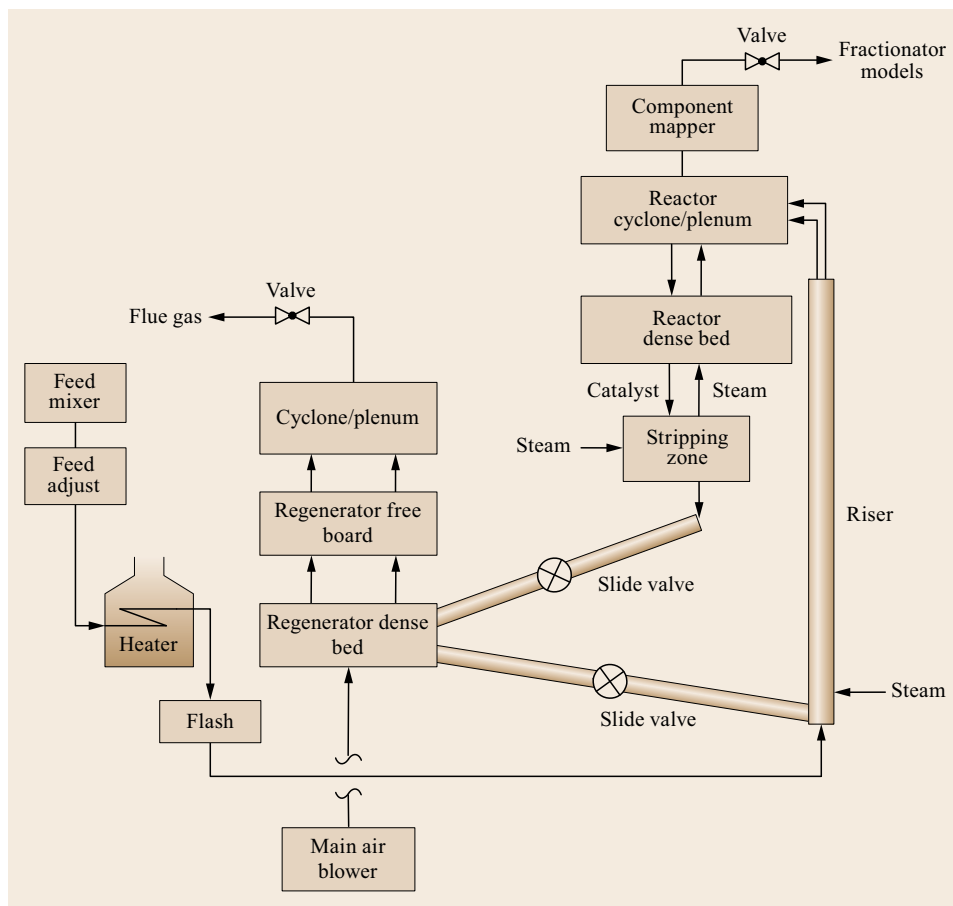

Fig. 28.2 Model components for Aspen FCC (riser/reactor/regenerator)

Hydrocarbon feed and regenerated catalyst models are connected to the inlet of the Riser model. The catalyst-stream model includes the mass flow, temperature, pressure, enthalpy of the catalyst/coke mixture, particle density of the catalyst/coke mixture, coke-on-catalyst weight fraction, and coke composition.

Pressure drop calculations are based on head, acceleration, and frictional effects. Pressure drop through the riser is modeled as a combination of pressure drop due to vapor and pressure drop due to solids. For the vapor, the frictional contribution is based on friction-factor correlations with the Reynolds number. For catalyst flow, frictional contributions are based on correlations for solid-vapor flow in a conduit. Proper prediction of pressure drop along the riser has a significant impact on predicted yields.

The riser model uses vertical or horizontal slip factor correlations (depending on the riser orientation) to determine the differential velocity between the vapor and the solid phases. The slip calculation is critical for determining bulk density profiles, which govern the path dependence of cracking profiles.

As coke is differentially produced along the length of the riser, additional solids are differentially transferred from the vapor to the catalyst surface. The physical effects of this transfer are described by continuity equations. The molar heat of adsorption for coke laydown is included in the heat balance. The heat of coke desorption is calculated in the regenerator model. Slip-factor correlations are based on fully developed flow. The model applies a correction for the turbulent, high-slip zone at the inlet of the riser.

The riser model effluent is connected to the reactor vessel models. These include the reactor dilute phase, the dense phase, and the cyclone system, which represents the segregation of effluent vapors and catalyst. The cyclone model performs a two-phase, loading-based ΔP calculation, for which cyclone inlet and body diameters are used. The cyclone model can be configured with one or two riser inlet ports.

The reactor dilute phase model is identical to the riser model without entry-zone and frictional effects. The reactor dense bed model can be configured to the exact geometry of an operating unit. It is used to represent

the inventory of spent catalyst above the stripping zone. For large vessels with significant holdup, this model can be configured as a fluidized bubbling bed system. For low holdup or riser-cracking systems, it is treated as a fluidized bed with a parameterized void fraction.

Spent catalyst and regenerator air are connected to the regenerator model. The regenerator includes three blocks, each of which can be configured for a specific unit. The first block (from the bottom up) is the regenerator dense bed. This model represents the bubbling, fluidized bed where the majority of coke burn occurs. The second block is the regenerator freeboard (disperse phase), which is the region between the surface of the bubbling bed (dense bed) and the inlet to the cyclones. The third block is the regenerator cyclone model.

The regenerator dense bed is modeled as a bubbling bed with heterogeneous coke burn and CO conversion to CO₂. Bulk density is modeled as a function of bed height and pressure. Promoters are modeled by updating selected coke-burn parameters. Combustion air composition is determined independently by the regenerator air model. Therefore, O₂ enrichment can be simulated and optimized.

The regenerator freeboard model represents the vessel region between the surface of the dense bed and the cyclone inlets. Inlets to the model are entrained, regenerated catalyst from the dense-bed model and the combustion-gas stream from the dense bed. Outlets from the model are the freeboard combustion-gas stream and the catalyst stream from the cyclones. The freeboard is modeled as a simple plug-flow reactor with homogeneous CO-to-CO₂ after-burn. Temperatures may rise rapidly in the presence of excess O₂.

The regenerator cyclone model performs a two-phase, loading-based ΔP calculation. Flue-gas compositions are calculated and reported on a standard dry mole percent basis for parameterization purposes. The flue gas stream can be connected to the valve model between the regenerator and CO boiler, or to a downstream power recovery system.

Inputs and outputs for the blocks described below are compatible with the vapor and catalyst streams used in the reactor/regenerator models.

The stripping zone model performs heat, mass and pressure balance calculations around the stripping zone. A tunable stripping efficiency curve is included. The stripping efficiency is related to the ratio of catalyst flow to stripping-steam flow.

The catalyst standpipes create a standing head that drives catalyst circulation. Different FCC designs make more or less use of standpipe technology. Standpipes typically end at a slide valve, which is used to control catalyst circulation. Standpipe diameter and length are variables in the standpipe model.

Table 28.6 Aspen FCC 21 reactive lumps

Gas lump
Gasoline lump
221–343 °C (P, N, As, Ar1, Ar2)
343–510 °C (P, N, As, Ar1, Ar2, Ar3)
510 °C-plus (P, N, As, Ar1, Ar2, Ar3)
Coke (2 lumps)

The catalyst transfer line model represents the pneumatic transport regime in the catalyst transfer line. Transfer-line diameter and length are configurable. Like the riser model, the catalyst transfer line model can be configured as vertical, horizontal, or inclined.

The slide valve model calculates ΔP for a two-phase, loading-based orifice. The valve coefficient is parameterized from measured slide valve position (percent open) and pressure differential across the slide valve.

Components with similar reaction kinetics are grouped into 21 lumps. These kinetic lumps are listed in Table 28.6. In practice, the 21 components provide sufficient granularity to model all of the important steady-state cause-and-effect relationships in the FCC reactor-regenerator complex. Kinetic parameters for the riser and reactor models are segregated from the hydraulics and heat balance relationships. This permits different FCC kinetic schemes to be implemented within the same rigorous riser/reactor models. The offline version of the model includes a simplified fractionator model and a product-property model.

The simplified fractionator includes a delumper model to convert the 21 kinetic lumps into > 80 pure- and pseudo-components, which are then divided into user-specified boiling fractions. A nonlinear distribution function generates ideal distillation curves with realistic fraction-to-fraction overlap. The fractionator can interconvert distillation methods, so a user can calculate D-86, D-1160, D-2887, and/or true boiling point (TBP) curves for gasoline and light cycle oil (LCO).

The product property model generates the product properties listed in Table 28.7. During projects, other product property calculations are added as needed. The online application at Suncor-Sarnia does not use the simplified fractionator model. Instead, it uses fully rigorous tray-by-tray models for the HCC fractionation section.

28.3.3 Aspen Hydrocracker

In many respects, AHYC is simpler than AFCC, mainly because it doesn't have to model the flow of a solid phase. Complexity arises for the following reasons:

- A separate reactor is used for each catalyst bed.
- The same set of reactions is used for both fixed-bed hydrotreating and fixed-bed hydrocracking units.

Table 28.7 Aspen FCC standard product properties

	API gravity	Specific gravity	Sulfur	Cloud point	RON	MON	PONA
As-fractionated product properties							
Gasoline	✓	✓	✓		✓	✓	✓
LCO	✓	✓	✓	✓			
HCO	✓	✓	✓				
Bottoms		✓	✓				
Standard-cut product properties							
Light naphtha	✓	✓	✓		✓	✓	✓
Heavy naphtha	✓	✓	✓		✓	✓	✓
LCO	✓	✓	✓	✓			
Bottoms	✓	✓	✓				

RON = research octane number, *MON* = motor octane number, *PONA* = paraffin/olefin/naphthene/aromatic ratio

- All recycle loops are closed.
- More components and reactions are required. The model employs 116 components and 195 reactions.
- Catalyst deactivation has a major impact on the economics of a fixed-bed hydrocracker.

AHYC is an update of SARCRACK, a hydrocracker model developed by Sun Oil Company [28.4], and modified by Suncor-Sarnia with assistance from DMC Corporation for online optimization. The component slate and reaction network for AHYC are consistent with publications by Klein et al. [28.4], Stangeland [28.5], Quann et al. [28.6, 7], Filiminov et al. [28.8], and Jacobs [28.9].

Figure 28.3 presents a diagram of the high-pressure reaction section of the hydrocracker at Suncor-Sarnia. The unit is a classical single-stage Unicracker with two reactors. In the first (R1), all three beds are loaded with high-activity hydrodenitrogenation (HDN) catalyst. In the second (R2), all four beds are loaded with a zeolite-based, distillate-selective hydrocracking catalyst.

For both reactors, the incoming gas is heated separately. The unit has two separator drums. The hydrogen-rich gas from the overhead of the high-pressure separator (HPS) is recycled. The HPS bottoms flow through a power-recovery turbine (PRT) to the low-pressure separator (LPS). LPS bottoms go through a preflash tower to the main fractionator.

Heavy naphtha from the main fractionator goes to the large catalytic reformer, which is used to produce both gasoline and feedstock for the aromatics plant. A portion of the bottoms from the main fractionator is recycled to R2. The remainder goes to the first of two distillation towers for recovery of middle distillate products.

AHYC is an open-equation, flowsheet-based model, which is used both online and offline at Suncor-Sarnia, where it was configured and tuned to rigorously represent the catalyst beds, quench valves, compressors, flash drums, heaters, exchangers, etc. in the commercial unit. A rigorous model for the hydrogen plant, a steam/methane reformer, was linked to the hydro-

Fig. 28.3 AHYC model for the Suncor-Sarnia hydrocracker: Reaction section

cracker model. The entire fractionation section – comprising a preflash tower, main fractionator, all five gas plant towers, and two middle distillate recovery towers – was modeled rigorously.

After R1, a component-splitter model was used to simulate the removal of NH_4HS upstream from the HPS. This is a simplification, but it eliminates the need for a three-phase electrolytic flash model in the HPS, and it has no effect on reaction kinetics, the composition of recycle hydrogen, or the composition of the LPS bottoms.

A relatively simple extent-of-reaction model was used to simulate the saturation of olefins, including the associated consumption of hydrogen and generation of heat. It was assumed that 100% of the olefins in the feed are removed in the first bed of R1.

As mentioned above, each catalyst bed is modeled separately. Kinetic constituents are segregated from hydraulic and heat balance relationships, which permits different kinetic schemes to be implemented within the same mechanical framework.

Trickle-bed hydrodynamics are modeled with equations described by *Satterfield* [28.10]. Reaction rates and flash calculations are performed at multiple collocation points in each reactor bed. This enhances the ability of the model to perform an accurate heat-release calculation (Table 28.9).

A customized version of the Langmuir–Hinshelwood–Hougen–Watson (LHHW) mechanism is used both for reversible (28.1) and irreversible reactions (28.2). The main steps in this mechanism are:

- Adsorption of reactants to the catalyst surface
- Inhibition of adsorption
- Reaction of adsorbed molecules
- Desorption of products.

Several inhibitors are included in AHYC reaction kinetics. These include H_2S , ammonia, and organic nitrogen compounds. The inhibition of hydrodesulfurization (HDS) reactions by H_2S is modeled, and so is the inhibition of acid-catalyzed cracking reactions – dealkylation of aromatics, the opening of naphthenic rings, and paraffin hydrocracking – by ammonia and to a much greater extent by organic nitrogen.

$$\text{Rate} = A \cdot k \cdot \frac{((K_i C_i \cdot K_{\text{H}_2} \cdot (P_{\text{H}_2})^x K_{\text{eq}}) - K_j C_j) \cdot P F^y}{I_a \cdot I_b \cdot I_c}, \quad (28.1)$$

where A = catalyst activity, k = rate constant, K_i = adsorption constants for hydrocarbons, C_i = concentrations of hydrocarbons, K_{H_2} = adsorption constants for hydrogen, P_{H_2} = concentrations of hydrogen, K_{eq} = equilibrium constant, PF = pressure factor, I_a, I_b, I_c , etc.

= inhibition factors.

$$\text{Rate} = A \cdot k \cdot \frac{K_i C_i \cdot K_{\text{H}_2} \cdot (P_{\text{H}_2})^x \cdot P F^y}{I_a \cdot I_b \cdot I_c}, \quad (28.2)$$

where A = catalyst activity, k = rate constant, K_i = adsorption constants for hydrocarbons, C_i = concentrations of hydrocarbons, K_{H_2} = adsorption constants for hydrogen, P_{H_2} = concentrations of hydrogen, PF = pressure factor, I_a, I_b, I_c , etc. = inhibition factors.

Reaction Pathways

The following reaction types were modeled in SAR-CRACK:

- Hydrodesulfurization (HDS)
- Hydrodenitrogenation (HDN)
- Saturation of aromatics
- Ring opening
- Ring dealkylation
- Paraffin hydrocracking
- AHYC also models olefin saturation and (in an empirical way) paraffin isomerization.
- The AHYC reaction scheme has the following characteristics:
 - 45 reversible aromatics saturation reactions involving components in each major distillation range. The components include naphthene-aromatic compounds.
 - 19 irreversible olefins saturation reactions. The model assumes that olefin saturation is complete within the first catalyst bed.
 - Saturation and dealkylation for sterically hindered sulfur and nitrogen lumps. This allows AHYC to use different HDS and HDN rates for easy-to-treat and hard-to-treat sulfur and nitrogen compounds.

Recent publications [28.11–14] confirm that a hydrotreater removes sulfur from organic sulfides, disulfides, and mercaptans with relative ease. Thiophenes, benzothiophenes, unhindered dibenzothiophenes and hindered dibenzothiophenes are successively harder to desulfurize.

Figure 28.4 illustrates the so-called *direct* mechanism for the HDS of dibenzothiophene, and Fig. 28.5 shows a widely accepted mechanism for the HDS of hindered dibenzothiophenes. Note that the direct HDS

Fig. 28.4 Direct mechanism for the hydrodesulfurization of dibenzothiophene

Table 28.8 Relative reaction rates of hindered and unhindered sulfur compounds

Sulfur compound	Rel. HDS rate	Boiling point (°F)	Boiling point (°C)
Thiophene	100	185	85
Benzothiophene	30	430	221
Dibenzothiophene	30	590	310
Methyldibenzothiophene	5	600–620	316–327
Dimethyldibenzothiophene	1	630–650	332–343
Trimethyldibenzothiophene	1	660–680	349–360

**Fig. 28.5** Mechanism for the hydrodesulfurization of hindered dibenzothiophenes

of dibenzothiophene requires 2 moles of hydrogen per sulfur atom, while the HDS of hindered dibenzothiophenes requires 5 moles of H_2 per sulfur atom.

Structural differences between sulfur-containing compounds translate into significantly different HDS reaction rates. Table 28.8 shows pilot plant data for the HDS of small amounts of pure thiophenes in a clean-diesel solvent. The catalyst and temperature were the same for each compound. Note that HDS rates for the first three compounds, which are unhindered, are 30–100 times faster than rates for the last three compounds, which are hindered.

Catalyst Deactivation Model

In AHYC, the catalyst deactivation model calculates the deactivation rate as function of the following:

- Coke precursors in the feed
- Time on stream
- Average bed temperature for each catalyst bed
- H_2 partial pressure.

The model predicts future catalyst activity, required temperature, yields, hydrogen consumption, and product properties. Alternatively, if the catalyst cycle life is fixed, the model can compute the optimal changes in feed rate, feed properties, and/or conversion needed to reach the target end-of-run date.

Figure 28.8 shows how the deactivation model can be used to predict future temperatures required to hit

a user-selected process objective. The process objective can be sulfur removal, nitrogen removal, or hydrocarbon conversion – for example, the conversion of 650 °F-plus to 650 °F-minus (343 °C-plus to 343 °C-minus) material.

At the hydrocracker at Suncor-Sarnia, the deactivation model is applied to each catalyst bed. This enables the development of strategies to bring all catalyst beds to end-of-run at (roughly) the same time, and prediction of future yields, selectivity, and product properties.

AHYC Model Fidelity

Table 28.9 presents data from an AHYC project at a US East Coast refinery. The data show the excellent fit that can be achieved with the model. During that project, AHYC predictions were compared to step-test gains from a model-predictive controller. The optimizer matched most gains within $\pm 20\%$ (relative). This shows that the model does a good job of predicting process behavior under conditions well away from those at which it was tuned.

28.3.4 Clean Fuels Planning

Hydrogen Requirements for Deep Desulfurization

We ran a series of case studies to calculate the hydrogen requirements for deep desulfurization in a high-pressure gas-oil hydrotreater.

For the saturation of aromatics in a hydrotreating or hydrocracking unit, equilibrium effects, which favor formation of aromatics, start to overcome kinetic effects above a certain temperature. This causes a temperature-dependent *aromatics cross-over* effect, which explains the degradation of important middle distillate product properties – including kerosene smoke point and diesel cetane number – at high process temperatures near the end of catalyst cycles. The cross-over temperature is affected by feed quality and hydrogen partial pressure, so it can differ from unit to unit.

Figure 28.6 shows results from a case study in which the weighted average reactor temperature (WART) was changed over a wide range in a model based on the treating section of the Suncor-Sarnia hydrocracker. Even though the WART was changed, the

Table 28.9 Aspen hydrocracker model fidelity

Variable	Measured value		Predicted value		Offset
Conversion	63.6 wt% feed		63.54 wt% feed		0.057
R1 WART ^a	724 °F	384.4 °C	724 °F	384.4 °C	0.55 °F
R2 WART	723 °F	383.9 °C	723 °F	383.9 °C	-0.71 °F

R3B1 outlet temp	725 °F	385 °C	725 °F	385 °C	0.001 °F
R3B2 outlet temp	726 °F	385.6 °C	726 °F	385.6 °C	0.001 °F
R3B3 outlet temp	743 °F	395 °C	743 °F	395 °C	0.003 °F

^a WART = weighted average reactor temperature

**Fig. 28.6** Product aromatics versus temperature

reactor temperature profile – equal outlet temperatures for the catalyst beds – was the same for every case.

The y-axis shows the mole fraction of total aromatics remaining in product. For this case study, the feed rate, feed type, and catalyst activity were kept constant, which means that deactivation effects were not included. With less-active end-of-run catalysts, the rates of forward (saturation) reactions are inhibited, so the aromatics cross-over effect is amplified.

Figure 28.7 shows results of a case-study in which the product sulfur was kept constant (fixed) at different levels between 500 and 15 wppm. Required WART and hydrogen makeup flow are plotted on the y-axis. Because the product sulfur was fixed, another normally fixed variable can be allowed to vary. For this study, the chosen variable was WART.

Again, we ran the case study using the hydrotreating portion of the Suncor-Sarnia hydrocracker model with an equal-outlet temperature profile. For 500 wppm sulfur in the product, the makeup H₂ flow

**Fig. 28.7** Aspen hydrocracker case study results: Hydrogen consumption and weighted average reactor temperature (WART) versus product sulfur content

is 15.2 MMSCFD. For 15 wppm, the makeup flow is 18.6 MMSCFD, more than 40% higher. Higher WART leads to increased conversion, increased HDN, and (up to a point) increased saturation of aromatics. This explains why the hydrogen consumption increased so much – and so nonlinearly – when the target product sulfur content went from 500 to 15 wppm.

We can also keep WART constant and achieve the desired level of HDS by allowing changes in liquid hourly space velocity (LHSV). When this is done, the effect on hydrogen consumption is less severe. But in the real world, decreasing the LHSV is equivalent to lowering feed rate or adding a reactor, both of which are expensive. The WART-based trend shown here is more relevant to an existing unit.

Figure 28.7 is consistent with the existence of both hindered and unhindered sulfur compounds in the feed. As mentioned above, the last traces of sulfur in diesel oil are locked inside highly hindered hydrocar-

bon molecules, which have to be cracked open before the sulfur can be removed.

Effects of Hydrotreating on FCC Performance

Many refiners include the hydrotreating of FCC feed in their plans to make clean fuels. To demonstrate the feasibility of running a rigorous model for an FCC-plus-pretreater complex, we connected AHYC to AFCC. To link the two, we created a component mapper model to compress the 97 reactive components from AHYC into the 21 lumps used in AFCC. We then connected the unconverted oil stream from the AHYC fractionator model to the feed-adjust block of AFCC.

Initially, the combined model was huge, containing more than 1.2 million nonzero terms in its matrix of variables. To allow the model to run in a reasonable amount of time on a Pentium III computer, we made some simplifications. In the reduced model, the four catalyst bed models are still fully rigorous. However, the hydrogen furnaces are represented with a heat-exchanger model, quench valves are modeled with mixers, a component splitter model is used for the wash-water system, and a group of component splitters is used for the fractionation section. These changes reduce the number of equations and nonzeros to 130 000 and 680 000, respectively. Despite these simplifications, the slimmed-down model remains, in our collective opinion, a useful tool for offline what-if studies and for economic comparisons of different process options.

We first looked at the effect of varying the amount of hydrotreated material in an FCC feed blend from 0.0 to 96.7 vol.%. Table 28.10 presents selected process conditions for the feed hydrotreater, which achieved 90% desulfurization and roughly 23 wt% conversion of vacuum gas oil to middle distillate and naphtha.

We modeled the effect of feed hydrotreating in two ways. The first and most logical approach was to

Table 28.10 Feed pretreater operating conditions

Variable	Units	Value
Feed rate	b/d	39 000.0
Number of catalyst beds		4.0
Weighted average reactor temperature	°F	720.0
	°C	382.0
LHSV	hr ⁻¹	1.2
Hydrogen partial pressure	psi	2000.0
	bar	136.0
Hydrotreater feed sulfur	wt%	1.95
Sulfur in hydrotreated FCC feed	wt%	0.195
Conversion of 343 °C-plus to 343 °C-minus	wt%	23.0

model the pretreating of the 100% of the FCC feed. We simply operated the pretreater model at several different severities and watched the response of the FCC model. Complications arose because upstream conversion in the pretreater affects the amount of feed going to the FCC model. When we compensated by increasing or decreasing the overall fresh feed rate to maintain a constant feed rate to the FCC, conversion in the pretreater changed due to the corresponding differences in LHSV. This is a classical – and very realistic – economic optimization problem, for which the combined AHYC/AFCC model is well suited. However, it doesn't easily lend itself to creating straight-forward graphs for publications.

In another approach to modeling the effects of FCC feed pretreating, the FCC model receives a blend of hydrotreated feed from AHYC with straight-run feed from a tank model. The latter case is discussed here.

Table 28.11 shows the properties of the four FCC feed blends that were used in the combined hydrotreater/FCC simulations. Table 28.12 presents FCC conversion and yield data. In each case, we held the FCC riser outlet temperature at 1030 °F (544 °C).

Table 28.11 FCC feed properties for blends of straight-run and hydrotreated feeds

Variable	Units	Case 1	Case 2	Case 3	Case 4
Straight-run VGO	b/d	30 000	20 000	10 000	1000
Hydrotreated VGO (90% HDS)	b/d	0	10 000	20 000	29 000
Total feed rate	b/d	30 000	30 000	30 000	30 000

**Fig. 28.8** Sulfur in FCC gasoline versus percent hydrotreated oil in the FCC feed

Figure 28.8 shows that the sulfur content of FCC gasoline is essentially linear with respect to the percent of hydrotreated oil in the FCC feed blend. Figure 28.9 shows that relatively more sulfur goes into heavy FCC products (LCO, HCO, and slurry oil) at higher percentages of hydrotreated oil in the feed.

This is consistent with the easy-sulfur/hindered-sulfur hypothesis, which predicts that nearly all of the sulfur left behind after high-severity hydrotreating

**Fig. 28.9** Sulfur in heavy FCC products versus percent hydrotreated oil in the FCC feed

is encased in hindered compounds. These compounds contain multiple aromatic rings, so they are more likely (relative to other sulfur compounds) to be incorporated into the coke that forms on FCC catalysts. When the coke is burned away, the sulfur is converted into sulfur oxides (SO_x), which ends up in the regenerator flue gas.

28.4 Conclusion

Rigorous models are being used for closed-loop real-time optimization at the Suncor refinery in Sarnia, Ontario. Single-unit rigorous models – and combinations of models similar to those being used in Sarnia – can be used offline to quantify nonlinear relationships between important refinery units, such as the FCC and its associated feed pretreater. These relationships are important when planning for clean fuels, especially

when selecting and designing processes for hydrogen production and deep desulfurization.

Acknowledgments. We are pleased to thank the following people for their contributions to RWO and to the development of Aspen FCC or Aspen Hydrocracker: John Adams, John Ayala, Darin Campbell, Steve Dziuk, Fernando Garcia-Duarte, Steve Hendon, Nigel John-

son, Ajay Lakshmanan, Jiunnshyan Liou, Skip Paules, Rosalyn Preston, and Charles Sandmann. This chapter appeared originally as Chapter 23 Practical Advances in Petroleum Processing, C.S. Hsu, P.R. Robinson (Springer 2006). It is reprinted here with kind per-

mission from the lead author and the publisher. The abstract was added by the editors of this book, who also made minor corrections in the text. It is being reprinted here, because it describes one of the few examples of refinery-wide optimization in the industry.

29. Rigorous Kinetics Modeling of Hydrogen Synthesis

Milo D. Meixell Jr

Closed-loop real-time optimization (CLRTO) with rigorous models improves the profitability of scores of process units in refineries and chemical plants. In addition to optimizing operations, the models serve as the basis for effective process monitoring and the identification of revamp opportunities. Rigor in every part of the plant – equipment, feed definition and reaction kinetics – is the key to success. Equipment constraints define the plant's capability, so CLROT models must include these too. Hydrogen synthesis online optimizers are part of several plant-wide optimizers.

This chapter describes the rigorous reaction kinetics employed for CLRTO in steam/hydrocarbon reforming plants. Kinetic relationships are shown for the core reactions, coking in different kinds of equipment, catalyst poisoning, heat transfer, and heat balances. Finally, comparisons are shown between model predictions and plant performance.

Hydrogen for industrial use is manufactured by the steam reforming of hydrocarbons, or is available as a byproduct of refinery or chemical plant operations. Hydrogen demand can exceed the amount available as a byproduct. Often, hydrogen supply limits overall plant throughput. An operating plant can exploit untapped capacity in existing steam reformer and related equipment designs with rigorous models that employ kinetics. During plant design kinetics models are not necessarily used because experience and relatively simple models allow designers to build hydrogen plants to supply whatever hydrogen amount, purity, and pressure that is desired. The objective of suppliers of hydrogen plants is to establish an economically feasible design, given

these predetermined criteria. Additional hydrogen, or less expensive hydrogen can be manufactured from these facilities after construction, when rigorous models are used in online, closed-loop optimization systems. These systems manipulate independent operating conditions (degrees of freedom) and maximize or minimize an objective function (usually operating profit) while honoring numerous constraints, such as tube metal temperatures, pressure drops, pressures, damper and valve positions. A good kinetic model is the cornerstone of the predictive capabilities of such online optimization systems. An online optimization system exploits equipment under operating demands and constraints that were not necessarily anticipated during design.

The steam reformer and associated models represent the most significant models in an overall hydrogen or synthesis gas plant real-time, closed-loop optimization project. The reformer does the great majority of converting the feedstock (i.e., natural gas, butane or naphtha, plus steam) to the primary reactant for downstream synthesis reactors: hydrogen. Consequently, detailed modeling is required to predict the correct product yields from varying feedstock composition at various operating conditions. Additionally, the primary reformer is subject to numerous constraints, such as tube metal temperatures, that also demand detailed modeling to predict. The primary reformer consumes significant energy, and the methane slip or hydrogen purity from it affects operating conditions in downstream equipment. The optimization system must be able to exploit these opportunities if optimal plant operation is to be achieved.

The reformer reactions (reforming and water gas shift) are modeled using the best available heterogeneous kinetic relationships from the literature [29.1–4], and have been validated with industrial data and literature data [29.5] over a wide range of conditions. Equilibrium relationships are appropriately incorporated into the rate relationships, but the model does not use the empirical *approach to equilibrium temperature* as the basis for predicting outlet compositions. Nor does the model use *pseudohomogeneous* rate relationships.

The steam reformer model can handle feeds from methane to naphtha, with all the typical components that are present in natural gas, as well as recycled synthesis purge gas, or hydrogen recovery unit tail gases. Naphtha feed is characterized as about 30 chemical species, some of which are pure components, and some are hydrocarbon fractions (pseudocomponents). Each hydrocarbon species participates in a reaction that includes adsorption onto the catalyst, reforming, and desorption. The model includes diffusion effects within the catalyst, as well as heat transfer resistance from the bulk gas to the catalyst surface.

Since the model is based on mechanistic rate relationships, the composition profiles (as well as temperature and pressure) are calculated at positions from

the inlet of the catalyst tube to the outlet. The differential reaction rate relationships, as well as the mass balances, heat balances, and pressure drop relationships are solved simultaneously. A global spline collocation algorithm is used to pose the problem, and an SQP (SQP) algorithm solves the relationships.

The heat transfer rate from the primary reformer firebox to the catalyst tubes is calculated along the tube using radiant and convective heat transfer relationships. Heat transfer is also calculated from the tube outer surface, across the tube metal, through the inside tube surface film to the bulk fluid, and finally from the bulk fluid to the catalyst particles. Measurements of the catalyst temperatures at several positions along the tube, as well as measured tube skin temperatures provide feedback that is used to update heat transfer parameters, as well as to validate the model.

Pressure drop calculations are included, which use the *Ergun* relationship [29.6]. This relationship predicts the pressure drop through packed beds, such as the primary reformer catalyst tubes and the secondary reformer (autothermal) bed. Measurements provide feedback that is used to update appropriate parameters in this relationship.

The kinetics developed for natural gas and naphtha steam reforming in fired and autothermal reactors were put to more stringent tests by applying them to two other reactors. One is a *prereformer*, an adiabatic fixed bed typically used upstream of a fired tube reformer for debottlenecking. The other reactor is a fired furnace with high carbon dioxide content in the feed, making a 1:1 ratio hydrogen to carbon monoxide synthesis gas, at 3.5 bars (as opposed to the typical 40 bars pressure in many steam reformers), which is processed in downstream Fischer–Tropsch reactors, ultimately making oxo-alcohols. Calculated and measured yields and temperature profiles in these reactors, using the same kinetics, are in excellent agreement.

These rigorous models, developed from credible literature sources, and validated against industrial data over a wide range of conditions, are the foundation of several plant-wide optimization systems, including those for synthesizing hydrogen, ammonia, methanol, and oxo-alcohols.

29.1 Steam Reforming Kinetics

The reaction scheme and associated kinetics are based on methane reforming and *heavier hydrocarbon* reforming studies reported in the literature. The methane reforming relationships must be included in any model

processing heavier hydrocarbons since methane is generated from these feeds, and subsequently reacts. The primary source of information used for methane reforming is *Xu* and *Froment's* most recent literature

articles on intrinsic kinetics and on using these along with diffusional resistance relationships to model industrial reformers [29.1, 2, 7]. The source of information for higher hydrocarbon steam reforming is based upon the work of *Rostrup-Nielsen* of Haldor Topsøe A/S, as well as that of others, whose work *Rostrup-Nielsen* has referenced extensively [29.3, 4, 8].

29.1.1 Methane Steam Reforming Kinetic Relationships

Numerous reaction mechanisms were investigated, and the best reaction scheme was determined by model discrimination methods described by *Froment* [29.1]. The kinetic expressions used for methane reforming account for adsorption of all the reacting species present (CO, H₂, CH₄, and H₂O), as well as reaction on the surface. The intermediate, adsorbed species concentrations, which are unmeasurable (at least in industrial equipment), are eliminated from the mechanistic steps (at steady-state), and only stable species concentrations (partial pressures) appear in the net reaction stoichiometry and the reaction rate expressions.

Net reaction stoichiometry

Reaction rate relationships

$$\begin{aligned} r_1 &= \frac{k_1}{p_{\text{H}_2}} \left(p_{\text{CO}} * p_{\text{H}_2\text{O}} - \frac{p_{\text{H}_2} * p_{\text{CO}_2}}{K_1} \right) \\ &\quad (\text{DEN})^2 \\ r_2 &= \frac{k_2}{p_{\text{H}_2}^{2.5}} \left(p_{\text{CH}_4} * p_{\text{H}_2\text{O}} - \frac{p_{\text{H}_2}^3 * p_{\text{CO}}}{K_2} \right) \\ &\quad (\text{DEN})^2 \\ r_3 &= \frac{k_3}{p_{\text{H}_2}^{3.5}} \left(p_{\text{CH}_4} * p_{\text{H}_2\text{O}}^2 - \frac{p_{\text{H}_2}^4 * p_{\text{CO}_2}}{K_3} \right) \end{aligned} \quad (29.2)$$

$$\begin{aligned} \text{DEN} &= 1 + K_{\text{CO}} * p_{\text{CO}} + K_{\text{H}_2} * p_{\text{H}_2} \\ &\quad + K_{\text{CH}_4} * p_{\text{CH}_4} + K_{\text{H}_2\text{O}} * \frac{p_{\text{H}_2\text{O}}}{p_{\text{H}_2}} \end{aligned}$$

The reaction rate *constants*, k_i s, are functions of temperature, activation energies, and frequency factors, in the classic Arrhenius form

$$k_i = A_i e^{-\left(\frac{E_i}{RT}\right)} \quad (29.3)$$

$i = 1$ to no. of reactions ($\cong 3$).

Similarly, the adsorption equilibrium constants are functions of temperature, heats of adsorption, and a fre-

quency factor

$$K_i = A_i e^{\left(\frac{\Delta H_i}{RT}\right)}, \quad i = \text{CO}, \text{H}_2, \text{CH}_4, \text{H}_2\text{O}. \quad (29.4)$$

The reaction equilibrium *constants* are functions of temperature. The equilibrium constants as a function of temperature are listed in [29.3, 4]. Those of [29.3] were used, and have been tabulated.

$$K_i = f(T) \quad (29.5)$$

$i = 1$ to no. of reversible reactions ($= 3$)

The kinetics discussed so far are intrinsic kinetics that are valid in the absence of diffusional or heat transfer resistances. Bulk phase concentrations (partial pressures) and temperatures are not present at the active sites within the catalyst pellets, since the pore structure offers very significant resistance to diffusion, and mild resistance to heat transfer exists between the bulk phase and the pellet surface. Little resistance to heat transfer exists within the pellets [29.4, p. 69].

The diffusional effects are accounted for using the classic *effectiveness factor* [29.2, 9–12].

$$\eta = \frac{\text{actual rate throughout pellet with resistances}}{\text{rate evaluated without resistances}}. \quad (29.6)$$

Evaluating the numerator of this expression requires simultaneous integration of the rate and diffusion relationships. *Froment* presents the results of that integration in [29.2, Fig. 6]. *Rostrup-Nielsen* lists results of Haldor-Topsøe's calculations in [29.4, p. 69]. These results are qualitatively similar, but differ in value due to numerous factors. Simplification of the effectiveness factor calculation can be applied for conditions that cause the diffusional resistance to be large [29.9, p. 431], and that simplification is implied in many of Haldor-Topsøe's equations [29.4, pp. 37, 69] [29.10]. The simplification [29.9, p. 434] is

$$\eta = \frac{3}{r_p} \sqrt{\frac{K(D_e)}{k(K+1)\rho_p}}. \quad (29.7)$$

Satterfield [29.11, p. 78] gives further insight to the simplification, when the diffusivities of the forward and reverse reactions are not equal.

Since the kinetics used in the DMCC model are from *Froment*, the effectiveness factor profiles in the primary reformer model are based upon his results. Rather than incur the computational burden of calculating the effectiveness factors for each reaction online,

they are entered as a function of length as constant profiles. Since the effectiveness factors are primarily functions of the catalyst pellet size, pore size, and pore size distribution, and since they are relatively weak functions of operating conditions over the normal range of these conditions, the effect of imposing them as constant profiles is very small. The results of reactor simulations with the effectiveness factor profiles fixed agree very well with measured results from industrial reformers, and with results presented in the literature. Offline calculations can be done to update the effectiveness factors if catalyst pellet size or pore size are changed significantly, or ultimately these calculations can be added to the online model. It is essential that effectiveness factors are used in conjunction with the intrinsic kinetic rate parameters, since the effectiveness factors account for phenomena that attenuate the intrinsic rates by factors on the order of 100. That is, effectiveness factors are on the order of 0.01.

The relationship among actual reaction rate, intrinsic rate, effectiveness factor, and catalyst activity is

$$r_{i,\text{observed}} = \eta_i \alpha r_{i,\text{intrinsic}}, \quad (29.8)$$

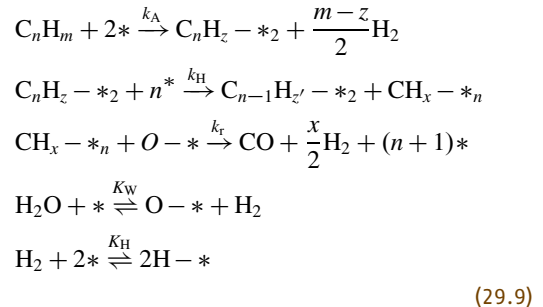

where η = effectiveness factor, α = relative catalyst activity (accounting for aging, sintering, pore closure, etc.), and $r_{i,\text{intrinsic}}$ = rate calculated with bulk fluid conditions. The catalyst activity is calculated as a parameter, updated from operating data.

29.1.2 Naphtha Steam Reforming Kinetic Relationships

Several intrinsic reaction-rate relationships have been derived for steam reforming of *higher hydrocarbons* (i. e., higher in carbon number than methane), based on Langmuir–Hinshelwood adsorption and reaction mechanisms [29.3, p. 118, 174] [29.4, p. 54]. These reaction rates (as with the reactions associated with the reforming of methane) are greatly attenuated in industrial tubular reactors by mass transfer resistance within the catalyst pellet and, to a lesser degree, by heat transfer resistance from the bulk fluid to the catalyst pellet surface. As with any intrinsic rate relationships, these rate expressions must be used in conjunction with a reactor model that accounts for these resistances for the model to be useful in assessing reformer performance, and predicting performance as independent conditions are manipulated. The relationship among intrinsic rates, observed rates, mass and heat transfer resistances, and catalyst activity has been shown in the

Methane Steam Reforming Kinetic Relationships section, Sect. 29.1.1.

One of the mechanisms [29.4, p. 54] is based on the following sequence of adsorption, reaction, and desorption.

The * symbol represents an active site on the catalyst surface. Concentration of $C_n H_z - *$ is generally assumed to be negligible, so the step 2 rate constant, k_H does not appear in the final rate expression. The rate constants k_A and k_r (adsorption and reforming) do appear in the rate expression. K_W and K_H are the adsorption equilibrium constants for water and hydrogen respectively.

The mechanisms account for chemisorption of the hydrocarbon and steam, followed by α -scission of the carbon-carbon bonds. The resulting adsorbed C_1 species react with adsorbed steam to form carbon monoxide and hydrogen. These mechanisms alone would result in no formation of methane, which is of course generated from naphtha feedstocks that are totally free of methane. Methane concentrations of 8–10 mol% (dry basis) are typical at the outlet of industrial naphtha steam reformers. Methane is generated when the hydrogen partial pressure is sufficiently high so that the reverse of the methane reforming reaction

is favored. This reaction, along with reforming to carbon dioxide, and the water gas shift reaction are solved simultaneously with the reforming reactions for the higher hydrocarbons. The mechanisms for these reactions are documented in the *Methane Steam Reforming* section, Sect. 29.1.1.

Competition between methane and the higher hydrocarbons for reactive sites on the catalyst surface is limited to a narrow axial position in the reactor tube, since the higher hydrocarbon species reform quickly, and since methane concentration buildup due to the reverse of the aforementioned methane reforming reaction is only significant after the great majority of the higher hydrocarbons are gone. The hydrogen partial pressure is only high enough to favor the reverse of

the methane reforming reaction when the higher hydrocarbon species have essentially disappeared. Therefore the denominator of the higher hydrocarbon rate relationships do not contain a methane adsorption term, nor does the denominator in the methane reforming reaction rate expressions have higher hydrocarbon adsorption terms. Rate expressions can be derived for the region in which the higher hydrocarbon and methane compete for active catalyst sites, however results of simulating a reactor with such a model will be essentially unchanged from the results obtained by applying the rate expressions discussed here.

The concentration profiles that result from solving the methane and the higher hydrocarbon reaction rates simultaneously agree well with the profiles reported by others [29.13, 14], and the reactor effluent species concentrations agree well with those observed from industrial reformers (Appendix 29.A). The effluent concentrations are fairly insensitive to reaction rates, since industrial reformers operate near equilibrium conditions. Effluent conditions will only be noticeably affected by reaction rates as the catalyst activity declines significantly. The temperature profile, especially in the first one third of the reactor, which is furthest from equilibrium, is affected significantly by reaction rates, and therefore is the most affected by the catalyst activity. The case study results in Appendix 29.B illustrate the concentration profiles, and the effects of catalyst activity on temperature profiles.

From [29.4],

$$r_i = \frac{k_A \cdot pC_nH_m}{\left(1 + \frac{n \cdot k_A}{k_r \cdot K_W} \cdot \frac{pC_nH_m}{pH_2} \cdot pH_2 + K_W \cdot \frac{pH_2O}{pH_2} + \sqrt{K_H \cdot pH_2}\right)^{2n}} \quad (29.11)$$

The exponent $2n$ in the denominator appears to be in error, since similarly derived rate expressions, listed below, have exponents of 2. Also, the $2n$ exponent leads to very unreasonable results for rates of reaction of higher carbon number hydrocarbons.

From [29.3, 14],

$$r_i = \frac{k_A \cdot pC_nH_m}{\left(1 + \frac{n \cdot k_A}{k_r \cdot K_W} \cdot \frac{pC_nH_m}{pH_2} \cdot pH_2 + K_W \cdot \frac{pH_2O}{pH_2}\right)^2} \quad (29.12)$$

From [29.3], including Boudart's interpretation of hydrogen and hydrocarbon site differences,

$$r_i = \frac{k_A \cdot pC_nH_m / pH_2^{y/2}}{\left(1 + \frac{n \cdot k_A}{k_r \cdot K_W} \cdot \frac{pC_nH_m}{pH_2} \cdot pH_2^{(1-y/2)} + K_W \cdot \frac{pH_2O}{pH_2}\right)^2} \quad (29.13)$$

The rate expression from *Catalytic Steam Reforming* (1984) [29.4] can be modified to include Boudart's hydrogen site interpretation, and can be solved in its original form, or the modified form by manipulating the value of y . A y value of zero restores the relationship to its original form. Additionally, that rate expression can be transformed into essentially the expression from *Steam Reforming Catalysts* (1975) by manipulating the value of K_H . A small value of K_H transforms the 1984 expression into the 1975 one. Generally, the final term in the denominator of the 1984 rate expression (the term including K_H) is much smaller than the other terms.

The rate expression from *Catalytic Steam Reforming* (1984) [29.4], modified to include the Boudart interpretation of the hydrogen site versus hydrocarbon site difference, is the relationship used in the model. The apparent error in the $2n$ exponent of the denominator has been corrected, and an exponent of 2 is used.

$$r_i = \frac{k_A \cdot pC_nH_m / pH_2^{y/2}}{\left(1 + \frac{n \cdot k_A}{k_r \cdot K_W} \cdot \frac{pC_nH_m}{pH_2} \cdot pH_2^{\frac{1-y}{2}} + K_W \cdot \frac{pH_2O}{pH_2} + \sqrt{K_H \cdot pH_2}\right)^2} \quad (29.14)$$

Each naphtha molecule is individually reformed, with its distinct set of rate constants, k_r and k_A . Each of these is a function of temperature and has its own pre-Arrhenius factor, as well as an activation energy (for k_r), and heat of adsorption (for k_A). The same K_H and K_W are used for each reaction. These too are functions of temperature, with their Arrhenius factors and heats of adsorption taken from *Froment's* most recent work [29.1]. The k_r and k_A values for each reforming reaction for hydrocarbons higher than methane are derived from rate data reported in the literature [29.3, 4, 15], and validated with overall reformer outlet compositions measured in industrial furnaces. Each reaction also has an effectiveness factor associated with it.

Naphtha is characterized as about thirty components, pure or pseudocomponents (several species of similar structure lumped together). The distribution of these components is chosen to best match measured specific gravity, volume average boiling fractions (ASTM-D86 method), and normal paraffinic, branched paraffinic (iso-paraffins), naphthenic, and aromatics (PINA) contents.

Numerous other rate expressions for steam reforming of higher hydrocarbons are listed in the literature [29.4, p. 55, 57]. Many of these are simplifications of the relationships shown here, with assumptions imposed on the relative contribution of the various terms. These assumptions may be valid for some operating

conditions, or for some catalysts. Many of the rate expressions are simple *power law* relationships that are difficult to relate to mechanistic pathways, and to physical attributes of the catalyst or the reacting species. The rate expression chosen for the model is one that has a broad range of applicability, for different catalyst types, and wide operating conditions.

Specific catalysts are characterized in part by their relative values of k_r , K_W , and k_A . The water adsorption equilibrium constant, K_W , is affected by the catalyst support. Alumina supports have lower values of K_W than magnesia supports [29.14]. Alkali content increases K_W . Increased alkali concentrations tend to decrease k_r , though. Catalysts' shape and size affect pressure drop and effectiveness factors. Their pore structure affects their effectiveness factors as well. Additionally,

the support affects the catalyst crush strength, and tendency to hold together under adverse conditions (i. e., wetting) that may be encountered during unplanned plant outages, severe operating conditions, or startup conditions. Migration of catalyst additives into equipment downstream of the reformers has caused fouling problems in some plants. Catalysts must maintain their activity and strength for several years to be commercially viable.

The following reactions are used in the primary reformer model, for butane and naphtha feeds. The model interprets the *StmReforming* qualifier, and determines the correct stoichiometry. The *User1* and *User2* qualifiers direct the model to use either the Froment reaction rate relationships, or the naphtha reaction rate relationships.

29.1.3 Coking

Coke deposition is a potential problem in steam reformers, and is favored by low steam-to-carbon ratio and high temperatures. High hydrogen composition also lowers the potential for carbon deposition. The following three reactions can deposit solid carbon, and the thermodynamic equilibrium relationships for these reactions, when carbon is graphite, are well known [29.3,

4, 14, 16–19].

Also, higher hydrocarbons can form carbon [29.3]

Equilibrium relationships with carbon of other forms have also been investigated and results reported in the aforementioned references. Whisker or filamental carbon is the form of carbon favored on nickel catalysts, and equilibrium of the aforementioned reactions with this form of carbon is reasonably well understood.

The first three carbon depositing reactions involve only methane and carbon monoxide, and are of particular interest in plants with methane feeds. These reactions can also occur in reformers with higher molecular weight feedstocks, since the reactants exist a short distance into the reformer tube, even when no methane exists in the feed. As mentioned in [29.19], *The mechanism of thermal cracking (pyrolysis) of higher hydrocarbons is more complicated*. Reference [29.14] highlights the relative risk of carbon laydown from several paraffinic, aromatic, and olefinic compounds.

Many literature articles imply that carbon deposition can be predicted and avoided by using equilibrium calculations. This implication is not correct, and several references acknowledge this fact. For methane feeds the equilibrium calculations provide reasonable guidelines, or *rules of thumb*, but still are not definitive in predicting whether coke formation will be encountered. For these feeds if the conditions (composition, temperature, and pressure) are constrained so that at equilibrium (with the appropriate carbon form) no carbon exists, then it is likely that none will deposit. As clearly stated in [29.4, p. 82],

The principle (of equilibrated gas) is no law of nature [...] It is merely a rule of thumb, indicating process conditions which are critical for carbon formation.

From [29.4, p. 85]:

The principle of equilibrated gas is no law of nature. Rates of carbon formation may be too slow. On the other hand, carbon formation may occur in spite of the principle, if the actual gas in the bulk phase, and thus the exterior of the catalyst pellet, shows affinity for carbon formation [...] Carbon formation is then a question of kinetics and the local approach to the reforming equilibrium.

Obviously, the defining relationships that would indicate whether carbon will deposit are the reaction rates associated with the actual gas (not the equilibrated gas), and include the carbon forming as well as the carbon gasifying reactions. These rates have been extensively studied [29.3, 4, 16] and are not presently well enough understood to justify including their reactions in the model. Reference [29.19] states [...] *the process conditions at which deposition (carbon) occurs can only be determined experimentally for each particular catalyst.*

Reference [29.4, Chap. 5] presents several mechanisms for coking reactions, for methane as well as higher hydrocarbons. The rate expressions presented cannot be directly and practically used in a reformer reactor model, since many of them are for *without steam present* conditions. Section 5.2.2 of Chap. 5 in [29.4] presents an empirical approach, which uses a critical steam-to-carbon ratio for each hydrocarbon species. Critical steam-to-carbon ratios must be established by experiment. This kind of simple empirical relationship can be added as a model and connected to the reformer model, if the need arises. Presently when applied online, operating conditions must be empirically constrained to avoid coke formation. Experience and advice from catalyst vendors can be used to establish the empirical guidelines. Consequently, operating conditions cannot as closely approach coking conditions as would be possible if the coking rates were well defined. Even if these rates were well defined, online analysis of reformer conditions (naphtha feed components of high coking potential, and down-the-tube temperatures) may still dictate that operating conditions be empirically established.

Some confusion may exist pertaining to how catalyst activity affects coke deposition, or the potential for coke deposition. There are three distinct effects of catalyst activity. First, an inactive catalyst can deliver a specified reformer outlet *methane slip* at only slightly higher outlet temperature compared to a catalyst that is significantly more active. Results in Appendix 29.B and [29.19, Fig. 12] show this significant rise of temperature. For the few furnaces with in-the-tube temperature measurements and the ability to control firing profiles, this rise of temperature can be avoided by automatically adjusting firing profiles. The allowable temperatures along the tube must be empirically determined, as mentioned. Results in Appendix 29.B illustrate this effect as well. Reformers without in-the-tube temperature measurements, or ones with limited capability of controlling firing profiles (i. e., top- or floor-fired) are at higher risk of coking due to inactive catalyst, since the rise in outlet temperature is subtle, and the rise in the process temperature near the tube inlet often goes unnoticed. The third effect of catalyst activity on coking is its influence on the coking reaction rates, which as shown are relatively poorly understood. It is clear that the first two effects of catalyst activity are captured well in this model, and that the effect on coking rate is not required to predict, and empirically avoids the higher temperatures near the tube inlet that arise due to inactive catalysts operated at a firing profile similar to that used for active catalysts.

Typical operating conditions in industrial reformers are sufficiently far from coking conditions so that significant benefits can be obtained by applying the model,

and constraining operating conditions empirically, as related to coking limits. Often, product values (hydrogen, ammonia or methanol) are sufficiently different from fuel values so that plant-wide optimum operating conditions are at a high steam-to-carbon ratio (where hydrogen production is favored, but at higher energy usage), and coking limits are not of concern. Plant operators, designers of steam reformers, and catalyst vendors often focus only on minimum steam-to-carbon ratios as being *optimum*, due to thermodynamic (energy per ton of product), and not economic objective functions.

29.1.4 Catalyst Poisoning

Catalyst *poisoning* is generally regarded as any process by which the number of catalyst active sites is reduced, and can occur due to sulfur coverage of active nickel sites, sintering of the nickel into fewer active sites, or coke deposition. The model lumps all those effects into the *activity* parameter.

The catalyst activity in the model can be a function of tube length, but typically is specified as uniform along the length. Measured data from an industrial reformer is essentially never available to allow the calculation of the activity profile. Even in reformers with in-the-tube temperature measurements, this information is usually insufficient to determine activity as a function of length. Process gas composition is required as a func-

tion of length to establish the activity profile. Clearly, such information can only be obtained in a laboratory environment.

References [29.19, 20] address sulfur poisoning in significant detail. Reference [29.19] illustrates the relative activity of a catalyst as a function of mean sulfur coverage. Also, that reference lists a Temkin-like adsorption isotherm for equilibrium sulfur coverage, as a function of temperature, hydrogen, and hydrogen sulfide mole fraction. As stated, it takes years to establish sulfur equilibrium in a reformer.

A reasonable approach might be to *enhance* the model by imposing an activity profile by incorporating the sulfur equilibrium, or an approach to the equilibrium isotherm, along the tube length. Without online, real time, or at least infrequent laboratory analysis of feed sulfur content, the model would have insufficient information to establish the sulfur isotherm, and subsequent activity profile. Sulfur levels in feedstocks may be very low (≈ 5 ppb) and difficult to detect. Also, it would be desirable to have feedback of sulfur content on the catalyst as a function of position in the tube, as well as feed sulfur history over the entire catalyst run length to properly validate the model. In view of these issues, and since the model with a uniform activity profile agrees well with measured conditions and outlet compositions, there appears little incentive to extend the modeling functionality in this area at this time.

29.2 Heat Transfer Rates and Heat Balances

Heat transfer rates are calculated to the catalyst tube from the firebox flue gas, through the tube wall, tube fouling, and inside tube film to the bulk fluid, as well as from the bulk fluid to the catalyst surface. As reported in the literature, the catalyst pellets are assumed to have a uniform temperature, since very little resistance to intrapellet heat transfer exists.

Heat balances are determined for all the reactor models discussed. Therefore the heat duties of the radiant tubes, convection section heaters, waste heat boilers, and associated steam drums are all explicitly calculated and reported. Heat losses are part of the models, as described in the *Heat Losses* section, Sect. 29.2.9. The enthalpies of all the streams entering and leaving each piece of equipment are calculated and reported. These streams include, for example, the process, fuel, air, and flue gas. Combustion, and all reaction-related heat effects, are handled in models using enthalpies of all species including heats of formation based on the elements at their standard states, so heats of reaction are avoided.

Heat balance terms such as furnace stack heat loss as a fraction of fired fuel heating value and furnace efficiency are not calculated, mainly since these *indices of performance* are not required in an optimization system that has the plant-wide operating profit as an objective function. These indices are remnants of local equipment or design *optimization* approaches. Typically a plant's operation should not be constrained nor its performance judged by these indices. Models can of course be easily used to calculate these indices, and *plant built* to the furnace models to perform these calculations online.

29.2.1 Firebox to Catalyst Tube

Firebox flue gas-to-catalyst tube heat transfer is primarily governed by radiation, but convection, although proportionally small, is included. The relationships used are derived from Chap. 19 of *Process Heat Transfer*, by *D.Q. Kern* [29.21, Chap. 19]

$$Q = \sigma F \alpha_{cp} (T_g^4 - T_{ff}^4) + h_c A_o (T_g - T_s), \quad (29.17)$$

where Q = total heat transferred, σ = Stefan-Boltzmann constant, F = overall view (exchange) factor (*Kern*, Fig. 19.15 in [29.21]), α = cold plane effectiveness factor (*Kern*, Fig. 19.11 in [29.21]), A_{cp} = cold plane area (of both sides of tube bank, or row), T_g = effective temperature of radiating gas, absolute, T_{ff} = temperature of tube front face (surface), absolute, h_c = convective heat transfer coefficient, A_o = outside area of tube, T_s = average outside tube surface temperature, absolute, $T_{ff} = T_s \cdot \text{PMDF}$, PMDF = peripheral maldistribution factor (accounts for circumferential heat flux maldistribution).

This equation is essentially Equation 19.9 from *Kern* [29.21], modified to allow variation of conditions along the tube length. The model integrates this heat transfer relationship along the length of the tube, while simultaneously solving the kinetics, pressure drop relationships, and all other equations related to the reformer (and the rest of the plant).

The effective gas radiating profile as a function of length is related to the burner placement in the firebox, as well as to the relative burner firing rates. The overall effective gas radiating profile is built up from the individual burner row profiles. The individual burner row profiles are similar to normal distributions of temperatures around the centerline location of the burners. The effects of adjacent burner rows overlap. Amplitudes of the temperature distributions are related to the firing rates of the burners. These amplitude-to-burner firing rate relationships have been derived from the steady-state gains of step response models relating *catalyst* temperatures (i. e., in the tube temperatures) to burner firing rates, and are included in the model. The chain ruling that may seem required to establish the relationship of the effective temperature profile amplitudes to the firing rates is implicitly done, since the steady-state gain relationships are added as constraints, and the amplitude variables then become dependent variables. Furthermore, the steady-state gain relationship intercept values are updated as parameters, for measured values of burner firing rates and measured *catalyst* temperatures. By this means the solution to the Parameter or Reconcile case (calculated prior to each Optimize case) can precisely match the measured down-the-tube temperatures, including the tube inlet (convection section heater outlet), in-the-tube *catalyst* temperatures, as well as tube outlet temperature. The Appendix 29.A simulation results and discussion illustrate that care must be taken so that the measured catalyst temperatures are not matched with unreasonable effective gas radiating and flux profiles.

Few plants have measured temperatures inside the catalyst tubes. When those temperatures are not avail-

able there may be little justification for building models that relate the individual burner profiles to an overall effective gas radiating profile. An overall effective radiating temperature profile is still justified, but without measured feedback its shape cannot be effectively updated online. A simpler gas temperature model can then be employed. Without in-the-tube temperature measurements it follows that temperature profile control in the tube is not practical. The absolute level of the radiating gas temperature, both in the case when the profile is built up from burner profiles and when it is not, is determined from actual operating conditions (namely measured or specified outlet temperature). The level of the temperature profile is that at which the resulting integrated heat transfer rate supplies the required heat to achieve the specified tube outlet temperature.

An important constraint on the effective gas radiating temperature profile is its relationship to the *bridgewall* temperature, which is the temperature of the flue gas leaving the radiating temperature after it has given up the total heat absorbed in the radiant section tubes and lost from the radiant section walls. This relationship is in many cases handled by a radiant section efficiency parameter. This model does not use that approach, but uses an offset between the length average effective gas radiating temperature and the *bridgewall* temperature as the analogous parameter. Others, such as *Wimpress* of C. F. Braun & Co. in [29.22] have used a similar approach. The offset parameter is updated online, and is determined by firebox heat balance determined from heat absorbed on the process side, fuel firing rate, and arch oxygen measurements. Heat balances using measured *bridgewall* temperatures from conventional thermocouples should not be attempted, due to the reasons explained in the *Convection Section* section, Sect. 29.2.7 of this report. The measured fuel flow, for the observed radiant duty, affects this parameter the most. The effective radiating gas temperature profile is not tied to the flue gas temperature at other than the *bridgewall* position, since the effective temperature (the radiation *source* temperature) is a result of all refractory as well as flue gas temperatures in line-of-sight of the tube front face temperature (radiation *sink* temperature) at any position. If the heat balance with the flue gas were calculated all along the tube, and if that temperature were used as the radiating source temperature, the resulting heat flux profile would not reflect the actual phenomena occurring, and would be significantly in error for most, if not all, industrial furnaces.

Figure 29.1 shows a typical net effective gas radiating temperature profile, along with the individual burner row by burner row profiles.

Fig. 29.1 Effective gas radiating temperature profile

29.2.2 Conduction Across Tube Wall

Heat transfer across the tube wall occurs by conduction. The one-dimensional form of Fourier's law of heat conduction [29.23, p. 245] is used as the governing relationship between heat flux, thermal conductivity, and temperature gradient. The tube wall thickness is an explicit *discretized* variable in the model. It therefore can vary with length, although most tubes are of uniform thickness. The thermal conductivity is also a model variable, but is considered constant as a function of length.

29.2.3 Fouling Resistance

A fouling (or *coke*) layer is included in the tube reactor model. Fouling thickness in the model can vary with length. The fouling thermal conductivity is a variable whose value can be specified, and is assumed invariant with length. Theoretically, measured tube metal temperatures at various lengths can be used to *back out* the apparent fouling profile, although inherent errors in pyrometer measurements make this impractical. With little or no fouling, the outside tube metal temperature profile approaches the shape of the process (inside-the-tube) temperature profile, and with appreciable fouling the outside metal temperature profile approaches the shape of the effective radiating gas profile. Hence, the fouling, even if assumed uniform, can be used as a parameter to more closely match tube metal temperatures close to the tube inlet, while the *peripheral maldistribution factor* can be used as a parameter to match the hottest measured tube metal temperature, usually near the tube outlet.

29.2.4 Inside Tube to Bulk Fluid

The inside tube surface to bulk fluid heat transfer coefficient is calculated using the Sieder–Tate correlation

for turbulent flow (similar to Dittus–Boelter), as listed in [29.24]

$$\frac{hD}{k} = 0.023 (\text{Re}^{0.8} \text{Pr}^{0.3}) \left(\frac{\mu}{\mu_0} \right)^{0.14}, \quad (29.18)$$

where h = inside heat transfer coefficient, D = inside tube diameter, k = process fluid thermal conductivity, Re = Reynolds number, Pr = Prandtl number, μ = bulk fluid viscosity, μ_0 = fluid viscosity at the tube wall.

29.2.5 Bulk Fluid to Catalyst Pellet

Heat transfer to the pellet is calculated by applying [29.25, Chap. 14, Eq. 28]

$$\Delta T_{\text{film}} = (T_{\text{gas}} - T_{\text{pellet surface}}) = \frac{L(-\text{rate})(-\Delta H_r)}{h_s}, \quad (29.19)$$

where the film temperature difference is between the catalyst surface temperature and the bulk fluid (gas) temperature. L is the characteristic length of the catalyst pellet (volume/arc), rate is the reaction rate occurring in the catalyst pores (moles/(time-volume)) and ΔH_r is the heat of reaction occurring in the catalyst pellet (energy/mole reacted). This relationship assumes that all the reactions occur inside the pellets, and that none occurs in the bulk fluid. This is a very good assumption in a steam reformer. The heat of reaction is backed out of the heat effects, since heats of reaction are not explicitly used elsewhere. Heats of formation are based on elements at their standard reference states, so the overall heat effects (sensible plus reaction) are included in enthalpies.

The bulk fluid to catalyst pellet heat transfer coefficient, h_s , is calculated as a function of fluid properties,

catalyst size, and fluid temperature using the heat transfer relationship from [29.12, p. 89, Table 4.2]

$$\frac{h_s D_p}{\lambda_f} = 2 + 1.1 \text{Pr}^{1/3} \text{Re}^{0.6} . \quad (29.20)$$

29.2.6 Within the Catalyst Pellet

Little resistance to heat transfer exists within the catalyst pellet [29.4, p. 69]. Consequently, the catalyst temperature is assumed to be uniform, at the catalyst surface temperature.

29.2.7 Convection Section

The convection section preheaters are modeled using standard heat exchanger models. Considerable differences between measured and calculated temperatures exist on the flue gas side, especially at the higher flue gas temperatures leaving the firebox, or just above the auxiliary burners. These discrepancies can be explained by the shortcomings associated with standard thermocouples employed in high-temperature service. The main problem with these thermocouples is that they cannot come close to thermal equilibrium with the very hot flue gas, so their measurements are consistently low. This problem is well understood, and documented in several heat transfer texts [29.26–28]. Reference [29.26] illustrates the large errors that can arise in high-temperature environments, and [29.27] highlights the futility of using temperatures measured with conventional thermocouples as the bases for heat balances. *Reed*, in [29.27], states,

[...] *experience shows that an attempt at heat balance where gas temperatures are taken from fixed thermocouples is largely a pointless exercise in calculation because of inaccuracy of gas temperature measurement and thus, gas heat content.*

Illustrations in [29.28, p. 33-17, 33-18] show thermocouples that are specially designed for high-temperature measurements.

The measured fuel flows, arch oxygen composition, and high pressure steam drum heat balance confirm that the heat duties calculated from the process side (as op-

posed to the flue gas side) are most accurate, as would be expected. The high-pressure steam system and boiler feed water measurements impact significantly on the convection section heat balance since boiler feed water preheat and steam superheat duties make up the majority of the convection section duty. The high-pressure steam import flow, and the expected versus measured and calculated synthesis gas compressor steam turbine performance further support the assertion that the process side, and not the flue gas side measurements are the most accurate.

29.2.8 Fuel and Combustion Air System

The fuel-air mixtures are combusted in *extent of reaction* models. Complete combustion to water vapor and carbon dioxide is assumed, with no residual carbon monoxide remaining. The model can be implicitly kept valid by lower bounding the flue gas oxygen content so complete combustion is maintained.

Combustion air preheat is modeled with standard heat exchanger models.

29.2.9 Heat Losses

The firebox model has a heat loss term that can be calculated as a parameter, however the loss term is essentially a small difference between large numbers (total heat fired minus total heat absorbed in radiant plus convection sections), so it is subject to large relative errors. Additionally, the heat *loss* may be calculated as a heat gain depending on the accuracy of the fired and absorbed heat duties. To keep the heat loss from the firebox reasonable, it is typically set to a small value, on the order of 1% of the heat fired.

There is also a heat loss term associated with the high-pressure steam drum. This term is typically used to understand the whether significant errors exist in boiler feed water flows, steam flows and temperatures, furnace convection section measurements, and fuel flow and composition measurements. During the optimization system commissioning, sensitivity of this term to the aforementioned measurements helps those commissioning the system eliminate the worst measurements, and establish the validity of the models.

29.3 Pressure Drop

Pressure drop calculations in the primary and secondary reformer models are based on the *Ergun* [29.6] relationship, as presented in [29.23]. Both the laminar flow and turbulent flow terms are included. The natural pa-

rameter that arises from the Ergun equation, which can be updated with measured pressure drop information, is the `TURBULENT_DP_COEF` term in the models of both the primary and secondary reformers. This term affects

Fig. 29.2 Pressure and pressure drop profile

only the pressure drop, whereas another term, the bed void fraction, which might also have been used as the parameter to update with measure pressure drop, also affects all the reaction rates. The bed void fraction affects the amount of catalyst in a fixed-volume reformer tube, and is not an appropriate parameter to use in this case. The void fractions of typical packed beds are shown in [29.29, Fig. 5.70]. Void fractions of 0.4 to 0.6 are typical, and can be determined for specific catalysts sizes and shapes from vendor specification sheets, by measurement, or, with more difficulty, by calculation.

The `TURBULENT_DP_COEF` is the appropriate performance indicator for catalyst pressure drop, and is a better indicator than pressure drop itself, since it is independent of all the known effects of flow rate (both hydrocarbon and steam), gas density, viscosity, catalyst particle diameter, and void fraction. Pressure drop itself is important though, due to the stress it imposes on the catalyst (which raises the potential for crushing) and normally the optimization system has an upper bound on pressure drop. That bound may or may not be active at the solution, depending on the catalyst condition, and whether the solution is maximizing throughput. The pressure drop profile illustrated by Fig. 29.2 is for a pri-

mary reformer when the pressure drop across the catalyst was fairly high. The differential pressure indicator showed a 2.9 kg/cm^2 drop across the catalyst tubes.

29.3.1 Secondary Reformer Reactions and Heat Effects

Most steam reformers are process furnaces, transferring the required endothermic heat from a firebox to the process inside catalyst-packed tubes. Some steam reformers are *autothermal*, getting their heat from oxidation reactions occurring within the catalyst bed. Secondary reformers in ammonia plants are an example of autothermal steam reformers.

There are several categories of reactions and heat effects calculated in the secondary reformer model. First, the primary reformer effluent is mixed with the process air. Then, the effect of consuming the oxygen that is admitted with the process air is determined. This effect was investigated by simulating several possible reaction pathways. The results were insensitive to the pathway chosen, so the simplest, and also the most thermodynamically favored route was used. This assumes that all the oxygen preferentially reacts with primary reformer effluent hydrogen. Sufficient hydrogen exists under all reasonable operating conditions so oxygen is the limiting reactant, therefore no methane is oxidized. The model includes oxidation of methane as a possible pathway, however it is presently not activated. That pathway can be activated without modifying the model by just changing input data (extent of reaction). The adiabatic *flame* temperature is calculated for this oxidation set of reactions, and the outlet from this *extent of reaction* model is the inlet to the secondary reformer packed catalyst bed (Fig. 29.3).

This model assumes that the oxidation is complete before the top of the catalyst bed, and that only methane reforming as described by [29.1, 2] occurs in the reactor bed. The same kinetic rate expressions are used

Fig. 29.3 Temperature profile as a function of bed depth

as in the primary reformer. The catalyst activity is of course different from the primary reformer activity, and is determined from operating data. An initial estimate of its value, relative to the primary reformer activity, was calculated as the primary reformer activity, times the nickel weight percent ratio, times the density ratio of the catalysts. This estimate assumes that the nickel mass in either catalyst supplies similar numbers of active sites. The activity calculated in this manner is close to the reconciled activity, based on measured compositions in the primary and secondary outlet, and operating conditions. Effluent compositions are very insensitive to assumptions concerning how the oxygen is reacted. For example, if some of the methane from the primary effluent is oxidized, rather than only hydrogen, the results are essentially unchanged. The high temperatures in the reactor cause the reaction rates to be relatively high, bringing the outlet near equilibrium. This near-equilibrium condition is a state, and not a path function, so it is not surprising that various reaction pathways affect the results so little.

The reactor bed is not assumed to be adiabatic, but loses heat from its walls. Presently a constant heat flux from the walls is assumed. A flux profile can easily be imposed, based on heat transfer driving force, but its effect will be negligible. In fact, if the reactor were assumed adiabatic the results would be essentially unchanged. The heat loss from the reactor walls was retained, so that the effects of the heat losses can be easily demonstrated.

29.3.2 Model Validation

The primary reformer models have been validated by comparing calculated to measured results, and by comparing predicted to observed results. Three cases of calculated versus measured results are presented, one for naphtha feed, and the other for butane feed. One case of predicted versus observed results is presented, for a naphtha feed. The online, closed-loop optimization system continuously supplies validation results, by reporting differences (biases) between calculated and measured results on every optimization cycle. These results, along with calculated parameters, can be monitored by trending their values as a function of time.

The first two validation cases are Parameter cases, while the third is a Reconcile case. In the first two cases only primary reformer calculations are done, while in the third case both primary and secondary reformer calculations are performed. The Parameter cases manipulate the process steam flow and outlet temperature to match observed outlet CO₂ and CH₄. In the Reconcile case the best values for the primary and secondary reformer catalyst activities are determined as well, us-

ing an objective function that minimizes the differences between calculated and observed outlet compositions of both reformers, calculated and observed primary outlet temperature, and calculated and observed process steam flow rate.

Validation Case 1 (Naphtha Feed Parameter Case)

For Validation Case 1, operating conditions, outlet composition, and feed composition are presented in Tables 29.1, 29.2, and 29.3, respectively. Figure 29.4 shows an outlet composition parity plot for dry gas with a naphtha feed. The feed composition used for this validation case was characterized as listed in Table 29.3, based on measured naphtha gravity, ASTM-D86 vol-

Table 29.1 Validation case 1 – operating conditions

Feed	Naphtha
Feed rate	17.7 t/h
Process steam rate	79.0 t/h (Parameterized to 82.92 to match effluent CO ₂)
Inlet temperature	470 °C
Outlet temperature	760 °C (Parameterized to 761.99 to match CH ₄)

ume versus boiling point, and PINA (paraffin, isoparaffin, naphthinic, and aromatic content) information, plus recycle desulfurization hydrogen stream measurements. The feed is a mix of the naphtha and desulfurization hydrogen streams. This naphtha feed molecular weight is 65.923.

Validation Case 1a (Naphtha Feed Simulate Case)

Table 29.4 presents outlet compositions for Case 1a. This case is simulated at the same conditions as the Case 1 Parameter case, except at an outlet temperature of 778 °C, compared to 762 °C.

A comprehensive set of plant operating conditions was not available for this case, but the plant indicated a methane slip of about 8.5%, observed by the plant for this outlet temperature. The calculated outlet methane dry mole percent of 8.8% is very close to the 8.5%

Table 29.4 Validation case 1a – outlet compositions

squared differences between the calculated and measured primary outlet compositions, outlet temperature, and secondary reformer outlet compositions. Primary reformer catalyst activity, secondary reformer catalyst activity, primary outlet CO₂ measurement minus calculated value difference, and secondary outlet CH₄ measurement minus calculated value difference were the degrees of freedom (the independent manipulated variables). The degrees of freedom are bounded to assure the results are most reasonable. By posing the problem in this manner the insensitive nature of the catalyst activities (due to near equilibrium conditions) is handled as well as possible. By step bounding the catalyst activities, the errors or *noise* in the composition and process steam flow measurements are not all forced into the catalysts activities, as would be the case if a *square* Parameter case were posed. The best weighting of the terms in the objective function is determined during commissioning when many sets of data are pro-

cessed in an open-loop mode. Over long time periods (months) the catalyst activities trend downward, since the step bounds are relative to the activity values from the last solution. Soft bounds (see DMO Users' Manual) may need to be employed if the data has significant error, causing otherwise (i. e., without soft bounds) infeasible problems to be posed.

This approach allows the relationship between firing duties and catalyst temperatures, if available, (derived from DMC controller steady-state gains) to be used, with all of the intercepts being updated as parameters, determined primarily by the measured catalyst temperatures. The catalyst temperatures are matched precisely at the solution of each Reconcile case.

The overall approach in determining the catalyst activities relies on reformer outlet compositions, which are near equilibrium to update rate parameters (catalyst activities). This kind of analysis is inherently problematic, but can be handled as described. Short-term trends of the catalyst activities (hourly, daily, or even over a week or so) will be subject to somewhat erratic, noisy behavior, but will not detract significantly from

the ability of the models to predict appropriate outlet compositions and reactor temperature profiles. As the catalysts become less active the aforementioned numerical problems diminish, and the activity trends will become smoother, for the same error in measurements, since the outlet conditions become further (but still not very far) from equilibrium.

The feed composition used for this validation case was characterized as listed in Table 29.10, based on typical butane feed, plus recycle desulfurization hydrogen stream measurements. The feed is a mix of the butane and desulfurization hydrogen streams.

As described, the secondary reformer model was solved along with the primary reformer model for validation case 3. The results are listed in Table 29.11.

The outlet methane concentration bias in the objective function was heavily weighted (to drive it toward zero, since the objective function is the sum of the weighted squares biases) and therefore explains the good agreement between calculated and observed values. The process air flow measurement bias (difference between measured and calculated) was a parameter, so the calculated nitrogen composition is precisely equal to the measured value. The air flow measurement bias was 4.4% of the measured value at the solution. The calculated outlet temperature is surprisingly close to the measured value. The heat balance around the high-pressure steam drum required only a 1.2% heat loss to close in this case. That balance is of course affected by numerous other measurements, so the calculated secondary reformer outlet enthalpy can only be said to be part of the overall consistent set of information.

29.A Appendix: Simulation Results

29.A.1 Primary Reformer

In Fig. 29.7, results are shown for naphtha and butane feeds. The naphtha feed case profiles are results from the *validation case 1*, and the butane feed results are from *validation case 3* described in the *Model Validation* section, Sect. 29.3.2.

The calculated versus outlet composition comparisons have been discussed. This section illustrates the profile results, and compares them to literature sources (for compositions), and to measurements (for temperatures). Only the key component concentrations are plotted, such as methane, hydrogen, carbon monoxide, carbon dioxide, and the main hydrocarbon species. The minor hydrocarbon species, nitrogen, and argon concentration profiles are not shown.

Fig. 29.6 Validation case 3 – outlet composition parity plot for dry gas with butane feed

Table 29.11 Validation case 3 – secondary reformer outlet conditions

Component	Calculated (Dry mol %)	Observed (Dry mol %)
Hydrogen	52.952	53.553
Nitrogen	22.254	22.254
Argon	0.327	–
Carbon monoxide	13.818	13.245
Carbon dioxide	10.164	10.583
Methane	0.4843	0.4843
Temperature (°C)	966.82	966.52

Both the naphtha and butane feed cases show the methane profile rising from very low inlet values to a maximum, and falling to the outlet composition. The hydrocarbon species compositions fall quickly, and are essentially zero at about 4–6 m from the tube inlet. These profiles are in close agreement with the profiles shown in [29.4, 14]. For more active catalysts, the hydrocarbon species disappear closer to the tube inlet. The simulated temperature profiles are also in good agreement with profiles in those references, but more importantly, they agree precisely with the measured profiles. Reference [29.19] shows that the temperature profile in a top-fired reformer is significantly different than in a wall-fired furnace.

Only one literature reference [29.13] was found that illustrated the hydrogen composition profile along the

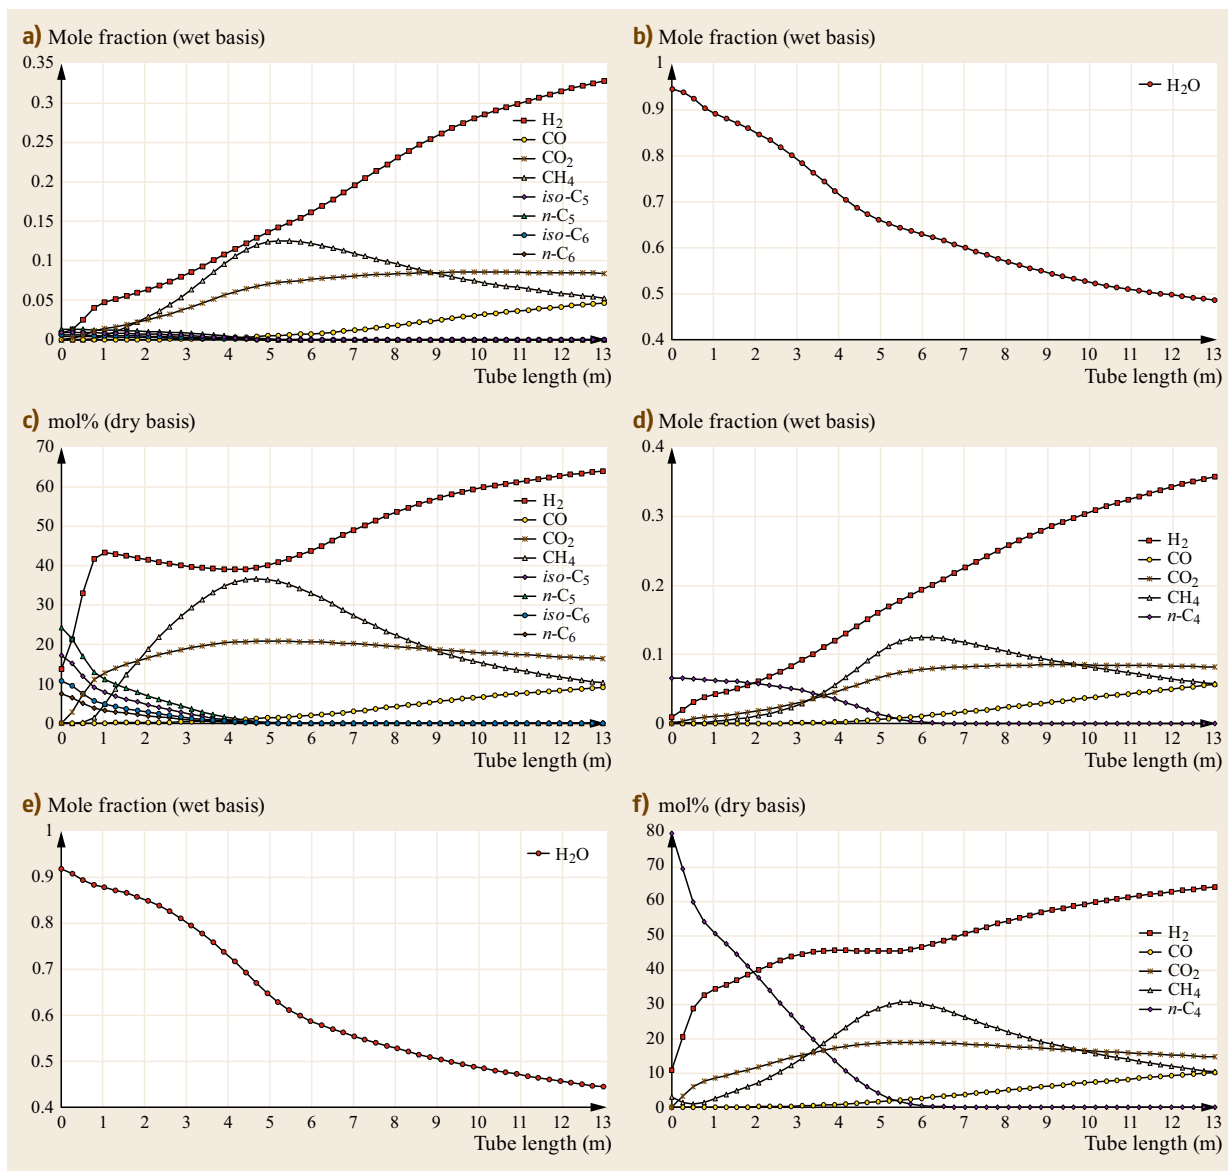

Fig. 29.7a-f Composition profiles for the naphtha (a-c) and butane (d-f) feed case

catalyst tube. The simulated results agree well with that reference's profile. At first the dry basis hydrogen composition profile appears strange, since it peaks at a position fairly close to the tube inlet (about 1–2 m), falls, then rises again. On a wet basis the profile is monotonic, and appears reasonable, since no decline occurs. The initial sharp rise in hydrogen concentration is due to the fast rates of reforming of the hydrocarbon species. As carbon dioxide concentration rises, it impedes hydrogen production via the water gas shift reaction, but as shown on the wet basis profile plots, the rate of change is still positive. Since water is a re-

actant, and not just a diluent of the hydrocarbon to prevent coking, dry basis profiles are misleading. The reference [29.13] dry basis hydrogen profile has the same peak and subsequent rise as the results plotted for naphtha feed. The hydrogen profile for butane feed, for the catalyst activity and firing profile representing late June 1994 operation, shows a much more subtle peak (Fig. 29.8).

The flux calculated at the top of the tube is quite small, but must be that small to allow the temperature to drop from the measured convection section feed/steam preheat exchanger outlet temperature to the uppermost

Fig. 29.8 Process temperature profiles measured versus calculated (butane feed)

measured catalyst temperature. The small flux is insufficient to supply all the net endothermic heat of reaction, so the temperature drops several degrees. Further down the tube the flux is sufficient to supply the reaction plus sensible heat, and the temperature rises. The flux profile is sensitive to the specified catalyst temperatures. Small discrepancies in the catalyst temperatures (or their position) require that the flux profile change significantly, if all the model and measured temperatures are required to match. Reconciliation of the measured temperatures, with shape constraints (rate of change or inflection point restrictions) on the flux profile can be used to assure a reasonable flux profile.

The measured tube metal temperature (TMT) is precisely matched at the solution of a Parameter or Reconcile case, since the *peripheral maldistribution factor* (Firebox to Catalyst Tube heat transfer section, Sect. 29.2.1) is used as a parameter to adjust the relationship between the average outside tube metal temperature, calculated assuming uniform heat flux distribution, and the front face tube metal temperature. The front face TMT is higher than the average TMT because

29.B Appendix: Case Study of Effects of Catalyst Activity in a Primary Reformer

Several cases were simulated to show the effects of catalyst activity. Plots of key operating conditions illustrate many effects that are unnoticed if only outlet compositions are examined. Table 29.12 shows how insensitive the outlet conditions are to catalyst activity, over a wide range. The plot of methane composition as a function of tube length for these cases is much more revealing. The

heat flux is not uniformly circumferentially distributed. The *peripheral maldistribution factor* is assumed constant in the Simulate or Optimize cases, which is a very good assumption. As mentioned in the *Fouling Resistance* heat transfer section (Sect. 29.2.3), the fouling can be used to match a measured TMT near the tube inlet.

29.A.2 Adiabatic Prereformer

An adiabatic prereformer was modeled with the same kinetics used in the previous models. A reactor bed was configured to represent an industrial reactor that was newly commissioned. Consequently the catalyst activity was assumed to be uniform, that is, no poisoned front had time to be established. The catalyst activity was reconciled so that one temperature in the nonequilibrium zone near the front of the reactor was matched. All other simulated temperatures then also matched the remaining measured temperatures, confirming that the kinetics were yielding appropriate heats of reaction, and compositions, all along the reactor bed. Effluent compositions were directly measured, and are plotted versus simulated compositions in the parity plot, showing excellent agreement.

Good agreement in this adiabatic reactor further confirms the validity of the kinetics. Issues related to heat transfer do not cloud the kinetics validity in this case.

29.A.3 Oxo-Alcohol Synthesis Gas Steam Reformer

A fired tube reactor was configured to match the dimensions and catalyst loading of an existing oxo-alcohol synthesis gas steam reformer. Simulation results at observed conditions (feed gas composition, outlet temperature, steam to carbon ratio, etc.) agree very well with observed results. Catalyst activity is first determined by matching an key effluent composition.

methane compositions for all the cases approach similar values near the tube outlet, but the methane composition profiles are significantly different at positions closer to the inlet.

The lower activity cases exhibit operating conditions (temperatures) that are likely to be unacceptable, as shown by the plots of the process temperatures. Both

Table 29.12 Effluent composition versus catalyst activity at constant inlet and outlet temperatures – naphtha feed cases. Inlet temperature = 462.0 °C. Outlet temperature = 761.8 °C. All cases have the same firing profile (not level)

Component	Catalyst activity					
	100%	90%	70%	50%	30%	20%
Hydrogen	63.9077	63.9072	63.9057	63.9029	63.8962	63.8872
Nitrogen	0.3675	0.3675	0.3676	0.3676	0.3677	0.3677

Carbon monoxide	9.0188	9.0186	9.0181	9.0171	9.0146	9.0109
Carbon dioxide	16.4000	16.4001	16.4004	16.4010	16.4026	16.4049
Methane	10.3000	10.3006	10.3022	10.3053	10.3130	10.3233

the overall temperature profile, as well as a *close up* of the first 3 m are shown. As discussed in the *Coking* section (Sect. 29.1.3), in the paragraph beginning with *Some confusion may exist...*, reformers with a less active catalyst operated at a similar outlet temperature as with an active catalyst, *at similar firing profiles*, exhibit higher, and likely unacceptable temperatures within the tube. The plotted profiles are similar in nature to those shown in [29.19]. The shapes are different due to top-firing [29.19] and wall-firing profile differences. The reason the temperature profiles change is because with a less active catalyst, less reaction heat sinks exist, and more of the heat input raises the sensible heat of the process fluid, and hence the temperature.

The unacceptable temperatures can be avoided. Two alternatives of avoiding them are simulated, one resulting in different unacceptable operating conditions (high methane slip), and the other with very acceptable conditions.

The first alternative focuses on the unacceptable temperatures encountered in the first few meters of the reactor, which may cause coking. In this alternative the temperature at approximately one meter from the inlet was the same temperature as the base, with 100% catalyst activity. This temperature was 449 °C. Table 29.13 and the accompanying plot (Fig. 29.9) show these results. To keep that temperature at 449 °C, and maintain the firing profile, the reactor outlet specification has to be relaxed. The independent operating condition is just moved from the reactor outlet, to the catalyst temperature. As illustrated, under these operating conditions, as the catalyst activity falls from 100% to 90%, and 70%, the methane slip rises dramatically. So does the reactor outlet temperature. As mentioned, this alternative is unacceptable, due to very high methane slip.

The second alternative is to minimize the tube outlet methane slip (dry basis), while modifying the firing profile, keeping the *CAT-I* temperature acceptable (in this case it was upper bounded at 449 °C), and while keeping the tube metal temperature (TMT) below acceptable limits. This was posed as an optimization problem. The objective in a plant-wide optimizer is not to minimize the reactor outlet methane content (profit is

Table 29.13 Effluent composition versus catalyst activity at constant upper bed catalyst temperature – naphtha feed cases. Inlet temperature = 462.0 °C. TI211-1 temperature = 449 °C. All cases have the same firing profile (not level)

Component	Catalyst activity		
	100%	90%	70%
Hydrogen	63.9077	63.1242	58.6711
Nitrogen	0.3675	0.3755	0.4209
Argon	0.0060	0.0061	0.0069
Carbon monoxide	9.0188	8.5117	6.1219
Carbon dioxide	16.4000	16.7405	18.3063
Methane	10.3000	11.2420	16.4730

maximized), but in this subplant problem it is the most realistic objective. The ability to modify the firing profile will depend greatly on the control system, burner design, fuel composition, and firebox design. In this case the range over which the optimizer could vary the firing was bounded simply by step bounding the amplitude changes for each burner row. In the overall furnace model the steady-state gain relationship between fuel fired and catalyst temperatures, as well as bounds on the duties that can be fired will constrain the range of firing. The amplitudes of the firing profiles will all be dependent variables, as described in the *Firebox to Catalyst Tube* heat transfer section, Sect. 29.2.1.

Results of this alternative for a catalyst activity of 90% show that the tube outlet temperature can be raised to 762.43 °C, slightly higher than the base (100% activity) case value of 761.8 °C, while not violating the *CAT-I* temperature limit, the TMT limit (of 884.92 °C, which is the same maximum as in the base case), nor the step bounds on the firing profile (shown in Fig. 29.10). The reason this case is at a slightly higher outlet temperature (and slightly lower methane slip) than even the base (100% activity) case is because the base case is not an optimized (profile) case. Had the base case been an optimized case, its methane slip would have been slightly lower than the optimized 90% activity case.

The optimized profile was reduced (to its lower step bound) for the top burner row, and increased (to the upper step bounds) for the next two burner rows. The

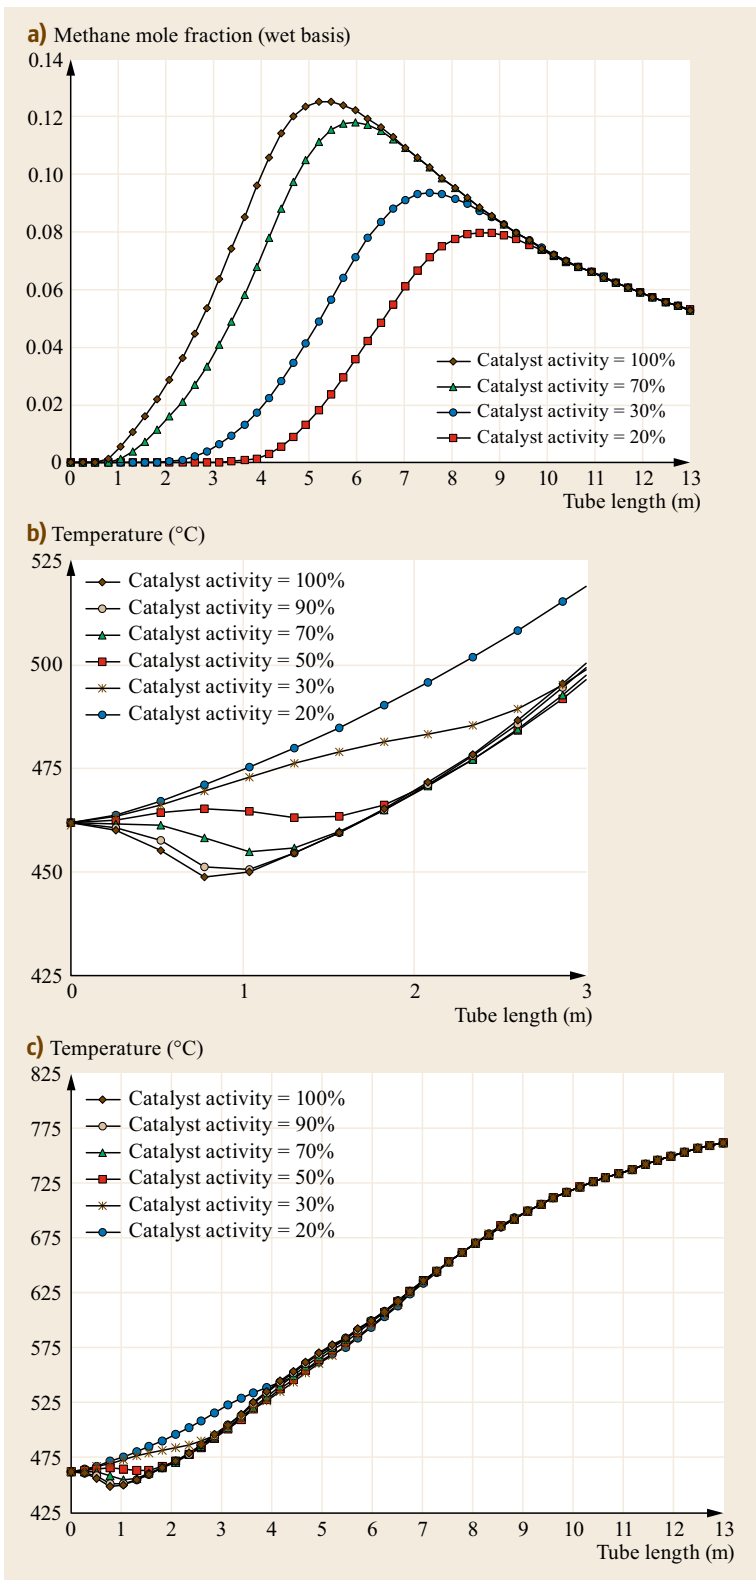

Fig. 29.9 (a) Methane composition profile as a function of catalyst activity. (b,c) Process temperature profile as a function of catalyst activity (at constant inlet and outlet temperatures, and firing profiles)

Fig. 29.10 Process temperature profiles for constant *CAT-I* temperature at 449 °C

bottom row firing was not at its limit, but the TMT in that section of the tube was at its maximum limit (884.92 °C). The resulting reactor outlet compositions show that the methane slip is slightly lower, and hydrogen composition slightly higher than the base case (Table 29.14). This is to be expected, even for a less active catalyst, for this system, which is close to equilibrium and at a slightly higher outlet temperature. This solution shows that profile control can essentially overcome the otherwise poor operating conditions that would accompany catalyst activity decline. The optimizer increases the heat flux to the part of the tube in which sufficient reaction heat sink exists, and decreases heat flux to the tube where insufficient reaction exists, and where temperature limits would otherwise be violated. Of course, at lower catalyst activities, and with less range of firing control, the debits associated with catalyst activity decline cannot be avoided. For

example, as the catalyst activity falls, the ability to reduce firing and maintain the *CAT-I* temperature below reasonable limits, while still maintaining a reasonable reactor outlet temperature, will cease to exist.

Table 29.14 Effluent composition for the maximize outlet temperature optimize case – naphtha feed cases. Inlet temperature = 462.0 °C. TI211-1 temperature upper limit = 449 °C. TMT temperature upper limit = 884.9 °C. There are step bounds on firing profile

Component	Catalyst activity 90%

Delayed Coking

30. Delayed Coking

Keith Wisecarver

Thermal processing is the most common refining technique for heavy residues. Thermal processing techniques include delayed coking, fluid coking, flexicoking, and visbreaking; of these, delayed coking is by far the most common method of thermal processing, with the ability to produce motor fuels from vacuum tower bottoms with a minimum of capital expenditure. Delayed coking capacity has increased greatly in recent years, mostly due to the heavier crude slates being used in refineries. Although delayed coking is an old process, there are many challenges associated with it, especially as crude slates continue to change and greater throughput is required of delayed coking units.

Delayed coking is the most common process for upgrading of vacuum residua as well as a primary method for upgrading tar sands for the production of syncrude. The delayed coking process begins with the heavy oil, usually a vacuum residuum, entering a furnace in conjunction with high-pressure steam and flowing at high velocities, reaching coking temperatures of approximately 900–930 °F at the exit of the furnace tubes. The feed proceeds through a transfer line to a coke drum. Cracking reactions begin in the furnace tubes and continue in the coke drum. Coke formation reactions are delayed in the sense that they take place in the drum rather than in the tubes.

The primary goal of delayed coking is usually carbon rejection, along with rejection of the metals, which can act as catalyst poisons in downstream processes, as well as rejection of a majority of the sulfur that is present in the feedstock. In other words, delayed coking produces lighter fuels with relatively high H/C ratios from heavier feedstocks with low H/C ratios, leaving behind carbon-rich coke and most of the metals. As such, it is the liquid fuels products that are the most valuable, and the coke can be considered a byproduct. However, there are exceptions, as in the production of anode-grade coke and especially of needle coke, where the coke can be quite valuable.

30.1 History of Thermal Processing

In early refineries, oil was boiled in small, iron stills to recover kerosene. After distillation was complete, the petroleum coke remaining in the still had to be dug out by hand. The first true thermal-cracking process, the Shukhov cracking process, was invented by Vladimir Shukhov in 1891 in Russia. The Burton process, developed by Standard Oil, Whiting, IN, USA, in 1912, was a method to convert gas oil to gasoline with the production of petroleum coke by thermal

cracking at temperatures of 700–750 °F and pressures of 90 psia. By gradual evolution of the art, it was found that heaters could be designed to raise residual stock temperature above the coking point without significant coke formation in the heaters. In 1919, the Dubbs process was invented. This process heated the oil to 900 °F at 150 psia at a low per-pass yield to prevent serious coke formation in the heating zone.

The first delayed coker was built by Standard Oil Whiting, IN, USA, in 1929, building upon the features of the previous thermal-cracking processes and separating the heater from the coke drum. The use of two coke drums in parallel enabled operation on a continuous basis.

In the years following World War II the drop in demand for heavy oil combined with the increased demand

for distillates resulted in a sharp increase in the number of delayed coking units, with more than a fivefold increase in coking capacity between 1950 and 1970. Since the 1980s, the production of heavier crudes has further increased the demand for coking. In 2014, the US delayed coking capacity, which accounts for about half the worldwide capacity, amounted to nearly 3 million bbl/day, an increase of almost 26% in the last decade.

30.2 Delayed Coking Process

30.2.1 Role of Delayed Coking in the Refinery

The most common feedstock to delayed cokers is the bottom product of the vacuum column, known as vacuum residuum. In a few cases, where the refinery lacks a vacuum unit, atmospheric residuum is sent to the delayed coker. Other feeds, such as aromatic gas-oils, tars, or cracked residua, are sometimes mixed with the main feed to influence the coker performance or to rid the refinery of certain unwanted products.

Delayed coking is the most popular method of upgrading residua. Hydrogen addition processes, such as resid hydrocracking and resid FCC, generally have higher capital and operating costs than thermal-cracking processes and have difficulty handling feeds with high contents of sulfur, nitrogen, and metals, as are commonly found in vacuum residua. Delayed coking is preferred due to its relative simplicity, high conversion rate to liquid products, and low operating and investment costs.

30.2.2 Process Description

Figure 30.1 shows the process flow diagram of a delayed coking unit. In some refineries, the vacuum residuum arrives at the coker unit hot, straight from the vacuum distillation unit. In most refineries, however, the vacuum residuum comes from storage tanks and is relatively cold. The feed is preheated by heat exchange with product streams, and then proceeds to the fractionator tower before going to the coker furnace. The coker feed enters the bottom of the fractionator at a temperature ranging from 680 to 750 °F (360–400 °C). Rarely, the coker feed is preheated in a tube furnace or in the convection section of the main coker furnace in order to achieve this temperature.

At the bottom of the fractionator tower, the fresh feed combines with some condensed product vapors to make up the feed to the coker heater. The addition of the feed at the bottom of the tower quenches the overhead vapor, helps to heat the feed, and condenses the heavier gas oils from the overhead vapor which are thus re-

Fig. 30.1 Delayed coking process diagram

cycled through the coker. The fractionator bottom also provides some surge storage capacity for the incoming fresh feed.

The fractionator bottoms, including the recycled heavy gas oils, are then heated in a furnace whose outlet temperature typically ranges from 900 to 930 °F (480–500 °C). Cracking reactions begin when the feed reaches about 800 °F. The heated feedstock enters one of the pair of coking drums where the cracking reactions continue. The cracked products leave as overhead vapor, while coke deposits at the bottom of the drum. For continuous operation, two coke drums are used; while one is on stream, the other is being decoked. The temperature drops by about 100–110 °F (37–43 °C) between the bottom and top of the coke drum; coke drum pressures typically range from about 15–60 psig (1–4 barg). Overhead products go to the fractionator, where the cracked products are recovered.

Delayed coking drums are operated under a coking/decoking cycle whose length can vary from 10 to 24 h. Once the coke drum is filled with coke, the feedstock is redirected into an empty, prewarmed drum. The full coke drum must then be steam stripped (to decrease the amount of remaining volatile matter in the coke), water quenched and drained, unheaded (removal of top and bottom flanges), decoked, reheated, purged with steam, hydrostatically tested, and finally, prewarmed with gases coming from the drum on service. These steps are carried out in a while the adjacent drum is being filled with coke. During the steam stripping and quenching cycles, the overhead products are transferred to the blowdown system in order to separate, recover, and recycle the hydrocarbons stripped from the coke drum. The blowdown system is also designed to receive oil condensates produced in the coke drums while the warming operation is conducted.

Upon completion of the steam-stripping stage and before proceeding to cutting the coke bed, the drum must be quenched by injecting water at the bottom of the vessel. Continuous flow of water into the drum contributes to decreasing the average coke bed temperature from around 800 °F to around 195 °F. Afterward, the coke drum is drained to a pad or drain sump, where coke fines are separated from water discharged from the bottom of the drum.

Shorter coking cycles allow increased throughput in the delayed coking unit, but are difficult to maintain due to the minimum time requirements for each of the steps of the drum cycle. Table 30.1 shows the typical time required for each step in a 16 h coking cycle.

Furnace

The coker furnace is designed to achieve a constantly rising temperature gradient using a symmetrical piping

Table 30.1 Coking operations for a typical 16 h cycle. (After [30.1])

Operation	Hours
Fill drum with coke	16
Steam to fractionator	0.5
Steam to blow down	0.5
Depressure, Water quench and fill	4.5
Drain	2.0
Unhead Top and bottom	0.5
Coke cutting	3.0
Rehead, steam test, and purge	1.0
Drum warm-up	4.0
Total time	16.0

arrangement, while maintaining high in-tube velocities, minimum residence time in the furnace, and optimum heat flux rate in order to minimize fouling. Velocity steam is added at about 1 wt% of the feed to achieve high in-tube velocity. The furnace outlet feeds directly to a transfer line which is usually kept as short as possible in order to avoid coking in the line, as this can cause an increase the furnace pressure which will lead to an increase in the fouling of the furnace tubes.

Coker furnaces typically have two to four horizontal passes per furnace, with a 4 in inner tube diameter and 0.25–0.5 in tube wall thickness. The trend in recent years has been toward double-fired heaters as opposed to single-fired heaters, to provide a more uniform heat flux. At least a 9% chrome alloy is normally used for the tubes. The feed undergoes partial vaporization and mild cracking as it passes through the furnace. Typically 10–25% of the feed has been vaporized or cracked to lighter materials by the time the feed exits the furnace. Coker furnaces usually have a total liquid residence time of around 2 min [30.2] with a cold oil velocity of around 6 ft/s (1.8 m/s) [30.3].

Fouling in the furnace tubes is a significant problem in delayed coker units. Fouling deposits act as an insulating layer inside the tubes, hindering the heat transfer from the surface to the bulk of the fluid. Fouling deposits also decrease the effective tube diameter, increasing the pressure drop in order to maintain constant flow rates. Since the bulk temperature has to be maintained, the surface temperature has to be increased leading to increase in fuel costs. Once the maximum allowable outer tube wall temperature is reached, the tubes must be decoked. The trend toward heavier delayed coker feedstocks has caused increasing problems with furnace fouling. While run lengths of nine months used to be common, in recent years many refineries have experienced decreased run lengths. Species that tend to contribute toward fouling include suspended impurities such as dirt, clay, sand, and rust that attach to the surface; precursors such as reactive olefin that may

undergo bulk reaction with oxygen (which can enter into the feedstock due to exposure to the atmosphere in storage tanks) to form insoluble polymeric peroxide gum foulant which in turn may adhere to the surface; asphaltene destabilization due to various effects such as temperature, pressure, or change in the liquid composition; and the presence of sulfur, which can lead to accelerated corrosion fouling of the tube surface [30.4]. Fouling is also correlated with the presence of metals, especially sodium and calcium, which are commonly present in delayed coker feedstocks.

Some refiners add recycle or condensate to help prevent furnace fouling. Fouling can also be decreased by increasing velocity steam to the tubes; increasing cold oil velocity in the tubes; and by effective furnace design, to eliminate hot spots on the tubes by reducing peak heat flux rates and minimizing flame impingement. It is also helpful to monitor temperatures, minimize process upsets, and assure proper desalting of the crude. Downtime for delayed coker heaters can be reduced by the use of on-line spalling of the coker furnace tubes.

Coke Drums

In the coke drum, the liquid feed, partially cracked in the furnace tube, continues to crack and form vapors which disengage and leave the drum, while the remaining heavy liquid polymerizes to form coke. Foaming is a major issue in the coke drum for many delayed coking units. Coke drums are designed to provide enough volume for the accumulation of coke produced during the coking cycle, at the same time allowing the maximum allowable superficial velocity that will prevent entrainment of the liquid and prevent foam from carrying over. Generally, coke drums are designed to allow 0.3–0.4 ft/s (0.09–0.12 m/s) superficial vapor velocity at the top of the drum. Antifoam is usually added to prevent foam carry over.

Commercial coke drums generally range from 13 to 30 ft (4–9 m) in diameter. Lower coke drum pressures are preferred for increased liquid yield, but the minimum pressure is set by the pressure drop through the overhead system; in practice, it is difficult to operate at pressures lower than 15 psig (1 bar).

Figure 30.2 illustrates how coke is formed in the drum. Liquid, along with steam and cracked vapor products, enters the bottom of the drum through the transfer line as a two-phase mixture. The vapor disengages from the liquid and exits the overhead of the drum. The heavy liquid remaining behind cracks further, generating more vapor, and eventually polymerizes to form coke. The coke layer forms from the bottom up, with a layer of bubbly liquid on top of the coke and usually a foamy or frothy layer on top of the bubbly

Fig. 30.2 Coke formation in the drum

liquid layer. Entrained liquid droplets disengage in the overhead space of the drum. The drum is switched out before the point is reached where liquid or foam will escape through the overhead line. In the modern refinery, the coke level and liquid level in the drum is usually determined through the use of nuclear backscatter devices mounted on the outside of the drum.

When the drum is full and switched out, the coke is steam stripped. Steam stripping must be done, not only to improve liquid recovery, but also to prevent the trapped liquid from plugging the channels in the coke bed, hence preventing the formation of *hot spots*. Hot spots are formed when steam (during stripping) and cooling water (during quenching) are not allowed to reach parts of the coke bed due to plugged channels or, in some cases (especially coke with a transitional morphology between sponge and shot), when the coke is too dense and lacks effective porosity. Steam must be flowing both before and immediately after the drums are switched, to prevent the unconverted liquid on top of the coke bed from flowing back down through the coke bed, where it can solidify to coke and plug the channels in the coke bed.

Steam stripping is usually carried out for 60 min, with steam typically flowing at the same rate as the velocity steam when the drum is online. When the steam

stripping is over, steam injection is increased for a short time, or in some cases water is immediately introduced at the bottom of the drum which instantly flashes to steam. Steam injection is then halted and the flow of cooling water is gradually increased. It is not uncommon to see a slight increase in the top vapor temperature in the drum right after the injection of water begins due to the increased flow of steam up through the coke resulting from water flashing. After that slight increase in temperature, cooling of the coke bed starts taking place. Once liquid water has filled the drum to the top of the coke level, the drum is drained and decoking can commence. The quench water rate must be carefully controlled to prevent cooling from taking place too rapidly, which can cause thermal stresses in the drum walls that can result in bulging of the drum.

Decoking

Removal of the coke drum top and bottom flanges, known as *unheading*, precedes the decoking or coke cutting step. Many delayed coker operations have moved to using deheader valves at the bottom of the drum. These are remotely operated, eliminating exposure risk to personnel, and providing isolation or control in the rare instance of a *drum dump*, in which there is a collapse of unstable and loose petroleum coke particles which flow freely out the bottom of drum upon deheading.

In the decoking step, high-pressure water (3500–4000 psig = 240–275 barg) is supplied by a jet pump during the cutting operation. Coke cuttings and water are discharged from the drum through a chute to the coke pad or pit. Simultaneously, petroleum coke piles up on the pad/pit, while water flows from this point to the settling maze. Once the cutting operation has concluded, dry coke is removed from the pad/pit area by front-end loaders (pad) or a clamshell (pit), transported to a crusher in order to reduce its particle size, and finally, transferred to coke piles by means of a belt or pipe conveyor.

An inappropriate quenching and/or decoking operation can lead to serious hazards for the operators, such as the presence of geysers when cutting water gets in contact with pockets of hot unconverted feed or *hot spots* embedded in the coke bed. Hot spots are also responsible for fires in the coke piles when hot volatile material in the coke burns when it is exposed to air.

Fractionator

The overhead vapors from the coke drum, consisting of steam and the products of the thermal-cracking reaction, are fed to the bottom of the fractionator. The fresh feed enters the fractionator two to four trays above the bottom vapor zone before proceeding to the coker fur-

nace. The introduction of fresh feed to the fractionator quenches the hot vapors from the coke drum, thus preventing any significant amount of coke formation in the fractionator. At the same time, it condenses a portion of the heavy ends of the coker product, which are then recycled back to the coker, while any lighter material in the fresh feed is stripped. Quenching the hot coke drum vapors also helps to preheat the feed, making the process more energy efficient. The amount of recycle is controlled by the fractionator pressure: higher pressure results in more recycle to the coker.

The hot vapors from the coke drum flow up through the quench trays where they contact the fresh feed. Above the fresh feed entry point, there are usually two or three additional trays below the gas-oil draw tray, which are refluxed with partially cooled gas oil. The gas oil is drawn off to a conventional side stripper having six to eight trays, with steam introduced under the bottom tray to vaporize the light ends and control the initial boiling point of the gas oil. Steam and vaporized light ends are returned from the top of the gas oil stripper to the fractionator one or two trays above the draw tray. A pumparound is also used to at the draw tray to provide better heat integration.

A heavy naphtha side draw is sometimes used. There are usually eight to ten trays between the gas-oil draw and the naphtha side draw or column top. If a naphtha side draw is employed, additional trays are needed above the naphtha draw tray.

The temperature of vapors rising to the gas oil draw-off tray is controlled to reach the desired gas oil end point. A higher temperature results in more heavies being drawn off in the gas oil, leaving less of the heavy gas oil to be recycled to the furnace.

The overhead condenser temperature is controlled to send most of the C_4 's and lighter to the gas stream and the C_5 's and heavier to the naphtha stream, which is then sent to a hydrotreater for sulfur removal and olefin saturation. The hydrotreated coker naphtha can be blended directly into the finished gasoline, but is often isomerized as the octane rating is poor.

The gas oil fraction is usually split into light and heavy coker gas oils before further processing. The light coker gas oil is usually hydrotreated and used as diesel fuel, while the heavy coker gas oil is fed to the cat cracker or sent to a hydrocracker, or used as a heavy fuel oil. The off-gas from the condenser goes to the gas plant where C_3 and C_4 are recovered as LPG and the lighter end can be used as fuel gas in the refinery.

30.2.3 Delayed Coking Reactions

Vacuum residua are extremely complex mixtures of tens of thousands of compounds, so a complete char-

acterization of the delayed coker feed is impossible. However, there are several relatively simple analytical tests including the Conradson Carbon Residue (CCR) test (or, alternatively the Microcarbon Residue (MCR) test), which gives a rough idea of the coking propensity of the feed, as well as SARA (saturate-aromatic-resin-asphaltene) analysis. In a SARA analysis, the feed sample is separated into a saturate fraction consisting of linear, branched, and cyclic saturated hydrocarbons; an aromatic fraction, consisting of one or more aromatic rings; a resins fraction, consisting of large heterocyclic molecules which are completely miscible in oil; and an asphaltene fraction, which consists of very high-molecular weight molecules having large aromatic cores. Asphaltenes are defined as material that is insoluble in *n*-heptane (or, depending on the analysis being done, in *n*-pentane or *n*-octane) but soluble in toluene. The asphaltenes are thought to be kept solubilized in the oil due to the presence of the large resin molecules, which in turn are solubilized by the aromatic and saturate fractions. Asphaltenes are easily converted to coke, whereas the other components are generally thought to have to crack and condense to form asphaltenes before coke can be formed.

Cracking reactions in the delayed coking process are endothermic and occur as free radical reactions. There are three types of reactions involved in cracking: dehydrogenation, which involves the loss of a hydrogen atom from an aromatic hydrocarbon, resulting in the formation of an aromatic free radical intermediate; rearrangement reactions, in which thermal rearrangement usually leads to formation of more stabilized aromatic ring compounds; and polymerization of aromatic radicals to form coke. Reactions occur in both liquid and vapor phases, but since the vapors leave the coke drum quickly the vapor-phase reactions are quenched before the coke formation step. The progression to coke in the liquid phase is thus

Reactions occurring in the delayed coker have been described by *Wiehe* [30.5, 6] using a *pendant-core model* of the residuum molecules. Here the residuum macromolecules are modeled as having pendant chains that thermally crack from large aromatic cores. The pendants are volatile once broken off, while the large cores remain nonvolatile and convert to asphaltenes as the pendants are broken off. These asphaltene cores are unreactive as long as they remain dissolved in the resins. As the conversion is increased, the asphaltene core concentration increases and the nonvolatile resin concentration decreases until the solubility limit of as-

phaltene cores in the remaining resins is exceeded. At that point, asphaltene cores phase separate to form a second liquid phase. The asphaltene cores crack off nonvolatile heptane-soluble fragments and recombine to form solid coke.

As coke is formed, the asphaltene concentration decreases from its maximum value. As the unreacted asphaltenes become depleted, the asphaltene concentration approaches a constant ratio to the nonvolatile heptane-soluble fraction because of the solubility limit of the remaining asphaltenes in nonvolatile heptane solubles. An induction period for coke formation has been widely reported in the literature, but the evidence indicates that at the conditions in the delayed coker (temperatures greater than 840 °F (450 °C)) there is no measurable induction period [30.7, 8].

30.2.4 Operating Variables

The three most important operating variables that determine the yield in the delayed coker for a given feed are temperature, pressure, and recycle ratio. At constant pressure and recycle ratio, the coke yield decreases and the liquid yield and gas-oil end point increase as the drum temperature is increased. This is primarily because high temperatures favor the vaporization of more of the heavy gas oils, which leave the drum before reacting further. However, there is only a narrow range over which the temperature can be adjusted. Since delayed coking is an endothermic reaction, the heater outlet temperature is the control point for adjusting the coking reaction temperature. In actual practice, if the temperature is too low, the coking reaction does not proceed far enough resulting in the formation of pitch or high VCM (volatile combustible matter) coke. If the temperature is too high the coke formed will be excessively hard and difficult to remove from the drum with the hydraulic decoking equipment. In addition, at higher temperatures the possibility of prematurely coking the heater tubes and/or the transfer line increases. Generally, one reaches the temperature limit when the furnace run lengths become short, requiring more furnace decokes and unit startups and shutdowns, thus affecting unit safety and maintenance costs.

At higher temperatures, the extent of conversion of heavier products increases, thereby increasing the yield of the gas and light naphtha fractions. Increasing the temperature of the process also results in increased generation of olefinic and aromatic hydrocarbons both in coker naphtha and gas oil.

At constant temperature and recycle ratio, the effect of increased pressure is to retain more of the heavy hydrocarbons in the coke drum. This retention increases the coke yield and slightly increases the gas yield, while

decreasing the pentane and heavier liquid product yield. According to *Lieberman* [30.9] reducing the pressure of the coke drum by 8 psi decreases coke yield roughly by 1.3 wt%, while liquid yield increases by 1.3 vol.%. The recent trend in the design of delayed cokers has been to maximize the yield of liquid products by designing for lower pressures. The limitations on reducing the pressure of the unit are primarily system pressure drop losses, vapor velocity in coke drums, and possible increase in equipment size and cost [30.10]. In order to achieve low-pressure operation, the coke drum overhead pressure is controlled by a pressure controller located at the fractionator overhead separator, which is set to maintain a positive pressure of 1–2 psig (70–140 barg) at the compressor suction. The coke drum overhead pressure is equivalent to this controlled pressure plus the pressure drop in the piping and equipment between the coke drums and the compressor.

Recycle or throughput ratio (TPR) is defined as the ratio of the volumetric flowrate of feed to the furnace over the volumetric flowrate of the fresh feed to the delayed coking unit. Recycle ratio has a significant impact on product yields. Increasing the TPR by 10 vol.% reduces the liquid yield by roughly 1.5 vol.% [30.11]. As the TPR is increased, continuous condensation and recirculation of heavy coker gas oil from the main fractionator through the furnace causes *overcracking* and, consequently, production of coke and light compounds. Even though recycle lowers the yield of the valuable liquid products, it is often used because addition of recycle tends to reduce the coke deposition in the furnace tubes. The TPR used in commercial delayed cokers generally ranges from 1.0 to 1.2.

The quality of the products from delayed coking process is directly affected by the physicochemical properties of the feed. The effect of feedstock properties on the delayed coking process can be estimated from a SARA analysis of the feed. The saturate fraction determines how paraffinic a feed is: the higher the percentage of saturates, the higher the amount of paraffins. Coking reactions start with the thermal cracking of paraffins and their side chains to form olefins and paraffins of lower molecular weight. The more paraffinic the residue, the higher the formation of lower molecular weight compounds will be, resulting in a yield increase of distillates and gases. On the other hand, paraffinic-type feedstocks with some sodium present foam readily compared to aromatic feedstocks which tend to have smaller foam heights.

Aromatics play an important role in the coking process. Once the paraffin chains have been cracked into lower molecular weight molecules (paraffins and olefins), the polymerization reactions take place, which

are promoted by the dehydrogenation of some of the cracked paraffins, such as cycloparaffins (naphthenes). These reactions lead to the formation of aromatic molecules which in turn can be condensed into polynuclear aromatics, generating a mesophase which converts into coke. In other words, aromatics are precursors to mesophase formation, and therefore of coke formation.

Resins and asphaltenes are the heaviest, most aromatic and most polar compounds found in delayed coker feedstocks. Feeds that are high in asphaltenes will have higher coke yield than paraffinic or aromatic feeds.

The weight fraction of carbon present in the crude oil is another variable that greatly affects the overall yields of the process. This variable is strongly related to the amount of asphaltenes present in crude oil; the higher the weight fraction of asphaltenes, the higher the weight fraction of residual carbon. A widely used method to determine this variable is the CCR test or MCR test, which allow a preliminary estimate of the coke yield. As a rough rule of thumb, the coke yield is about 1.6 times the value of the MCR.

Other properties of the feed, such as metals, sulfur, and nitrogen, have no significant impact on the overall yields of delayed coking process; nonetheless, the quality of the products is highly affected by these properties.

In general, the kinetics of polymerization reactions are slower than for the thermal-cracking reactions. Therefore, coke drums provide the necessary residence time to proceed to coke formation. Short coking cycles do not allow completing cracking and polymerization reactions, so as a consequence, the concentration of VCM in the petroleum coke tends to increase when the coking cycle is shortened.

30.2.5 Coker Products

Coke Formation

Coke can exhibit a variety of morphologies, with the type of coke morphology dependent on feedstock properties and, to a lesser extent, on drum temperature and pressure. Needle coke, named for its needle-like structure, is produced from feedstocks without asphaltenes present. It is made from highly aromatic feedstocks such as FCCU decant oils, and requires carefully controlled coking conditions at high pressures (100 psig = 7 barg) and high recycle ratios (1 : 1). Needle coke, used in graphite electrode manufacturing, is considered a specialty product and commands a high price.

For delayed cokers running with vacuum resid as a feedstock, coke morphology is usually divided into two types: sponge coke and shot coke. Coke morphology can be correlated to the ratio of the C₇ asphaltenes of the feed (that portion of the feedstock that is in-

soluble in *n*-heptane) to CCR of the feed. Feedstocks with a C_7 asphaltene to CCR ratio of less than 0.5 tend to make sponge coke which, as the name implies, has a spongy, porous texture. On the other hand, feeds with a C_7 asphaltene to CCR ratio greater than about 0.65 tend to form shot coke. This morphology is characterized by small (0.06–0.25 in diameter) spheres, usually embedded in a matrix of coke material. In some cases, however, these shot clusters can grow large enough to plug the coke drum outlet. Asphaltene to CCR ratios between 0.5 and 0.65 generally form a transitional type coke, with some characteristics of both shot and sponge coke. Figure 30.3a,b shows typical looking examples of shot and sponge coke.

Shot coke is believed to form when droplets of asphaltene material, having separated out of solution from the feed, enter the coke drum at high velocities and quickly polymerize to form coke. Shot coke formation thus requires a high-asphaltene feedstock and is favored at higher temperatures, where coke formation occurs quickly, and low pressures, which causes in an increase in vapor velocity. The production of shot coke has increased greatly in recent years due to the heavier crudes being used in refineries.

Coke morphology can be affected by the recycle ratio used. Shot coke formation can sometimes be avoided by increasing the recycle ratio. This is probably due to the fact that the heavy coker gas oil has very little asphaltene content, so blending it with the fresh feed lowers the asphaltene content of the furnace charge. There is also thought to be a solubility effect in that recycle typically is a medium volatility, aromatic rich stream which has the ability to dissolve the heavy aromatics. In short, the higher the recycle ratio, the better the coke quality.

Coke that has been adequately steam stripped typically contains 5–15 wt% volatile matter.

Volatile Products

A number of investigators have developed correlations for delayed coking yields, including Gary and Handwerk [30.12], Castiglioni [30.13], Maples [30.14], Smith et al. [30.15], and Volk et al. [30.16]. The Gary and Handwerk, Castiglioni, and Maples yield correlations generally are based only on feedstock properties, mainly CCR, whereas the Smith et al. and Volk et al. are based on coker drum temperature and pressure as well as feedstock properties. Muñoz et al. [30.17] summarized these correlations and compared them to commercial operating data. The data came from 13 different commercial cokers, using feeds having CCR ranging from 15.6 to 31 and API gravity ranging from 0.1 to 10.3, run at temperatures between 900 and 930 °F (480–500 °C), pressures between 15 and 40 psig (1–3 barg), and TPR between 1.05 and 1.10. Their conclusion was that correlations that include the effect of operating conditions [30.15, 16] are more accurate than those that consider only feed properties [30.12–14]. Overall, the Volk et al. correlation exhibited the lowest errors. The average absolute error of all predicted yields were in the following increasing order: Volk et al. (10.14%) < Smith et al. (27.57%) < Castiglioni (28.03%) < Maples (41.63%) < Gary and Handwerk (49%).

The correlations of [30.16], obtained from microreactor data, were based on microcarbon residue (MCR, in wt%), temperature (T , in °F), pressure (P , in psig), and liquid space velocity (LSV, in min^{-1}). The range of operating conditions used to develop the correlations is 900–950 °F (480–510 °C), 6–40 psig, and MCR from

Fig. 30.3 (a) Shot coke morphology, (b) sponge coke morphology

16 to 29 wt%. The correlations are

$$\text{liquid (wt\%)} = -1.1139 \times \text{MCR} + 0.0419 \times T \\ - 0.2897 \times P + 1103.08 \times \text{LSV} \\ + 41.59 ,$$

$$\text{coke (wt\%)} = 0.9407 \times \text{MCR} - 0.0609 \times T \\ + 0.1529 \times P - 319.759 \times \text{LSV} \\ + 65.075 ,$$

$$\text{gas (wt\%)} = 0.1729 \times \text{MCR} + 0.0191 \times T \\ + 0.13646 \times P - 786.319 \times \text{LSV} \\ - 6.762 ,$$

$$\text{naphtha (wt\%)} = -0.3086 \times \text{MCR} + 0.0137 \times T \\ + 0.1571 \times P - 819.63 \times \text{LSV} \\ + 16.461 ,$$

$$\text{diesel (wt\%)} = -0.3339 \times \text{MCR} - 0.02635 \times T \\ - 0.0392 \times P + 70.957 \times \text{LSV} \\ + 50.452 ,$$

$$\text{gas oil (wt\%)} = -0.4714 \times \text{MCR} + 0.0546 \times T \\ - 0.4076 \times P + 1851.76 \times \text{LSV} \\ - 25.315 .$$

The correlations could not be used to predict yields from industrial cokers because of the lower liquid yields obtained in the microreactor, as compared to those observed in refineries, which becomes worse at the lowest feed rate. Also, the correlations include the effects of LSV, which has a different meaning for the microreactor than for commercial units. For these reasons, Volk et al. proposed the following correction to the above equations

$$\text{coke}^* (\text{wt\%}) = 0.91 \times \text{coke} ,$$

$$\text{gas}^* (\text{wt\%}) = 0.82 \times \text{gas} ,$$

$$\text{liquid}^* (\text{wt\%}) = 100 - (\text{coke}^* + \text{gas}^*) ,$$

$$\text{gasoline}^* (\text{wt\%}) = 0.75 \times \text{gasoline} \times (\text{liquid}^*/\text{liquid}) ,$$

$$\text{diesel}^* (\text{wt\%}) = 0.90 \times \text{diesel} \times (\text{liquid}^*/\text{liquid}) ,$$

$$\text{gas oil}^* (\text{wt\%}) = \text{liquid}^* - (\text{gasoline}^* + \text{diesel}^*) ,$$

where the * indicates a corrected value.

It is worth noting that none of the published correlations for delayed coker yields includes the effect of recycle.

Coke Usage

Petroleum coke is typically used as a source of energy, usually by burning but in some cases by gasification, or as a source of carbon for industrial applications. Fuel

grade coke represents nearly 80% of worldwide production and is a source of fuel for cement kilns and electric power plants. Calcining the coke, by heating it in a rotary kiln at temperatures over 2500 °F (1370 °C), increases the carbon content of the coke thus making it suitable, if it is sufficiently low in sulfur and metals (generally less than 2 wt% sulfur and less than 0.5% ash content), for use in the aluminum, graphite electrode, steel, titanium dioxide, and other carbon consuming industries.

More than 85% of all calcined petroleum coke is used to produce anodes for smelting alumina into aluminum via the Hall–Héroult process, and there is no other commercially viable method to produce primary aluminum. Although originally anthracite coal was used as the carbon source, calcined petroleum coke supplanted anthracite as soon as petroleum coke became commercially available due to its superior combination of electrical conductivity, resistance to chemical and physical degradation, higher carbon content, and low ash and sulfur content.

Calcined petroleum is also used in the production of titanium dioxide, and in the steel industry as a partial replacement for metallurgical coal as a feedstock for coke oven batteries, and as a partial substitute for pulverized coal directly injected into blast furnaces. All of these uses require high-quality sponge coke.

Needle coke is used to produce the electrodes used in electric arc furnace (EAF) steel production. No other material has needle coke's combination of electrical conductivity and physical properties required for EAF electrodes, making it a high-value product.

Calcined petcoke is also used in lime production and as a substitute for fuel oil in brick and glass manufacturing due to its low ash content as compared with coal.

Shot coke is unique in that the small spheres of shot each have a slick shiny exterior coating of needle-type coke, while the inside of each sphere contains isotropic or amorphous type coke. Shot coke cannot be used in making aluminum anodes because the outer needle coke layer of the shot sphere has a very low coefficient of thermal expansion while the inside of the sphere, being isotropic, has a very high coefficient of thermal expansion. When rapidly heated in a calcining kiln, the outer layer is cracked and pulled away from the center; thus when used in an anode with a coal tar binder, the binder adheres to the outer layer, resulting in cracks between the ball and the skin and thus causing the anode to crack in an aluminum smelter cell. The only significant use of shot coke is as a low quality fuel, especially in cement kilns where its generally high sulfur content is an advantage rather than a disadvantage.

30.3 Other Thermal Processes

30.3.1 Flexicoking

Flexicoking and fluid coking are similar processes that are sometimes used as an alternative to delayed coking. In this flexicoking process, hot feed, after contacting overhead effluent vapors for heat exchange, is sprayed on to a fluidized bed of hot coke particles. Here cracking takes place at much higher temperature than delayed coking (temperatures up to 1050 °F (565 °C)). Coke inventory is maintained by transferring bed coke from the reactor to a heater via a transfer line. Hot coke from the heater is circulated back to the reactor through a coke transfer line, supplying the heat necessary to maintain the reactor temperature. Excess coke is sent to a gasifier where the coke reacts with air and steam to produce a clean fuel gas. Approximately 97% of the coke generated in the reactor is consumed in the process, with a small amount of product coke recovered from the fines system. The fines are used in metallurgical, metals recovery, and fuels applications. Product fluid coke can be withdrawn from the heater to adjust the gasification level. This coke has a lower sulfur content compared to the coke produced in the reactor, making it more attractive for sale. Flexicoking produces a similar range of liquid products to delayed coking and provides an effective way of utilizing coke that might otherwise be difficult to dispose of. It has a considerably higher capital cost compared to delayed coking, however, and the greater complexity of the process can be a drawback. As of 2011, there were five commercial flexicoking installations with a total capacity of around 200 000 bbl/day.

30.3.2 Fluid Coking

Fluid coking is a simplified version of flexicoking. The Fluid Coking process burns only enough of the coke to satisfy the heat requirements of the reactor and the feed preheat. Typically, this is about 20–25% of the coke produced in the reactor. The rest of the coke is withdrawn from the burner vessel and is not gasified as it is in a flexicoker. As a result, there are only two fluid beds used in a Fluid Coker rather than three: a reactor and a burner which replaces the heater. Fluid coking has the advantage of its simplicity and reduced capital cost as compared to flexicoking. The main advantage of the flexicoker over the fluid coker is that most of the heating value of the coke product is made available as low sulfur gas which can be burned without an SO₂ removal system on the resulting stack gas, whereas SO₂ removal would be needed if coke containing 3–8 wt% sulfur is burned directly in a boiler. In addition, the coke gas can be used to displace liquid and gaseous hydrocarbon fu-

els in the refinery process heaters and need not be used exclusively in boilers as is the case with fluid coke.

As of 2014, the US fluid coking capacity was nearly 160 000 bbl/day.

30.3.3 Visbreaking

Visbreaking is a relatively mild thermal-cracking operation which is mainly used to reduce the viscosity and pour point of vacuum resid to meet No. 6 fuel oil specifications or to reduce the amount of cutting stock required to dilute the resid to meet these specifications. Refinery production of heavy fuel oils can be reduced from 20% to 35% and cutter stock requirements from 20% to 30% by visbreaking. The gas-oil fraction produced by visbreaking is also sometimes used as cat cracker feed.

In the visbreaking process, the goal is to crack off the long paraffinic side chains attached to aromatic rings in the vacuum resid, as these are the primary cause of high pour points and high viscosities. The amount of cracking is limited because if the operation is too severe, the resulting product can become unstable and form polymerization products during storage. The product improvement resulting from visbreaking is a function of the feed quality. Highly paraffinic feedstocks are easily cracked and a viscosity reduction of 25–75% can be achieved. For highly asphaltenic feeds, stability of the final product is a problem, so only smaller changes in fluid viscosity can be achieved.

The principal reactions occurring in visbreaking are: cracking of the side chains attached to cycloparaffin and aromatic rings at or close to the ring so the chains are either removed or shortened to methyl or ethyl groups; cracking of resins to lighter hydrocarbons and compounds which convert to asphaltenes; and (if temperatures above 900 °F (480 °C) are used) some cracking of naphthene rings.

There are two types of visbreaker processes: coil or furnace visbreaking, and soaker visbreaking. The coil or furnace visbreaking operation looks very much like a delayed coking operation, with furnace exit temperatures between 885 and 930 °F (475–500 °C), except that the feed is quenched upon exiting the furnace rather than being allowed to coke. In the soaker visbreaking process, feed leaves the furnace between 800 and 820 °F (426–438 °C) and passes through a soaker drum which provides additional reaction time at this temperature before quenching takes place.

Visbreaking is usually used in locations where motor fuel demand is relatively low and heavy fuel demand is relatively high. In areas such as the United States,

with high motor fuel demand and low demand for heavy fuel oil, visbreaking is rather rare. In 2014, vis-

breaking capacity in the United States was a mere 16 000 bbl/day.

30.4 Future Challenges

As crude slates have become heavier, the need for delayed coking has grown, creating a need to increase delayed coker throughput. This can sometimes be done by reducing the coking cycle time, but requires faster decoking and quench times. Heavier feeds also tend to make poor quality shot coke, sometimes leading to free flowing coke dumps or coke with hot spots, which create safety issues. Finding a market for shot coke can be difficult as well, which has created a problem with stockpiles of coke at some refineries.

Furnace fouling is a significant problem in delayed coking units. There is a need to develop ways to better understand causes of furnace fouling and find ways to prevent it.

Proper use of antifoam is important to prevent foamover events and to allow operating with a lower coke drum outage (the measured height of coke below the top head). Improvements are needed to foaming models in order to predict and understand severe foaming events and to optimize usage of antifoam. Overuse of silicon-based antifoam is not only costly but can cause poisoning of downstream units; for this reason, development of effective non-silicon-based antifoam is needed.

Finally, there are environmental issues with delayed cokers that are coming under increasing scrutiny. There is a need to understand and predict sour water quality from delayed cokers. Also, VOC emissions during the deheading and decoking steps are currently not well understood.

31. Transitioning Refineries from Sweet to Extra Heavy Oil

Martin R. Gonzalez

A sweet-sour petroleum refinery shifting to heavy crude processing will face a number of challenges, many requiring investment to overcome. The difficulty in processing these feeds is related to the properties of extra-heavy oil, including a high aromatics content and a relatively high concentration of contaminants that pose a threat to reliability and product quality.

In this chapter, the relationship between feed composition and unit design is explored, with unit revamp and new-build strategies discussed for process units to adapt to the new crudes. Among other investments, significant scope is likely to include fractionation upgrading for improved removal of asphaltenes, volatile metals, and salts, as well as hydrotreaters modifications to deal with contaminants and counter the hydrogen deficiency of the oil.

31.1 The Evolving Refinery

The transition to extra-heavy Canadian crudes places unprecedented demands on the operating units within an existing refinery. Overcoming these challenges requires innovation as well as the effective utilization of familiar technology. In this section, technology hurdles for a transition to heavy oil are discussed, using a typical sweet-crude refinery configuration for illustration.

A block-flow diagram for a typical US refinery configured for gasoline production is shown in Fig. 31.1. Refineries such as this one are likely to employ the following main technologies:

- **Crude fractionation:** Many refineries have crude units designed for sweet- and medium-sour crudes, with some traditional heavy crude being processed.
- **Fluid-catalytic cracking (FCC) pretreat:** Refineries designed for the gasoline production in the United States tend to have FCC as their primary conversion technology. Some will have only partial FCC-feed hydrotreating, meaning that some of the sweeter straight-run gas oil is sent straight to the FCC without being pretreated.
- **FCC gasoline:** FCC naphtha must often be hydrotreated further to lower sulfur to acceptable level for the gasoline pool. However, many refiners do not

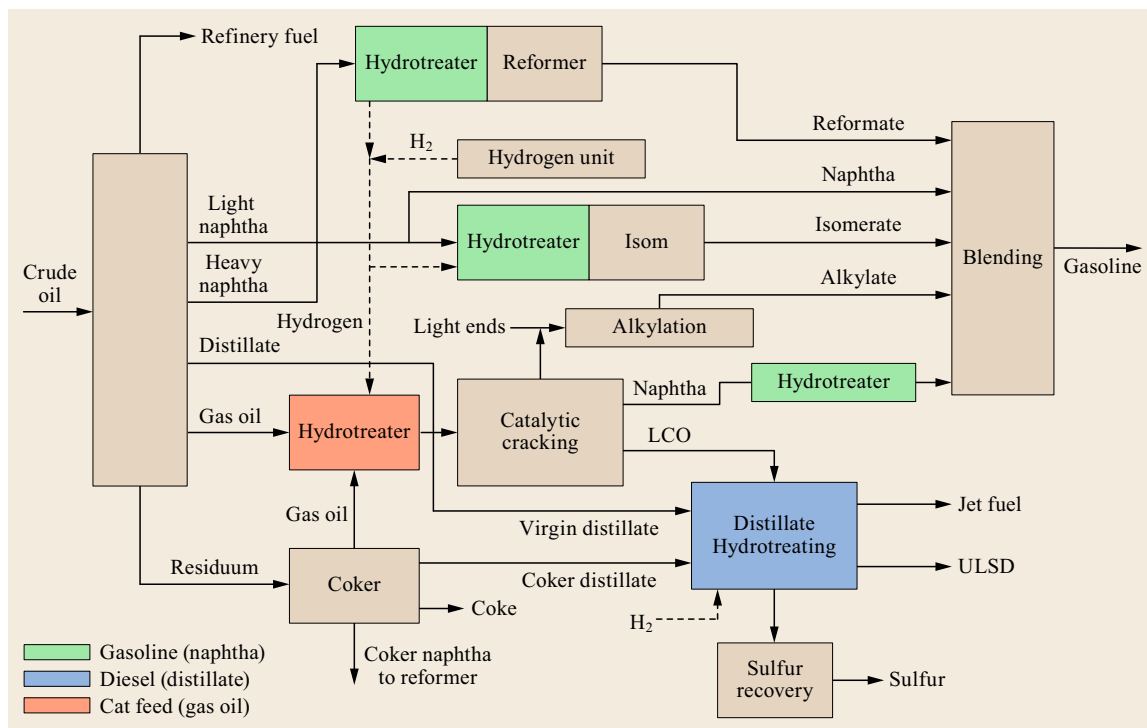

Fig. 31.1 Typical refinery configured for gasoline production. (Courtesy of BP)

have capacity to process the entire volume of FCC gasoline. They will instead desulfurize a smaller volume and let the rest go to blending without further processing. To be most effective, they may strategically segregate naphtha streams into *high* and *low* sulfur concentrations. Alternatively, or in addition, refiners may use fractionation to concentrate the difficult-to-remove sulfur into a *heavy* cut that will be hydrotreated more severely than the *light* cut [31.2].

- **Delayed coking:** Many refineries rely on thermal cracking technologies like delayed coking for residuum conversion. As they may not have open capacity to process the larger volume of residuum contained in bitumen-based crudes, they will need to consider investment in addition coking capacity, or in residuum hydrocracking technologies.
- **ULSD production:** The refinery may have a diesel unit that was designed to meet the prior sulfur requirement of 500 ppm, and has been repurposed for 15 ppm diesel, as was done by many to achieve the 2006 ultralow sulfur diesel (ULSD) specification [31.3]. Such a unit is likely to operate below 1000 psig in pressure, and may not have the severity to produce ULSD from higher sulfur intermediates. Further, the unit may not have the compressor capacity to provide the gas circulation rate necessary

for hydrogen-deficient feeds, having been designed for conventional crudes.

- **Octane-upgrade units:** Many refineries use light-duty hydrotreaters to desulfurize the feed to reformers and C₅/C₆ isomerization units. These units may not be configured for the effective removal of nitrogen and other poisons, or for handling a larger volume of olefinic naphtha, should the coker be expanded for bitumen processing. In addition, the volume of C₅/C₆ naphtha from these new crudes may exceed capacity of the isomerization unit. All these considerations will manifest as constraints to the refinery considering a shift to extra-heavy crudes.
- **Hydrogen supply:** Hydrotreating the new feedstocks and cracked intermediates is likely to require additional hydrogen, possibly a few times higher than that available in the refinery.
- **Treatment:** A refinery designed for medium-sour crudes may neither have the necessary sulfur recovery capacity, nor the amine circulation rate or sour water regeneration capacity needed.

An investment for Canadian crude at such a refinery would include conversion of the crude unit to enable processing of bitumen-derived crudes. This might imply metallurgy upgrades or even construction of new

furnaces and/or a bigger vacuum tower. Also, desalting capacity and efficiency may need to be improved to handle water-soluble impurities.

Coking capacity would need to be increased, or other residuum processing unit added such as a resid

hydrocracker. The downstream equipment would also need to be upgraded, to handle the change in quality of intermediates. This investment can be significant, owing to the differences between conventional and extra-heavy crudes.

31.2 Characterization of Extra-Heavy Crudes

Bitumen-derived crudes are characterized by the following qualities, relative to conventional crudes [31.4]:

- Low hydrogen content, in the range 10–11.5%, with a correspondingly high aromatics content.
- A high total acid number (TAN) likely to contribute to higher corrosion rates.
- Higher levels of sulfur in the gas oil and diesel range.
- High levels of asphaltenes. Blending with lighter *in-compatible* crudes can cause these species to lose solubility and deposit in crude trains.
- The presence of clays, which can aggravate asphaltene precipitation. Removal of clays and salts from crude depends on the effective desalter operation.

In addition, the crude may contain synthetic crude components, derived from bitumen having been upgraded through cracking and light hydrotreating, to stabilize the more reactive components. As such, the superficial concentrations of sulfur and nitrogen will seem low. However, it must be realized that the S and N species present and the way they are distributed will be different from conventional crudes [31.4].

The differences encountered in the type and concentration of sulfur, nitrogen, aromatics, and contaminants will drive the nature of the investment a refinery makes to accommodate processing of crude from the Canadian oil sands. These differences and their implications for design are discussed in the following sections.

31.3 Crude Desalting

The difficulty in removing chlorides, filterable solids, amines, and H₂S scavengers from heavy Canadian crudes is often underestimated. In fact, the desalting section of the crude complex can require significant investment to upgrade. The filterable solids are iron oxides, sulfides, sand, and clay, which can be held in a *rag layer* emulsion through the stabilizing force of the tramp amines and H₂S scavengers. Concentrations of filterable solids can vary tremendously, with some crudes having well under 50 ptb (pounds per thousand barrels) and others having close to 300 ptb [31.5, 6].

In desalted crude, the refiner transitioning to extra-heavy Canadian crude may experience 3–5 ptb of salt, where levels less than 1 ptb had been achieved before. Even worse, the desalter may have more frequent upsets, leading to excursions of very high salt concentrations for short periods of time. A high salt content can lead to a dramatic increase in crude unit corrosion. The problem can be aggravated by the organic and inorganic chlorides present in some extra-heavy crudes.

Chloride salts will hydrolyze in atmospheric and vacuum towers, forming corrosive HCl. It is common, with heavy Canadian crude processing, for corrosion and salt build-up of salts to increase in the vacuum tower.

For these reasons, a high-desalting efficiency is a critical aspect of Canadian extra-heavy oil processing. Desalters for this type of operation are sized larger than those for traditional crudes. Whereas the latter can be designed for settling based on gravity and viscosity, resolving the relatively stable interface emulsion formed from extra-heavy crudes requires a higher residence time. Additional expense may be required for the right mix valve design and to all a higher wash water rates so that appropriate droplet size may be achieved. In addition, new transformers may be needed that can supply a range of voltages for optimization, and the heat exchanger network may need to be redesigned to allow operation of the desalter at the optimal temperature.

31.4 Aromatics Content Affecting Diesel and Jet Fuel Production

Yui has published cetane numbers of diesel from synthetic crude oil, that is, crude derived through bitumen upgrading and lightly hydrotreated [31.7]. Cetane is a measure of the ignition delay during combustion [31.8].

The products generally had low cetane numbers – about 33, compared to a specification of 40 required in the United States. The poor combustion properties were associated with a high aromatics content of over 40%, although other factors, such as the degree of branching of paraffin side chains, were found to be significant [31.9].

Nevertheless, a commercial aromatics saturation process was shown to improve cetane number, producing a high-quality diesel that met all fuels specifications. Employing a noble metal or nickel–tungsten catalyst to saturate aromatic rings, the process achieves a total aromatics content as low as 5% by weight. In this way, a cetane improvement of up to 6 numbers is routinely achieved. Yui demonstrated a linear relationship between cetane number and aromatics content through this method. Aromatics saturation reached a maximum at about 572 °F [31.10].

It is important to note that typical ULSD units require much higher temperatures for sulfur removal. However, the maximum hydrogen uptake is generally lower at higher temperature due to equilibrium limitations for aromatics saturation reactions [31.11].

Similarly, jet fuel produced from the kerosene boiling range material of synthetic crude oils tends to have a high aromatics content. This can be problematic for meeting the aromatics specification itself, or for meeting smoke point [31.7]. Jet A and Jet A-1 have specifications of not more than 25% aromatics by volume [31.12].

However, *dilbit*-type crudes, which are typically produced by diluting bitumen with natural gas condensate, can have an aromatics content of 15–20%, the concentration depending partly on cut-point. In winter, the assays will tend toward a greater volume of low-aromatics material in the kerosene boiling range. With this in mind, the optimal volume of jet fuel to be produced by a heavy-oil refinery may be determined by crude mix, with dilbits favoring higher production.

31.5 High Aromatics Content Affecting Gas Oil Conversion

The shift from conventional crude to bitumen-derived crude can result in 20% lower conversion of gas oil in an FCC. This is not only because of the lower hydrogen content – from about 12.5% to about 10.5% by weight – but also because the primary upgrading processes used to produce any synthetic portion may result in aromatic species that have shorter side-chains [31.13].

Gas oils contain polynuclear aromatic species in concentrations as high as 60% by weight. Direct processing of multiring aromatics is associated with high cycle oil yield and low gasoline yield, with a gasoline quality that is paraffinic and olefinic. With hydrotreating, more mono-aromatic species are created, leading to a greater yield of higher octane gasoline.

Beyond this, it is possible to *over-hydrotreat*, creating a gas oil with a very high hydrogen content that is mostly naphthenic. Feeding a naphthenic feed to FCC can result in a high yield of gasoline that is lower in octane, and in a high dry gas yield. Depending on the nature of the starting gas oil, the optimal hydrotreating severity is one that achieves between 1 and 2% hydrogen uptake by weight. As a guideline, 1.5 wt% hydrogen content increase corresponds to approximately 1000 SCF/bbl chemical hydrogen uptake [31.13].

For these reasons, the refinery transitioning from sweet crudes to extra-heavy oils is likely to need an increase in gas-oil hydrotreating capacity and/or severity. Severity can be considered to be a combination of pressure, space velocity, and temperature. Temperature is usually limited on the high side by the onset of undesirable cracking and accelerated coke-laydown, and on the low side by the activation energy required to initiate desulfurization reactions. With the practical range of operating temperature constrained by these other factors, the design variables that determine the severity of a new unit are space velocity (i. e., catalyst volume) and unit pressure.

Space velocity and pressure will trade-off against each other in the sense that, at higher pressure, the necessary reactor size is smaller to achieve the same conversion objective. Starting with a higher pressure also leaves more options open for debottlenecking because additional reactors can be added later. Once a design pressure is determined, however, the design pressure rating of vessels and major equipment will be fixed, making a significant pressure increase nearly impossible at a later stage. A gas oil unit operating at a higher pressure may also be more ro-

bust in recovery from upsets and feed-quality excursions.

A higher pressure design has the disadvantage of requiring thicker reactor walls and compressors of greater horsepower, both of which may add significant capital and operating cost, and can make unit start-ups and shutdowns more complex. As design pressure increases significantly, it is also more likely that a higher flange rating will be required, making the cost of all the piping in the high pressure section significantly more expensive. A life-cycle cost analysis should always be performed when choosing operating pressure and reactor volume. As a practical matter, it may be optimal to design for the highest pressure possible without forcing the flange rating to the next higher class.

As with distillate hydrotreating, units that are designed for pretreating of FCC feed can have a very high hydrogen consumption of 1000 SCF/bbl or greater. Al-

though it is common for hydrogen consumption in ULSD units to decrease through the catalyst cycle, gas-oil hydrotreaters tend to exhibit much less variability, and may even have a higher consumption at end-of-run as reactor temperature is raised. This is partly owing to the higher deactivation rate of hydrodesulfurization (HDS) activity as compared to hydrogenation activity [31.14].

A further implication of high hydrogen consumption in gas oil and diesel hydrotreaters is that additional hydrogen generation capacity may need to be constructed to satisfy the increased demand. In this way, the transition from sweet to extra-heavy oils can double or triple the original refinery hydrogen requirement. To avoid the cost of capital, the refinery may have an option to contract a third-party gas supplier to construct the equipment, thereby transforming the refinery's investment into a long-term operating cost.

31.6 Vanadium and Nickel in Crude and Gas Oil

Vanadium occurs naturally in crude, and is concentrated in cuts at 800 °F and heavier. Canadian extra-heavy oils contain higher concentrations of vanadium. Gas oil produced in a crude or coking unit can entrain nondistillable residues that contain vanadium. This amount is in addition to volatile vanadium that boils in this range through the course of natural distillation [31.15].

The refiner transitioning to extra-heavy oils will desire to maximize the volume of gas oil produced, by operating at a very high 95% and final boiling point. Because vanadium is a severe hydrotreater poison, an optimized design may include scope to protect the hydrotreater, as well as scope on the crude and coking units to improve fractionation and minimize entrainment.

It is not uncommon for V in FCC feed streams to be as high as 5–10 ppm. In cases of severe entrainment, concentrations of V in heavy vacuum gas oil can reach 20 ppm. The volume of entrained residuum need to be very small for this to occur, as vacuum residuum can contain levels of over 800 ppm. Similarly, entrainment of residuum can also occur in atmospheric gas oil.

To minimize V in virgin cuts, the proper investment must be made in flash zone, wash section, and stripping section. The strategy for investment should be to reduce localized velocities that entrain residuum, while providing enough wash oil volume to prevent entrained residuum from reaching the gas oil draw. For volatile V, it is important to maximize stripping section efficiency rather than relying on vaporization in the vacuum heater to lift gas oil volume. The vacuum tower inlet

device may also need to be redesigned to reduce localized velocities. Because stripping steam may need to be increased while coil steam is added to combat furnace coking, the size of the vacuum ejector may also need to increase, and this can be a significant investment.

Some refiners may be surprised to learn that heavy coker gas oil (HCGO) vanadium may increase when processing extra-heavy crudes. HCGO vanadium goes up with vacuum residuum metals, vacuum unit cut point, and HCGO final boiling point. Further, entrained material from the coke drum can contain V at concentrations over 1000 ppm. Here, the factors governing entrainment are coke drum and main fractionator vapor velocities. Steaming of the hot coke drum may cause entrainment, in addition to that which occurs during normal operation. Lower operating pressure in coke drum and fractionator will make entrainment worse because superficial velocity increases.

Vanadium in crude exists mainly as vanadyl porphyrin species. Porphyrin rings, whose structure is shown in Fig. 31.2, are chelating agents that occur commonly in nature. Vanadyl porphyrins in crude tend to be associated with very large hydrocarbon molecules. As such, they are usually components of asphaltene micelles. In hydrotreating, vanadium is deposited on the catalyst surface as vanadium sulfide. Studies have shown that rates of vanadium and nickel removal are directly proportional to asphaltene conversion in gas-oil hydrotreating [31.16].

Because metals deposit in the catalyst pore near the external surface of the catalyst, they deactivate catalyst

Fig. 31.2
Porphyrin ring

by preventing diffusion of the reactant to the active site. HDS activity is more susceptible to poisoning by nickel and vanadium than hydrodenitrogenation (HDN). As Ni and V levels of a hydrotreater feed increase, the addition of hydrodemetallization (HDM) catalyst to the

catalyst loading scheme becomes necessary. HDM catalysts have wide pores in the 100–300 nm range, which makes them effective for reactions involving large hydrocarbon structures, such as those that commonly contain nickel and vanadium in crude. Wide pores are also less likely to become blocked by metals that lay down at the pore mouth [31.14].

Because wide pore HDM catalysts have lower surface areas than catalyst designed for high HDS activity, the incorporation of HDM catalyst into a new design will require addition of a large catalyst volume, lest the sulfur removal capability be reduced. The sizing of metals guard beds or guard reactors must take into account the desired cycle length. It is not uncommon to design for 3–5 ppm Ni + V. For a 2–3 year catalyst cycle, the volume of such guard vessels can be 20–30% of the total catalyst volume. Both FCC pretreat hydrotreaters and hydrocracker first-stage hydrotreating sections need to be protected in this manner.

31.7 Asphaltene and Clay Precipitation

Asphaltenes are complex high-boiling point polyaromatic species. Although the structure of asphaltenes has been much debated and much studied, it is commonly agreed that they are comprised of the following components [31.16]:

- Sulfur in the form of benzothiophene rings
- Nitrogen in pyrroles and pyridine ring structures
- Groups of five or more aromatic rings joined by very long paraffin chains and having long side-chains
- Nickel and vanadium in a chelated form with porphyrin rings (whose main functional components are pyrrolic nitrogen)
- Oxygen in functional groups including carboxylic acids.

Asphaltenes are believed to have molecular weights over 1000 g/mol. In practice, asphaltenes are characterized by their tendency to precipitate from crude as black or brown solids that will decompose when heated, rather than melt. As such, determination of asphaltene concentrations is generally by mixing with *n*-pentane or *n*-heptane, for which there exist several ASTM methods [31.17].

The stabilization of asphaltenes in crude is thought to be through suspension with resinous and aromatic layers in the form of colloids. Although there are several factors known to bring about the onset of precipitation, the most concerning for a refinery transitioning to extra-heavy oils involves a change in the solvent power

of the resin layer. This can occur when a bituminous crude is mixed with a sweeter crude that has a lower aromatics content. For this reason, refiners have developed models to determine crude *compatibility*, based on viscosity, gravity, and other factors relating to mutual solubility [31.17].

Asphaltene precipitation from crudes can lead to fouling in heat exchangers, column internals, and fired heaters on crude units. Some refiners processing Northern Alberta bitumen restrict their vacuum furnace transfer line temperatures to 700 °F (≈ 370 °C) to avoid rapid coking of tubes. In some cases, run lengths longer than a year are difficult to achieve on atmospheric towers due to asphaltene precipitation on the stripping trays in atmospheric towers [31.18].

In a delayed coker, a high asphaltene content leads to the production of shot coke in a drum. Shot coke is a safety concern because water impacting a hot area during cutting may cause an eruption of small coke pellets to be propelled by the expansion of steam. To remove operating personnel from harm's way may require automatic *de-heading* devices for the top and/or bottom of the drums. Although costly, these valves improve availability by decreasing the time required to remove the head from a drum. Inclusion of a remote cutting station allows an operator to control drum de-heading and coke cutting from a safe distance [31.19].

Precipitation of asphaltenes often occurs along with other fine solids. This may include particles of pyrite or titanium oxide, or *ultrafine* clay platelets less than

< 0.3 μm in size. These clays tend to bind with organic matter that is both polar and aromatic. As such, they are often associated with water with which they can form emulsified droplets in oil [31.20].

The concentration of clay microfines in bitumen has been found to differ by production method [31.21]. Specifically, whereas bitumen produced through the

hot-water extraction process (HWEP) may contain up to 2% by weight of solids, that produced through steam-assisted gravity drainage (SAGD) can have a much lower concentration of clays and fines, in some cases nondetectable. However, it has been noted that nickel and vanadium concentrations can be greater in SAGD bitumen crudes [31.20].

31.8 Fouling in Gas-Oil Hydrotreaters

A phenomenon similar to crude incompatibility occurs in gas-oil hydrotreaters, leading to an accumulation of deposits in feed filters and in catalyst beds. Asphaltenes that may make their way into gas oil cuts by entrainment in crude units can lose suspension due to the chemical transformation of aromatic components during hydrotreating. Because of their aromatic nature and high nickel and vanadium content, asphaltene species can also suppress HDS reactions through competitive adsorption on active sites, and by blocking catalyst pores [31.16].

During hydrotreating, it is thought that asphaltenes lose aliphatic side-chains, while the maltenes holding them in suspension are hydrogenated. The net result is an increase in the aromatic nature of the asphaltene and a loss of solvency in the bulk fluid [31.22].

The deposition of particles comprised of asphaltenes, clays, and corrosion products has been known to occur in catalyst beds and even between beds, leading to high reactor pressure drop. Such particles tend to mass together in packed beds, taking up the space between individual pellets. The hydrodynamics are such that a greater mass of particles accumulates in the bed at a low liquid velocity, while at a higher velocity, more particles – especially smaller ones – will tend to pass through the bed [31.23].

Thus, although it may be counter-intuitive, over the course of the catalyst cycle of an operating unit, higher pressure drop may develop at low unit charge rates, compared to that which would develop at high rates.

Design of reactors in the pulsed flow regime, as is the practice of many licensors, may also help in this regard, as the celerity of the pulses can help to flush particles out of a catalyst bed. Factors that will affect flow regime include reactor dimensions, unit pressure, and gas flow rate and molecular weight [31.24, 25].

Risk of feed filter pluggage is higher for gas-oil hydrotreaters processing bitumen-derived crudes. In addition to mixture incompatibility causing asphaltenes to drop out of solution, some foulant-generating chemical mechanisms are introduced with bitumen derived gas oil. For example, it has been found that coker gas

oils from Canadian bitumen contain relatively high concentrations of pyrrolic nitrogen species that generate oil-insoluble filter deposits in hydrotreaters [31.26].

These pyrroles result from breakdown of porphyrin rings associated with the asphaltenes in bitumen, and they have a relatively low molecular weight. Such compounds oxidize easily, initiating the formation of insoluble polymers. The binding of these polymers with clay and other materials produces gummy material capable of plugging filters. The problem is worsened by the presence of corrosion products containing iron, as they can act as catalysts for polymer formation. Olefins are also present in coker gas oils, and these may participate in the reactions. Small concentrations of dissolved oxygen left in the coker products from steaming of coke drums will exacerbate the problem by accelerating the generation of free-radical chain initiators [31.27].

Figure 31.3 shows an example of deposits found in hydrotreaters that process gas oils derived from Cana-

Fig. 31.3 Scanning electron micrograph of feed filter deposits collected at a gas-oil hydrotreater in a Canadian extra-heavy oil refinery. (Courtesy of BP)

dian extra-heavy oils. In this figure, the individual species have been identified using scanning electron microscopy. Clay, salt, and metal oxides can be observed, in addition to carbonaceous masses that are likely asphaltenes.

The presence of asphaltenes, clays, and components reactive for polymerization bears significant implications for the design of gas-oil hydrotreaters, including hydrocracker pretreat units. The presence of nickel and vanadium in the 3–5 ppm range will necessitate a large volume of demetallization catalyst. Coupled with exposure to asphaltenes and other foulants, the risk to unit availability may be such that dedicated guard reactors will be required. The advantage of this is that the reactors can be bypassed in the event that high pressure drop develops. Operation can continue, or the design can allow an on-line change-out.

To make this possible, the unit must generally incorporate high-pressure, tight shut-off valves with the proper redundancy and verification of zero energy. Even if the guard reactors are not to be taken out of service, provisions may need to be made to keep the bypassed

reactor warm by sweeping with hydrogen. In either case, the valves and piping can be complex and add significant cost. Such units have been designed to accommodate asphaltene levels as high as 500 ppm on a routine basis.

To prevent the foulant material from entering the unit, it is generally wise to install unit feed filters of adequate capacity, sized for a desired frequency of change-out. A pair of filter banks operating in parallel will help to reduce exposure of the unit to fouling material, as one bank can be changed while the other remains in operation. However, note that the unit will have to reduce feed rate if the filters develop high pressure drop faster than the refinery maintenance team can replace the elements.

Filters that back-wash automatically are commonly installed in high fouling services. For a refinery operating a large coker, it may be advantageous to install such *backwash* filters on coker gas oil because of the likelihood that coke fines will be present. In that situation, traditional cartridge-type filters may be installed on the feed to the gas-oil hydrotreater to reduce cost.

31.9 Sulfur and Nitrogen in Bitumen-Derived Crudes

The incentive for a refinery to process bitumen-based crudes is illustrated by the price differential between Western Canadian select (WCS) and West Texas intermediate (WTI) crudes, which averaged \$ 20–30 per bbl (US) in 2013–2014 [31.28]. The refinery investing to reposition for Canadian heavy crudes might expect to capture this margin.

Characterization of these crudes can be difficult because they are usually blends of oils with very different properties. Raw bitumen extracted from Canadian oil sands is too viscous to flow in a pipeline, so it must be diluted with a lighter oil to produce the final crude. If the diluent is natural gas condensate or a similar light naphtha, the resulting crude is called a *dilbit*. Alternatively, the diluent used may be a mix of lighter products generated from thermal cracking or hydrocracking of raw bitumen, that is, a synthetic crude. Bitumen diluted with synthetic crude produces a *synbit* crude [31.1].

Bitumen-based crudes have densities of 930–940 kg/m³ (API gravity 18–21°), compared to 825–840 kg/m³ (39–40° API) for light sweet crudes [31.29]. The difference in density reflects the highly aromatic nature of bitumen crudes.

Sulfur and nitrogen concentrations in crude go up dramatically with increasing crude density (decreasing API gravity). This is illustrated in Fig. 31.4, plotted from data gathered by Ball et al. for crudes of similar origin to Athabasca bitumen [31.30].

Canadian heavy crudes with API gravities in the 18–20° range can contain 3–4% sulfur, which is more than 10 times the sulfur level of WTI crude having an API gravity of about 40° [31.4, 29].

In addition to total sulfur and nitrogen levels being much higher than conventional crudes, the S and N distributions in dilbit and synbit also look very different. This is because cracking reactions form species

Fig. 31.4 Concentrations of sulfur and nitrogen by API gravity, for crudes of origin similar to Athabasca

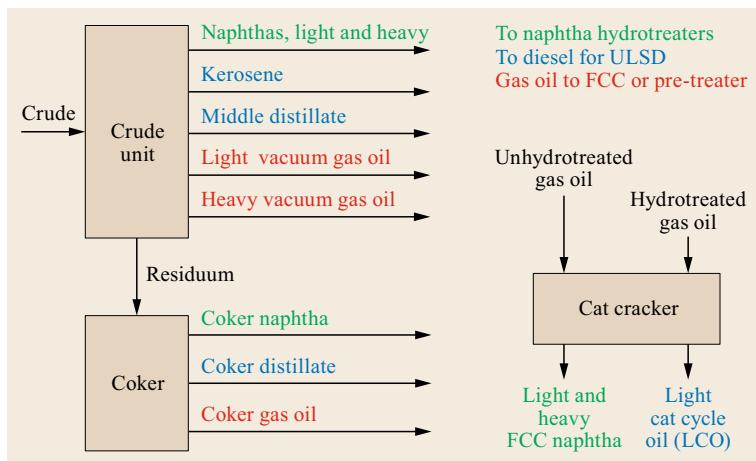

Fig. 31.5 Typical refinery intermediate streams to hydrotreaters. (Courtesy of BP)

that do not occur in nature. Also, thermal cracking processes (e.g., delayed coking) necessitate downstream hydrotreating to stabilize the products. Hydrotreating lowers the total sulfur and nitrogen content, while leaving behind the species that are hardest to convert. To further desulfurize and reduce nitrogen from these *upgraded* intermediate streams can be difficult.

Figure 31.5 illustrates the variety of intermediate products processed by hydrotreaters, including those

from other conversion processes such as FCC and coking. A strategy for processing must begin with consideration of the individual crude component sources, and an understanding of the species that will result by fractionation in each cut of crude. The demands for hydrotreating gas oil, diesel, and naphtha cuts of bitumen-based crudes and their derivatives are considered, in turn, in the following sections.

31.10 Hydrodesulfurization and Hydrodenitrogenation of Gas Oils

Desulfurization and denitrogenation of bitumen-derived gas oils, including heavy virgin gas oil and coker gas oil, have been studied by *Yui et al.* and others [31.4, 22, 31, 32]. While sulfur in heavy gas oil from conventional crude can be about 1.0%, straight-run gas oil from an Athabasca bitumen is 3.0–3.5%. Sulfur in heavy gas oil resulting from thermal cracking of Athabasca bitumen is typically in excess of 4.0%. Likewise, nitrogen can be 2000 ppm for Athabasca straight-run and 4000 ppm for coker gas oil, which is much higher than the 1000 ppm level of conventional crude.

Gas oil sulfur must be brought down to a few 100 ppm, so that FCC and hydrocracker naphthas will have a low enough sulfur level to allow blending into gasoline. Nitrogen removal is also important, for these units to achieve a high catalytic conversion.

Further, nitrogen removal is important for achieving adequate conversion in an FCC or hydrocracker. However, the nature of the nitrogen species – being largely pyrrolic and including substituted carbazoles – is such that they are difficult to remove and also inhibit sulfur removal by competing for active sites [31.32, 33].

Thus, desulfurization and denitrogenation of bitumen-derived gas oils require very high severity in a hydrotreater, including reactor pressures of 2000 psig (13 MPa) or higher, and liquid-hourly space velocities of 1.0/h or lower over high-activity catalysts.

Asphaltenes in gas oil have been found to inhibit desulfurization by adsorbing onto active sites and blocking catalyst pores. Hydrotreaters for bitumen gas oils often employ wide-pore demetallization catalysts to help convert asphaltenes. Interestingly, asphaltenes with high sulfur content tend to convert easier than those with low sulfur content, owing to breakage of the weaker carbon–sulfur bond as compared to a carbon–carbon bond [31.22].

In combination, high-activity desulfurization catalyst and wide-pore demetallization catalyst can total well over a million pounds in a 100 000 bbl/day gas-oil hydrotreater. Reactors, vessels, and flanges rated for the required pressure can all be very large and, therefore, costly to manufacture and install.

A concern for hydrotreaters processing a high-nitrogen feed is ammonium bisulfide (NH_4HS) corrosion in reactor effluent systems. Ammonium bisulfide condenses as a salt from the interaction of ammonia and

hydrogen sulfide gases in the reactor effluent stream. Solid NH_4HS can plug tubes in effluent heat exchangers or air coolers. The salt is hygroscopic and very corrosive when water wet [31.34].

For this reason, hydrotreaters taking high-nitrogen feeds commonly employ a water wash system. However, owing to the fact that wash water containing more than 2% by weight NH_4HS can be corrosive, high volumetric flow rates are sometimes required. A typical design point allowing mild corrosion can be 4% NH_4HS , concentration by weight in wash water effluent, for which a few hundred gpm *sweet water* may be needed.

A supply of such fresh water, and the means to treat the spent water will require additional equipment including wash-water feed drums, sour-water strippers, and the appropriate injection and mixing devices. Further, it is usually necessary to segregate the water systems used for hydrotreaters from those used in FCC in order to avoid cyanides that can accelerate the corrosive effects of NH_4HS .

Even at moderate concentrations of NH_4HS – between 2 and 8% – higher grades of steel may be needed for any piping or vessels in contact with this sour water, including piping for oil products that may contain

sour water carried over from separators. Concentrations above 8% are aggressively corrosive to carbon steel [31.34].

Ammonium salt corrosion can also attack stripper overhead systems. In this situation, ammonium chloride salts have also been implicated. Gas-oil hydrotreaters may be particularly at risk owing to the inclusion of hot low-pressure separators (HLPS) in the design. Small concentrations of chloride in oil may flash off in these drums, or strip off in strippers, operating in the 450–550 °F (230–290 °C) range. Sufficient cooling to form salts can take place in the small-bore piping of overhead handling systems, including lines for relief valves [31.35].

Once formed, these salts can corrode out piping rapidly in localized areas, where thinning can go undetected by a refinery inspection program, leading to an eventual release of light hydrocarbon with a high H_2S concentration.

Because the hydrotreating severity requires large vessels, while corrosion and fouling concerns demand more ancillary equipment and expensive metallurgy, a gas-oil hydrotreater can be very expensive to build and to maintain for a refinery processing bitumen-based crudes.

31.11 Production of ULSD and Jet Fuel

As with gas oil, the desulfurization of middle distillates from bitumen-based crudes can be difficult because of the high sulfur levels, the aromatic nature of the oil, and the presence of inhibiting nitrogen species. Although lighter species are generally easier to convert, the target sulfur levels are typically much lower, being 15 ppm sulfur for ULSD compared to 300–800 ppm for a typical gas oil unit. A solution often employed by refiners to accommodate Canadian heavy crude distillates in an existing ULSD unit is to revamp the hydrotreater by adding a reactor. Addition of a large tail reactor can be a relatively inexpensive way to reduce the space velocity of a unit by half.

It has been well established that the most difficult sulfur species to convert in ULSD are dibenzothio-phenes, particularly those with substitution at the 4- and 6-positions [31.14]. These species exist in feeds at levels of a few 100 ppm, and they are the usually last remaining sulfur species in ULSD product. Like any hydrotreated diesel, middle distillate from a synthetic crude or synthetic synbit fraction will have a disproportionate concentration of these difficult species, even though the total sulfur concentration may be relatively low [31.9].

As in gas oil, the nitrogen present in bitumen and coker distillates will contribute to corrosion of hydrotreater effluent systems and pluggage of air cooler tubes. Because sulfur is generally lower in this diesel-range cut, it is less likely that sour-water corrosion will be an issue. However, ammonium chloride accumulation has been known to result in localized corrosion and leaks. A water wash designed for NH_4HS removal may be ineffective for NH_4Cl removal, due to the salt's hygroscopic nature and its tendency to deposit further upstream in the effluent system [31.36].

A guideline commonly followed for water-wash design requires that at least 25% of the water introduced remain as unvaporized liquid water at the point of injection [31.37]. Thus, the necessary water flow rate will increase with hot high-pressure separator (HHPS) temperature requirement – which aids H_2S removal in the stripper – and hydrogen recirculation ratios. Temperature and hydrogen rate are, of course, variables of hydrotreating severity that a refinery will increase in order to remove refractory sulfur species.

Jet fuel production requires processing of kerosene-range distillates. Because the total sulfur specification

for jet fuel is fairly high at 3000 ppm, desulfurization has not been required by many refineries. Instead, the predominant technologies for jet fuel production have been based on *sweetening* of kerosene by reacting mercaptans to form disulfides, in order to satisfy the total mercaptan level specification [31.12].

However, the shift to a crude mix that results in a kerosene cut with more than 3000 ppm sulfur may require a refinery to hydrotreat jet fuel in order to remove sulfur. HDS severity need not be very high as sulfur re-

moval of about 50% is usually enough. Nevertheless, in lieu of a capital investment, the additional volume of oil to be hydrotreated means that the ULSD production must decrease, or another gasoline or diesel stream will to go unhydrotreated.

It should be noted that the fraction of the kerosene steam that is synthetic is likely to meet the total sulfur requirement for jet fuel. The aromatics content and smoke point may need to be upgraded as discussed in a previous section [31.7].

31.12 Fouling in Naphtha Hydrotreaters

A refinery that improves its bitumen-processing capability by installing more coking capacity may have to invest to mitigate risks to its naphtha hydrotreaters. These risks include a reduction of heat transfer in pre-heat exchangers, building of pressure drop in feed systems and reactors, poisoning of catalyst, and incomplete nitrogen conversion that could create availability problems for reforming and isomerization units.

The fouling tendency of coker naphtha owes to the relatively high concentration of olefins and diolefins, and especially to the presence of conjugated diolefins, which are prone to polymerizing once initiated by exposure to oxygen or by reactive pyrroles [31.38].

Watkinson et al. have studied the byproducts and initiation of fouling in naphtha [31.39]. The accumulation of fouling deposits can begin at temperatures as mild as 270 °F (130 °C). The first products of fouling are soluble gums, with molecular weights as high as 600 g/mol. As reaction continues, gums can concentrate and eventually become insoluble deposits.

At temperatures of about 370 °F (190 °C), deposits formed are more likely to adhere to heat-exchanger tubes, where they can hamper heat transfer or create high pressure drop. When this occurs in a hydrotreater, the unit may no longer be able to reach a target catalyst temperature or to maintain its maximum feed rate.

On a heat exchanger surface, the gum deposits can transform to thermally stable fines that are dark in color and have a high carbon content. Deposits have been identified with a hydrogen to hydrocarbon ratio that is only slightly greater than 1.

Deposits formed in the feed pre-heat section of a hydrotreater can carry through to the lead reactor, causing high pressure drop there. Once pressure drop develops, the unit may not be able to maintain a high feed rate or its target hydrogen circulation rate. An outage for catalyst replacement may be necessary, or a *skim* and replacement of the topmost portion of catalyst.

A technique sometimes used to delay the onset of pressure drop from fouling is to use of top bed grading with a high void fraction, to allow particulates to accumulate in a manner that will not immediately restrict flow [31.40].

The fouling potential of coker naphtha is about 300 times that of straight-run naphtha. To avoid a severe availability penalty, when increasing the volume of coker naphtha to an existing hydrotreater, it may be necessary to first stabilize the coker naphtha. Units designed for saturation of conjugated diolefins operate at mild temperatures (320–425 °F (160–220 °C)) and high space velocities (greater than 4.0 per h LHSV). Severity must be kept mild in such units, to avoid saturation of olefins, which can generate a large heat release and also lead to catalyst bed fouling via local hydrogen starvation [31.38].

Reduction of diolefins in a selective coker naphtha hydrotreater can be as great as 90%, with a starting concentration of about 4% by weight. Rates of diolefin saturation are maximized at about 350 °F (180 °C). However, sulfur and nitrogen removal are not performed below 400 °F (200 °C) [31.41].

A further advantage of a dedicated diolefin saturation unit is the opportunity to incorporate a guard catalyst that would otherwise take up space intended for active catalyst in the main naphtha hydrotreater. Silicon is present in coker naphtha in the form of tri- and tetrasiloxanes, which are products of the decomposition of silicon-based foam-control agents [31.38]. Such units are sometimes incorporated into the refinery's coker, a relatively convenient if a new coker is being built.

Exposure to oxygen from air has been shown to promote fouling of naphtha by free-radical chain initiation via formation of hydroperoxides. Concentrations of only a few ppm dissolved oxygen can lead to significant fouling [31.39].

Several strategies exist for mitigating or preventing oxygen-initiated fouling. Because dissolved O₂ is

usually introduced into naphtha by exposure to air in tankage, one option is to introduce nitrogen gas for blanketing tanks. However, it can be costly to run N_2 piping to a tank field and to maintain the system in reliable working condition.

Chemical additives can be effective for reducing gum formation in coker naphtha hydrotreaters. Here, a two-pronged approach is recommended, with an oxygen scavenger injected in the naphtha run-down line into tankage and a dispersant injected at the unit to prevent agglomeration of foulant species [31.42].

Some unit designs incorporate a stripping tower into the feed system, using hydrogen gas to strip out dissolved oxygen from oil entering the unit. With naphtha

serving as the *lean oil*, these towers can serve a second purpose by improving the purity of the hydrogen even as it is used for stripping. However, for fouling mitigation, this strategy is only effective for oils that have not already begun to react in feed tankage. For maximum effectiveness, the absorber–stripper design should allow stripping of straight-run naphtha only, with cracked naphthas coming to the unit directly and contacting the straight-run naphtha downstream of the stripper.

Utilization of a diolefin reduction unit has the added advantage of reducing the risk of gum formations, should the naphtha need to be stored in tankage, because the most reactive components in coker naphtha have been stabilized.

31.13 Sulfur and Nitrogen Removal from Naphtha

Sulfur and nitrogen must be removed from feeds to catalytic naphtha reforming units and C_5/C_6 isomerization units because they are poisons to the catalyst. Further, these units often use chlorided catalysts, and so, will have chloride present in the effluent system.

Organic nitrogen will convert to ammonia on precious metal catalysts, and the ammonia will combine with chloride to form corrosive ammonium chloride salts. The depositing of these salts in distillation towers and piping can make it difficult to maintain product quality, and can generate hydraulic restrictions. As a result, these units typically have hydrotreaters designed to reduce sulfur and nitrogen each to 0.5 ppm by weight or less.

The most common disposition for coker naphtha is feed to a reformer to improve stability and upgrade its octane for blending into gasoline. However, nitrogen in coker naphtha produced from Canadian bitumen can be in the 200–300 ppm range, as opposed to levels of a few ppm that are characteristic of straight-run naphtha. Hydrotreating of cracked stocks to produce a synthetic crude can bring the nitrogen level down to that of straight-run or even lower [31.43].

Sulfur inhibits the function of the precious metal on reforming and isomerization catalysts. Coker naphtha sulfur can be about 1.5% by weight, which is greater than straight-run naphtha by a factor of 6 or more. Sulfur is arguably a lesser problem than nitrogen because it is unlikely to form a corrosive salt in a reformer.

Nevertheless, an increased concentration of high-sulfur coker naphtha can lead to a product sulfur level above 0.5 ppm, because of a reaction between olefins and hydrogen sulfide that forms mercaptans at high reactor outlet temperatures [31.44].

Thus the need to remove nitrogen may necessitate an increase in severity of the naphtha hydrotreater. This can be accomplished by adding catalyst volume or enabling the feed furnace to achieve a higher temperature, as limited by mercaptan formation. A significant increase in pressure is rarely an option, as pressure will be limited by pressure rating of equipment and piping.

Removal of the heaviest fraction of feed by distillation can also be very effective for reducing nitrogen concentration, and eliminating from feed those heaviest ring species that are difficult to convert. This type of prefractionation will have the added benefit for a catalytic naphtha reformer that production of coke on catalyst will be slower for a feed containing fewer heavy aromatics.

Splitting of reformer feed in this way is most beneficial if performed on the combined desulfurizer product or feed to the desulfurizer rather than one component. However, distilling such a large volume can be energy intensive. Instead, a split performed on the coker naphtha only can capture nearly all the benefit requiring much less energy and smaller equipment. If the final boiling points of the straight-run fraction are not excessive, removal of the heaviest 20% of coker naphtha can be of greater benefit and will be more economical than removing the heaviest 10% of combined feed.

It should be recognized that such fractionation will remove volume from reformer feed, possibly resulting in a lower reformer total charge rate. If the split occurs on hydrotreated product, the diverted fraction can be sent directly to gasoline blending, thereby gaining total gasoline volume but at a lower octane, compared to

reforming. Otherwise, the rejected volume will generally need to be processed in another naphtha, diesel, or jet fuel hydrotreater to lower the sulfur level.

The higher olefin concentration that will accompany an increase in coker naphtha volume to a naphtha hy-

drotreater will result in an increased heat release that may need to be mitigated through addition of hydrogen quench between catalyst beds or between reactors. Depending on the starting configuration of the unit, this can be a costly modification.

31.14 Choice of Resid Conversion Technology

When adding capacity for conversion of bitumen to fuels and chemical feedstocks, the refiner has choice of technologies. The choices generally fall into two categories:

1. Carbon-rejection technologies, such as delayed coking
2. Hydrogen-addition technologies represented by the various forms of hydrocracking. Several studies have been performed to compare the merits of each, including analyses of the return on investment [31.4, 45–48].

The following general conclusions can be made:

- Total liquid yield from hydrocracking is over 100% by volume, when taking into account the density difference. Coking yield will be about 75% liquid.
- The ratio of gasoline to diesel production is greater with hydrocracking than with coking, although at least one study found that diesel yields by mass are approximately the same for both types of processes [31.49].
- Capital investment in a hydrocracker can be up to 50% greater than the investment in a delayed coking unit. Operating expenses will also be greater, owing in part to the cost of hydrogen compression.

- Coker products require stabilization by hydrotreating. The associated investment can be significant if newly build hydrotreating units are required. Alternatively, a large, complex refinery may be able to leverage the capacity of existing units to optimize cost while improving overall feedstock flexibility.
- A key consideration must be the refinery's solids handling capability, including access to markets for sale of petroleum coke and shipping infrastructure, by rail or truck.
- Hydrogen addition schemes are more attractive at low natural gas prices, methane being the primary feedstock for hydrogen production. Natural gas prices have declined to \$4–5 per million BTU with the recent boom in US tight oil production, having come down from highs above \$10 per million BTU a few years earlier. Nevertheless, prices are projected to rise again due to increasing production costs [31.50].

The discussion in this report has assumed residuum processing by coking process in order to highlight the difficult technical issues associated with processing of cracked intermediates. Further, a starting assumption included the revamp of a gasoline-based refinery with large FCC capacity, and the desire to maintain high utilization of existing cracking capacity.

31.15 Other Investment

The foregoing discussion has centered on the technology issues for bitumen-crude processing that directly trigger unit modifications or new builds. There are a number of other systems in a refinery that must be upgraded or supplemented in order to enable the new or modified kit to function as intended. As we have seen, the hydroprocessing units are impacted in a wide variety of ways, and this is likely to be the area with the greatest complexity of changes, even if not the greatest cost to modify. It is not surprising, then, that the majority of ancillary investment is

brought about by the new tougher hydroprocessing requirements.

A refinery processing 20–25% heavy crude, with the remainder being sweet and/or sour crudes, can shift its diet reliably to 75–85% heavy Canadian crude. In terms of hydrogen deficiency, it has been estimated that the difference in hydrogen content between a conventional crude and a raw bitumen is equivalent to about 1320 SCF/bbl [31.4]. In reality, a mix of synbit and dilbit crudes will be required to contain between 50 and 75% bitumen by volume. Thus, a large refinery bringing

in an incremental 250 kbd bitumen-based crudes may need on the order of 200 million standard cubic feet per day additional hydrogen supplied to its hydroprocessing units, in order to maintain the same volume and quality of final products as before.

The average sulfur content of the total crude mix can increase by 1.5–2.0 wt% by weight. For a 400 kbd refinery processing about 120 million lbs/day, this could mean that an increase in sulfur recovery capacity of about 1000 long ton/day is needed. To ensure environmental compliance, some investment in tail gas treating will also be necessary. Tail gas units ensure that the sulfur remaining in the sulfur recovery units' effluent gas is converted and captured.

The means by which sulfur is removed from individual crude cuts and intermediate streams involves transformation of the sulfur into H₂S in hydroprocessing units. The H₂S is picked up by amine flowing through absorber columns. Thus an increase in H₂S production rate will require a larger amine circulation system, with all of the infrastructure that entails. This is likely to include an investment in amine-stripping capacity of a few thousand gpm for the size of the refinery considered here.

As discussed above, there will be a greater demand for wash water in hydroprocessing and other units, to prevent build up of corrosive salts. In addition to needing new pumps and piping to supply the *sweet* water, sour water stripping capacity will need to be upgraded, likely through addition of a few thousand gpm for this hypothetical refinery.

31.16 Conclusion

The sustained price differential between conventional crudes and those derived from Canadian oil sands creates an attractive prospect for a sweet crude refinery to invest in crude repurposing. Investment will be driven by differences in crude composition, including a heavy fraction that is highly aromatic and a slew of contaminants that will interfere with processing, or that may negatively impact finished fuel quality.

Major components of investment may include residuum-processing capacity, crude fractionation including desalting, and a variety of hydroprocessing upgrades. If coking is chosen for residuum processing, the intermediate products must be hydrotreated, and this requirement triggers additional hydroprocessing scope.

Specifically, significant scope may include:

- Upgrading of crude unit and coker fractionation to avoid entrainment of asphaltenes and volatile met-

Not discussed in detail in this report is the potential for accelerated corrosion from a higher naphthenic acid content, as indicated by the TAN. The TAN of some bitumen-based crudes can be very high, such as 2.4 mg KOH/g for Peace River Heavy, compared to less than 0.5 for a typical light or medium sour crude [31.29].

However, some conventional US crudes also have a very high TAN. Further, it has been found that TAN by itself may not be the best indicator of crude corrosivity, due to the varied nature of organic acids in crude and the presence of other species that may passivate metal [31.50].

Nevertheless, crudes with high TAN will generally be offered at a discount. A refinery trying to gain feedstock flexibility by enabling Canadian heavy crude processing may not realize the full benefit of its investment without upgrading metallurgy of piping to accommodate a higher corrosion rate.

High TAN crudes put furnace transfer lines primarily at risk due to the temperature-dependency of acid-corrosion mechanisms. The risk will include pipe operating above 450 °F (232 °C) in and around hydroprocessing reactors on gas oil and diesel units. As an example, consider that the 80 kbd Suncor Sarnia refinery replaced 18 000 ft (≈ 5500 m) of pipe to accommodate a 2.4 mg KOH/g TAN crude mix in 2006. Carbon steel and chrome-enhanced piping was replaced with 316 and 3171 steel alloys to achieve a 15 year life [31.51, 52].

als (nickel and vanadium). In some cases, this may require construction of new large-diameter towers and higher duty furnaces. Crude desalting efficiency will also need to be improved, and piping upgraded in metallurgy to resist an increase in crude corrosivity.

- Addition of gas-oil hydrotreating capacity to improve FCC feed quality may be necessary if the refinery is configured for gasoline production. Gas oil will be high in asphaltenes, metals, and clay that can foul the unit and poison hydrotreating catalyst. Accommodating these contaminants may require inclusion of large guard reactors and feed filters.
- Improved diesel and jet hydrotreating capability including more reactor volume to improve qualities related to the aromaticity and sulfur content of the bitumen portion. Further, the synthetic portion is es-

entially lightly hydrotreated coker or hydrocracker product, containing refractory sulfur that must be removed.

- Improvements in naphtha hydrotreating severity to prevent nitrogen in cracked fractions from reaching sensitive reforming and isomerization units.
- Increased hydrogen supply as required by the hydroprocessing functions to produce fuels of the same quality as before.

- Supplemental sulfur recovery capacity, sour water stripping, and amine recirculation and regeneration, to enable the hydroprocessing units to reliably remove sulfur and nitrogen from intermediate cuts.

With careful consideration of the characteristics of bitumen-derived crudes, a sweet crude refinery can execute a successful design and achieve a high degree of reliability.

Carbon Dioxide

32. Carbon Dioxide Mitigation

Sultan M. Al-Salem, Xiaoliang Ma, Mubarak M. Al-Mujaibel

Stringent regulations on carbon dioxide (CO₂) emissions from industrial sources (in general) and petroleum refineries (in particular) are being enforced world wide. Low-sulfur clean fuels enhance the demand for petroleum refinery utility gases (e.g., hydrogen, H₂), which in turn leads to an increase in carbon-emission-intensive processes. This will ultimately force refineries to start implementing CO₂ mitigation measures, which are increasingly evident in the strategies of industrial countries. In this work, we describe the major processes that contribute to a typical petroleum refinery's global CO₂ emissions. Typical sources include unit utilities (i. e., heaters, boilers, and furnaces), fluid catalytic cracking units, hydrogen production (HP) units, flaring, and acid gas removal. A case study for a mega refinery structure is also given detailing a methodology for estimating CO₂ emissions from various processes. The carbon footprint and specific emissions of various sources being considered are also reported.

Global warming is the increase in average temperature of the Earth's surface, air, and oceans, which will increase flooding and ice cap melting, and influence climate change. The Intergovernmental Panel on Climate Change (IPCC) concluded that the increase in greenhouse gases (GHGs) is dominantly the result of fossil fuel burning [32.1]. The major greenhouse gas is CO₂ and the major source of anthropogenic CO₂ emission is from fossil fuel combustion. A study has shown that industrial sectors account for 70% of global CO₂ emissions [32.2]. In particular, CO₂ emissions from refineries account for 5% of the global CO₂ emissions (≈ 1 billion metric tons of CO₂ per year) and ranks third among the world's stationary CO₂ producers behind the power sector and the cement industry [32.3]. It is estimated that for a 300 MBPD petroleum refinery, 0.8–4.2 million tons of CO₂ is emitted annually, depending on the refinery's configuration.

Carbon mitigation techniques and methods have become one of the most studied topics among engineering disciplines. Mitigation techniques and strategies can be

discussed in terms of the most influential contributing factors to the carbon load of an industrial facility or in this case petroleum refineries. The increasing demand for cleaner fuels gives rise to increased carbon emissions by increasing hydrogen and utilities demand in refineries. However, more stringent regulation of fossil fuels makes carbon management a priority research topic today. This is especially true when it comes to carbon capture and storage (CCS) implementation in oil refineries. The purpose of carbon capture is quite basic in theory, which is to produce a concentrated stream of CO₂ that can be readily transported to a CO₂ storage site. CCS involves three distinct processes [32.4]:

- Capturing CO₂ from the gas streams emitted during fuel and chemical conversion processing
- Compressing and transporting the captured CO₂ by pipeline or tankers
- Storing CO₂ underground in deep saline aquifers, depleted oil and gas reservoirs, or unmineable coal seams.

There are currently over ten capture projects worldwide demonstrating viable techniques for carbon capture, with over 74 geological storage projects [32.4]. In general, CO₂ can be captured from all industrial fossil-fuel-burning processes with substantial amounts of CO₂. Dispersed carbon sources (e.g., transportation, agricultural, service, and residential sectors) do not present themselves as a viable source. CO₂ can be captured either before or after combustion using a range of existing and emerging technologies. CO₂ capture can be allocated to the following categories [32.2]:

- *Postcombustion capture*: Defined as capture of CO₂ emitted from combustion of fossil fuels in air. This technique hosts a number of technologies and is commonly applied in a number of industrial processes. Postcombustion systems utilize well-known technologies for gas separation. Separation with sorbents or solvents is a prime example of such technology. This is achieved by passing CO₂-rich gas in intimate contact with solvents or sorbents capable of capturing CO₂. Application of a membrane (polymeric, metallic, or ceramic) is another common technology for postcombustion capture.
- *Oxy fuel combustion capture*: This method is suitable for burners in refineries, where pure oxygen is used instead of air in combustion processes to produce CO₂ and water, as air contains about 78 vol.% of N₂ as a diluent. If the fuel is burnt in pure oxygen, the flame temperature is excessively high. However, the produced CO₂- and H₂O-rich gas can be recycled to the combustor to reduce the concentration of oxygen.
- *Precombustion capture*: Physical or chemical absorption of CO₂ after producing syngas (CO + H₂) by reacting fuel and oxygen. The CO is then reacted with steam (catalytically) in a shift converter to produce CO₂ (later separated) and H₂O.

Much attention has been focused on postcombustion capture in recent years. Researchers have focused efforts on a number of solutions for effective CO₂ capture from postcombustion sources, including application of physical and chemical sorbents and amine-based solutions for gas treatment (details in later sections). CO₂ sorbents might rank highest in current research activities for CO₂ capture due to very promising results demonstrated in a number of systems with varying operating conditions. A variety of solid physical sorbents (physisorbents) may be used to remove CO₂ from flue gases including porous carbonaceous materials, zeolites, alumina, silica gels, and metal-organic frameworks (MOFs). Porous activated carbon (AC), graphene and carbon nanotubes (CNT) are common examples of carbon-based solid sorbents [32.5]. Pressure swing ad-

sorption (PSA), a common industrial process used in refineries to recover mainly hydrogen (H₂) from off-gases, has been reported to remove CO₂ by using AC as an adsorbent [32.6–8]. This seems to be a very promising technology for carbon capture and warrants further review and development. PSA is a process that is common in refineries and typically utilized for gas separation. AC was also used by *Do* and *Wang* [32.9] to demonstrate the adsorption isotherm of CO₂ at three different temperatures with pressures up to 20 kPa. CO₂-adsorption capacity using Ajax AC was reported to decrease drastically with increasing temperatures. The rising concern in relation to CO₂ and its impact on our future has warranted legislation in industrial countries regulating their emissions. After a number of summits and conventions that stated clearly that global warming is a manmade phenomenon due to greenhouse gas (GHG) emissions, research in CO₂ capture has been active. Petroleum refineries are definitely a source of CO₂ that could be viewed as a resource (rather than an economic burden). This is because of the vast array of possible applications for CO₂, which are described in the next section.

CO₂ has been recognized as a greenhouse gas that leads to warming effects on the environment. Carbon mitigation reduces emissions from fossil fuel burning. In refineries, it has been noted that a trade-off exists between product quality and carbon emissions. Effectively, the high demand for certain clean fuels increases carbon emissions from refineries. This is something that capture technologies can deal with in terms of reducing the carbon emissions. Implementing such technologies can significantly reduce the carbon footprint of a refining facility.

Carbon capture can also be useful in terms of enhanced oil recovery (EOR). EOR is applied in oilfields approaching the end of their life and can produce additional oil in the range 10% or more. These operations are applied in order to improve the oil flow in the reservoir, by altering its flow properties or its interaction with the rock. One of these techniques is EOR promoted by CO₂ injection [32.10]. A common way of storing CO₂ is underground aquifer storage. Storage of CO₂ in deep saline (subsea) aquifers has been demonstrated in a commercial-scale project in Sleipner, Norway. About 1 million tons of CO₂ has been stored in this site since 1996 with no leakage detected so far. Using CO₂ to enhance oil recovery has been demonstrated at the Weyburn project in Canada. About 2 million tons of CO₂ per year has been stored there since 2001. Pilot projects suggest that CO₂-enhanced coal-bed methane (ECBM) and enhanced gas recovery (EGR) may be viable, although these are still in developmental and research stages [32.4]. In the Gulf countries, most refineries are

close to the oil fields. This is a significant benefit for CO₂ storage and CO₂-injection EOR as it reduces the cost for transportation of the CO₂ captured from the refineries to the oil fields.

In order to mitigate CO₂ emission from refineries, it is essential to understand the major CO₂ emission sources and the composition and properties of the gases, from which CO₂ is emitted from a typical refinery. In this chapter, the major CO₂ emission sources from a typical refinery were assessed on the basis of an anal-

ysis of the typical refining processes and a literature review. A case study for estimation of CO₂ emission from a refinery in the State of Kuwait was conducted. The challenges for carbon capture and mitigation in relation to petroleum refineries were discussed. The objective of this study is to provide important information about CO₂ emission sources from a typical refinery and to help the petroleum refining sector in making strategic decisions in relation to CO₂ mitigation from petroleum refineries.

32.1 Main Sources of Carbon Dioxide (CO₂) Emission in Petroleum Refineries

Crude oil has less value in its original state and also limited applications before refining. Even after desalting, dewatering, and degassing, crude oil is still a complex mixture of hydrocarbons ranging from very light to heavy compounds. Hence, to achieve the prime objective of a petroleum refinery, i. e., to produce valuable products such as liquefied petroleum gas (LPG), gasoline, kerosene, jet fuels, diesel, fuel oil etc., crude oil has to go through a number of successive physical and chemical processes [32.11].

Petroleum refineries differ in complexity and configuration. Hence, each refinery is unique in its treated crude oils, operating conditions, location and product specifications. Refinery configuration is defined by the set of refining processes, unit throughputs and design capacities, which gives the refinery complex its classification [32.12] (Table 32.1). Low in complexity refineries are the ones that are commonly referred to as topping refineries, nominally physically processing the crude with distillation processes. When hydrotreating and catalytic reforming processes are added to the refinery's configuration, it is known as a hydroskimming one characterized with moderate complexity. Typically, when fluid catalytic cracking (FCC), Alkylation and/or hydrocracking is added to the configuration, the refinery will be called a high complexity one. When coking is added the refinery is a very high complexity one, and usually called a deep conversion one.

Refining processes could be classed based on the physical separation and chemical transformation of the throughput to each unit, as shown in Fig 32.1. The major processes can be summarized as follows:

- Crude distillation
- Conversion (cracking)
- Upgrading
- Treating
- Separation

- Blending
- Utilities.

Crude oil distillation is a process whereby the crude oil is separated based on boiling ranges of products into fractions or cuts for further processing. There are two types characterized by feed and operating conditions. These are atmospheric and vacuum distillation processes. Conversion processes are essentially concerned with the breakdown (cracking) of heavy crude fractions. Light refinery streams are produced from these processes for further processing and blending. Examples of these processes are: fluid catalytic cracking (FCC) and hydrocracking. Upgrading processes, such as catalytic reforming, isomerization and alkylation, rearrange molecular structures to improve the properties (mainly octane number) and value of gasoline and diesel components [32.13]. Separation processes either by physical or chemical means are concerned with quality control for further processing similar to the case in fractionation and aromatics extraction. While *treating* is the group of processes dedicated to sulfur, metal and aromatics removal from streams, including hydrotreating of FCC and reformer feedstock, hydrotreating of fuel and lubricant base oil products, and benzene saturation. *Blending* is the process whereby different streams are combined to produce finished products that meet the required specifications (gasoline, diesel, jet fuel, etc.). Finally, refinery utilities are required to provide power, water, and heat for the refinery operations. Typically fired heaters and boilers are employed to supply utilities for units. A large amount of electricity is also consumed for pumps, compressors, and processing control units.

The production and management of all the refinery complex products and their specification result in numerous activities that contribute to the total load of carbon dioxide (CO₂). A typical source of CO₂ in a petroleum refinery is the utilities required for the dif-

Table 32.1 Petroleum refineries configuration and main characteristics (after [32.13])

Refinery configuration	Complexity rank	Main definitions and comments	Characteristic process
Topping	Low	These refineries have only crude distillation units with no capabilities to alter the natural yield pattern of the crude they process These refineries separate crude oil to refinery gas, refinery fuel, naphtha, distillates (kerosene, diesel, jet fuel) and heavy fuels Product specifications are governed by the crude specifications	Crude distillation
Hydro-skimming	Moderate	In addition to crude distillation these refineries have catalytic reforming, hydrotreating units and product blending capabilities Naphtha is upgraded to gasoline and sulfur content is controlled in products These refineries are common in low gasoline demand regions	Crude distillation Catalytic reforming Hydrotreating
Conversion	High	Also known as cracking refineries, hence including catalytic cracking and/or hydrocracking Heavy crudes are converted into light streams Sulfur levels in product are controlled by hydrotreating process Substantial capability for yield and quality improvement	Crude distillation Catalytic reforming Hydrotreating FCC and/or hydrocracking Alkylation and other upgrading
Deep conversion	Very high	These refineries include all the above categories, in addition to coking units to convert the residual oil to light streams as additional feed to other conversion processes Maximum yields of high-value refined products Maximum capability for quality improvement	Crude distillation Catalytic reforming Hydrotreating FCC and/or hydrocracking Alkylation and other upgrading Coking

ferent unit operations, such as pumps and compressors and processing control in the refinery, which requires the burning of fuel gas or other carbon-rich sources of energy.

Other processes that emit CO₂ as part of their daily operational routine include (1) FCC, where CO₂ is emitted as a result of coke deposition burning on catalyst, (2) steam methane reforming (SMR), or gasification of heavy hydrocarbons, which are more commonly termed hydrogen production (HP) units, where the feedstock is treated with steam, or with both steam and oxygen, to produce hydrogen, CO₂ and other acid-gases as well as H₂S. CO₂ and H₂S are removed by absorption using amine solutions as a part of the petroleum refineries process scheme.

A comprehensive analysis of CO₂ emissions from various typical refining units is necessary to understand CO₂ emission sources. This should account for both direct and indirect emissions associated with a certain process. In general, the total CO₂ emission per year (Q_{CO_2} , tpa (tons per annum)) for a refining unit can be calculated as

$$Q_{CO_2} \text{ (tpa)} = Q_{\text{(feed/product)}} (\text{Em}_{\text{heating}} + \text{Em}_{\text{feed-conv}} + \text{Em}_{H_2} + \text{Em}_{\text{steam}} + \text{Em}_{\text{electricity}}), \quad (32.1)$$

where $Q_{\text{(feed/product)}}$ is the amount of feed (or product) treated in the refining unit per year (tpa), $\text{Em}_{\text{feed-conv}}$

(t CO₂/t feed) could be defined as the CO₂ emission from complete conversion of each ton of feed to product; and $\text{Em}_{\text{heating}}$ is the CO₂ emission from the combustion of the fuel for heating each ton of feedstock, which can be calculated as per the following equation

$$\text{Em}_{\text{heating}} = \left(\frac{\text{En}_{\text{heating}}}{\text{LHV}_{\text{fuel}}} \right) \text{Em}_{\text{fuel},f}, \quad (32.2)$$

where $\text{En}_{\text{heating}}$ (BTU/t-feed) is the energy required for heating one ton of the feed, LHV_{feed} (BTU/t fuel) is the lower heating value of the fuel, Em_{fuel} (t CO₂/t fuel) is the CO₂ emission factor of fuel combustion and f (in %) is the heating efficiency (due to heat loss). The LHV of some major fuels are listed elsewhere in *Staffell* [32.14] (Table 32.2) and the CO₂ emission factors for some refinery fuels could be found in the report of Hydrocarbon Publishing Company [32.15] (Table 32.3).

Em_{H_2} (t CO₂/t feed) is the CO₂ emission for the generation of hydrogen required for treating each ton of feed, which can be calculated as per the following

$$\text{Em}_{H_2} = \text{Cons}_{H_2} \times \text{Em}_{H_2,f}, \quad (32.3)$$

where Cons_{H_2} (wt%) is the hydrogen consumption based on weight to feed and $\text{Em}_{H_2,f}$ (t CO₂/t H₂) is the CO₂ emission factor for the production of hydrogen gas. The $\text{Em}_{H_2,f}$ value is in a range from 10 to 12 t CO₂/

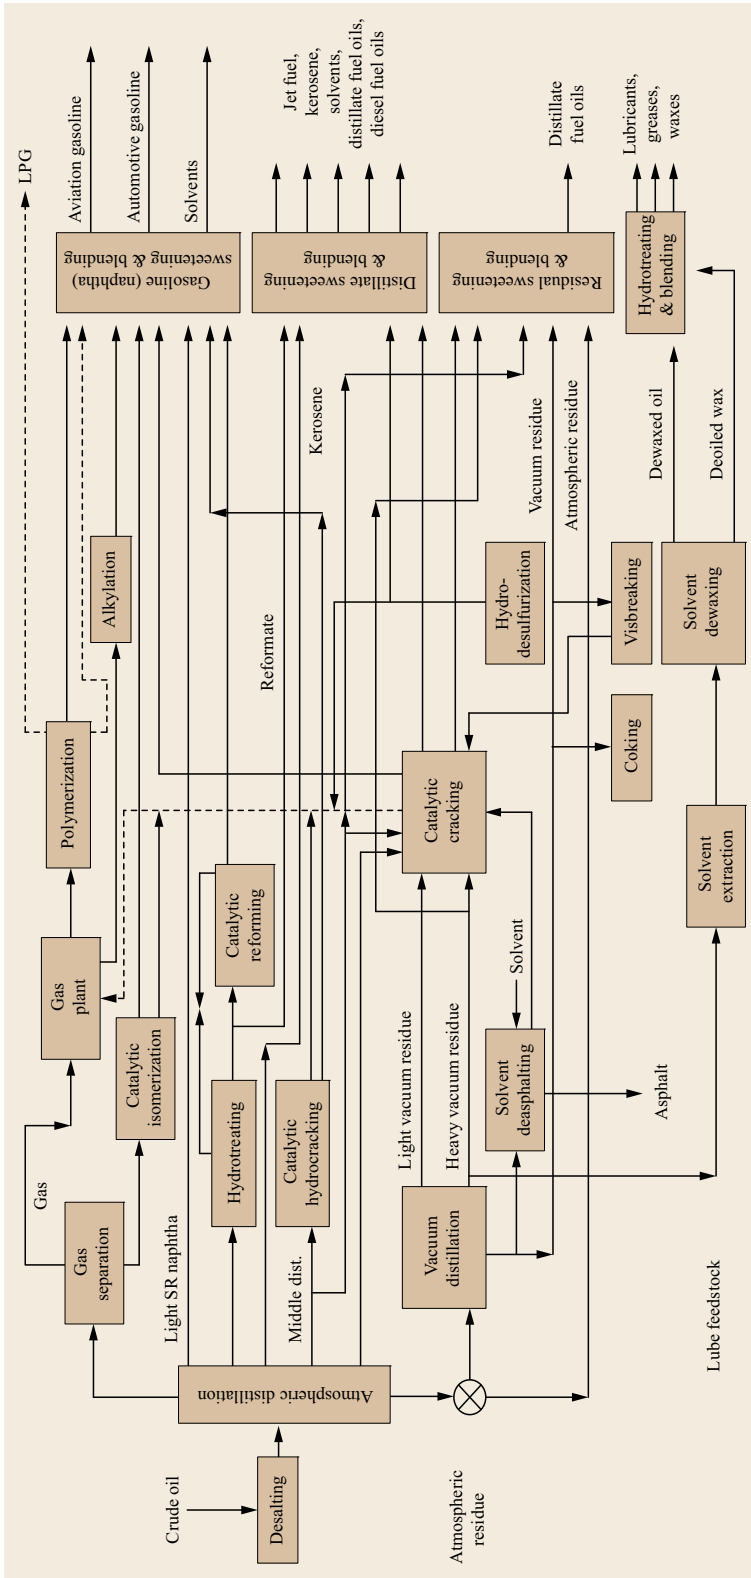

Fig. 32.1 Simplified modern refinery process flow diagram (after [32.16])

Table 32.2 The lower heating value (LHV) of some major fuels at standard temperature and pressure (STP) (after [32.14])

Fuel	Density at STP (g/m ³)	Net LHV (MJ/kg)
Crude oil	856	43.05
Petrol/gasoline	741	44.15
Diesel	837	42.91
Fuel oil	959	40.87
LPG	533	46.28
Kerosene	807	43.69
Coal	–	25.75
Natural gas	0.768	45.86
Hydrogen (1 atm)	0.0838	119.95

Table 32.3 CO₂ emission factors for some refinery fuels (after [32.15])

Fuel	CO ₂ emission factor (MM mt/EJ)
Natural gas	50.38
Refinery gas	60.80
Distillate fuel oil	69.37
Residual fuel oil	74.76
Coke	96.78
Coal	88.34

t H₂ for the production of H₂ from natural gas, according to *Bonaquist* [32.12]. Em_{steam} (t CO₂/t feed) is the CO₂ emission from the generation of steam required for treating each ton of feed. In many cases, Em_{steam} is estimated together with Em_{heating} and could be calculated as

$$Em_{\text{steam}} = Q_{\text{steam/feed}} \times Em_{\text{steam,f}}, \quad (32.4)$$

where $Q_{\text{steam/feed}}$ (t steam/t feed) is the amount of steam required for treating each ton of feed, Em_{steam,f} (t CO₂/t steam) is the CO₂ emission factor for generation of steam. The emission factor for steam is 88.18 kg/MM BTU as reported by the U.S. EIA (En-

ergy Information Administration) [32.18]. Em_{electricity} (t CO₂/t feed) is the CO₂ emission from the electricity power required for treating each ton of feedstock, which includes electric power for pumps, compressors, coolers, and separators. Em_{electricity} can be calculated as

$$Em_{\text{electricity}} = E_{kWh/feed} \times Em_{\text{electricity,f}}, \quad (32.5)$$

where $E_{kWh/feed}$ (kWh/t-feed) is the power required for treating each ton of feed, and Em_{electricity,f} (t CO₂/kWh) is CO₂ emission factor for generating electricity. The Em_{electricity,f} value suggested by the US EIA [32.17] for different fossil fuels and other fuels are shown in Table 32.4.

Below is analysis of the CO₂ emission from the individual refining processes, including crude oil distillation (COD), atmospheric residue hydrodesulfurization (ARDS), hydrocracking, hydrogen production (HP), fluid catalytic cracking (FCC), catalytic reforming, and acid gas removal (AGR).

32.1.1 Crude Oil Distillation

Crude oil distillation is a physical process that is considered as the front end of a petroleum refinery, regardless of configuration and complexity. The function of crude distillation is to separate raw crude oil into a number of intermediate refinery streams (more commonly termed *cuts*), characterized by their boiling ranges. The desalted crude oil is fed to an atmospheric distillation column. Each fraction leaving the crude distillation unit (CDU) is defined by a unique boiling point range. The fractions consist of hundreds or thousands of distinct hydrocarbon compounds. The atmospheric residue from this process is fed to a vacuum distillation tower for further separation of vacuum gas oil (VGO) from the atmospheric residue. CDU capacities typically range between 10–400 MBPD with a typical height of 50 m [32.16].

Table 32.4 CO₂ emission factor from electricity generation (after [32.17])

Fuel	Emission factor (kg CO ₂ /kWh)	Fuel	Emission factor (kg CO ₂ /kWh)
Anthracite	0.920	Crude oil	0.630
Coking coal	0.780	Natural liquids	0.480
Other bituminous coal	0.860	Refinery gas	0.400
Sub-bituminous coal	0.920	Liquefied petroleum gases	0.500
Coke oven coke	0.770	Kerosene	0.650
Coal tar	0.720	Gas/diesel oil	0.690
Brown coal briquettes (BKB)/peal briquettes	0.800–1.500	Fuel oil	0.670
Gas works gas	0.420	Petroleum cokes	1.000
Coke oven gas	0.420	Peat	0.760
Blast furnace gas	2.200	Industrial waste	0.400–2.000
Natural gas	0.400	Waste (nonrenewable)	0.450–3.500

Crude distillation could be summarized by a number of sequential processes in a petroleum refinery. These are desalting, the atmospheric distillation (topping) unit, and vacuum distillation. Energy management through optimal heat use for the different required processes is paramount for reducing the carbon emission from the distillation process. This should be achieved by minimizing the fired heaters duty while not compromising the products quality. The main utility of crude oil distillation is the crude oil furnace (direct fired heater or pipe still), which is responsible for heating the crude oil to a 75% vapor mixture with an outlet temperature between 350–380 °C.

The distillation process in refineries starts with desalting to remove the salt (expressed as NaCl) in the oil to minimize corrosion, fouling, and catalyst deactivation due to deposition. The basic principle is to wash the salt from the crude with water, which is typically achieved via a two-stage desalting process. The second desalter is cleaned (or under maintenance) whilst the first is in operation [32.16]. The typical power require-

ment for this process is between 0.01–0.02 kWh/bbl feed (0.0735–0.147 kWh/t).

Crude oils are preheated before and after the desalting unit at 120–150 °C and 228 °C, respectively, via a series of heat exchangers. A preflash drum is used to generate the vapor product which is then routed to the atmospheric crude distillation unit (CDU, Fig. 32.2). A furnace is employed in this stage to give the vapors the required temperature (343–399 °C) [32.11]. The heat required for separation in the distillation tower is provided according to the enthalpy of the feed. Heat is typically removed from the tower by an overhead condenser and pump-around streams. The latter is defined as a liquid stream withdrawn from a point below a side stream tray that is cooled by the cold crude feed as part of the preheat exchangers train.

Vacuum distillation units (Fig. 32.3) are employed in the last stage of the distillation processes, where residue from the atmospheric CDU is fed to a vacuum distillation unit typically under pressures of 25–40 mmHg. The distillates (cuts or products) of the

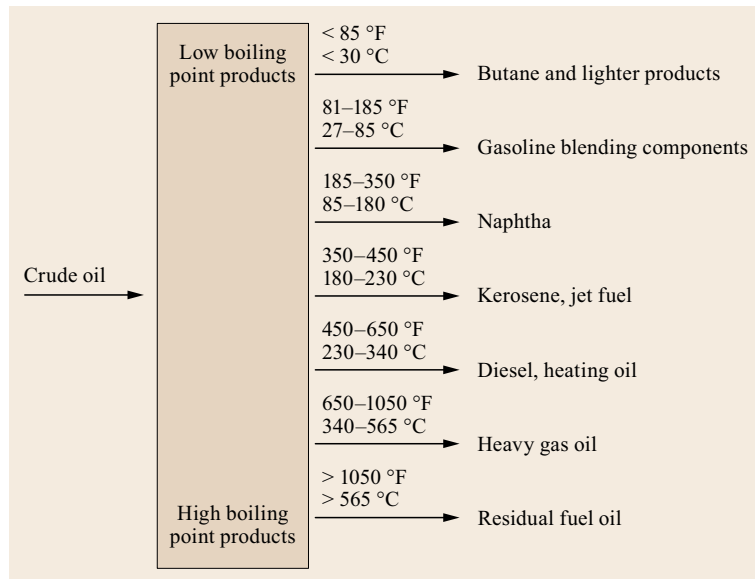

Fig. 32.2 Products from typical atmospheric distillation (after [32.19])

Fig. 32.3 Typical distribution of vacuum distillation products

vacuum unit are classified as light, middle, and heavy vacuum gas oil (LVGO, MVGO, HVGGO), respectively. After heat exchange in the crude preheat exchangers train, the atmospheric residues are fed to the vacuum unit (Fig. 32.3). The unit processes this feed to produce the required distillates in order to achieve maximum economic value for the crude oil barrel. Since the distillation units are not involved in chemical conversion and hydrogen consumption, according to (32.1)–(32.5), the total CO₂ emission per year (Q_{CO_2} (t/yr)) for the atmospheric/vacuum distillation of crude oil can be calculated as per (32.6) or (32.7)

$$Q_{\text{CO}_2\text{-CDU}} \text{ (t/yr)} = Q_{\text{feed}} (\text{Em}_{\text{heating}} + \text{Em}_{\text{steam}} + \text{Em}_{\text{electricity}}) \quad (32.6)$$

$$Q_{\text{CO}_2\text{-CDU}} \text{ (t/yr)} = Q_{\text{feed}} \left[\left(\frac{\text{En}_{\text{heating}}}{\text{En}_f} \right) \text{Em}_{\text{fuel},f} + Q_{\text{steam/feed}} \times \text{Em}_{\text{steam},f} + E_{\text{kWh/feed}} \times \text{Em}_{\text{electricity},f} \right] \quad (32.7)$$

Equation (32.7) clearly indicates that the annual CO₂ emission amount depends not only on the treated amount of the feed, but also on the CO₂ emission factor of fuel and the heating efficiency. Typical power required for the vacuum distillation unit is 0.3 kWh/bbl feed (2.206 kWh/t) and fuel of 0.03 MM BTU/bbl feed (0.2206 MM BTU/t) [32.20]. An industrial example is given for typical fired heater duty applied to CDU, showing process design capacity and heater duty for various throughputs (Table 32.5). There are a number of considerations when developing an emission factor for distillation processes. One should consider the type of fuel and utilities included, in addition to design requirements (actual throughput). We can estimate the CO₂ emissions from atmospheric and vacuum distillation of crude oil based on heating requirements (fired heaters duties using fuel oil) as 3.7 and 4.2 kg CO₂ per bbl (or 0.0272 and 0.0309 t CO₂/t feed) of feedstock, respectively.

32.1.2 Atmospheric Residue Hydrodesulfurization (ARDS) Unit

ARDS units (an application of hydrotreating) process the residue generated from crude atmospheric distillation units (CDU), commonly known as the bottom of the barrel, to produce fuel oil of certain specifications. The feed to ARDS units is typically hydrogenated catalytically to allow for the production of a low-sulfur fuel oil (LSFO) or other feedstock for further conver-

sion, as shown in Fig. 32.4. The following series of reactions take place in ARDS as depicted in (32.8), (32.9), (32.10), and (32.11).

Fixed-bed reactors are typically employed in this process along with a fractionating section. The feed is preheated by the reactor effluents then mixed with hydrogen. ARDS reactions are exothermic; hence the reactor effluent is quenched with cold recycle before entering the next reactor in the ARDS series. Representative feed and product properties are listed in Table 32.6 for a typical industrial ARDS unit of 218 m³/h. Other hydrotreating processes in a petroleum refinery include middle distillates and naphtha hydrotreating, in addition to gas oil and kerosene desulfurization.

Estimating the CO₂ emission from utilities in ARDS could be done by using the emission factor of 0.781 kg/bbl or 0.00512 t CO₂/t feed (based on design capacity). Since ARDS doesn't convert the feed to CO₂ and Em_{steam} is negligible, the total CO₂ emission per year ($Q_{\text{CO}_2,\text{ARDS}}$) for an ARDS unit can be calculated as

$$Q_{\text{CO}_2} \text{ (tpa)} = Q_{\text{feed}} (\text{Em}_{\text{heating}} + \text{Em}_{\text{H}_2} + \text{Em}_{\text{electricity}}) \\ Q_{\text{CO}_2} \text{ (tpa)} = Q_{\text{feed}} \left(\frac{\text{En}_{\text{heating}}}{\text{En}_f} \text{Em}_{\text{fuel}} \times f + \text{Cons}_{\text{H}_2} \times \text{Em}_{\text{H}_2} + E_{\text{kWh/feed}} \times \text{Em}_{\text{electricity},f} \right) \quad (32.12)$$

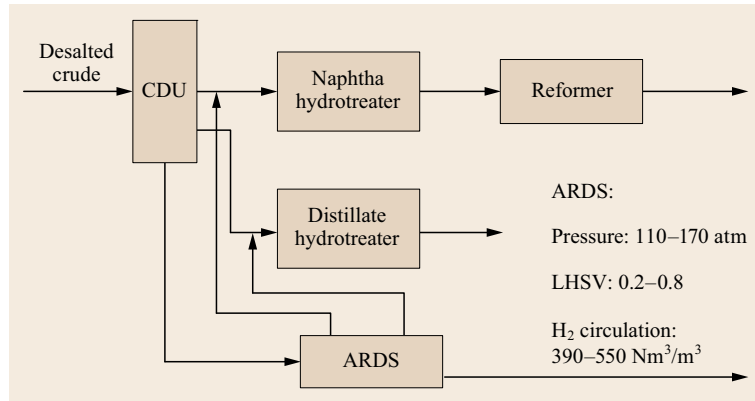

where Q_{feed} (tpa) is the amount of AR feed treated in the ARDS unit per year. Equation (32.12) indicates that the CO₂ emission is dependent on the heating and hydrogen consumption. The hydrogen consumption for ARDS is about 1–3 wt%. The heating duty for the fractionating section feed heater, recycle gas (after scrubbing) heater, and hydrogen charge heater in an ARDS unit with a design capacity of 36.3 MBPD used in different sections of the processing of fuel gas is shown in Table 32.7. The En_{heating} value estimated on the basis of the data shown in Table 32.7 is 0.417×10^9 J/t feed.

32.1.3 Hydrogen Production (HP) Units

Hydrogen production could be considered the core of utility production in refineries. The demand for hy-

API – American Petroleum Institute

drogen in refineries is increasing due to the increase in demand for clean fuels. Refiners can use a number of feedstocks (refinery gas, liquefied petroleum gas, naphtha, and natural gas) to produce hydrogen. Deep

conversion refineries with a high level of bottom of the barrel conversion can have a H₂ demand of up to 2.7 wt% of total crude input. In general, refineries follow four steps in steam methane reforming (SMR) or hydrogen production (HP), these are [32.22]:

1. Feedstock treatment, where sulfur is removed with other contaminants
2. Steam methane reforming, where feedstock and steam is converted to syngas (CO + H₂) at high temperatures
3. Heat recovery for syngas and water/gas shift reaction incorporation to increase the hydrogen yield; and finally
4. Hydrogen purification, which is typically done with an amine scrubbing process or a pressure swing adsorption (PSA) process to achieve final product purity.

The reforming reaction between steam and hydrocarbon is an endothermic one. The reactions taking place in the process (as a whole) are summarized below.

For saturated hydrocarbons

Water/gas shift reaction for H₂ recovery

Table 32.7 Fired heaters for ARDS unit with a design capacity of 36.3 MBPD used in different sections of fuel gas processing

Heater no.	Heating section	Section throughput (BPSD)	Fired heater duty (GJ/yr)
Heater 1	Recycle gas (after scrubbing) heater	100 000	290.5×10^3
Heater 2	Hydrogen charge heater	36 300	488.2×10^3
Heater 3	Fractionating section feed heater	66 590	63×10^3
Total			841.7×10^3

According to the data shown in the above table, $En_{\text{heating}} = 0.417 \text{ GJ/t-feed}$

Thus, (32.13) + (32.14) result in (32.15)

In the adiabatic shift reactor vessel, the moderately exothermic water/gas shift reaction converts carbon monoxide (CO) and water (steam) to CO_2 and H_2 . The CO_2 is typically vented to the atmosphere after removal, which makes up for one of the major CO_2 hot spots in a petroleum refinery. In addition, HP units require utilities that add to the total load of carbon emissions from refineries (Table 32.8). The total CO_2 emission per year (Q_{CO_2-HP}) for HP units can be calculated as

$$Q_{CO_2-HP}(\text{tpa}) = Q_{H_2} \cdot (Em_{\text{heating}} + Em_{\text{feed-conv}} + Em_{\text{electricity}}), \quad (32.16)$$

where Q_{H_2} is the amount of hydrogen product per year from the hydrogen production plant, Em_{heating} is the CO_2 emission from the combustion of the fuel required for heating to produce each ton of hydrogen, which can be calculated as

$$Em_{\text{heating}} = \left(\frac{En_{\text{heating}}}{LHV_{\text{fuel}}} \right) Em_{\text{fuel}} \times f, \quad (32.17)$$

where En_{heating} is the energy required for heating to produce each ton of hydrogen, and LHV_{feed} is the lower heating value of the fuel. Using natural gas as fuel, the LHV_{feed} value is 45.86 MJ/kg feed, or 43.57 MM BTU/t feed (Table 32.2). $Em_{\text{fuel},f}$ is the CO_2 emission factor of fuel combustion. The CO_2 emission factor for natural gas is 2.768 t CO_2 /t fuel. According

Table 32.8 Utility requirements for HP units in refineries (after [32.15])

Utility type	Requirement	
Power	0.15 kWh/kg H_2	150 kWh/t H_2 , 0.512 MM BTU/t H_2
Fuel	105 MJ/kg H_2	99.8 MM BTU/t H_2
Feed Gas	0.26 mol/mol H_2	4.52 t feed/t H_2

to Table 32.8, En_{heating} is 99.8 MM BTU/t feed, thus, Em_{heating} can be calculated, being 3.17 t CO_2 /t H_2 , assuming a 50% heat loss. $Em_{\text{electricity}}$ can be calculated as

$$Em_{\text{electricity}} = E_{kWh/feed} \times Em_{\text{electricity},f}. \quad (32.18)$$

According to Table 32.8, the $E_{kWh/feed}$ value is 150 kWh/t H_2 . As defined previously, $Em_{\text{electricity},f}$ is the CO_2 emission factor for electricity generation. If we assume fuel oil is used for power generation, $Em_{\text{electricity},f}$ is 0.670×10^{-3} t CO_2 /kWh according to Table 32.4. Consequently, the $Em_{\text{electricity}}$ value is 0.101 t CO_2 /t H_2 . $Em_{\text{feed-conv}}$ (t CO_2 /t H_2) is CO_2 emission for complete conversion of feed to produce each ton of H_2 (complete conversion of carbon in the feedstock). It can be calculated thus

$$Em_{\text{feed-conv}} = Q_{\text{feed}/H_2} \times Em_{\text{feed} \times f}, \quad (32.19)$$

where Q_{feed/H_2} (t feed/t H_2) is the amount of feed required to produce each ton of hydrogen and $Em_{\text{feed} \times f}$ (t CO_2 /t feed) = the CO_2 emission for complete conversion of each ton of feed. Assuming that natural gas with 90 vol.% methane and 10 vol.% ethane is used as feed, Q_{feed/H_2} and $Em_{\text{feed} \times f}$ values can be calculated as 2.26 t feed/t H_2 and 2.768 t CO_2 /t feed, respectively. Thus, $Em_{\text{feed-conv}}$ value is 6.26 t CO_2 /t H_2 . The estimated results for hydrogen production are summarized in Table 32.9. The CO_2 emission factor for production of hydrogen is 9.53 t CO_2 /t H_2 . CO_2 emission for conversion of feed accounts for 65.7% as for heating and electric power, it accounts for 33.3 and 1.1%, respectively.

Table 32.9 CO_2 emission from hydrogen production plant

	CO_2 emission	
	t CO_2 /t H_2	%
Em_{heating}	3.17	33.3
$Em_{\text{feed-conv}}$	6.26	65.7
$Em_{\text{electricity}}$	0.101	1.1
Q_{CO_2-HP}/Q_{H_2}	9.53	100

32.1.4 Hydrocracking

By definition, hydrocracking is the treatment of feedstock with hydrogen (hydro) to convert higher molecular weight compounds to light molecular weight ones (cracking) using a catalyst. Hydrocrackers are used to produce middle distillates with low sulfur content such as kerosene and diesel (Table 32.10). The process was developed by I.G. Farben in 1927 for conversion of lignite to gasoline and ever since its development it has allowed operation at relatively low pressures with higher conversion to gasoline, jet fuel, naphtha, etc. [32.20].

Feedstocks are hydrotreated to saturate the olefins and remove the sulfur, nitrogen, and oxygen compounds. Metals are retained on the catalyst, and nitrogen and sulfur are removed by conversion to ammonia and H₂S, respectively. A number of reactions take place in the process, including olefin saturation and partially aromatic ring saturation. Desulfurization and denitrogenation reactions produce exothermic heat to the amount 65–75 BTU/SCF of hydrogen consumed. The saturation of olefins also provide additional exothermic heat (140 BTU/SCF of hydrogen consumed). The overall heat of reaction for typical hydrocracking feed preparation is 25 000 BTU/bbl of raw feed. On average, the required hydrogen is about 27–54 m³ [32.3] H₂/m³ feed. Operating temperatures and pressure vary according to the age of the catalyst. General utility requirements are given in Table 32.11.

The CO₂ emission (t CO₂/yr) from the hydrocracking unit can be calculated as

$$Q_{\text{CO}_2\text{-Hydrocracking}} = Q_{\text{feed}} (\text{Em}_{\text{heating}} + \text{Em}_{\text{H}_2} + \text{Em}_{\text{steam}} + \text{Em}_{\text{electricity}} + \text{Em}_{\text{cooling}}) \quad (32.20)$$

Table 32.10 Typical feedstocks and products in hydrocracking units

Feedstock	Product
Kerosene	Naphtha
SR diesel	Naphtha and/or jet fuel
Atmospheric gas oil	Naphtha, jet fuel and/or diesel
Vacuum gas oil	Naphtha, jet fuel and/or diesel
Deasphalted oil	Olefin plant feedstock

Table 32.11 Typical hydrocracker (10 621 BPD, 1604 t/day) utility requirements for petroleum refineries (after [32.15])

Item	Amount per day	Amount per ton of feed
Steam	797 mlb	0.225 t steam
Power	138 mkWh	86.0 kWh
Cooling water	3.3 mgal/min	11.2 m ³
Fuel	2124 MM BTU	1.324 MM BTU

32.1.5 Fluid Catalytic Cracking (FCC) Unit

The main objective of fluid catalytic cracking (FCC) is the conversion of feedstock to gasoline and other valuable products. FCC also minimizes the production of less valuable products (i. e., coke, clarified oil, etc.) [32.23]. However, due to current high energy costs and progressively tightening environmental regulations, refiners have recently been expanding their FCC focus to include improved energy efficiency and reduced CO₂ production [32.23–26].

FCC units supply their own fuel for the conversion of products and further downstream fractionation. This fuel is the by-product of the cracking reactions left on the catalyst, commonly referred to as coke. With heavier feeds that contain less hydrogen and inherently produce less liquid volume, higher coke burning capabilities are needed, or we need to find a way to increase coke production to improve product yields. The key is to produce enough coke to increase the conversion of the feed until the optimum yield pattern is achieved. A typical FCC unit is shown in Fig. 32.5.

Typically FCC accounts for 20–35% of a refinery's CO₂ emissions via its regenerator's stack. Most of the CO₂ produced in the FCC regenerator is required as a result of satisfying the FCC heat balance and is the result of the coke (carbon residue on catalyst) combustion. Hence, it is essential to control the FCC system to provide optimum performance by feedstock quality control, taking into consideration equipment limitations and environmental constraints [32.22].

The CO₂ emission for catalytic cracking each ton of feed can be calculated as

$$Q_{\text{CO}_2\text{-FCC}}(\text{tpa}) = Q_{\text{feed}} (\text{Em}_{\text{heating}} + \text{Em}_{\text{feed-conv}} + \text{Em}_{\text{electricity}}) \quad (32.21)$$

where Q_{feed} (t/yr) is the amount of FCC feed treated per year, $\text{Em}_{\text{heating}}$ (t CO₂/t feed) is the CO₂ emission from the combustion of the fuel added to heat each ton of FCC feed, $\text{Em}_{\text{electricity}}$ (t CO₂/t feed) is the CO₂ emission from the generation of electricity required to treat each ton of feed, $\text{Em}_{\text{feed-conv}}$ (t CO₂/t feed) is the CO₂ emission from the regenerator for burning coke formed from each ton of FCC feed. If assuming that f (4.6 wt%) is the coke content in the FCC product, $\text{Em}_{\text{feed-conv}}$ could be estimated as $f(44/12)$ which equals 0.169 t CO₂/t feed.

32.1.6 Catalytic Reforming

Catalytic reforming converts petroleum naphtha to high-octane gasoline pool components. These high-

Fig. 32.5 A typical fluid catalytic cracking (FCC) unit showing the main energy balance elements of the reactor (left) and regenerator (right): 1. Spent catalyst throughput; 2. Regenerated catalyst throughput (after [32.26])

octane components are mainly branched and aromatic hydrocarbons which are less prone to ignite prematurely in internal combustion engines hence reducing the knocking effect [32.27]. The process transforms C₇–C₁₀ hydrocarbons to aromatics and *iso*-paraffins by selective reforming (catalytically). The process is highly endothermic and energy intensive. The main role of the process is to produce gasoline (about 37 wt%) to be added to the total pool of the refinery products [32.16]. Other units such as FCC, methyl *tert*-butyl ether (MTBE) production unit, alkylation unit, and isomerization unit all contribute to this pool. Reforming is operated in two modes in refineries. The first is a high severity mode which produces 80–90 vol.% aromatics. The second is a middle severity one, where a 70 vol.% aromatic content of high-octane gasoline is obtained [32.16]. The typical feedstocks for the process are heavy straight run (HSR) gasoline/naphthas (82–190 °C) and heavy hydrocracker naphthas. These are composed of what is known as PONA (paraffins, olefins, naphthenes, and aromatics). Typical feedstocks and reformer products (in terms of PONA) are summarized in Table 32.12.

A number of reactor configurations exist for this process, including axial and radial flow tubular and spherical reactors. Membrane reactors are also employed in this process consisting of a combination of

chemical reactor and membrane. They are used in reaction systems in which removal of reaction products from reaction media or addition of reactants along the reactor is beneficial. This effective configuration has various advantages such as increasing reaction rate, reducing by-product formation, lower energy requirements, and relatively safe operation. *Gary and Handwerk* [32.20] have detailed the utilities required in catalytic reforming per bbl feed: steam 30 lb, power 3 kWh, cooling water 600 gal, and fuel gas (LHV) 0.3 MM BTU. The CO₂ emission (t CO₂/yr) for catalytically reforming each ton of feed can be calculated as

$$Q_{\text{CO}_2\text{-reforming}} (\text{t CO}_2/\text{yr}) = Q_{\text{feed}} \times (\text{Em}_{\text{heating}} + \text{Em}_{\text{steam}} + \text{Em}_{\text{electricity}} + \text{Em}_{\text{cooling}}), \quad (32.22)$$

where $\text{Em}_{\text{cooling}}$ is the CO₂ emission from the generation of cooling water required to treat each ton of feed. It should be noted that the catalytic reforming can generate a significant amount of hydrogen gas, which can be used for hydroprocessing units, thus reducing the CO₂ emission (total carbon footprint) from the hydrogen production plant which should be considered in the CO₂ emission from the refinery.

32.1.7 Acid Gas Removal (AGR)

Acid gas removal processes are common in petroleum refineries and are a crucial part of the operations in gas treatment plants. Natural gas consists of hydrocarbons and acid gases (hydrogen sulfide, H₂S, and carbon dioxide). The process of removing hydrogen sulfide is commonly referred to as a sweetening process. Typ-

Table 32.12 Typical PONA analyses for reformer feedstock and product (after [32.20])

Component	Feed (vol.%)	Product (vol.%)
Paraffins	45–55	30–50
Olefins	0–2	0
Naphthenes	30–40	5–10
Aromatics	5–10	45–60

ical natural gas sold requires less than 5 ppmw H₂S with a heating value between 920 and 980 BTU/SCF. The actual specifications depend on the use and local country's regulatory requirements, which gives refiners added tasks of tailoring processes to meet demands.

Acid gas removal processes could be allocated to two main types: adsorption and absorption [32.28]. Adsorption is defined as a physiochemical phenomenon in which gas is concentrated on the surface of a solid or liquid to remove impurities. Usually, carbon is the adsorbing medium, which can be regenerated upon desorption [32.29]. What is adsorbed is typically in proportion to the surface area of the solid; hence, adsorbents are granular solids with large surface areas per unit mass. Conversely, absorption is achieved either by dissolution (a physical phenomenon) or by reaction (a chemical phenomenon). Typically, petroleum refineries employ a chemical absorption process (using solvents) in acid gas removal. Research and development are being undertaken in this area for more effective and efficient solutions with environmental benefits [32.29–32]. Chemical processes employ a solvent of alkaline nature such as amines or carbonates. Acid gases are stripped off the solvent in desorption by reducing pressure or increasing temperatures. Amines used in such processes can be categorized as primary, secondary or tertiary, depending on how many terminal nitrogen atoms are substituted by organic groups (Table 32.13).

The process of amine acid gas removal typically starts with sour gas entering through an inlet scrubber to remove entrained solid. The sour gas then enters the bottom of the absorber column and flows upward through the absorber in countercurrent contact with the aqueous amine solution, where the amine absorbs acid gas components from the gas stream.

The sweet gas exiting the top of the absorber passes through a separator and then flows to a dehydration unit before being ready for sale as a product. The rich amine solution from the bottom of the stripper column is pumped through an amine–amine heat exchanger to release the entrained acid gas and then through a cooler before being introduced to the top of the absorber column as a lean amine solution. The exiting gas from an accumulator contains H₂S and CO₂ which are typically

sent to sulfur recovery units and incinerators, respectively.

32.1.8 Estimated Amount of CO₂ Emission from Petroleum Refineries

Petroleum refineries convert crude oil to valuable products via a wide range of physical and chemical processes. CO₂ may be emitted via a number of sources in a refinery. Typically, these sources can be divided into [32.3, 33, 34]:

- **Furnaces and boilers:** They supply the heat required for separation of liquid feedstock and for the different utility units and combined represent 30–65% of refinery emission. Furnaces and boilers are typically referred to as utility sources.
- **Fluid catalytic cracking (FCC) unit:** This process is used to convert some heavier fractions, such as vacuum gas oil (VGO) or atmospheric residue (AR) into a more valuable product typically contributing to the gasoline pool of the refinery. It can be responsible for up to 35% of CO₂ produced in a refinery [32.3].
- **Hydrogen production (steam methane reforming, SMR):** Hydrogen production units produce hydrogen and CO₂ via reforming of natural gas or other hydrocarbon fuels. 20% of the total CO₂ emission in a refinery could be from hydrogen production.
- **Utilities production:** If a refinery produces steam or electricity (for pumps and compressors), CO₂ is a direct by-product of such a process which can contribute up to 50% of the total refinery CO₂ emission load.

The total CO₂ emission from a refinery can be estimated by summation of CO₂ emission from all processes in the refinery. According to the U.S. EPA [32.35], GHG emissions from petroleum refineries were estimated to be 214 million tons of CO₂ equivalents based on production rates in 2005. The majority of this estimate was from CO₂ emission rates. In the case of Europe, it was estimated that 114 refineries emitted about 155 million tons of CO₂ [32.36]. The specific emissions of a refinery can range from 0.02 to 0.82 t of CO₂/t of crude oil processed, depending

^a CO₂ emission factor for this refinery is 0.895 t CO₂/t feed (crude oil)

on the refinery configuration and quality of feedstock used.

The Hydrocarbon Publishing Company [32.15] noted a trend between refinery CO₂-equivalent emissions per barrel of gasoline produced and crude quality in terms of sulfur content and API (American Petroleum Institute) gravity. It is evident that the CO₂ emission increases with increasing sulfur content and decreasing API value. They also estimated the CO₂ emission from

various point sources at a hypothetical 250 Mbbl refinery with a hydrogen plant and an fluid catalytic cracking unit (FCCU). The results are depicted in Table 32.14. The CO₂ emission for heating and steam account for 21.3%; for the FCCU regenerator, 17.7%; for hydrogen production, 5.4%; for engines, turbines, and electricity, 4.0%; and for flares and incinerator, 1.6%. The CO₂ emission factor for this refinery is about 0.90 t CO₂/t feed (crude oil).

32.2 Case Study: CO₂ Emission Estimation from a Refinery in the State of Kuwait

In the following section, we demonstrate the methodology for assessing the CO₂ emissions from a refinery chosen in the State of Kuwait. Kuwait is an oil-producing country (member of OPEC (Organization of the Petroleum Exporting Countries) and OAPEC (Organization of Arab Petroleum Exporting Countries)) that refines about 1 million barrels of crude oil per day. Its economy is dependent on crude oil sales and petroleum-related activities. The methods of estimation are all up to date and are concerned with the processes carbon footprint (i.e., carbon dioxide emission from point source). The refinery dataset and process information is gathered from relevant parties and on-site data.

The refinery considered here is one of the largest on the Asian continent and has been in operation for over 60 years. Over its lifespan, a number of revamps

has been commissioned for this facility. It contains two sides; the first side is the refinery where crude oil is processed to produce a number of petroleum products (including naphtha, gasoline, diesel), the second side is a gas plant where natural gas and gas condensate is treated. The main objective of the gas plant side is to extract liquefied petroleum gas (LPG) products (propane and butane) from the treated gas. The refinery has a number of utility operations and consumes electric power purchased from the state's government.

The refinery's capacity is 460 MBPD with a total area of 10.5 km². The side hosts a number of topping units for crude oil distillation (atmospheric and vacuum) treating various grades. The side also hosts hydrotreating units (ARDS, kerosene desulfurization unit, gas oil desulfurization), conversion units (hydroc-

racking, FCC, naphtha reformers), and other supporting units (HP units, recovery units for various processes, etc.) The gas plant side as mentioned above is part of the refinery's overall scheme.

32.2.1 Carbon Dioxide (CO₂) Estimation

Hydrogen Production (HP) via Steam Methane Reforming

There are four steam methane reformers (SMR) for hydrogen production (HP) in the refinery (see Sect. 32.1.3 for process details). They are all of identical design in terms of capacity producing 49.5 MMSCFD hydrogen of 97% purity. Utilization capacity of each unit varies (according to 2012 average data) between 55 and 76%. Thus, the total hydrogen production rate by mass is 111.9×10^3 t H₂/yr.

The main function of the units is to meet the hydrogen demand for the refinery, and in particular the hydrocracking (HCR), atmospheric residue desulfurization (ARDS), kerosene desulfurization (KD), and gas oil desulfurization (GOD) units. Hydrogen is produced as per the reaction depicted in (32.13), (32.14), and (32.15). The CO₂ produced in the shift reaction is removed by a Benfield system.

The compositions of feed and typical products are shown in Table 32.15. The feed gas is desulfurized by absorption to remove all sulfur components using a di-*isopropanolamine* (DIPA) solution. The desulfurized gas is then mixed with steam (31.6 kg/cm²) and passed through the reformer cells to produce carbon monoxide (CO), carbon dioxide (CO₂), and hydrogen at 843 °C. A high-temperature shift convertor is used to convert the bulk of the CO to CO₂. A Benfield solution (K₂CO₃ + diethanolamine + water) is used to remove the CO₂ produced in the shift convertor from hydrogen. The solution is then regenerated and CO₂ is vented to atmosphere.

The four HP units in the refinery have identical capacity which was used to estimate the CO₂ vented to atmosphere. According to the discussion above (Sect. 32.1.3), the CO₂ emission (Em_{feed-conv}) for complete conversion of natural gas to produce each ton of H₂ without considering heating and utility is 6.26 t CO₂/t H₂. Thus, the CO₂ emission from the four HP

units without considering heating and utility is 700×10^3 t/yr, which is calculated by multiplying Em_{feed-conv} (6.26 t CO₂/t H₂) with the total hydrogen production rate (111.8×10^3 t H₂/yr).

Fluid Catalytic Cracking (FCC) Unit

The FCC unit has a design capacity of 40 000 BPD and processes feedstock to produce a number of products, mainly gasoline and liquefied petroleum gas (LPG). The olefin-rich LPG is further processed to produce propylene, alkylate, and MTBE. The FCC unit consists of the following sections:

1. Reactor/regenerator
2. Main fractionator
3. Gas concentration unit
4. Power recovery.

Figure 32.6 shows a simplified flowchart of the FCC unit in the refinery considered. The reactor/regenerator is where the cracking reactions, catalyst separation and regeneration take place. The feed to the unit is the preheated raw oil (220–265 °C) combined with the hot stream of regenerated catalyst introduced to the bottom of the reactor's riser. Table 32.16 shows the main product yields as per the design of the unit in the studied refinery, with typical operating conditions shown in Table 32.17.

The reactor vapor is sent to the main fractionator to be separated to heavy cycle oil (HCO), light cycle oil (LCO), distillate, heavy gasoline, and overhead vapors. The overhead vapors are partially condensed and collected in a receiver and both hydrocarbon liquids and gas are further processed in the gas concentration unit (GCU). The final products from the GCU can be summarized as:

1. Off-gas
2. LPG
3. Light gasoline.

The fluid catalytic cracking (FCC) unit has an operating capacity of 43 000 BPD; with a coke production of 4.62 wt% as per the unit's design with 89.2% utilization capacity. Consequently, the CO₂ emission from the FCC unit can be estimated as 339.4×10^3 tpa. On the basis of the average data for 2012, the FCC stack flue gas composition is reported in Table 32.18. The CO₂ composition is 15.2% of the stack, which gives an indication of a considerable quantity. The composition of the FCC stack flue gas is similar to the flue gas from a general coal-based power station. There is no carbon monoxide (CO) present in the FCC stack due to excess air pumped in to ensure complete combustion. There is about 0.05 vol.% of SO₂ in FCC flue gas, which may influence the performance of some sorbents

Table 32.15 Main feed and products qualities of HP units in the refinery being studied

Feed composition	mol% (dry)	Product composition	mol% (dry)
CO ₂	1.70	H ₂	97

Heavy gasoline	13.37	Coke	4.62

and should be considered in the CO₂ capture from FCC flue gas.

Flaring

Flaring in refineries and other industrial facilities occurs as an alternative to venting hydrocarbons to the atmosphere. It is an important safety measure for controlling operation shutdowns and start-ups, in addition to controlling operating pressures. Flaring results in the combustion of hydrocarbons with CO₂ and steam as

products. The refinery considered in this study hosts 15 flares for control and release purposes on both the refinery and gas plant sides. According to the April 2013 data survey in the refinery, the main reasons for the flaring in this facility are as follows:

- Hydrogen header pressure fluctuation in ARDS
- Hydrogen make-up compressor seal pot valve passing in ARDS
- Overhead flaring of hydrocracker splitter
- Make-up gas compressor leaks in hydrocracker
- HP units compressor discharge
- Excess gas generation due to severe operating condition in ARDS unit
- Maintenance of crude column condensers
- Unit shutdowns and startups
- LPG storage flares
- LPG train flare.

Table 32.19 Flaring activities analysis and estimated CO₂ emission

Component	Amount
Flaring (total hydrocarbon amount reported in refinery)	76 650 MMtpa
Refinery capacity	460 × 10 ³ BPD
CO ₂ emitted from flaring activities	72 890 tpa

It is essential not to overlap between excess flaring activities and normal operations that might include CO₂ emissions as part of its composition. *Martin* et al. [32.37] reported a correlation based on emission inventory analysis that estimates the amount of GHG (CH₄ and CO₂) emitted by refineries flares. This was used in this study to estimate the amount of CO₂ (Table 32.18) emitted based on the following

$$FCE = 3.12 RT, \quad (32.23)$$

where FCE is the flares CO₂ emissions (kg) and *RT* is the refinery's throughput in tons. Kuwait's crude (more commonly termed Kuwait export crude, KEC) has been of 30.2 API in recent years with an estimated density of 875 kg/m³. Hence, a throughput of 23.34 million tpa for this refinery is calculated and 72 880 tpa is the estimated CO₂ emission (*Q*_{CO₂-flaring}) from flaring in this refinery (Table 32.19).

Acid Gas Removal (AGR)

On the gas plant side of this refinery, C₃, C₄, and gasoline are cryogenically extracted through extraction/dehydration, cooling/chilling, fractionation, and product treating. Moisture and liquids are removed from the entering gas to prevent freezing in the cold section of the plant. Natural gasoline recycle is used as an absorbent in the absorber to recover C₃ and C₄, amongst other products. Rich liquids that form at the absorber bottom are transferred to a stripper to reduce C₃ and C₄ content. The stripper bottom includes C₃, C₄, gasoline and associated C₂ and lighter gases. The stripper's condensate is fed to a fractionating plant comprising deethanizer, depropanizer, and debutanizer. The utilities of the fractionating plant will be discussed in the next section.

The gas plant contains an acid gas sweetening unit to remove H₂S and CO₂ from the gas feed. Diethanolamine (DEA) solution is used in this unit of 230 MMSCFD capacity. The gas feed enters an absorber where H₂S and CO₂ are absorbed using DEA. The treated gas is fed to a separator to separate the carried DEA. The design specifications reported for this unit are summarized in Table 32.20, which show the three cases of treated gas in this process. Using the absorber balance equation for CO₂, we can estimate the amount of CO₂ existing in the system as follows [32.38]

$$E(\text{CO}_2) = V_{\text{in}} \left(\frac{\text{vol}_{\text{in}} - \text{vol}_{\text{out}}}{1 - \text{vol}_{\text{out}}} \right). \quad (32.24)$$

When *vol*_{out} ≈ 0.0%, (32.24) becomes

$$E(\text{CO}_2) = V_{\text{in}} \times \text{vol}_{\text{in}}, \quad (32.25)$$

where *E*(CO₂) is the existing amount of CO₂ from the system in SCFD, *vol*_{in} is the mol fraction of CO₂ in the entering stream, and *vol*_{out} is the existing mol fraction taken as (1.2% maximum). Estimated amounts are also shown in Table 32.20.

Acid condensate is treated in a similar fashion but in a different unit in this refinery. The composition of the condensate is shown in Table 32.21. A density of 750 kg/m³ is assumed for this condensate [32.38]. Converting the flow rate of the entering stream to unit volume can allow the assessment of the total amount of moles. From the unit balance we can estimate the CO₂ emission amount (*Q*_{CO₂-ASC} (t CO₂/yr)) exiting the system taking CO₂ mol% (maximum out) as 0.5% (Table 32.21)

Utilities

Utilities play a major role in petroleum refineries. They supply through fired heaters and boilers the energy needed for units to operate at desired conditions. Fuel oil or gas is typically employed as a fuel for various

utility operations. Fuel oil was used in the estimation of CO₂ emitted in this work. Excluding the gas plant side, there are 45 fired heaters in operation in the refinery. Table 32.22 shows estimated CO₂ emission from the utilities of the refinery side.

The gas plant side contains nine fired heaters for the different LPG trains (deethanizer, depropanizer, and debutanizer). On the basis of a similar category for the past utility calculation for residual fuel oil. Table 32.23 summarizes the gas plant utilities duties and reports the

estimated CO₂ emission on the basis of an emission factor of 78.87 kg CO₂/MM BTU.

Analysis of Results and Discussion

The estimated CO₂ emissions from different sources in the refinery are listed in Table 32.24, and the CO₂ emission distribution per unit operation in the whole refinery is shown in Fig. 32.7. The results obtained for this refinery are discussed hereafter. The total amount of CO₂ emitted from the site is estimated between 4.91×10^6 tpa (without considering the CO₂ emission for consumption of electricity), depending on the AGR and condensate treatment units feed. As indicated in the previous sections, utilities represent the major source of CO₂ in refineries. Open literature is lacking in information regarding the distribution of CO₂ emission for utilities. However, as shown in Table 32.24 and Fig. 32.8, combined CO₂ emissions from the utility for heaters and boilers is 2.77×10^6 t CO₂/yr, which accounts for 56.3% of all CO₂ emissions from the refinery. Some unit operations in the refineries are quite energy intensive, such as 585×10^3 t CO₂/yr for atmospheric crude distillation, 414×10^3 t CO₂/yr for hydrogen production

Table 32.22 Fired heater (utilities) on the refinery side and CO₂ emissions based on fuel oil emission factor

Process	CO ₂ emission (tpa)

**Fig. 32.7** CO₂ emissions from various utilities in the refinery. Note that CO₂ emission for the production of hydrogen in hydroprocessing is not included in the CO₂ emissions of the units

units, 294×10^3 t CO₂/yr for catalytic reforming, and 206 million t CO₂/yr for residual hydrotreating. Utilities on the gas plant side emitted 9.44×10^5 tpa of CO₂.

In comparison to the total CO₂ emission from different units, including feed-containing/feed-conversion CO₂ and CO₂ emission from utilities, the CO₂ emission from the acid gas sweetening and condensate ranked highest at 1.12×10^6 tpa, accounting for 22.9% of the whole CO₂ emission of the refinery. The CO₂ emission from the hydrogen production units is 1.11×10^6 tpa, ranking second. The third highest CO₂ emission is

from atmospheric crude distillation, being 5.85×10^5 t CO₂/yr. The CO₂ emission from the utility for all hydroprocesses, including residual hydrotreating, hydrocracking, kerosene HDS and treating and distillate HDS and treating, is about 4.20×10^5 tpa, accounting for 8.5%. The CO₂ emission from the FCCU for the generation of catalyst is 3.39×10^5 tpa, accounting for 6.9%. The CO₂ emission from flaring is very limited, accounting for only 1.5%.

Supporting units utilities (combined) are considered to be the largest emission source in the refinery. How-

Fig. 32.8 Distribution by source of the total CO₂ emitted in the refinery

ever, it is very hard to manage such utility units and treat each individually for better energy management. Better energy management of hydrogen production, atmospheric crude distillation, catalytic reforming, and residual hydrotreatment will result in better carbon mitigation. It is estimated that by reducing the load of these units by 25%, the total carbon emissions of the refinery decrease by 7.6%. Hydrogen production is a major CO₂ emission source from the refinery. The whole refinery's CO₂ emission will be reduced by 5.7% if one reduces hydrogen consumption in all hydroprocesses by 25%.

CO₂ emission from acid gas removal (AGR, for both gas and condensate) ranks first (1.124×10^6 t/yr) with a contribution of 22.9%. Many past studies assessed refineries without considering AGR. This is

probably due to lack of data or the unit not being part of refinery operations. CO₂ is typically vented with a minimal hydrocarbon fraction to the atmosphere in this process [32.38]. Utilities represent 56.3% of the total refinery's emissions in this case study. *van Straelen et al.* [32.3] showed that utilities with furnaces and boilers can contribute up to 60% of the total refinery assessment with HP units reaching up to 20% in an electricity-producing refinery. The assessment conducted in this work agrees with their reports. A subdivision of two types of refineries was given by the IEA (International Energy Agency) [32.4], showing that an FCC refinery could have process heaters (utilities) contributing 44% of the CO₂ emissions total, while a hydrocracking refinery has 55% for utilities.

32.3 Challenges in Carbon Capture and Mitigation for Petroleum Refineries

Nominally, the main challenge in carbon capture is twofold: (1) The optimization of refineries utilities and energy consumption, and (2) capturing CO₂ from similar quality sources to be mixed in a single stream. Better energy management in a refinery leads to more cost-effective operation and a reduction in the total carbon footprint of the different processes. Emerging developments in the past few years have focused on developing technologies for capturing CO₂ from flue gas. This is mainly the case for FCC, where this process can contribute up to 20% of the total CO₂ load from a refinery. The amount of coke and subsequent CO₂ produced in

the reactor is a direct result of the quality of the FCC feed and the operating conditions imposed on the unit by the operator. The unit yields are directly related to the quality of the feed and the operating severity set by the enthalpy balance. *Wolschlag et al.* [32.23] discussed the opportunities for carbon emission reduction in FCC and suggested the following:

- *Improved energy optimization:* Gap analysis is suggested to identify root causes (insufficient maintenance, inefficient energy system design, inefficient process operation, procedures and control,

or outdated technology). This could be achieved by correlating the process parameters with process energy indicators. Hence, process conditions can be connected with energy-related parameters.

- *CO₂ reduction through energy efficiency revamps:* This is mainly concerned with power recovery in FCC units. An example of such is the five-body train of a hot-gas expander, main air blower, start-up steam turbine, motor/generator and gear box as necessary. In this configuration, the expander is coupled to the main air blower and provides a direct transfer of energy to the shaft to minimize power transfer losses to the air blower.

Legislation on refineries and environmental rules and regulations have given rise to CO₂ reduction planning in the past decade or so. This will drive operational changes to improve process efficiencies, which paves the way for simulation packages to have a front seat in carbon-reduction schemes. This is especially true nowadays where heavier crudes are considered to be the sole feedstock in many refineries (new or revamped). The use of a simulation package has led to a 50% reduction in flaring after implementing an on-line program [32.25]. The simulation package includes inferential fuel gas quality and volume imbalance prediction, and a furnace-monitoring and advisory system. Additional benefits reported include: improved furnace efficiencies, more consistent product qualities (for example, where the process furnace is a feed heater or re-boiler), and more reliable process operation. Coupled H₂ and CO₂ management has also been studied recently in refineries. By developing a mixed integer nonlinear program (MINLP), *Al-Hajri* [32.39] has optimized refinery operations by controlling fuel, FCC, and hydrogen reduction units.

Energy management in an oil refinery is an integral part of CO₂ reduction strategies, especially with recent new regulations governing sulfur content of gasoline and diesel. This leads to an increase in capacity and hydrogen consumption. It is estimated that the total amount of crude oil processed in U.S. refineries increased in comparison to the start of the 1990s by 5% to comply with gasoline and diesel specifications. In Brazil, an increase of 1.5 million tons of CO₂ was estimated due to a change in gasoline and diesel specifications in 2009. This leads directly to more energy-intensive operations that require more hydrogen for cleaner fuel production. It is estimated that a refinery uses 7–15% of its crude oil input in its processes in direct or indirect heat requirements [32.40]. To deal with energy management challenges, technologies that show potential include:

1. Alternatives for saving energy at refineries
2. Less severe alternatives for intensive process operations (e.g., hydrotreating)
3. Oil gasification and CO₂ removal at the refinery.

Szklo and *Schaeffer* [32.40] described the first two options as achievable in the near to medium term. However, the third option could be considered to still be in developmental stages. *Petrick* and *Pelegriano* [32.41] stated that a 15–20% target reduction of energy use is achievable for U.S. refining activities, with emphasis on waste heat recovery utilization in petroleum refineries.

Improvement of heat integration and waste heat recovery has been discussed in recent literature for more energy-efficient systems in refineries [32.38, 42, 43]. The following treatment options are possible:

- Use of waste heat in absorption refrigeration systems and utilizing heat to preheat feeds.
- Improvement of furnace efficiencies combined with computer-controlled combustion.
- Direct feed of intermediary products without storage to recover loss heat (omitting cooling stage).

Using solar energy to heat feed stock or generating steam to replace the hydrocarbon fuels is another option to reduce the CO₂ emission in refineries. It may be promising for refineries in hot areas, such as the Middle East.

Modern refineries have higher emissions because they can use heavier crudes and produce more light products, especially gasoline and diesel. Catalytic reformers, FCC units, and vacuum distillation unit (VDU) could also be equipped with combined heat and power (CHP) units with a CO₂ capture ability [32.4]. These units represent 30–40% of the refinery energy consumption. They are placed on top of the list of unit operations that require energy management and carbon mitigation strategies.

Development of new refining technologies that have low CO₂ emission is crucial for future refineries. This effort may focus on the following areas:

1. Development of more effective catalysts, which are able to improve processing performance significantly and reduce energy consumption in processing.
2. Development of non hydroprocesses for production of clean fuels, such as adsorptive desulfurization, adsorptive denitrogenation, and oxidative denitrogenation.
3. Development of separation processes with low energy consumption, such as membrane separation, adsorption and abstraction, instead of the energy-consuming processes applied in current refineries.

32.4 Concluding Remarks

It is paramount to consider carbon management strategies as an inherent part of petroleum refinery operation schemes. Capturable amounts of CO₂ can be successfully integrated into carbon capture plants which might result in high cost avoidance [32.44–46]. This might be a very efficient way to reduce the CO₂ emissions in a refinery, in addition to generating income and profit from the integration of carbon plants.

Utilities, as discussed earlier, can have a drastic effect on the CO₂ emissions rate from a refinery. Better energy management schemes can reduce the CO₂ emissions rates. Each refinery is unique in terms of its processes and configuration. This allows for more responsible operation and for green initiatives to be

integrated into such facilities making them more environmentally friendly.

The conventional refining technologies, including hydroprocesses and FCC, show higher CO₂ emission. The focus of research should be the development of new refining technologies that have low CO₂ emission rates.

Conventional

33. Conventional Lube Base Stock

Brent E. Beasley

This chapter reviews the basic unit processes in modern conventional lube manufacturing. As this is a large subject area, this chapter will focus on giving the reader an overview of the major processes most frequently found in the lube-manufacturing plant. It will neither cover all technologies or processes nor will it discuss detailed plant design and operation as this would easily require another book. The reader should come away with a general understanding of the conventional lube-manufacturing process and key factors affecting the unit processes.

33.1 Lube Base Stock Manufacturing

Lubes and specialties are high-value products that have a variety of end uses. Some end uses include:

- *Automotive*: engine oils, automatic transmission fluids (ATFs), gear oils
- *Industrial*: machine oils, greases, electrical oils, gas turbine oils
- *Medicinal*: food grade oils for ingestion, lining of food containers, baby oils
- *Specialty*: food grade waxes, waxes for candles, fire logs, cardboard.

Lube manufacturing is a complex process and it involves several processing steps. Crude is distilled and the bottoms, atmospheric resid, is sent to a vacuum distillation unit (VDU) sometimes called a vacuum pipestill (VPS) for further fractionation. Vacuum fractionation is used to separate the atmospheric resid into several feed streams or distillates. Conventional solvent processing uses selected solvents in physical processes to remove undesirable molecules (asphaltenes, aromatics, *n*-paraffins). Hydroprocessing is used to convert or remove the trace undesirables such as nitrogen, sulfur and multiring aromatics, or to enhance the base stock properties to make specialty, high-quality products.

The manufacture of lubes and specialty products makes a significant contribution to refining profitability, even though the yields and therefore volumes are relatively small.

The business drivers of the lube business are for increased production to reduce per barrel costs, to reduce

operating costs (OPEX), and for higher quality products to meet ever increasing product quality standards.

Refiners produce base stocks or base oils, and lube oil blenders produce finished oils or formulated products:

- Base stocks are products produced from the lube refinery without any additives in the oil or wax.
- Base oils are blends of base stock.
- Finished oils or formulated products are blends of base stock or base oil with special additives.

Lube base stocks are given various names. Some of the common names include:

1. Neutrals – from virgin distillates, for example, 100 N, 150 N, 600 N
2. Bright stock – from deasphalted oil (DAO), for example, BS150
3. Grades – for example, Society of Automotive Engineers (SAE) 5, 10, 30, etc.; ISO 22, 32.

The most common name is neutral (N) which was derived in the days when the lube distillates were acid treated (sulfuric acid) followed by clay filtration. After the clay treating, the oil was acid free or neutral. The viscosity number in this example, 150 N, is the approximate mid-point viscosity of the grade range in the ASTM (American Society for Testing and Materials)/BSI (British Standards Institution) Viscosity Classification System expressed in Saybolt seconds universal

(SUS) at 100 °F (≈ 38 °C). Bright stock is a heavy lube grade that is made from deasphalted resid. The name refers to the *bright* appearance of the product as compared to the resid feed. Bright stocks are very viscous. A typical bright stock, BS150, has a viscosity of 150 SSU at 210 °F (≈ 100 °C).

Grades may refer to the actual viscosity. For example, International Standards Organization (ISO) = cSt at 40 °C. Grades may be also be assigned arbitrarily, such as those assigned by the Society of Automotive Engineers (SAE).

There are many other grade names that are used to differentiate special products. These products may have special high-valued qualities that may make them very profitable, even though they tend to be lower volume products.

33.2 Key Base Stock Properties

Viscosity is a key lube oil property and is a measure of the fluidity of the oil. There are two measures of viscosity commonly used; kinematic and dynamic. The kinematic viscosity is flow due to gravity and ranges from approximately 4 to 20 cSt (centistokes) for solvent neutrals and about 30–32 cSt at 100 °C for bright stock. The dynamic viscosity is flow due to applied mechanical stress and is used to measure low-temperature fluidity. Brookfield viscosity for ATFs at -40 °C and cold cranking simulator (CCS) for engine oils at -25 °C are examples of dynamic viscosity measurements.

Lube-oil volatility is a measure of oil loss due to evaporation. NOACK volatility measures the actual evaporative loss which is grade dependent and can run 6–35 wt%.

The gas chromatographic distillation (GCD) can be used to measure the front end of the boiling point curve and may be used as an indication of volatility, for example, 10% off at 375 °C.

VI is based on an arbitrary scale that is used to measure the change in viscosity as a function of temperature. The scale was first developed in 1928 and was based on the *best* and *worst* known lubes at the time. The best paraffinic lube was assigned a value VI = 100 and the worst naphthenic was assigned a value VI = 0. The quality of base stock has been improved dramatically since 1928 with the VI of high-quality base stock in the 150+ range.

The pour point is the temperature at which the fluid ceases to pour and is nearly a solid. Typically, the pour point ranges from -6 to -24 °C for heavy to light neutrals.

The cloud point is the temperature at which wax crystals first appear.

Base stocks are assigned to five categories [33.1]:

1. Group I base stocks contain less than 90% saturates and/or greater than 0.03% sulfur and have a viscosity index (VI) greater than or equal to 80 and less than 120.
2. Group II base stocks contain greater than or equal to 90% saturates and less than or equal to 0.03% sulfur and have a VI greater than or equal to 80 and less than 120.
3. Group III base stocks contain greater than or equal to 90% saturates and less than or equal to 0.03% sulfur and have a VI greater than or equal to 120.
4. Group IV base stocks are polyalphaolefins (PAOs).
5. Group V base stocks include all other base stocks not included in Groups I–IV.

Saturates, aromatics, naphthenes are measures of these molecular types present in the base stock.

Color (appearance) and stability are the measure of color and change in the presence of light or heat.

Conradson carbon (CCR) or micro-carbon residue (MCR) is a measure of the ash left after flame burning. Additional base oil quality considerations may be found in [33.2].

33.2.1 Lube Oil Feedstocks

Lube oil feedstocks are taken from the bottom of the crude barrel (Fig. 33.1).

Lube crudes are generally paraffinic or naphthenic in composition. A paraffinic crude is characterized by a higher wax content. West Texas and Arab Light are good-quality paraffinic crudes. Naphthenic crudes are characterized by their low wax content, and they make low-to-medium quality lubes, for example, South Louisiana. In conventional solvent lubes, the atmospheric resid (bottoms from the crude distillation tower) is upgraded to lube products through the following processes:

- Vacuum distillation
- Solvent extraction (*n*-methyl-2-pyrrolidone (NMP), furfural, phenol)
- Solvent dewaxing (methyl ethyl ketone (MEK)/methyl isobutyl ketone (MIBK), MEK/toluene, propane)
- Hydrofinishing (may be integrated with extraction)
- Propane deasphalting
- Hydroprocessing for higher quality.

Fig. 33.1 Lube plant feedstocks are taken from the bottom of the crude barrel

Table 33.1 Lube oil molecules contribute to lube oil properties

Molecule	Base stock quality affected	Process involved
<i>n</i> -Paraffin	High pour, VI no S and CCR	Dewaxing
<i>i</i> -Paraffin	High VI and sats, med pour	
2 Ring naphthene	Mid VI, low pour, high acids	Extraction, hydrofinishing
1 Ring aromatic	Mid to high VI	Extraction
Multi-ring naphthene	Low VI, low pour, high acids	Extraction, hydrofinishing
Multi-ring aromatic	Low VI, low pour	Extraction
Organic sulfur	Good stability, antioxidant	Hydrofinishing
Organic nitrogen	Poor stability	Hydrofinishing
Organic sulfur and nitrogen	Removed by hydrofinishing	Hydrofinishing
Asphaltenes	High CCR, poor color	Distillation, deasphalting

33.3 Lube Oil Chemistry

Lube oil is produced from a wide variety of crude oil molecules. The molecular types and their effect on lube

oil quality are summarized in Table 33.1, along with the lube processes that act on them.

33.4 Typical Lube Processes

The typical lube process is depicted in Fig. 33.2 and 33.3. In the following, the individual process steps are explained. The impact of each step on the product quality is summarized in Table 33.2.

33.4.1 Lube Vacuum Distillation Unit (VDU) or Vacuum Pipestill (VPS) – Viscosity and Volatility Control

The VPS is generally the first process unit. The VPS's goal is to fractionate the atmospheric resid or reduced crude so that the base stock will have the desired viscosity. The fractionation also controls the volatility and it is required to meet base stock volatility specifications. Fractionation also controls the flash point. The boiling point separation is accomplished by using high-efficiency distillation/fractionation hardware. Secondary effects include asphalt segregation in the vacuum resid from the VPS (potential by-product), reduction in CCR, and color improvement.

33.4.2 Solvent Extraction – Viscosity Index Control

Extraction is typically the second process, although this is not always the case. The primary goal of extraction is to develop the VI that is required and to make the saturates content that is required. This is accomplished through solvent extraction of the aromatic fraction of the distillate using NMP, furfural, or phenol. The VI is raised by removing the aromatic (low VI) molecules. Secondary effects of extraction include reduction in the refractive index, density, and CCR, and improvement in color and oxidative stability.

33.4.3 Solvent Dewaxing – Pour Point Control

Solvent dewaxing is usually the last process unit, because the dewaxer is the most expensive to build, has the highest operating costs, and is the most complex

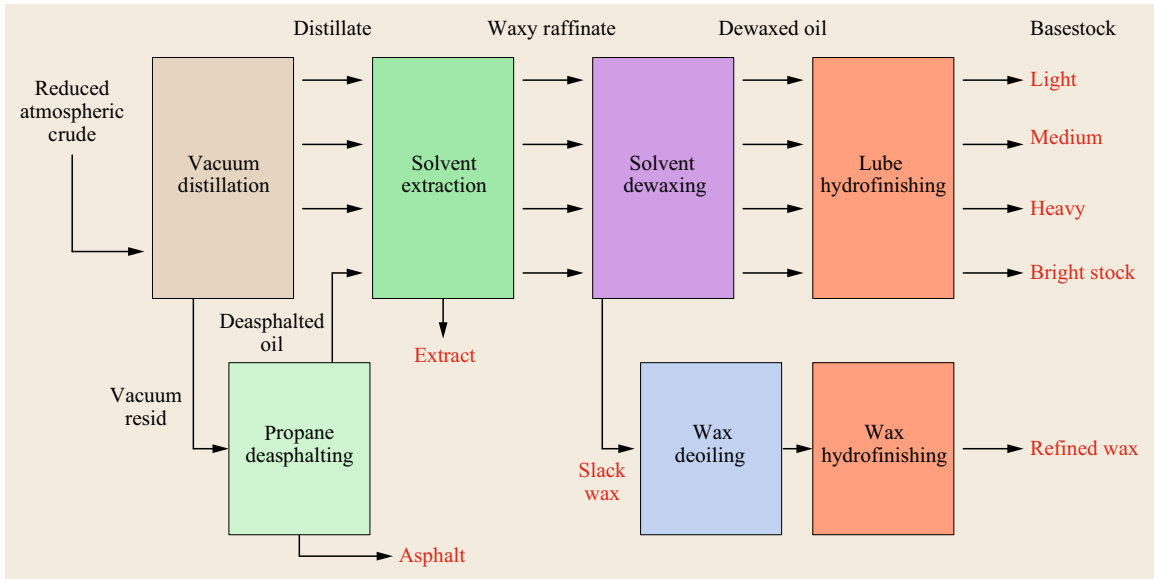

Fig. 33.2 Typical lube process flowchart

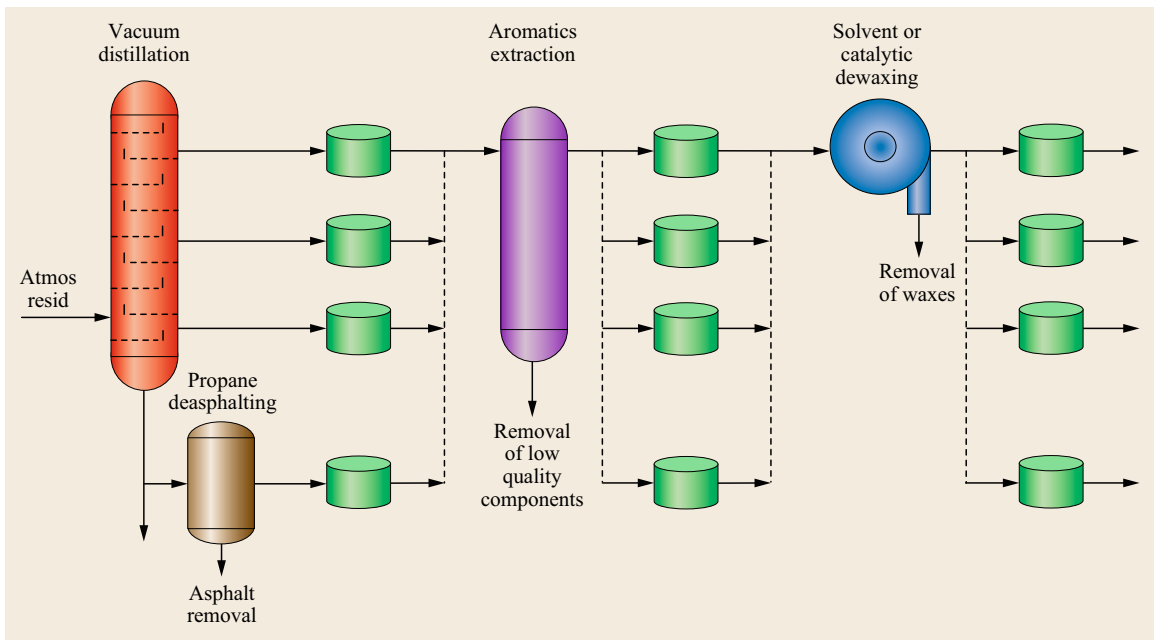

Fig. 33.3 Lube-manufacturing scheme

to operate. The primary goal of solvent dewaxing is to make the pour and cloud point requirements. This is accomplished by paraffin separation by the solubility of nonparaffins in cold solvent, fractional crystallization, and filtering the sold paraffins from the slurry. This may be done in *ketone* units which use MEK, MEK/MIBK, and MEK/toluene solvents, or in propane units which use liquefied propane as the solvent. Secondary effects

include viscosity increase, density increase, sulfur and CCR increase.

33.4.4 Hydrofinishing – Stabilization

Hydrofinishing follows extraction or dewaxing. The primary goal is to improve appearance (color and color-hold) and to remove impurities such as the solvent,

Table 33.2 Summary of lube process impact on product quality

	Distillation	Deasphalting	Extraction	Dewaxing	Hydrofinishing
Feed stock	Atmospheric resid	Vacuum resid	Distillate or deasphalted oil	Raffinate	Raffinate or dewaxed oil
Lube product	Distillate	Deasphalted oil	Raffinate	Dewaxed oil	H/F oil
By-products	Vacuum resid	Asphalt	Extract	Wax	Naphtha
Main lube quality improved	–	Con carbon ↓	VI ↑	Pour point ↓	Color improved

Nitrogen	–	↓	↓	↑	↓
Saturates	–	↑	↑	↓	↑ (slightly)
Hash point	↓	–	–	–	–
Refractive index	–	↓	↓	↑	↓

^a – Indicates main lube product quality improvement

nitrogen, acids, and sulfur to meet the required specification. This is accomplished by hydrogen saturation and chain breakage that uses hydrogen at mild pressures and temperatures in the presence of a catalyst. Secondary effects include slight improvement in VI, slight improvement in saturates, reduction in viscosity, lower acidity, reduction in CCR.

33.4.5 Solvent Desphalting

When used it always precedes extraction. The primary goal is to remove asphaltenes, which could be a possible by-product and to make the viscosity specification that is required. This is accomplished by asphaltenes separation by the solubility of nonasphaltenes in a solvent

and the precipitation of asphaltenes using, for example, propane as a solvent. Secondary effects include a reduction in CCR and metals, an increase in saturates and VI, and color improvement.

33.4.6 Refined Wax Production

Wax deoiling and hydrofinishing follow the dewaxing unit. The primary goal is to reduce the oil content of the wax and to meet melting point and needle penetration requirements. This is accomplished by soft wax solubility and physical separation in the deoiling equipment. Hydrofinishing's goal is hard wax saturation and chain breakage. Secondary effects include the removal of impurities, color improvement.

33.5 Key Points in Typical Lube Plants

- The majority of operations are *blocked operation* instead of *in-step*. Blocked operation requires intermediate tankage between units and allows the optimum operation of each unit on each viscosity grade.
- The dewaxing unit is usually the last unit in the manufacturing process. The dewaxer is the most expensive to build, has the highest operating costs, and is the most complex to operate.
- Bright stock is the most expensive conventional lube to manufacture and requires the addition of a deasphalting unit.
- Integration of extraction and hydrofinishing units saves energy, and the elimination of a hydrofiner furnace saves capital. However, this arrangement is less flexible than a stand-alone hydrotreater.

There are exceptions to the general flow. Some plants that process extremely high wax content crudes position dewaxing after vacuum distillation. Some plants position high-pressure hydrotreating upstream of dewaxing.

Hydroprocessed lubes will be covered in other chapters and include:

- Lubes hydrocracking
- Wax isomerization
- White oils hydrogenation
- Catalytic dewaxing.

Other processes include:

- Clay contacting or acid treating, both are older stabilization processes.
- Duo – Sol a process that combines propane deasphalting and solvent extraction.

33.6 Base Stock End Uses

Conventional lube base stocks are formulated into a multitude of finished products:

- Motor oils
- Transmission fluids
- Gear oils
- Turbine oils
- Hydraulic oils
- Metal working (cutting) oils

- Greases
- Paper machine oils.

Specialty products may include:

- White oils: foods, pharmaceuticals, and cosmetics
- Agricultural oils: orchard spray base oils
- Electrical oils: electrical transformers (heat transfer).

33.7 Lube Business Outlook

Lubricant base stocks are produced in approximately 170 refineries worldwide which have a total capacity of over 900kBD (kBD = kilo barrels per day). The average capacity utilization is somewhere around 80%, to meet an industry demand of just over 700kBD. However, almost all new capacity is hydroprocessing based, making Group II or Group III base stocks. Hydroprocessing quality and cost advantages continue to apply economic pressure on conventional lube manufacturing and additional rationalizations are expected with a subsequent loss of manufacturing share.

The lubricant market is roughly equally split between transportation lubricants (engine crankcase oils, transmission fluids, greases, etc.) and industrial process oils. Demand is growing at an average rate of 1%/yr, as

robust growth in the developing economies (e.g., China, India) is being partially offset by declining demand in the mature markets (North America, Europe) due to extended drain intervals for the higher quality engine oils. Engine builders tend to drive the transportation lubricant quality, as economic and environmental drivers push engine oils toward better oxidation stability, better low-temperature properties, lower volatility, and lower viscosity. These desired characteristics drive formulators to favor hydroprocessed base stocks which have higher VI. However, many other applications, such as most industrial and process oils, as well as older engine oils, still favor the characteristics of solvent-refined Group I base oils, which are expected to continue to play an important role in meeting the world's lubricant needs for years to come.

33.8 Feedstock Selection

Crude selection is extremely important for the profitable production of lubes. Downstream unit operability is affected by crude selection as are rates and yields. Typically, manufacturers would prefer operating at maximum throughput, thereby spreading costs over a larger volume. Poor crude selection can result in downstream bottlenecks reducing overall throughput.

33.8.1 Lube Crude Selection

Lube oil manufacturers may have a lube crude approval (LCA) process to assess the opportunity to manufacture base stocks from crudes available in the marketplace. The LCA process defines the detailed steps to qualify a new crude for purchase by

the refinery to make base stock and/or wax products.

The first step entails identifying economically attractive crudes. These crudes are characterized, or assayed, to quantify their lube yield and qualities. The assay process includes subjecting a small sample of the crude to an atmospheric distillation, vacuum distillation, extraction, and dewaxing to produce the desired base stock products. This information enables the manufacturer, through the use of modeling techniques, to predict the process response of the crude of interest to make the required base stock products. These modeling techniques may also allow the manufacturer to investigate process variables and operating optimization for distillation, extraction, and dewaxing to assess manufacturing flexibility. Not all crudes are acceptable for base stock manufacturing as yields may be too low or base stock products may not meet requirements.

With an acceptable assessment of the new crude, the refiner may elect to validate the crude for base stock manufacture. This may entail running a plant test to make base stock products from the new crude. The products made from the plant test are typically blended into formulated oils and subjected to testing to demonstrate acceptable product performance.

Results of the plant test are reviewed with a focus on lube plant manufacturing performance and base stock product quality to determine if the new crude can be approved for base stock manufacture:

1. Lube plant manufacturing performance – actual rate, yield, and operability. The actual operating conditions are compared to the predicted processing conditions to assess if the new crude processed as expected.
2. Base stock product quality – Plant testing protocol should be defined to ensure base stock products meeting acceptable quality specifications are made. Care should be taken to avoid making base stocks that may not be representative of how the crude will typically be processed to make base stocks. The range of acceptable base stock qualities should be defined by the test protocol. Plant test product disposition may need to be defined as part of the plant test.
3. Options may include blending the plant test products to dilute the new crude component or quarantining the product tank until product testing has been completed. Product testing failure will prevent the crude from being approved.
4. Results from the manufacturing test will determine if the crude will be accepted. The certification test must have been acceptable and the crude processed as expected. There must not be any evidence that base stock quality is unacceptable. If the above is completed successfully, the crude may be approved and added to the manufacturer's list of approved crudes.

The approval protocol may require periodic re-evaluation of the crude in recognition that the crude may change.

33.9 Lube-Crude Assays

A lube-crude assay is a laboratory process to measure the lube processing response from crude to base oil. It is an important step in a manufacturer's lube crude selection. A crude assay will include process yields for desired base oils at their quality specifications. The manufacturer can use the assay data to predict the process response for their refinery and to assess the desirability of purchasing particular crude. The assay results may be used to calculate the impact on profitability.

Key steps to complete a typical lube assay include:

1. Secure a representative sample of the crude. This may best be achieved by collecting a sample at a load port.
2. Fractionate the crude into discreet components first to separate the light, nonlubes boiling material. The bottoms are then sent to a high vacuum distillation.

The distillation produces several distillate blends for extraction. The distillates produced are sufficient to cover the base stock viscosity range.

3. The distillates are then extracted using a lab pilot unit and the preferred extraction solvent (e.g., furfural, NMP, or phenol). Waxy raffinates are produced from the extraction.
4. The waxy raffinates are then dewaxed using solvents of interest (MEK, MEK/MIBK, MEK/toluene, etc.) to produce a dewaxed oil and a slack wax.
5. The dewaxed oils will be characterized to quantify their properties and yields. This will enable an economic assessment to be made with respect to the crude's lube potential.

There are several lube assay objectives in distillation. One is to relate key lube properties such as

viscosity, sulfur, density, refractive index, etc. to boiling point. Another is to determine the yield of material boiling in the lube range and a third is to determine the yield of material boiling in the asphalt range.

The objectives of the lube assay extraction are to generate data that will determine the ability of the crude to produce base oil capable of meeting the base oil specifications. Obviously, this is of great importance in the selection of lube crudes for the plant. Key lube oil qualities related to process response are determined over the full lube oil viscosity range. Yields are used in manufacturing economic calculations. All crudes were not created equal, although there may be similarities

in a given region. For example, Middle Eastern crudes may contain high sulfur, high aromatics, and high isoparaffins, while North Sea crude may be low in sulfur, contain high saturates, and have a medium wax content. There are always outliers in every region. Crude production from a given *field* may change over time. If so, this may require that the assay is repeated to update the crude's relevant information to remain current.

In summary, the lube assay will characterize the potential of a crude to produce a specific base stock (viscosity, VI, saturates, wax, sulfur, basic nitrogen, etc.) and to determine the expected yields from distillation, extraction, and dewaxing.

33.10 Vacuum Distillation

Vacuum distillation is used to fractionate the heavier molecules in the crude. In the majority of plants, it is the beginning point for lube manufacturing. Vacuum distillation is applied to avoid the high-temperature fractionation, which would lead to undesirable coking and loss of lube oil yield.

Vacuum distillation equipment is often referred to as the VDU or VPS.

The objective of the VPS is to achieve test product quality for viscosity, volatility, and flash point. Maximizing the yield of the most valuable products requires using the right-cutting schemes. Steady control will minimize distillate variability. Good fractionation makes for sharp separation which is beneficial to good performance in downstream equipment. VPS per barrel costs can be minimized by operating the VPS at high capacity with long run lengths and making the best possible use of utilities and chemicals per barrel.

Fractionation is a separation by difference in boiling points of light and heavy components in the distillation tower achieved by the intimate contact between hot rising vapor with the cooler falling liquid. The hot vapor strips the lighter components from the liquid and the cold liquid condenses heavier components from the vapor. Stripping requires heat in order to vaporize the lighter components and the condensation of heavy components releases heat. Good contact between the phases is essential to achieve maximum fractionation efficiency. In the presence of vapor, the liquid may be carried upward in the form of a mist, foam, or spray, and may contaminate the desired distillates with heavy components. The contamination is known as entrainment and should be avoided.

The concept of a *theoretical stage* is a useful one and refers to the length of the VPS section required for the vapor and the liquid to reach equilibrium. The sharpness of the separation between adjacent streams

may be measured in theoretical stages or the minimum number of theoretical stages (N_s), which represents the number of theoretical stages at the infinite reflux to effect the separations.

Sidestreams from the distillation tower are typically named from the top (lighter products) down to the bottom (heavier streams). Typical atmospheric and vacuum sidestream nomenclature for a typical atmospheric and vacuum tower is shown in Table 33.3 (typical boiling point range of fractionated stream).

Cut points are used to describe the pipestill product. Volume cut points are the cumulative yield on the crude and is expressed as a liquid volume percent of the product. Temperature cut points are the boiling points that correspond to the volume cut point. A key objective of the VPS is to set the viscosity of the final product. This basic product property is set in the distillation by setting the cut points of the product streams. Nominal lube product boiling ranges are shown in Table 33.4. Volatility, another key product specification, is the amount of material removed at a certain temperature and is controlled in the distillation by cut point targets and front-end fractionation. It affects engine oil thickening and evaporative losses. The flash point is the

Table 33.3 Typical distillation tower sidestream names

Name	Description
AOH	Atmospheric overhead (−30–200 °C)
A1SS	Atmospheric 1, or first, sidestream (150–210 °C)
A2SS	Atmospheric 2, or second, sidestream (175–300 °C)
A3SS	Atmospheric 3, or third, sidestream (190–400 °C)
LVGO	Light vacuum gas oil, vacuum tower overhead (200–400 °C)
V1SS	Vacuum 1, or first, sidestream (350–425 °C)
V2SS	Vacuum 2, or second, sidestream (390–600 °C)
V3SS	Vacuum 3, or third, sidestream (450–620 °C)
VRES	Vacuum resid stream (500– > 900 °C)

Table 33.4 Nominal lube product boiling range

	Two product sidestreams (°C)	Three product sidestreams (°C)	Two product sidestreams (°F)	Three product sidestreams (°F)
Vacuum gas oil	345–385	345–370	650–725	650–700
Light neutral	385–455	370–425	725–850	700–800
Medium neutral	–	425–490	–	800–915
Heavy neutral	455–540	490–550	850–1005	915–1025
Overflash	540–580	550–580	1005–1075	1025–1075
Vacuum resid	580+	580+	1075+	1075+

ignition temperature above the liquid surface and affects engine oil thickening and is a safety concern for the storage of a liquid product. Cut point targets and fractionation in the main tower and stripper are used to control the product flash point.

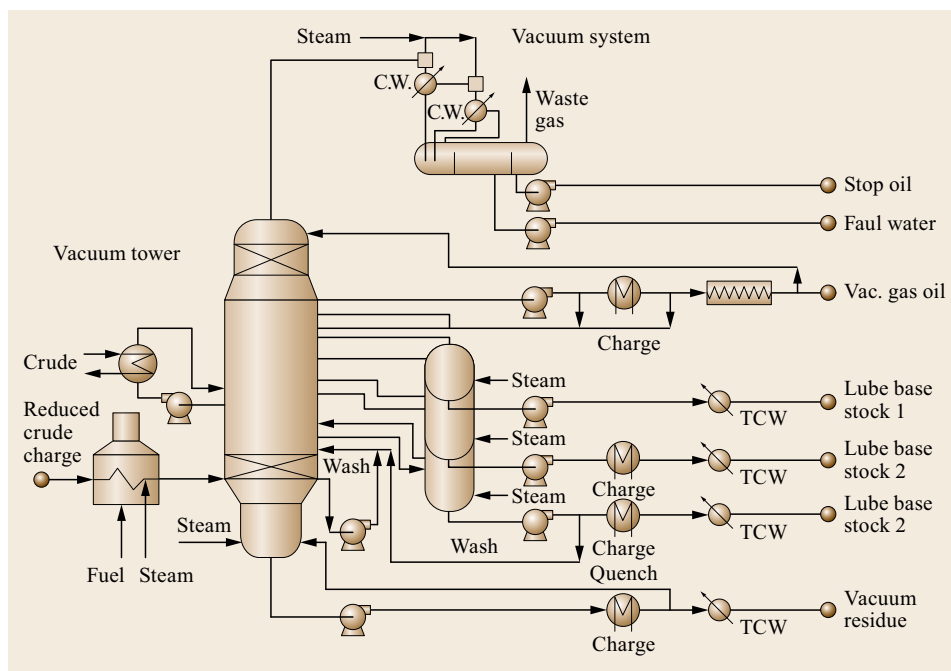

Distillate yields are affected by crude type, product viscosity and volatility specifications, the distillation tower-cutting scheme, fractionation efficiency, and the theoretical stages between the sidestreams. Poor fractionation efficiency can be caused by operating at feed rates above equipment design. If the feed is significantly lighter than the tower is designed to handle, fractionation efficiency may suffer. Mechanical damage such as dislodged or damaged internals, leaks or plugs in spray headers used to distribute liquids in the tower, leaking trays, etc. will degrade fractionation efficiency. Insufficient wash oil or reflux in the tower contributes to poor separation. The poor distribution of liquid or vapor reduces contact and leads to poor fractionation efficiency. When pumparound duties get out of balance fractiona-

tion efficiency is reduced. This can be caused by reflux rates being above or below design specifications and by flooding or entrainment occurring in overloaded sections of the tower.

Poor tower fractionation efficiency may adversely affect downstream lube operations. Insufficient separation of light grade front ends may result in light oil carryover in extraction, increasing solvent ratio requirements, possibly reducing throughput and will increase energy usage. Dewaxing throughput and yields are adversely affected across all grades by the presence of *tail ends*.

Crude oil was first distilled in batch distillation like a lab technique beginning in the 1850s. Advancements were made by increasing the size of the batch vessel. A continuous process was developed by using a series of batch stills – called a battery. The first continuous pipestill appeared in the 1920s and the *modern* pipestill came on the scene in the 1930s.

A typical lube VDU is shown in Fig. 33.4.

**Fig. 33.4** Typical lube vacuum tower design

33.10.1 Feed Preheat Exchangers

Feed preheat exchangers are used to recover heat from sidestreams and pumparounds and to make the overall distillation more energy efficient. Preheating minimizes the loss of heat to the atmosphere or cooling water. Heat integration reduces fuel consumption in the furnace and steam may be generated for stripping in the vacuum unit. Atmospheric and vacuum units may be heat integrated.

33.10.2 Pipestill Furnace

The furnace partially vaporizes the feed to the tower. A typical furnace has multiple parallel passes and the outlets are combined as feed to the distillation tower.

Steam may be injected into the vacuum furnace coil to increase the vaporization of feed at a lower temperature and to reduce the residence time. The vacuum cut points are set by the extent of the vaporization in the flash zone where temperatures may range from 390 to 420 °C. Furnace firing is controlled to achieve the desired vacuum cut point.

33.10.3 Tower Flash Zone

The flash zone is a large area in the tower that allows for the disengagement of liquid and vapor. The height of the zone affects the separation. The flash zone is designed to facilitate disengagement. Internals in this section consist of annular rings or vapor horns and collector rings for the bottoms stripping inlet.

33.10.4 Tower Wash Section

The wash section cleans entrained liquids from the flash zone vapor phase. Vapor in excess of the amount needed to meet distillate requirements is referred to as overflash. The wash section condenses the overflash. It also provides some fractionation between the heavy lube sidestream and the vacuum resid stream.

The wash zone may include a Glitsch grid or random packing. An open structure gives a low pressure drop while providing a high surface area to capture and retain resid. The resid is washed away by the wash oil that is applied through a spray header. The overflash, or spent wash, may be 40–50% resid and is removed and either sent to tankage as another sidestream or returned to the bottoms section for stripping. Maintaining wash oil flow is extremely important for efficient long-term operation. Loss of wash oil will result in rapid fouling.

33.10.5 Wash Oil

The wash oil that is used for de-entrainment is also important for improving the separation between the bottom sidestream and the resid stream. Separation is enhanced by the condensation of overflash by vaporizing the bottom sidestream. The amount of overflash that is required is affected by packing type, depth, and source of the wash oil. Overflash flow rates should be carefully monitored to make sure that there is no degradation in the bottom sidestream fractionation, there is no increase in pitch entrainment to the heavy solvent neutral stream, and there are no major increases in coking in the wash bed zone.

33.10.6 Purpose of Pumparounds

Pumparounds are used to remove heat from the tower and to adjust the vapor–liquid flow in the tower. They condense vapors rising in the tower and create an internal reflux for the fractionation stages below the pumparound. They also reduce vapor loads in sections of the tower above the pumparound. A pumparound takes liquid from the tower, cools it, and returns it higher up in the tower. The liquid condenses vapors in the pumparound section creating liquid reflux for fractionation lower in the tower. VPSs do not use overhead reflux seen in other distillation towers; a top pumparound is used instead.

33.10.7 Tower Fractionation

As mentioned earlier, fractionation is used to generate the various product sidestreams off the tower by condensing rising hot vapor with falling colder liquid. At each stage in the fractionation section, the highest boiling components are condensed, releasing heat that boils the highest liquid components putting them into the vapor phase. Contacting between the phases is needed for the heat and mass transfer. Contacting equipment may include bubble cap trays, sieve trays, Glitsch grid, structured packing, and many others. The number of theoretical stages between adjacent sidestreams typically varies from 1 to 3. The current trend is toward using packing.

33.10.8 Fractionation Packing

Packing used for fractionation can also reduce the pressure drop in a tower compared to trays. Tray designs are more limited in Delta P reduction. The packing surface allows intimate contact between vapor and liquid without having to have the vapor pass through the liquid. The liquid phase coats the packing surface as

a film so that the liquid phase movement is restricted only by the resistance of the packing surface. Packing has been used in high liquid loading service such as pumparounds and also in main fractionation sections. Packing is sensitive to liquid maldistribution, so spray rates, pan level control, and pumparound rate control are critical. A high-quality liquid distributor is preferred. Examples can be seen in Figs. 33.5 and 33.6.

If the liquid flow to the packing is low and a spray distributor is used, the sprays can collapse so that the liquid contact with the vapor degrades causing low viscosity and poor volatility of the stream below. If the pumparound rate is too high, liquid may be atomized at the spray distributor and the small liquid droplets may

be entrained upward. If the liquid stream is from the pumparound, the product above the pumparound will be contaminated with heavy components. If there is leakage or overflow from the sidestream draw off pan, the falling liquid does not contact the vapor, and it will reduce the viscosity of the stream below and also result in poor volatility.

33.10.9 Bottoms Stripping Section

The objective of the bottoms stripper is to strip distillate from the flash zone liquid, revaporize residual distillate that may be in the spent wash, and correction of bottoms flash. The bottom stripper typically has a design of

Fig. 33.5 Various types of random fractionation packing

Fig. 33.6 Various types of structured fractionation packing. (Photos by Ted Sideropoulos, courtesy of ExxonMobil Research and Engineering)

4–6 bubble cap trays or sieve trays. Some of the newer designs use packing. Steam is used to reduce the hydrocarbon partial pressure to vaporize lighter molecules. A quench recycle is used to cool the stripped bottoms below 360 °C (680 °F) to reduce coking and cracking of the hydrocarbons.

33.10.10 Sidestream Strippers

Lube distillates are sent at their bubble points to sidestream strippers. Steam is injected, reducing the partial pressure of hydrocarbons which effectively removes lighter hydrocarbons, improving volatility beyond that obtainable without side stripping. About 10–30% of the stream may be removed in the stripper. If the heavier streams are not stripped, this will reduce the yield of lighter lubes. Stripping is an important part of the overall operation to achieve the best separation and produce the desired products. A stripper typically consists of 4–6 sieve trays but packing may also be used.

33.10.11 Overhead Pressure

Pressure has a very large effect. Low pressure (20–133 mbar overhead) is employed to reduce boiling points, allowing operation at temperatures low enough to minimize thermal degradation and cracking. The overhead vapors include steam, light hydrocarbons, and inerts. In the lower pressure (20–66 mbar) design, there is no precondenser before the first ejector. In higher pressure designs (53–133 mbar), a precondenser is employed and overhead pressure is dictated by condensing temperature (vapor pressure of water at the condensing temperature). Steam ejectors or vacuum pumps compress atmospheric pressure and pump away the noncondensable hydrocarbons and inerts. Precondensers will reduce the overall load on the compression system. Ejectors use steam for compression in two or three stages. Each ejector typically has an intercondenser. Secondary and tertiary ejectors may sometimes be replaced by a liquid ring vacuum pump.

33.10.12 Tower Overhead Pressure with Precondensers

In a precondenser design, the lower the cooling water temperature, the higher the achievable vacuum. The precondensers must operate below the water dew point to condense steam in the overheads. To achieve the lowest tower pressure, the tower should be operated at a low top temperature to minimize condensable hydrocarbons. Inerts should be minimized by reducing air

egress and by keeping the bottom temperature at or below 360 °C to avoid excess thermal cracking and the formation of light gases. Cooling water flow should be sufficient to minimize the cooling water outlet temperature which sets the equilibrium conditions in the precondenser and therefore the achievable tower vacuum.

33.10.13 Tower Overhead Without Precondensers

Towers without precondensers may operate at pressures lower than the vapor pressure of water at the condensing temperature. Lower pressure has both advantages and costs:

- Advantages:
 1. Higher distillate/resid cut point
 2. Less furnace coil and stripping steam required
 3. Pressure is controlled at a constant value (versus varying with cooling media temperature).
- Costs:
 1. Higher ejector steam rate
 2. Larger diameter tower.

33.10.14 Tower Pressure – Ejectors

The steam ejectors pump away the remaining vapor pressure of water, hydrocarbons, and inerts. Ejector systems typically have two stages or three by 50% ejectors. Because of the criticality for tower operation, most systems are overdesigned, and it may be possible for the tower to operate with one 50% ejector in each stage. Intercondensers (first stage) and after condensers (second stage) condense the steam from the ejectors, tower steam, and condensable hydrocarbons. Motive steam flow must be maintained for the best operation.

33.10.15 Factors Affecting Lube Distillate Production

- Crude type
- Equipment operation:
 1. Cutting scheme selected. Sidestream product viscosity and yield are shown for a two sidestream versus three sidestream cutting scheme in Table 33.5.
 2. Fractionation efficiency
 3. Pumparound heat removal capability
 4. Sidestream product stripper operation
 5. Equipment constraints
 6. Operational stability.
- Product inspection measurement precision.

Table 33.5 Two sidestream versus three sidestream product comparison. SUS: Saybolt universal seconds

Two sidestream products		Three sidestream products	
Viscosity (SUS at 100 °F/30 °C)	Yield on crude (vol.%)	Viscosity (SUS at 100 °F/30 °C)	Yield on crude (vol.%)
150	9.8	100	9.2
450	8.5	300	7.7
		700	5.3
Total	<u>18.3</u>	Total	<u>22.2</u>
Resid (1000 + °F) (538 + °C)	18.3	Resid (1075 + °F) (579 + °C)	16.8

33.11 Pipestill Troubleshooting

Steps of pipestill troubleshooting are described below.

33.11.1 Material Balance and Viscosity Measurements

1. Tabulate rates of crude feed, reduced crude, overhead condensate rate, and all VPS sidestream and bottoms rates for material balance calculations.
2. Take a sample of VGO and each sidestream and measure viscosities (100 °C) of all the VPS products.
3. Calculate yields, cumulative yield ranges, and mid-yield points for all the VPS products and combine with measured viscosities.
4. Compare viscosity to yield for each product. Compare to assay or lab-generated distillation cuts and viscosities.

33.11.2 Tower Pressure Survey

- Use the same vacuum gauge to measure tower absolute pressures. (Pressures are low and different gauges can have a calibration offset. Best results are obtained by moving the same gauge to the desired locations.):
 1. Make pressure measurement at the flash zone, tower top, and points in between.
 2. Determine Delta P across the strippers, both with steam on and with steam off.
 3. Measure ejector interstage pressures and condenser Delta P noting temperature differences between condenser liquid and vapor outlet as well as Delta T across the condensers.
 4. Determine pressure drop across spray nozzles.
 5. Transfer line pressure drop.
 6. Ejector motive steam pressure.
 7. Steam source pressure.
 - Inferences based on findings:
 1. If overall tower pressure drop is too low from the flash zone to the top, then there may be damage to the tower internals or hydraulic problems.
- If the pressure drop is too high, then flooding, plugging, or internal damage may be indicated.
2. Pumps typically have higher pressure drop than the fractionating sections.
 3. No or low Delta P in a tower section may indicate missing trays or the absence of liquid. High Delta P in a tower section may indicate that the drawoff is partially restricted or blocked, that may be due to high liquid rates in that section of the tower, flooding, or too much stripping steam.
 4. Check spray nozzle Delta P actual versus expected. If higher than expected, the spray nozzle may be plugged. If lower than expected, the header may be leaking or missing a nozzle(s).
 5. If stripper Delta P is too high, then this may be an indication that too much steam is being used. If the Delta P is too low, there may be too little steam being used of the trays or packing are damaged.
 6. If the precondenser Delta P is too high, this may be an indication of poor design, flooding, or fouling. If too low, equipment damage may be indicated.
 7. Review ejector interstage pressures versus design. Low interstage pressure may be an indication of the second stage overload.
 8. Tower pressure cycling may be due to steam ejector underload and high ejector discharge pressure.
 9. Condenser liquid and vapor temperatures should be about 3 °C apart. If the temperature difference is greater than this, it may be an indication of bypassing.
 10. Increase in cooling water temperature (in versus out) should be about 5–8 °C. If too low, this may indicate fouling or bypassing. If too high, the cooling water rate may be too low.
- Comparison to design – higher or lower rates:
 1. Cooling water
 2. Vacuum system
 3. Steam injection.

33.12 Solvent Extraction

The properties of the lube oil that are set by the extraction process are the VI, oxidation stability, and thermal stability. These properties are related to aromatics, sulfur, and nitrogen levels present in the base stock (Fig. 33.7).

Base stock VI has historically been used as a performance indicator for the base stock. The VI specification sets the extraction severity required to achieve the target. VI is also an indicator of relative stability from the same feed. VI is crude sensitive under constant extraction conditions.

Molecular structure affects lube quality. The impact of molecular type on lube oil VI and stability is shown in Table 33.6. Solvent extraction and dewaxing processes preferentially separate the molecules as shown in Fig. 33.8. Extraction separates *n*-paraffins, *i*-paraffins, naphthenes, and some aromatics from the distillate into the raffinate phase. Dewaxing rejects the *n*-paraffins and some *i*-paraffins from the raffinate to produce a dewaxed oil or base stock. The dewaxed oil will contain the *slice* of molecular types as shown in Fig. 33.8.

The extraction process is a physical separation that is used in all conventional lube plants. The solvent is added to the distillate to produce a raffinate, the desired product, and an extract that contains a higher percentage of aromatics and impurities. Typical solvents used are NMP, furfural, and phenol. Properties of the solvents are shown in Table 33.7. NMP solvent properties

relative to furfural and phenol are shown in Tables 33.8 and 33.9, respectively. The development of the NMP based EXOL N extraction process is described in [33.3–6].

33.12.1 The Characteristics of a Good Extraction Solvent

A good extraction solvent will have a high selectivity for the undesirable lube. The molecular weight of the oil affects its solubility. Solubility decreases with increasing molecular weight (Fig. 33.13a). Solubility increases with increasing solvent dosage (Fig. 33.13b). The solvent must also have good solvent power so that a low solvent to feed ratio may be used in the extraction plant. The solvent promotes rapid mass transfer. The solvent partitions between the raffinate and extract phases, and must be recovered; an easy recovery via distillation is desired. High density is also a characteristic of a good

Table 33.6 Impact of molecular type on lube oil VI and stability

	VI	Stability
Paraffins	Excellent	Good
Mono-naphthenes	Good	Fair
Polynaphthenes	Fair	Fair
Mono-aromatics	Good	Fair
Polyaromatics	Poor	Poor

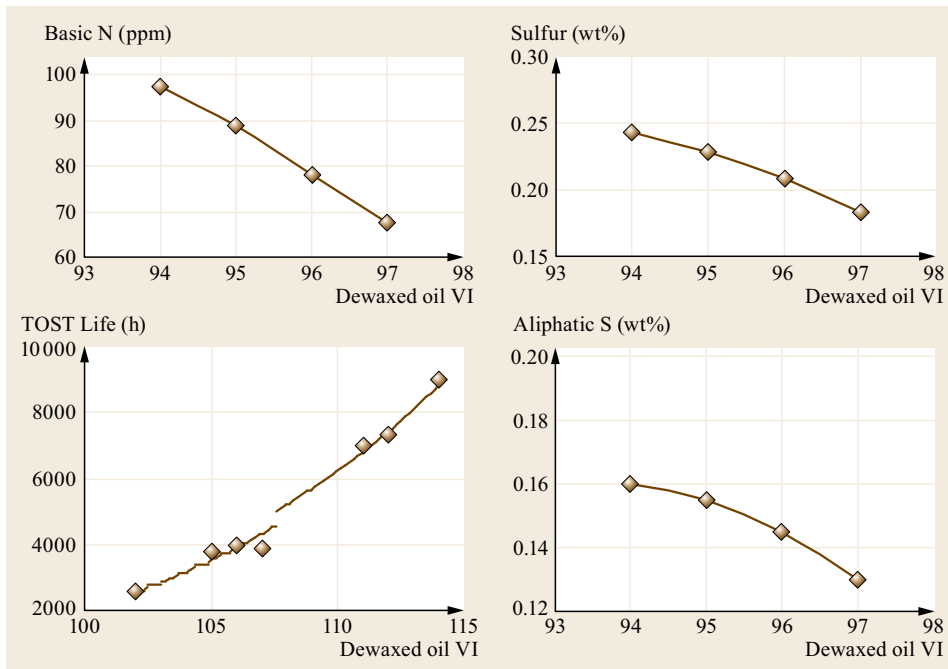

Fig. 33.7 Impact of extraction on VI and lube oil properties

	Molecule	Base stock quality affected	Process involved
Extraction	<i>n</i> -Paraffin	High pour, VI No S & CCR	Dewaxing
	<i>i</i> -Paraffin	High VI & sats, med pour	
	2 ring naphthene	Med VI, low pour, high acids	Extraction, hydrofinishing
	1 ring aromatic	Med to high VI	Extraction
	Multi-ring naphthene	Low VI, low pour, high acids	Extraction, hydrofinishing
	Multi-ring aromatic	Low VI, low pour	Extraction
	Organic sulfur	Good stability, antioxidant	Hydrofinishing
	Organic nitrogen	Poor stability	Hydrofinishing

Table 33.7 Physical properties of typical extraction solvents

	Furfural	<i>N</i> -Methyl-2-pyrrolidone	Phenol
Structure			
Molecular weight	96	99.1	94.1
Specific heat (at 130 °F/54 °C)	0.42	0.47	0.56
Boiling point (at 1 atm)	323 °F/162 °C	399 °F/204 °C	359 °F/182 °C
(Flash point)	(137 °F/58 °C)	(187 °F/86 °C)	(175 °F/80 °C)
Melting point	-37 °F/-38 °C	-11.6 °F/-82 °C	105.6 °F/40 °C
Latent heat @ B.P., BTU/LB	194	187	206
Toxicity	Moderate	Low	High
Specific gravity (at 20 °C)	1.16	1.03	1.07

Table 33.8 NMP solvent properties relative to furfural

NMP solvent property	
Thermally stable	Heat integration with no measurable solvent decomposition
More selective	Higher yields at lower solvent treats
Lower latent heat	Requires less energy for solvent recovery
Chemically stable	Eliminates the need for feed deaerator for removal of oxygen
Higher boiling point	More efficient heat integration

extraction solvent as this allows the rapid separation of the oil and solvent phases. High demulsibility is needed for a rapid separation of the oil and solvent. The solvent must be chemically and thermally stable in the lube extraction

and recovery equipment. The ideal solvent would work for a wide range feedstocks that the refiner might process. Solvent must be available at a reasonable cost and noncorrosive to conventional materials of construction, and it must be environmentally safe.

33.12.2 Extraction Process

A simplified extraction flow diagram is shown in Fig. 33.9. Distillate is brought in contact with the solvent and aromatics, and polars are preferentially dissolved in the solvent phase. Saturates do not dissolve and remain in the hydrocarbon or dispersed phase. The hydrocarbon phase is lower in density than the solvent phase and rises as bubbles through the continuous

Table 33.9 NMP solvent properties relative to phenol

NMP solvent property	
Lower toxicity	Much safer
More selective	Higher yields and/or lower solvent treats
Lower latent heat	Less energy required for solvent recovery
Higher boiling point	More efficient heat integration
Lower melting point	Less steam tracing required, less chance of solidifying in piping
No hydrogen bonding effect with the oil	More efficient stripping, easier to achieve low-solvent concentration in product
No azeotrope	Simplifies water recovery

phase. After contact, the raffinate and extract solution are sent to their respective solvent recovery sections. Integration of a hydrofiner on the raffinate product is done in some lube plants for heat integration because this eliminates the need for an additional hydrofiner furnace.

There are several types of continuous treater tower designs used in conventional lube plants (Fig. 33.10). These include trayed towers, packed towers, and rotating disk contactors. The treater tower internals are designed to promote contact and separation of the oil and the solvent phases.

An example of a tray design is shown in Fig. 33.11.

An example of a typical rotating disk contactor is shown in Fig. 33.12.

There are several factors that affect extraction efficiency and in general the efficiency depends on the mixing/settling and coalescence characteristics of the system. Important factors include:

1. Hardware and staging
2. Throughput
3. Viscosity/gravity of oil/solvent
4. Solvent dosage and composition

5. Temperature and temperature gradient
6. Solvent quality
7. Dispersion energy.

33.12.3 Extraction Process Variables

Independent variables are controlled by the operator and include:

- Treat ratio – the volume ratio of the solvent to feed
- Solvent composition (water for NMP, phenol)
- Bottom and top treater temperature.

Dependent variables rely on the independent variables:

- Raffinate quality:
 - VI
 - Saturates content as an indicator of the degree of aromatic removal.
 - Sulfur.
- Raffinate yield – primarily dependent on the treat ratio at constant VI.

33.12.4 Solvent Contaminants

Water from steam stripping in the solvent recovery section must be removed. In the furfural solvent system, water is removed for process effectiveness and product quality. Water contamination in furfural reduces dewaxed oil (DWO) VI and leads to furfural degradation. In NMP and phenol systems, excess water is removed for process control.

Oil in the solvent results from incomplete solvent-oil separation and may be due to entrainment from flash vessels, volatilization, or stripper flooding. Characterization of the solvent contamination by GCD can be used to determine if contamination is occurring by light or heavy oil fractions. A light oil contamination suggests that there is an accumulation of distillate of the

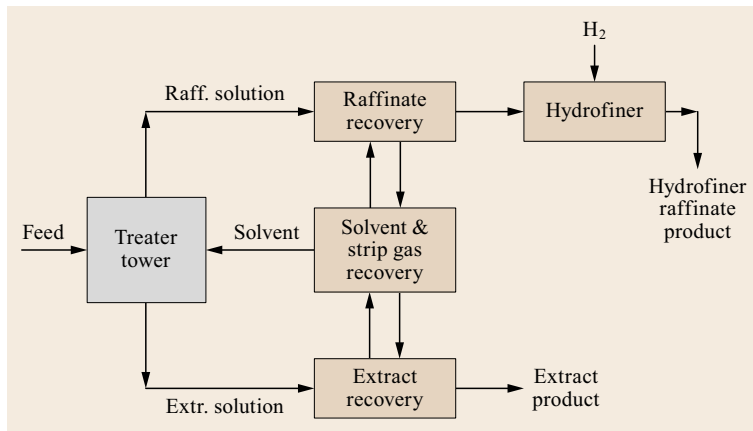

Fig. 33.9 Simplified extraction flow diagram

Fig. 33.10 Types of continuous extractors

Fig. 33.11 ExxonMobil patented dual pass cascade weir tray [33.7]

front end. The presence of heavy oil suggests that the entrainment oil in the solvent can reduce the raffinate yield and increase the treat rate required.

33.12.5 Solvent Recovery

The objectives of solvent recovery sections are to:

1. Recover furfural/NMP/phenol from product streams
2. Purify furfural/NMP/phenol for recycle
3. Maximize energy efficiency while recovering solvent.

Simplified recovery sections are shown below.

Fig. 33.12 Typical rotating disk contactor

Typical raffinate recovery flow diagrams are shown in Fig. 33.14.

Typical extract recovery flow diagrams are shown in Fig. 33.15.

33.12.6 Minimizing Solvent Losses

Recovery Sections

Excess solvent (NMP or furfural) in the product is costly. NMP and furfural concentrations can be reduced to < 20 ppm and < 50 ppm respectively, however, it requires additional energy during solvent recovery. The final concentration is an optimized balance of cost of solvent loss versus additional energy costs in recovery. The furnace coil outlet temperature (COT) is set based on the operating pressure. Typical furnace COTs are higher for NMP than furfural due to solvent boil-

ing points and the concern for furfural degradation. If fuel gas failure occurs at the furnace, the plant immediately goes on oil recycle. The solvent concentration in the product can rise to several percents if the COT is too low. Very high furnace temperature leads to an increase in solvent decomposition and premature furnace coking.

Other Contributors to Solvent Losses

1. Some solvent is lost through line flushing during product sampling. To reduce losses, end sample line flushes back to the unit.
2. Address miscellaneous leaks at flanges.
3. Startup and shutdown operation, typically will increase solvent losses in the year the shutdown is taken.
4. Check valves on bypass lines may not hold and may allow bypassing of solvent.
5. Water sent to the biox unit might contain a solvent.
6. Phenol will oxidize and form deposits in the unit. Effective management of solvent loss in lbs/BBL of feed is considered to be:

$$\begin{aligned} \text{NMP} &\leq 0.03 \\ \text{Phenol} &\leq 0.10 \\ \text{Furfural} &\leq 0.20. \end{aligned}$$

Furfural will decompose when exposed to oxygen or excessive temperatures.

Sources of oxygen ingress include:

1. Pump suction
2. Vacuum systems
3. Oil feed poorly deaerated
4. Poor/nonexistent inert gas blanketing.

33.13 Corrosion in NMP Plants

Pure NMP is not corrosive to carbon steel. However, because of NMP's high dielectric constant, other corrosive compounds will readily ionize in NMP and become very aggressive. The NMP condensing circuit may be at risk to accelerated corrosion from accumulated corrosive elements or corrosion/erosion from high velocities.

The refiner can take the following corrective actions. Firstly, avoid corrosive species ingress into the

circuit. Remove H₂S from recycle stripping gas with a ZnO bed. Neutralize acids with neutralizing additives or caustic injection. Consider alloy upgrade in areas of known corrosion or areas of known impingement or very high velocity such as 316 SS impingement baffles in exchangers. Insulate, overhead line to the first condenser to avoid premature condensation, leading to impingement issues.

33.14 Analytical Tests for Extraction

There are numerous analytical tests that are used to assess the extraction operation and to help optimize the

treater tower. A few of the most important tests are listed in Table 33.10.

Table 33.10 Typical analytical tests for extraction

Test	ASTM test no.	Application
Refractive index typically measured between 20–30 °C	D 1218	Correlation with dewaxed oil quality: VI, saturates, etc. Better for yield calculations than relying on process flow meters
Density at 15 °C	D 4052	Better for yield calculations than relying on process flow meters
Water in solvent by Karl Fischer	D 6304-3, E 203-1	Process optimization (NMP, phenol)
Treater carryunder		Measures the amount of distillate bypassing the treater and being downgraded from lubes to fuel
Oil in solvent 1. Percent 2. Characterization		Oil in solvent adversely affects raffinate yield
Dewaxed oil		
Test	ASTM test no.	Application
Viscosity VI	D 445, D 2270	Primary base stock specification
Molecular analysis	D 2007, D 2887 D 2140, D 2501	Troubleshooting Base stock quality

33.15 Dewaxing

Waxy raffinates from extraction are not useful as lubes because they contain too much wax. Referring to our molecular drawing (Fig. 33.8), we can see that the objective of dewaxing is to remove the paraffins from the raffinate to produce a final dewaxed oil base stock that when additized becomes the finished lube base oil.

Dewaxing is a physical process that adds a solvent to a raffinate (or distillate), and once the mixture is cooled, the *n*-paraffins drop out of the solution as solid wax crystals. The slurry is filtered to remove the wax crystals and to produce a dewaxed oil or base stock and a valuable wax by-product. Wax may be further refined to make hard wax by melting away the soft wax. Hard wax may meet U.S. Food and Drug Administration (FDA) standards for use in direct or indirect contact with food.

The majority of dewaxing processes today use methyl ethyl ketone (MEK), methyl isobutyl ketone (MIBK), mixtures of MEK and MIBK, or mixtures of MEK and toluene or propane. There are advantages and disadvantages of each solvent system.

Dewaxing sets the primary properties, as shown in Table 33.11.

A general flow plan for a dewaxing plant is shown in Fig. 33.16.

Table 33.11 Properties set by dewaxing

Dewaxed oil properties	Wax properties
Pour point	Oil content
Cloud point	Melting point
Low-temperature fluidity	Needle penetration

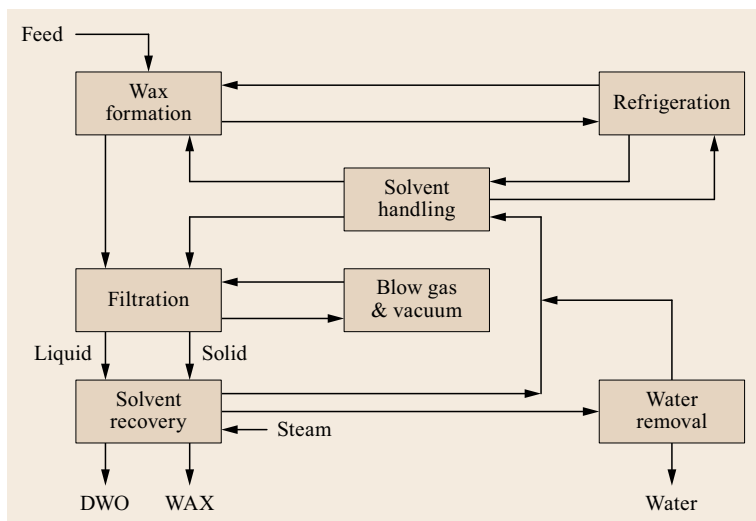

Fig. 33.16 Simplified dewaxing flow diagram

33.16 The Role of Solvent in Dewaxing

As soon as a solvent is added to the raffinate, the oil is diluted and the viscosity of the oil solvent mixture decreases, allowing filtration to take place more easily. The polarity of the oil–solvent mixture increases, decreasing the solubility of the wax and promoting the formation of more compact wax crystals. Also, as soon as a solvent is added, the resulting filtrate becomes more dilute, loading up filtrate pumps, and solvent recovery facilities. Properties to consider in selecting a dewaxing solvent:

1. Solubility
2. Selectivity
3. Solvent boiling point lower than the boiling point of the oil
4. Low heat capacity
5. Heat of vaporization
6. Low viscosity
7. Nontoxic
8. Noncorrosive
9. Low freezing point
10. Inexpensive
11. Readily available.

Ketone units typically use a dual solvent system consisting of MEK and either MIBK or toluene. The MEK acts as an antisolvent to reject wax molecules from the solution. This reduces refrigeration requirements but excessive MEK may cause oil phase separation. The second solvent keeps the oil in the solution, but it also dissolves some wax. MIBK and toluene act as pro-solvents.

The comparison of solvent properties are given in Table 33.12.

MEK/MIBK refrigeration requirements are lower than MEK/toluene because the pour–filter spread is smaller due to the lower wax solubility. The pour–filter spread is the difference between the dewaxed oil pour point and the filtration temperature required to meet the dewaxed oil pour point specification. Wax has a higher solubility in toluene than MIBK, and MEK/toluene systems will require a lower filtration temperature to achieve the same pour point. MEK/MIBK solvent mixture viscosity is lower than MEK/toluene. Filtration rates are higher for MEK/MIBK. Toluene costs less than MIBK.

Table 33.12 Typical dewaxing solvent properties

Solvent	Wax solubility (g/100 ml)	Viscosity at 0 °C (cSt)	BP (°C)	Latent heat of vaporization (cal/g)	Specific heat (cal/(g °C))
MEK	0.25	0.40	80	106	0.55
MIBK	0.90	0.61	116	87	0.46
Toluene	13.0	0.61	111	99	0.41

33.17 Ketone Dewaxing Processes

33.17.1 Incremental Ketone Dewaxing Plant

Incremental ketone dewaxing plants use a combination of scraped surface exchangers (SSEs) that use cold filtrate for cooling the slurry followed by scraped surface chillers (SSCs), which uses a refrigerant (propane, propylene, ammonia) to cool the slurry to the filtration temperature. A solvent may be added at the beginning or along the train in *increments*. A simplified incremental dilution dewaxing flow diagram is shown in Fig. 33.17.

The solvent may be mixed with the raffinate before the scraped service exchanger as primary dilution. The slurry passes through a feed heat exchanger to melt any crystals that may have formed in tankage. The slurry temperature is then reduced in a feed precooler. The slurry flows to the SSEs and through the tube side of the exchanger. Cold filtrate from the filters is used to cool the feed below the cloud point and initiate crystallization. Solvent may be added in increments to reduce the slurry viscosity and enhance heat transfer. Slurry flows to SSCs and through the tubeside. Propane, propylene,

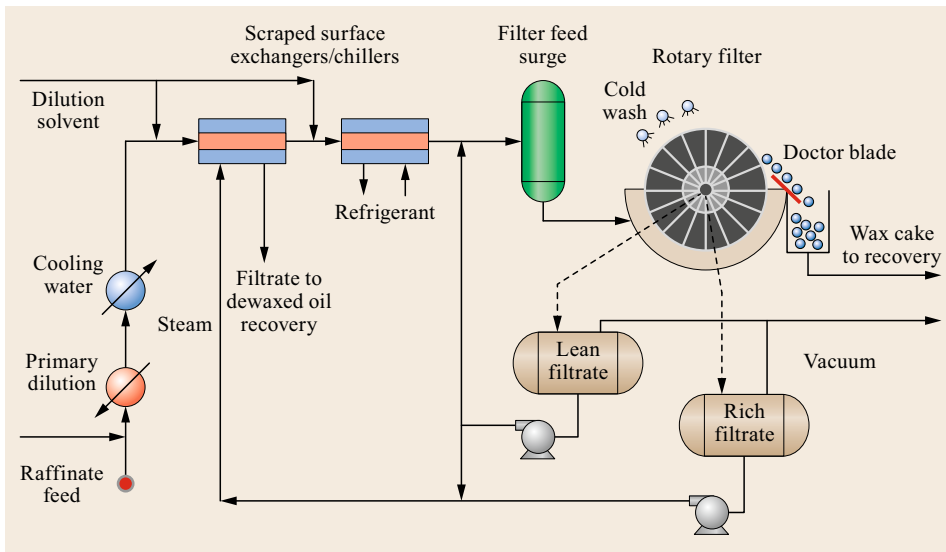

Fig. 33.17 Simplified incremental dilution dewaxing

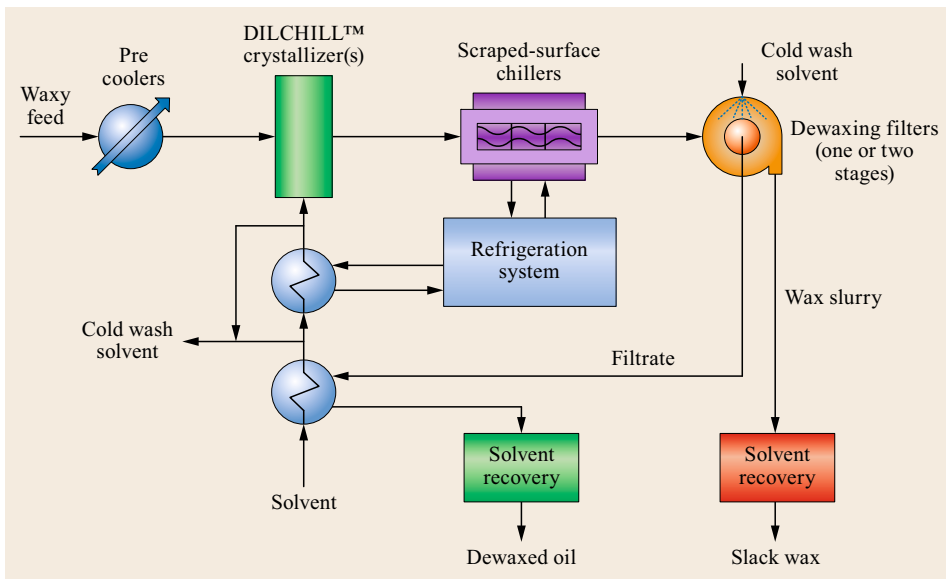

Fig. 33.18 Simplified DILCHILL™ dewaxing [33.8, p. 40], [33.9, Fig. 11.3] (courtesy of ExxonMobil Research and Engineering)

and ammonia are typical refrigerants used on the shell side. The slurry exits the last scraped surface temperature at filtration temperature and enters the filter feed drum. The slurry flows by gravity to the filters where the wax crystals are filtered across a rotary vacuum filter. Wax is removed from the filter and sent to the wax recovery section. Oil and solvent – filtrate – is collected and sent through the shell side of the SSEs on its way to the dewaxed oil recovery section. Filtrate may also be recycled back to the slurry to adjust the final dilution before filtering.

33.17.2 DILCHILL™ Dewaxing

In DILution CHILLing, the scraper surface exchangers (SSEs) are replaced with a multistage crystallizer. A simplified DILCHILL™ dewaxing flow diagram is shown in Fig. 33.18. A cold solvent is added at each stage and the slurry is mixed with an impeller. The crystallizer replaces all the SSEs with a single mixer. A simplified DILCHILL™ dewaxing crystallizer tower is shown in Fig. 33.19. The development and commercial experience of DILCHILL™ is described in [33.10–13].

The key features of DILCHILL are summarized below:

- Less oil is occluded in the wax crystal due to the vigorous *micromixing* in the crystallizer.
- Higher filtration rates and lower oil-in-wax are achieved as a result of compact, spherical crystals. Fig. 33.20a,b are micrographs that compare the wax crystals produced by DILCHILL™ and incremental dilution.
- Lower dilution solvent.

Fig. 33.19 Simplified DILCHILL™ dewaxing crystallizer tower [33.8, p. 38]

- Lower operating costs.
- Easier operation.
- Higher service factor.

33.17.3 Dewaxing Process Variables

Independent variables are controlled by the operator and include:

- Charge rate
- Solvent composition
- Precooler outlet temperature
- Dilution ratio (increments)
- Chilling rate

Fig. 33.20a,b Comparison of wax crystals formed in conventional incremental dewaxing (a) and in DILCHILL™ dewaxing (b). Optimum crystal formation leads to faster filter rates, lower solvent/oil ratios and lower oil-in-wax content [33.8, p. 38]

- Filter wash solvent ratio
- Wash temperature
- Mixing energy (DILCHILL™ only)
- Filtration temperature
- Filter speed
- Dewaxing aids.

Dependent variables rely on the independent variables:

- Filter feed rate

- Dewaxed oil quality:
 1. Cloud point
 2. Pour point
 3. Low-temperature properties
- Dewaxed oil yield
- Wax yield:
 1. Oil in wax
 2. Melting point
 3. Needle penetration.

33.18 Process Variable Effects

As mentioned earlier, crude selection can have an influence on downstream units. Table 33.13 shows the impact of the crude source on the dewaxed oil yield.

Table 33.13 Typical base stock yields. SUS: Saybolt universal seconds ►

Base stock	Minimum fluid point (°C)	Arab light Yield (vol%)	Statford Yield (vol%)
100 SUS	-18	81	79
300 SUS	-9	81	79
700 SUS	-7	85	80
Bright stock	-7	85	78

33.19 Solvent Composition

33.19.1 Miscible and Immiscible Operations

MEK is an antisolvent for the wax and helps to reduce its solubility. If the MEK content is too high, the base stock may become insoluble and a phase separation will occur. MIBK or toluene is added to help solubilize the oil. Both of these pro-solvents have a higher affinity for wax molecules than MEK. The higher the concentration of pro-solvent, the more wax stays in the solution and ends up in the filtrate. This raises the pour point of the dewaxed oil, and since the manufacturer must meet dewaxed oil pour point specification, the manufacturer is forced to reduce the filtration temperature to remove more wax. The reduction in filtration temperature increases the viscosity of the slurry, filtration rates are slower, and oil removal from the wax cake becomes more difficult. Thus, the objective is to use the maximum amount of MEK without having a phase separation. A plot of the phase separation temperature or miscibility temperatures versus solvent composition may be used to help set the optimum solvent composition. A typical miscibility curve for MEK and Toluene for heavy neutral lube oil is shown in Fig. 33.21.

The ideal would be to operate as close to the miscibility curve as possible. However, this curve shifts depending on the base stock. Wax molecules in heavier grades move out of the solution earlier and this has the effect of shifting the miscibility curve to the left.

Plants equipped with solvent splitters to separate the MEK from the MIBK or toluene, after it has been recovered in the DWO and wax recovery sections, may blend to the optimum solvent composition for each base stock. Manufacturers without the capability of changing solvent composition will set the plant solvent composition based on the heaviest grade to avoid immiscible operation. This increases the pour filler spread, because the pro-solvent composition is too high for the lighter grades. This will also affect plant processing capacity.

Fig. 33.21 Typical heavy neutral miscibility curve for MEK and toluene

The shift from miscible to immiscible operation occurs over a narrow range of solvent composition as can be seen in Fig. 33.23. When the plant moves deep into immiscible operation then phase separation occurs, the oily phase, containing the desirable high VI molecules, will hang up in the filter cake and be very difficult to remove, increasing the oil in the wax content of the wax and reducing the dewaxed oil yield. Dewaxed oil properties may be adversely affected and VI may decrease. Filtrates produced under miscible and immiscible operating conditions are shown in Fig. 33.22, where the clear filtrate was produced under miscible operating conditions. Interestingly, in severely immiscible operation, the dewaxed oil pour point may actually decrease as the waxy molecules remain in the wax cake.

33.19.2 Effect of Viscosity on the Filtration Rate

Higher viscosity base stocks will filter more slowly, as can be seen in Fig. 33.24. Increasing the MEK concentration in the solvent reduces the slurry viscosity, but the maximum amount of MEK is limited by miscibility considerations.

33.19.3 Effect of the Chilling Rate on the Filtration Rate and Dewaxed Oil Yield

Increasing the chilling rate forces wax molecules to come out of the solution quicker. When the wax molecules come out of the solution, they may either form a separate nuclei (nucleation) or attach onto an existing nucleus (growth). When the chilling rate is high, nucleation is favored over growth with the result

Fig. 33.22 Comparison of immiscible and miscible filtrates. (Photo by B.E. Beasley, courtesy of ExxonMobil Process Research)

that with the smaller average crystal size, the wax is more difficult to filter, and the wax retains a higher oil content. The effect of chilling rate on DWO yield and filtration rate shown in Table 33.14.

33.19.4 Effect of Temperature Profile

The preferred temperature profile for incremental and DILCHILL™ dewaxing is a linear profile. Both methods of dewaxing add solvent, either in increments along the SSE/scraped surface chiller/crystallizer (SSC) train or in stages in the crystallizer. Thus, the flow rate increases from the feed to the filters. Other tempera-

Fig. 33.23 Impact of change in solvent composition on miscibility. (Photo by B.E. Beasley, courtesy of ExxonMobil Process Research)

Fig. 33.24 Effect of oil viscosity on filtration rate

Table 33.14 Example of the effect of the chilling rate on the yield and filtration rate

Chilling rate (°C/min)	DWO yield (vol%)	Filtration rate (gal/(ft ² hr))
2.2	85.3	2.00
4.4	82.0	1.94
6.7	81.3	1.92
8.9	79.8	1.90

ture profiles are possible. Filtration rates in plants with a convex temperature profile are typically not as good as those with a linear profile. This may be due to the very high chilling rates in the SSC or last few DILCHILL™ stages, required to reach the filtration temperature, and which favors nucleation at the expense of growth and leads to a smaller average crystals. Typically, concave profiles offer no advantage over linear. In the rare case where a concave profile has produced improved filtration rates, it has been surmised that a high chilling rate at the beginning of the train, which will favor nucleation, was needed to establish *seed* crystals for growth.

33.19.5 Effect of Solvent Dilution Ratio

Filtration Rate

A solvent may be added in increments along the SSE/SSC train or in the DILCHILL™ crystallizer. The solvent reduces the slurry viscosity and facilitates filtration. When the dilution is too low, the slurry viscosity will be too high, and the slurry filtration will be reduced. This is often referred to as *viscosity limited*. When the dilution is too high, the volume of liquid to be filtered exceeds the capacity of the filter (filter cake resistance is limiting) and the filtration is said to be *hydraulically limited*. This balance results in an optimum dilution ratio dependent on the base stock being processed (Fig. 33.25), the solvent composition being used, and the crystallization which sets the filter cake resistance. Light base stock operations are more likely to be chilling or refrigeration limited rather than filtration limited because the light base stock pour points are typically lower than the heavy grades, while the average wax crystal size is larger, reducing wax cake resistance.

DWO Yield

Increasing the dilution ratio will reduce the oil in wax and increase the dewaxed oil yield.

33.19.6 Effect of Water

Water may enter with the feed from the extraction process or from tankage. Water may also enter the system from leaks in water coolers or condensers that are used in the dewaxing plant. Water may re-enter the solvent system through inadequate performance of the dehydrator section in the plant. Water is a strong antisolvent. Water reduces the solubility of wax and oil molecules so that they come out of a solution at a higher temperature. This has the effect of shifting the miscibility curve to the left. Typically, the increase in water concentration from the normal levels is an indication of a process/equipment problem and the root cause must be found and dealt with quickly.

Excessive water may drop out of the solution and form ice in the slurry or inside the scraped surface equipment. It may also flow downstream to the filters where it may be captured in the wax cake or on the filter cloth.

33.19.7 Effect of Increased Raffinate VI

Raffinate VI may be increased in extraction through more severe extraction. This increases wax concentration in the raffinate stream. These waxy molecules will come out of the solution in the dewaxer at a higher temperature, resulting in the miscibility curve shifting to the left. This will require the manufacturer to add more prosolvent to avoid immiscible operation.

Fig. 33.25 Effect of dilution ratio on filtration rate, heavy neutral

33.19.8 Effect of Pour Point Giveaway on Product Quality and Dewaxed Oil Yield

When a base stock produces dewaxed oil with a lower pour point than the specification, the plant is *giving away* this product quality. Examples of quality giveaway are shown in Table 33.15. The economic penalty for pour point give away is a lower filtration rate and a lower throughput and a decreased dewaxed oil

Table 33.15 Examples of quality giveaway

Base stock	Pour point reduction (°C)	Typical VI loss	Typical yield loss (vol%)
Solvent neutrals	3	1	1.0
Bright stock	3	0.5	1.0

yield. Lower pour point also means that more wax has been removed and this will lower the dewaxed oil VI.

33.20 Scraped Surface Equipment

SSEs and SSCs are used in incremental dewaxing and SSCs in DILCHILL™ dewaxing. SSEs and SSCs are double pipe exchangers with slurry inside the central tube and the cooling media (filtrate or refrigerant) in the annular area around the inside tube (pipe). Typical installed SSEs are shown in Fig. 33.26.

The scraped surface continuous crystallizer is built as a double-pipe element, generally with a 6, 8, 10, or 12 in diameter inner pipe and a larger diameter outer pipe. The area between the inner pipe and the outer pipe is filled with cooling fluid. The inner pipe contains a rotating scraper blade element, which mixes the process fluid flowing through the inner pipe, and removes deposits which form on the inner pipe wall as cooling occurs.

The scraped surface continuous crystallizer is a heat exchanger, but quite an unusual one, because it generally functions as a cooling crystallizer. Heat transfer occurs across the wall in the inner pipe, with cold fluid outside, and process fluid inside. As cooling occurs,

crystals tend to form and foul the inner pipe wall. The scraper blades rotate on the inner pipe wall and remove these deposits that would inhibit heat transfer. The majority of crystallization takes place in the bulk of the fluid, as opposed to the wall, thus allowing growth of easily separable crystals. Generally, the scraper blades rotate at moderate speeds of 15–30 rpm. This speed promotes adequate heat transfer, consistent with good crystal growth and easy separation:

- Solvent and raffinate slurry are cooled by cold filtrate or refrigerant.
- Tubes may be stacked in stacks of 8, 10, or 12.
- Tube extends from 20 to 40 ft.
- Inner tubes may be configured for flow in either series or parallel.
- Spider bearings are used for shaft support.
- One double pipe assembly usually consists of four or five individual pipe shafts connected by spider shafts that run through the spider bearings

Fig. 33.26 Typical SSEs

which support the internals. Each pipe shaft is fitted with spring loaded scraping blades whose design is specific to the SSE supplier. A drive shaft extends through a seal or packing at the drive end.

- A sprocket is attached to the shaft outside the tube and the shaft is turned by the sprocket that is driven by lubricated chains which are connected to all the sprockets on one side of the tube bank.
- The chain is driven by a fixed speed drive motor or more commonly two motors mounted above the tube bank.
- Shaft speeds range from 2 to 30 rpm.

The scraped surface equipment removes wax from the wall by scraping. The internals are designed to maximize the open cross-sectional area in the tube in

order to reduce the pressure drop. Modern design uses 12 in inner pipe for optimum heat transfer and pressure drop. Over time, wax accumulates on the cold internals, such as the spider bearing and other cold surfaces affixed to the shaft. The build up of wax will increase the pressure drop across the tube. When the pressure drop begins limiting the equipment, it will either be cleaned on-line or off-line by washing with hot solvent. Lube plant operations developed procedures that optimize SSE cleaning with minimum impact on the process.

33.20.1 Scraped Surface Equipment Suppliers

BORSIG and Armstrong are the leading suppliers of scraped surface equipment.

Fig. 33.27a-c Typical SSEs. View of SSE drive chain (a), view of chiller drum above SSE (b), SSE drive shaft bearing and seal assembly (c) (Photos courtesy of Armstrong)

Both Armstrong and BORSIG supply steel and bronze which are softer than the inner pipe wall. Each uses a spring to apply pressure on the scraper blade to push it against the tube wall so that it scrapes the wax off the wall as the internal shaft is turned.

Armstrong Scraped Surface Equipment

The drive end of a typical Armstrong SSE is shown in Fig. 33.27a. A chiller drum mounted on top of the tubes is shown in Fig. 33.27b. The Armstrong drive shaft assembly is shown in Fig. 33.27c. The design benefits of the drive unit:

- Rugged drive system.
- Easily understood by the maintenance personnel.
- Mechanical seals are frequently used to avoid leakage around the driven shaft.
- The drive staff is stabilized to avoid any bending which would reduce the life of the seal.
- The use of two heavy duty self-aligning bearings locks the drive shaft into place, and prevents any unwanted movement, which could cause leakage.
- The drive is bolted on which means that the unit must just be spaded off; there is no need for hot work. Once unbolted, the drive housing can be taken

Fig. 33.28a,b Armstrong SSE internals – design views. Pipe shaft with leaf spring assembly and scraper blades (a), Cross-section of shaft showing leaf spring and scraper assembly (b), leaf spring (c) (courtesy of Armstrong)

Fig. 33.29a,b Armstrong SSE internals – assembled views. Top end view of pipe shaft, leaf spring, scraper blade and spider bearing (a), end view of pipe shaft, spider bearing (b)

into the workshop for new mechanical seals to be fitted in a clean dry place. This reduces repair time and keeps the unit clean.

The design benefits of the scraper shaft:

- The drive system allows free turning off the drive shaft.
- The shaft is sealed against leakage of the process fluids.

An Armstrong pipe shaft with mounted springs and scraper blades is shown in Fig. 33.28a. Cross-section of the pipe shaft showing the leaf spring and scraper

blade assembly is shown in Fig. 33.28b. A six finger leaf spring is shown in Fig. 33.28c. Advantages of Armstrong springs:

- Extra long life – fatigue is minimized.
- Three springs per blade gives maximum scraping capability.
- Each spring made of 6 finger elements of either 316 SS or Monel.
- Lower pressure drop than plunger-type internals.
- Six elements per spring greatly reduces downstream damage from broken parts as the springs stay attached to the blade.

Fig. 33.30 Borsig SSE at the manufacturing site (a). Borsig internals being inserted into the tubes (b). (Photos courtesy of BORSIG)

Fig. 33.31a,b Drive system and chain tightener of an SSE. End view of chain drive (a), close up view of chain tightener assembly (b) (Photos courtesy of BORSIG)

Fig. 33.32 Drive system with scraper shaft of an SSE. (Photo courtesy of BORSIG)

- Leaf springs consisting of one piece of stainless steel had a tendency to break across the radius as stress raisers were caused at every revolution. The Armstrong patented wire spring resolved this issue and offers better service life than the compression (plunger-type) spring. A major European refinery using these springs opened a chiller once, which had not been opened for 9 years, and it had less than a dozen broken springs. A fabricated Armstrong pipeshaft, leaf spring, scraper assembly and spider bearing are shown in Fig. 33.29a. A fabricated pipeshaft, spider bearing, leaf spring and scraper blade are shown in crosssection in Fig. 33.29b.

Borsig Scraped Surface Equipment

BORSIG supplies SSEs of 6, 8, 10, and 12 in inner pipe diameters to meet the volumetric flow rates and heat transfer needs which might be required. A typical Borsig SSE at the manufacturing site shown in Fig. 33.30a. Borsig internals being inserted into the tubes is shown in Fig. 33.30b. A typical scraper shaft ready for packing is shown in Fig. 33.34. Borsig SSE ready for shipment is shown in Fig. 33.39, installed SSEs in Fig. 33.40 and 33.41a–c.

The design benefits of the drive unit (see Fig. 33.31a end view of chain drive assembly and

Fig. 33.33 Drive system – drive shaft and mechanical seal of an SSE. (Photo courtesy of BORSIG)

Fig. 33.34 Standard design of a scraper shaft as used for lube oil dewaxing in an SSE. (Photo courtesy of BORSIG)

Fig. 33.35 Scraper shafts ready for packing. (Photo courtesy of BORSIG)

Fig. 33.31b close up view of chain tightener assembly):

- The sprocket wheel is supported by a fixed bearing neck, which takes up the radial load caused by the chain pulling force. A critical alternating bending stress on the drive shaft is prevented.
- Owing to the absence of radial load on the drive shaft, a considerable improvement of the drive shaft seal is obtained.
- Potential bearing service life over 100 000 operating hours.

Fig. 33.36 Spider bearing in an SSE (courtesy of BORSIG)

- Gear housing for outdoor installation completely water- and dust-tight.
- In the case of shear pin failure, the sprocket wheel still rotates on main tapered roller bearings.
- Maintenance intervals more than 4 years.
- Removal of drive shaft, bearings, and drive shaft seal is possible without dismantling of chain drive (typical drive shaft and seal assembly shown in Fig. 33.33).
- Superior design for applying mechanical seal.

The design benefits of the scraper shaft and scraper blades are (Fig. 33.32):

- A stream-lined design especially with 10 and 12 in units (no intermediate pipe etc.) guarantees low-pressure drop due to low-flow resistance and less product deposition both resulting in longer running time of the units.
- Low wear of scraper blade due to optimum spring force.
- High blade/spring lift resulting in long service life of scraper blades.
- Robust design, also of the scraper blade holders, therefore insensitive to overloading.
- Running of the scraper shaft in the opposite direction presents no risk of breakage for spring and holders.

Fig. 33.40 Row of installed SSEs with access decking. (Photo courtesy of BORSIG)

Fig. 33.41 Two end views of installed SSE and one top view above the SSE (long tubes near the bottom of the picture). (Photo courtesy of BORSIG)

Fig. 33.42 Tube damage resulting from spider bushing failure. (Photos courtesy of Armstrong)

Fig. 33.43 Damage resulting from single leaf spring failure

- Coil springs (helical springs) affecting self-centering of the shafts, thus reducing the load on the bearings.
 - Corrosion resistant Monel K500 springs.
 - Rugged scraper shaft design.
 - Connection of each scraper shaft section with two solid bolts.
 - Plunger head design of the scraper blade holders (Fig. 33.34).
- Independent holders for each scraper blade.
 - No loose blades in the inner pipe should a spring brakes, blade is still held in position by the holder.
 - Damaging of inner pipe is excluded due to a special scraper shaft design, that is, stopping ring at the plunger prevents the plunger head to touch the inner pipe when the blade is worn out.

Fig. 33.44a-g Examples of damages in SSEs. (a) Damaged scraper blades, (b) damaged scraper leaf springs and blades, (c) broken chain link, (d) chain drive, (e) chain link wear, (f) bushing wear at chain link, (g) link and pin slack

- The scraper blade material is mild steel, brass, fibre-glass, or other material dependent on the product.

The design benefits of the spider bearing design (supports):

- Self-locking spider supports, not rotating with the shaft (wear in the inner pipe is excluded).
- Spider bearing supported scraper shaft is exactly fixed in the middle of the inner pipe. This guarantees equal load on all scraper blades and the scrapping is optimized.
- Spider-bearing-wedge design provides easy de-installation of the supports (Fig. 33.37a,b and Fig. 33.38).
- Spider-bearing design is stream-lined and guarantees low-pressure drop and less wax sticking (Fig. 33.36).
- Spider-bearing journals and drive shafts are hardened (i. e., with Colmonoy 6 or Wolfram Carbide).
- Support-bearing and drive shaft bushings can be made of bronze, stellite 6 or polyether ether ketone (PEEK).

33.20.2 SSE Equipment Issues

SSEs may require very high maintenance support as compared to other equipment in the lube plant. Excessive wax build up in the tubes may result in shear pins, which protect the internal shaft from damage, failing, and the shaft will stop turning. This reduces the ef-

fective heat transfer, which can further limit the plant on chilling limited base stocks. Seals and packing may leak contributing to solvent losses in the plant. Poorly lubricated chains will break or jump off the sprockets. Overall heat transfer coefficients may be low. Performance should be monitored, which is typically not an easy task. Internals must be overhauled when performance has permanently degraded.

Each SSE supplier uses a spring to apply pressure on the scraper blade to push it against the tube wall so that it scrapes the wax off the wall as the internal shaft is turned. Operators who buy cheap steel blades from local fabrication shops may save thousands of dollars compared with OEM equipment spare parts but in the end they will cost hundreds of thousands of dollars as the inner pipe wall wears beyond the corrosion allowance.

The internals weigh about 850 kg. Over a 40 ft scraped length when the spider bushings fail, the spider shafts wear and the resulting rotational ellipse just trepan the lower part of the inner pipe (Fig. 33.42).

An example of single leaf spring failures is shown in Fig. 33.43. Note that there are missing scrapers as well as twisted metal. Examples of SSE equipment damage may include damaged scraper blades (Fig. 33.44a), damaged scraper leaf sprongs and blades (Fig. 33.44b), broken chain links (Fig. 33.44c), broken chain drives (Fig. 33.44e), excessive wear at a chain link (Fig. 33.44e), excessive bushing wear at the chain link (Fig. 33.44f) and excessive chain link and pin slack (Fig. 33.44g).

33.21 Filters

Filters are used to separate the wax crystals from the slurry. The slack wax and filtrate are collected and sent to their respective recovery sections in the plant to recover and recycle solvent.

33.21.1 Operation

Rotary vacuum filters are used in ketone dewaxers and rotary pressure filters are used in propane plants. The principles of operation are the same. A typical filter is shown in Fig. 33.45.

The filter drum rotates at speeds from 0.2 to 1.6 rpm. The surface of the drum is divided into segments that run the length of the filter. Newer designs have 30 segments. Each segment has a lead and trail pipe connected to the segment at several locations running the length of the drum. The segment lead and trail pipes combine so that there are 30 lead and trail pipes, one for each segment, that carry filtrate to the mas-

ter valve, which is also called the trunnion valve. The master valve is stationary while the filter drum rotates. (A variable speed filter drive is shown in Fig. 33.47a.) The master valve has internal bridge blocks that effectively segregate the filtrate collected from the filter into as many as four distinct compartments or *pick-ups*. (Static master valve plate with bridge blocks shown on left of Fig. 33.46a. Rotating master valve plate shown on right in Fig. 33.46a. Typical piping at the master valve shown in Fig. 33.46b)

Starting from the deflector blade, the drum rotates into the slurry in the vat and filtration begins at the first *wet pick-up* port or No 1 vacuum. The filter segment continues its rotation into the *second wet pick-up* or No 2 vacuum. The rotation continues and the filter moves into the wash area or *first dry pick-up* and finally into the *drying area* or *second wet pick-up*. The drying area may also be washed with cold solvent. The filter rotates into the purge zone where N₂ blow gas is applied to the trail

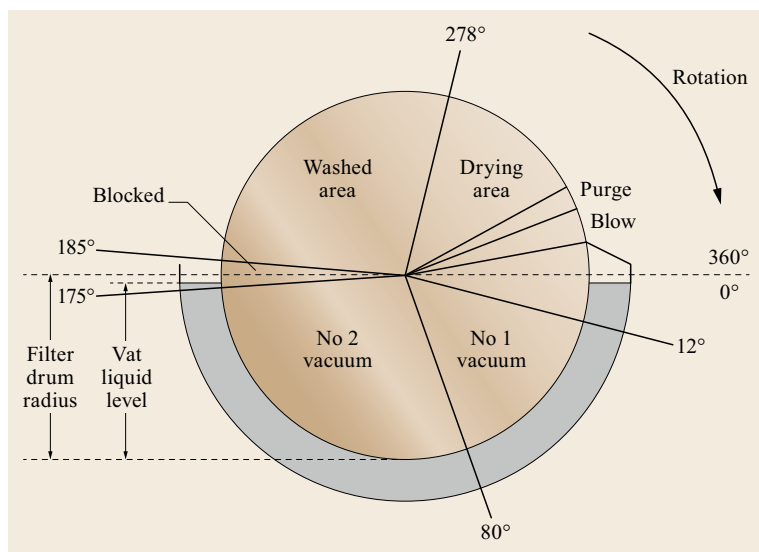

Fig. 33.45 Typical filter wash – dry segments

Fig. 33.46a,b Filter master valve. Static master valve plate (stator) with compartments shown on the *left* and rotating master valve plate (rotor) shown on the *right* (a). Installed master valve assembly with static piping attached to the static master valve plate (b). (Photos by B.E. Beasley, courtesy of ExxonMobil Process Research)

pipe while the lead pipe stays under vacuum. The purge zone clears out the filtrate in the pipes and increases the dewaxed oil yield by preventing the filtrate in the pipes from being blown back through the pipes and into the wax scroll with the wax. The segment moves into the blow gas zone and blow gas is applied to the lead and trail pipes and the cake *pops* off of the filter and slides across the Teflon deflector blade and into the wax scroll.

The scroll is an Archimedes screw (Fig. 33.47e) that moves slack wax from the outer ends of the filter to a center pipe. The slack wax falls down the pipe and may either proceed down a slide where it may be combined with slack wax from other filters into a slack wax drum or into a wax *boot* or vessel. This is a small drum dedicated to the filter. From the large wax drum

or the wax boot, the slack wax is pumped to either wax recovery, the second stage of dewaxing or de-oiling depending on the plant configuration.

33.21.2 Filter Media

The filter drums used in ketone dewaxing (rotary vacuum) and in propane dewaxing (rotary pressure) have filter cloths secured to the drum surface. The filter cloth retains the wax crystals while allowing the filtrate to pass through the filter cake or through the filter cloth and into the internals of the filter drum and eventually to the filtrate receiver drum.

Many different types of material have been used over the years. These include woven and nonwoven ma-

Fig. 33.47a–e Typical rotary vacuum filter. (a–b) Filter drum (c) solvent wash sprays and drip pipe (d,e) support grid and wax scroll. (Photos by B.E. Beasley, courtesy of ExxonMobil Process Research)

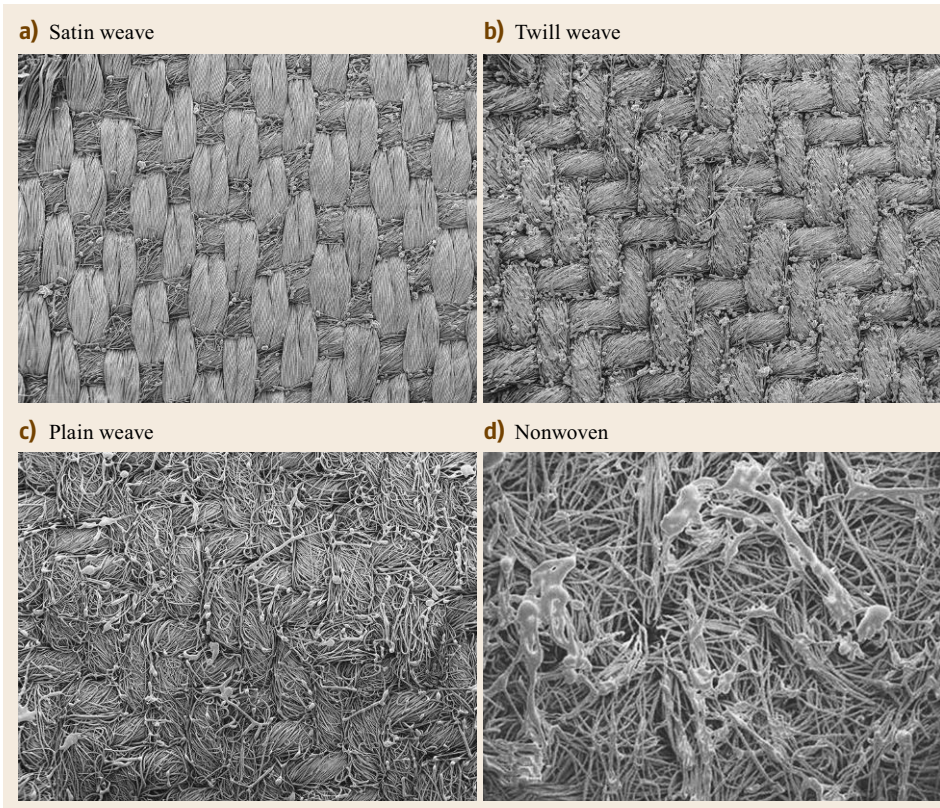

Fig. 33.48 SEM of typical filter medium. Stain weave (a), twill weave (b), plain weave (c), nonwoven (d). (Photos reprinted, courtesy of Madison U.S. Filter)

materials, single and dual layer cloths. A few examples are shown in Fig. 33.48.

The requirements of a good filter cloth are:

1. Low interfacial resistance for high filtration rates.
2. High filtration rates lead to high wash acceptance or lower filter speeds for increased dewaxed oil yields.

3. Elimination of wax bleed through and haze formation.
4. Thermally stable at hot wash temperature.
5. Chemically stable in ketone and propane service.

A comparison of typical filter cloth materials is given below.

Additional considerations include the mechanical stresses generated in vacuum and pressure filters that lead to fabric stretch and wear associated with filter blow gas. The filter cloth may suffer mechanical damage during installation, or from exposed deflector blades or other sharp or raised edges. The cost of the filter cloth is small as compared to the loss of production time incurred when a filter has to be re-clothed or when the dewaxed oil quality does not meet product specification.

Fiber selection, fabrication technique (woven, non-woven), and cloth finishing all play an important role in determining filter cloth performance.

Fig. 33.49 Typical filter cloth fouling

The ExxonMobil patented proprietary filter cloth has been used in ketone and propane dewaxing processes for many years. It has higher resistance to

Fig. 33.50a–d Filter cloth installation. (a) Caulking bars hammered into caulking bar groove. (b) Removal of excess cloth. A small cloth strip is used in all grooves that do not have cloth overlap to provide tight fit. (c) Technicians tamp down the caulking bar as the wire is wound onto the drum. (d) Wire tension take up device. (Photos by B.E. Beasley, courtesy of ExxonMobil Process Research)

fouling due to several unique design features and has shown > 15% improvement in filtration relative to woven cloths can be achieved. Feed filter rate versus cloth exposures to slurry for ExxonMobil (EM) proprietary cloth and a typical woven cloth are shown in Fig. 33.49.

Filter cloth is cut to the length of the filter and depending on the width, several sections are required. The cloth sections are held in place on the surface of the

drum by a caulking bar, which is hammered into the caulking bar groove during the cloth installation. A steel wire is wrapped, under tension, around the drum to further secure the cloth. The wire will tend to migrate away from the drive end and many filters have installed a take-up tensioner device to extend the length of time before wire breakage occurs. Typical filter cloth installation shown in Fig. 33.50a–d. Filter cloth support grids are shown in Fig. 33.47b,d,e.

33.22 Cold Wash Distribution

Cold ketone wash is applied to the filters either through sprays or drip pipes or both. (A typical combination of sprays and drip pipes is shown in Fig. 33.47e.) There are advantages and disadvantages to both designs and both are in practice today. Cold wash is essential to reduce the oil in wax, increase dewaxed oil, and increase the wax product value. (Effect of filter–wash–dry sequence of DWO yield shown in Fig. 33.52.)

Good distribution is necessary to spread the wash completely over the wax cake and avoid dry sections. The wash must not impinge with excessive velocity onto the wax cake in order to avoid knocking it off or digging channels or grooves. The wash system should be resistant to fouling. Spray nozzles and drip pipes are the major wash distribution systems in use today. Both are acceptable provided the system is properly designed and operated within the design parameters.

ExxonMobil patented Drip Pipes provide excellent coverage and are capable of good turndown.

Wash falls by gravity onto the wax cake minimizing potential dislodging of the cake by wash impingement. Stainless construction and upstream filtration prevent fouling.

Fig. 33.51 Example of poor filter cold wash distribution. (Photo by D.S. Sinclair, courtesy of ExxonMobil Process Research)

Poor wash/spray distribution (example of poor wash distribution shown in Fig. 33.51):

- Poor wash distribution can result from collapsed sprays creating a wide area without coverage.
- If cold wash flow from the spray nozzles is too high wax may actually be blown off the filter cake. Evidence of this may be seen as an accumulation of wax on the filter windows.
- Conventional (not ExxonMobil) drip pipes may not be balanced, resulting in some areas with no flow and some areas with too much flow.
- Excessive wash flow rates through the spray nozzles may cut grooves in the cake and wash wax and solvent back into the vat resulting in recycling.
- Combinations of too high a flow through conventional drip pipes will collapse spray cones. Excess accumulation in a local area may cut grooves in the wax cake.

Drying out/compressing wax cake due to the lack of wash over portion of top pick-up zone not only affects DWO yield, but also drops filter feed rate (FFR):

Fig. 33.52 Effect of filter–wash–dry sequence on oil yield. Bars show the oil in wax (OIW) by refractive index (RI) correlation with D3235, dots show the DWO yield in wt% by RI correlation with D3235

Fig. 33.53 Impact of wash application on FFR

- Recent plant test redistributed wash solvent to prevent large *dry* area on descending side of the filter and resulted in 15% increases in FFR.
- Figure 33.53 shows the effect of continuing to apply vacuum without wash and then reapplying wash – FFR improved again, but did not reach up to the previous level.

33.23 Wash Acceptance

Wash acceptance is the amount of wash that can be accepted through the wax cake before it begins to spill or run off the wax cake. The volume of filtrate collected as a function of time decreases in a square root relationship, for noncompressible wax cakes, until the end of the filtration step. At that point filtration is complete, the wax cake formation has stopped and the wash is applied to the cake. The flow of wash through the cake is at the same rate as the last increment of filtrate just

at the final moment of filtration (ignoring for the moment slight differences in liquid viscosity and wax cake compressibility). If too little wash is applied, the oil in wax will be higher than optimum and yield will be lower. If excess wash is applied, it will either roll off into the filter vat or into the scroll. Cumulative filtrate and wash volumes versus time are shown in Fig. 33.54. Normalized filtrate and wash rate versus time, shown in Fig. 33.55.

33.24 Wash Efficiency

Cold wash, distributed over the wax cake by drip pipes or sprays, will displace the cake liquids, reducing the oil in wax and increasing the yield. This occurs in two steps. The first step is a piston displacement where the wash liquid pushes out the cake liquids. In the second step, oil from within the wax crystal diffuses into the low oil concentration wash liquid. The theoretical reduction in oil content may be predicted by the Butler equation, which was developed by an Imperial Oil (Sarnia, Canada) researcher, Roger Butler, as a model for wash efficiency. Butler envisioned a cylindrical tube filled with oil being displaced by wash. Initially, its piston displaced up to 50% oil removal, and then the curve shifts to a parabola. The Butler equation can hence be formulated as $y = 1 - x$ for $x < 0.5$ and $y = 1/(4x)$ for $x > 0.5$. The efficiency of oil removal for any amount of wash is the comparison of the actually measured ratio *oil before wash* to *oil after wash* (A in Fig. 33.56)

and the prediction of the Butler curve (B in Fig. 33.56). Figure 33.56 shows various wash efficiencies in comparison to the Butler curve [33.14].

The wash efficiency is defined as the actual oil in wax obtained for a given amount of wash applied relative to that predicted by the Butler curve. Efficiencies may be less than 100%. This may be result from:

- Poor spray distribution
- Fouled, leaking, or missing spray nozzles
- Poor distribution along the drip pipe, *out of level* on older designs
- Fouled drip pipes
- Area of excessively fouled filter cloth may occur when *drying* is practiced
- Cracked filter cake, solvent flows through crack instead of cake
- Wash rate exceeding wash acceptance

Fig. 33.54 Filtrate volume versus time. Wash acceptance (filtration time = wash time, incompressible cake)

Fig. 33.55 Normalized filtrate or wash rate versus time. Wash acceptance (Filtration time = wash time, incompressible cake)

Fig. 33.56 Wash efficiency

8. Wash temperatures significantly lower than filtration temperature, which seals off wax crystals.

Wash efficiencies may be found to exceed 100%. This may be due to:

1. Hydraulic compression of the wax cake, *squeezing* oil out of the cake without using any wash solvent such as may occur in the drying section of the filter.
2. Higher crystal or wax cake compressibility in the presence of wash.

Some plants will dedicate a significant portion of the filter area to *drying* and will block or drips in this area. The intent is to reduce the oil in wax to increase yield and possibly debottleneck wax recovery. An unintended consequence is that the vacuum that remains on in this section will pull the wax cake into the filter cloth, accelerating the filter fouling, which will reduce wash acceptance and increase oil in wax. It will also require more frequent filter washing which will reduce plant throughput. These competing factors must be balanced by the manufacturer to achieve the optimum filter performance.

33.25 Filter Hot Washing

The filtration rate of a filter decays over time due to plugging of the filter cloth by small wax crystals. A typical decay curve is shown in Fig. 33.57. The feed rate measured by flow meter is plotted against the number of *dips* or exposures of the filter cloth to the wax slurry. The shape of the decay curve depends on the filter media, in this case an ExxonMobil proprietary cloth.

As the filtration rate decays throughout is lost and at some point the filter must be taken offline and washed to restore the filtration rate. The time during which the filter is off-line also represents lost production. The optimum time between washes is the economic balance between production lost due to the decay curve compared to the time to wash the filter and bring it back on line. An example of a series of decays and washes is shown in Fig. 33.58. If the shape of the decay curve is known and the wash time is known the optimum wash time may be determined analytically.

Hot ketone solvent is used to wash the filters. Cold wash solvent is blocked off and hot solvent flows through the same sprays or drip pipes, over the filter

cloth, melting the wax crystals, thereby cleaning the cloth. Filter washings are collected in a filter washing drum. The washings may be:

Fig. 33.58 FFR decay curves and filter washes

Fig. 33.57 The feed rate decay curve (light neutral) shows how the FFR decreases after several filter revolutions, the number of dips in rpm time

1. Injected with the feed as *predilution*
2. Injected between first and second filter stages
3. Injected into the appropriate stage of the DIL-CHILL™ crystallizer
4. Sent to wax recovery.

Hot wash temperature is controlled. If the temperature is too low, it may not adequately melt the wax crystals. If the wash temperature is too high, wire migration may occur resulting in reduced wire life and/or an increase in the frequency of wire retensioning.

33.26 Dewaxed Oil/Wax-Solvent Recovery

The objective of the dewaxed oil and wax recovery section is to remove solvent from the product stream for recycle back to the chilling train and the filters. This is done using low- and high-pressure flashes and a high-temperature flash followed by steam stripping and vacuum drying (dewaxed oil). Solvent concentrations are reduced to meet the product specification. High concentrations in the product represent avoidable solvent losses and increase operating expenses. In some cases, excessive high temperature operation in the recovery section can lead to light oil vaporization and accumulation in the solvent. This represents avoidable excess energy costs. The operation of the solvent recovery system becomes an economic optimization problem.

Dry *waxy solvent* from wax recovery should be segregated from the dry *clean* solvent recovered from the dewaxed oil recovery section. *Waxy solvent* tends to have wax in it and cannot be cooled to the same temperature as that of the *clean* solvent from the dewaxed oil recovery. It may be cooled and temperature blended with the *Clean* and used as filter wash. Flow restrictions may be set on flow to wax recovery to prevent wax carryover and downstream fouling.

Wet solvent from the stripper and the solvent from the low-pressure flash is sent to the dehydrator for solvent recovery.

A typical recovery section is shown in Fig. 33.59.

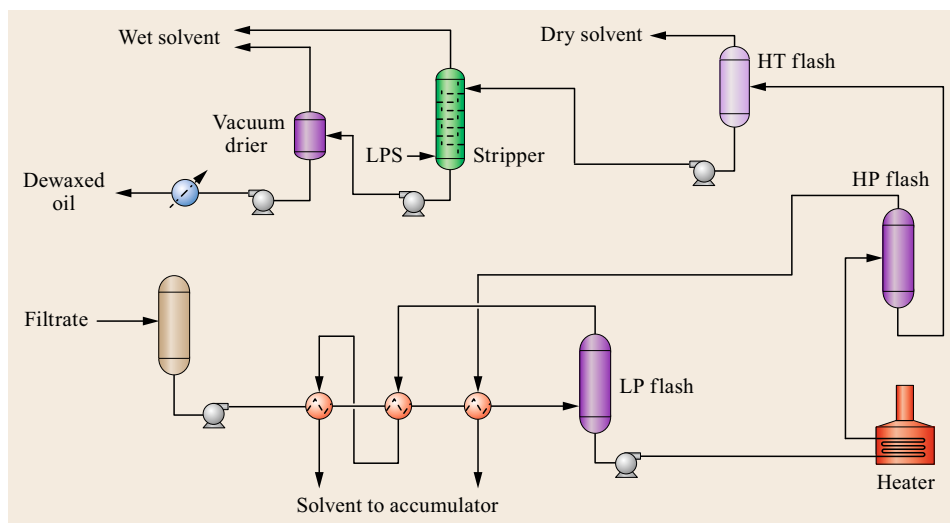

Fig. 33.59
Typical dewaxed oil recovery section flow diagram

33.27 Solvent Dehydration

Solvent from the low-pressure flashes is sent to the dehydrator tower. Overheads from the dehydrator tower are combined with stripper overheads and the overhead from the water tower is sent to the decanter. The solvent rich phase from the decanter is sent back to the dehydra-

tor. The water rich phase is sent to the water tower. Dry solvent from the dehydrator bottoms is returned to the unit. The water from the water tower is sent to waste water treatment. A typical solvent dehydration flow diagram is shown in Fig. 33.60.

Fig. 33.60
Typical solvent
dehydration flow
diagram

33.28 Solvent Splitter

The solvent splitter allows the manufacturer to separate the solvent mixture back into MEK and MIBK or toluene which can then be added back to the solvent mixture in the plant to optimize the solvent composi-

tion and minimize the *pour-filter* temperature spread to achieve maximum throughput. A typical solvent splitter flow diagram is shown in Fig. 33.61.

Fig. 33.61
Typical solvent
splitter flow
diagram

33.29 Two-Stage Dewaxing

A second stage of filtration can be used to reduce the oil in wax and to increase the dewaxed oil yield. Solvent (called repulp or repuddle) is added to the wax from

the first stage, typically in the wax scroll or wax boot depending upon the plant design, and pumped to a filter feed drum that feeds the second stage of filters.

Filtrate from the second stage is *lean* in oil and can be used in the first stage operation. It may be blended with *fresh* solvent and used as a first stage wash, or it

may be added as the final increment of dilution in an incremental plant. Recycling the second stage filtrate reduces the overall solvent usage.

33.30 Deoiling

The deoiling process is used to produce a hard wax containing a very low oil content. Waxes produced in deoiling have melting point and needle penetration specifications. Waxes intended for food grade use must also meet UV absorption specifications and require wax hydrotreating.

In recrystallization deoiling, lean solvent is added to the wax from the dewaxing plant and the resulting slurry is pumped through a heat exchanger where the wax crystals are melted. The wax is then recrystallized in SSEs and SSCs. Typically two stages of deoiling are used to meet the low oil in wax specification. Typical

Fig. 33.62
Typical chilling section in recrystallization deoiling

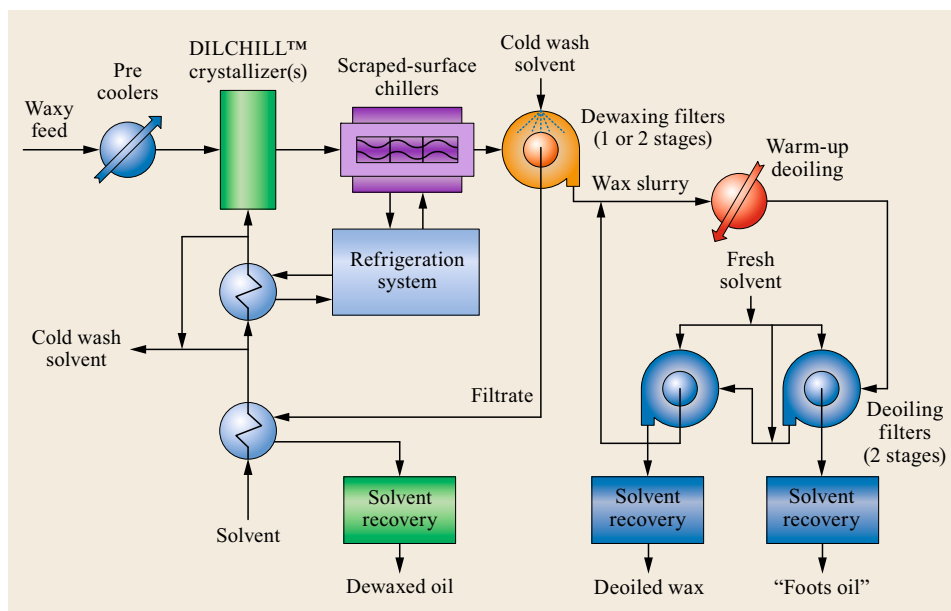

Fig. 33.64
Simplified
DILCHILL™
dewaxing/warm-
up deoiling flow
diagram [33.8,
p. 40]

Fig. 33.65 Typical light neutral refined wax yields versus deoiling temperature

Fig. 33.66 Typical light neutral wax melting point and needle penetration versus deoiling temperature

chilling and filtration sections in recrystallization deoiling are shown in Fig. 33.62 and 33.63, respectively.

DILCHILL™ dewaxing is ideally suited for warm-up deoiling. The spherical nature of the crystals facilitates the melting of the soft wax and re-crystallization is not required. A simplified DILCHILL™ dewaxing/warmup deoiling flow diagram is shown in Fig. 33.64.

The deoiling (filtration) temperature in the deoiling plant is key to meeting final wax properties. As the temperature is increased, the soft wax melts and is removed leaving behind the higher melting, harder wax. A typical light neutral refined wax yields versus deoiling temperature is shown in Fig. 33.65. Typical light neutral wax melting point, needle penetration and DWO yield versus deoiling temperature are shown in Fig. 33.66.

Table 33.16 Typical yield comparison from dewaxing, two-stage dewaxing and deoiling of a heavy neutral

Yields (vol%)	One-stage dewaxing	Two-stage dewaxing	One-stage deoiling
Dewaxed oil	68	73	68
Slack wax	32	27	0
Soft wax (foots oil)	0	0	19
Finished wax	0	0	13

Needle penetration decreases whereas melting point increases. The melting point and needle penetrations define the specification *box* for the manufacturer. Usually the *box* is wide enough that a range of deoiling temperatures may be used that will produce a hard wax that

meets all product specifications. In this case, the manufacturer will select the lowest deoiling temperature that will achieve the desired product properties because this

will give the manufacturer the maximum yield. A yield comparison from dewaxing, two-stage dewaxing and deoiling of a heavy neutral is shown in Table 33.16.

33.31 Propane Dewaxing

Propane dewaxing uses liquid propane as the solvent. (A simplified propane dewaxing flow diagram is shown in Fig. 33.67.) Propane is normally a gas at ambient temperature and the vessels in the unit must be pressure vessels. This also includes the filter. Filtration in propane dewaxing is pressure filtration versus ketone dewaxing that uses vacuum filtration. The propane temperature depends on the pressure so that it is of paramount importance that the pressure must be controlled. It is often said that in propane dewaxing, propane is always either flashing or condensing. This adds an additional level of complexity that is not present in ketone dewaxing.

There are advantages and disadvantages to ketone versus propane dewaxing. A brief comparison is shown in Table 33.17.

Warm liquid propane is added to waxy raffinate and the slurry is prechilled in a shell and tube prechiller, with the slurry in the tube side. The warm dilution

ratio is controlled by the operator. Like the feed pre-cooler in ketone dewaxing, the outlet temperature of the prechillers is maintained just above the cloud point of the slurry to avoid fouling in the prechiller. Some newer designs use a prechiller tower.

The feed solution passes through the prechillers and into the warm solution drum. Up to this point, the propane dewaxing process is a continuous process. The warm solution drum alternatively feeds one of the two chillers and the process now becomes a batch process.

Large batch chillers cylindrical (older) or spherical in design accept prechilled slurry from the warm solution drum and batch chilling begins. Pressure on the chiller is slowly released and the liquid propane evaporates, cooling the batch of slurry in the chiller. A simplified propane dewaxer chilling section is shown in Fig. 33.68.

In older plants, control of the *vent gas* sets the chilling rate. This may be done with two pressure control

Fig. 33.67 Simplified propane dewaxing flow diagram (also see [33.9, Fig. 11.4], courtesy of Exxon Research and Engineering Company)

Table 33.17 Propane versus ketone dewaxing

	Propane	Ketone

Two-stage	Yes	Yes
Deoiling	Yes	Yes

valves (chiller vent valves). Advanced control and valve design has been successfully applied to allow adequate pressure control using a single valve.

Make-up propane is added to replace the vented propane so that at the end of the cycle the dilution in the slurry, the cold dilution ratio (CDR) is at the desired target. Similar to ketone dewaxing where the filtration rate depends on the solvent dilution to the filters, the filtration rate in propane dewaxing is dependent on the CDR, which is also the dilution that will be seen at the filters. The CDR also has a large impact on the pour point. Wax molecules are highly soluble in propane, more than toluene. Increasing the CDR will carry more wax molecules into the filtrate and increase the pour point of the dewaxed oil. This requires the manufacturer to reduce the filtration temperature (by reducing the filtration pressure) to compensate. Because of the large pour-filter spread that exists in propane dewaxing, the base stock pour point is typically limited to -15 . This is a drawback for the propane dewaxing process.

Slurry in the chiller is cooled to the target conditions and then the bath is transferred to the filter feed drum that provides holding capacity for the filters.

Under ideal conditions, the transfer of the cold slurry would occur the moment after the chiller target temperature has been reached. In practice, two conditions may exist. If the chiller final chill temperature has been reached and the filters are not ready to accept the new batch, then the slurry is held in the chiller and the slurry *waits* for the filters. This is referred to as *wait time*. If the filters are ready to accept the next batch of feed but the chiller has not reached its final chill temperature so that it is ready for transfer, the filter levels will drop and the filters will be starved for feed. This is referred to as *starve time*. Chilled slurry is transferred

**Fig. 33.68** Simplified propane dewaxer chilling section

to the filters. After transfer has been completed, the chiller is warmed by pressuring with propane, which condenses on the walls of the chiller. The wall temperature is *warmed-up* to a high enough temperature such that when the prechilled slurry from the warm solution drum is fed to the chiller, shock chilling at the wall will not occur. Warm-up takes time which limits the production. The steps in the chiller cycle are:

1. Fill with prechilled slurry
2. Chill slurry to target temperature by venting propane, add make-up to make target CDR
3. Wait time for filters
4. Transfer slurry to filter feed drum
5. Warm-up.

Total cycle times may range from 20 to 30 min.

Rotary pressure filters are used to filter the slurry. Filtration rate is a function of the pressure drop across the filter. The temperature of the slurry also depends on the pressure. This requires carefully controlled pressure balance from the filter feed drum to the filters and to the filtrate drum. If the pressure in the filtrate drum is too high, the temperature will be high and the resulting dewaxed oil pour point will be too high. If the filter pressure is not increased to maintain the Delta P then filtration rate will also be reduced.

Wax and propane and oil and propane are sent from the filters to their respective recovery sections. High-pressure flash, low-pressure flash, stripper and drier vessels are used to recover propane from the product.

33.31.1 Effect of Water

Solvent *Drip Pipes* that are used to distribute the liquid propane wash over the wax cake in the filters, will

foul if the water content in the propane is too high. The water freezes and will reduce the wash flow and/or may change the wash distribution. The oil in wax will

increase and the overall dewaxed oil yield will drop. Methanol or acetone may be added to the propane to *de-ice* the drip pipes.

33.32 Two-Stage Propane Dewaxing

Two-stage dewaxing may be used to reduce the oil in wax and increase dewaxed oil yield and to reduce solvent requirements. Repulp/repuddle propane is added to the slack wax from the first dewaxing stage. The slurry is pumped to the second-stage filters. Control of the pressure balance is critical to avoid shock chilling and second-stage bog-downs that will limit plant throughput. The second-stage filtrate may be used as the first-stage wash or as dilution.

33.32.1 Propane Deoiling

Propane deoiling is accomplished using high-pressure filters that are required to handle the higher temperatures that must be used to melt the softwax. The finished

wax produced from deoiling is a valuable by-product and margins may at times exceed dewaxed oil margins.

33.32.2 Propane Filter Washing with Hot Kerosene

Temperatures required to successfully melt the wax from the filter cloth do not allow the use of liquefied propane as it requires very high pressure. Instead, kerosene is used to wash the filters. Kerosene wash temperature is typically controlled. If the wash temperature is too low, the wax crystals will not be melted and if the wash temperature is too high, wire migration will increase leading to reduced wire life and/or more frequent wire retensioning.

33.33 Analytical Tests in Dewaxing

There are numerous analytical tests used to assess and optimize the dewaxing operation. A few

of the most important tests are listed in Table 33.18.

Table 33.18 Analytical tests in dewaxing

Test	ASTM test no	Application
Pour point	D 97, D 5949, D 5950, D 5985, D 6749	Key specification for dewaxed oil
Oil-in-wax %	D 721, D 3235	Wax specification, measure of yield performance
RI at 20–30 °C	D 1218	Yield calculation, solvent composition
Miscibility curve		Used to set solvent composition for each stock to avoid immiscible operation
Gas chromatographic distillation	D 2887	GCDs may be for troubleshooting and predicting dewaxing performance
Feed cloud point	D 2500, D5551, D 5771, D 5772, D 7773	Helps set feed precooler outlet temperature
Water-in-solvent	D 6304-03, E 203-1	Excess water may lead to immiscible operation and icing of solvent chillers

33.34 Dewaxing Aids

DeWaxing aids (DWA) may be used in ketone dewaxing but are always used in propane dewaxing. Typically, the DWA doses used in propane plants are 2–3 times higher than those used in ketone plants. While DWAs are economically justified for use on all grades in the propane plant, performance on light neutrals in ketone plants has typically not been economically justified.

DWAs are expensive and may represent the single largest controllable operating expense in the propane plant. Filtration rates in the propane plant may be improved from a level that is almost inoperable to several times the highest rate experienced in the ketone dewaxing plant. Oil in wax may be greatly reduced increasing overall yield and enhancing the wax product value.

DWAs are required to achieve high filtration rates in propane dewaxing. Typically, a DWA consists of a polymer backbone with alkyl side chains. Factors affecting the DWA performance include:

1. Raffinate feed.
2. Polymer *backbone* chemistry.
3. Molecular weight, number distribution.
4. Side chain distribution.
5. Active ingredient.
6. DWA ratio (when combined with other additives) in blend. Feed filter rate as a function of DWA ratio for a light neutral is shown in Fig. 33.70.
7. DWA dose, the concentration used. Filtration rate improvement for a light neutral as a function of DWA dose is shown in Fig. 33.69.
8. Asphaltene contamination.
9. Regulatory requirements (FDA approval).

Major DWA polymer backbone chemistries include:

1. Polyalkyl methacrylate (PAMA)
2. Polyalkyl acrylate (PAA)
3. Copolymerization of PAMA, PAA
4. Dialkyl fumarate vinyl acetate (DAFVA)
5. Ethylene vinyl acetate (EVA)
6. Wax naphthalene condensate.

Molecular weights of the DWA may vary from 10000 to 1000000. Molecular number, the *branchiness*, may range from 7000 to 300000. Side chain lengths may vary from C₁₄ to C₂₆ and with various distributions. Active ingredient may range from 10% to 100% with 15–30% the most typical. Dewaxed oil (light or heavy neutral) or toluene may be used as diluent. DWA viscosity will depend on the active ingredient and the diluent and the viscosities can be quite high and may affect pumpability.

33.35 DWA Mechanism

The exact mechanism of how the DWA works is still being studied. Leading theories include:

1. Co-crystallization of the DWA into the wax crystal matrix that changes growth direction of crystal planes
2. Agglomeration mechanism
3. Wax crystal modifier that associates with the surface to change crystal growth plane.

Fig. 33.69 Light neutral DWA dose response curve, DWA ratio 1 : 1

Fig. 33.70 Effect of DWA ratio on light neutral

Typically, DWA is stored at elevated temperatures. Positive displacement or centrifugal pumps are used for injection and various meters may be used to monitor the flow rate. Mass flow meters have been used with great success in the application.

Studies have shown that DWAs may be combined to give synergistic performance. Currently, because of the large number of variables (feed, DWA chemistry, etc.), it is not possible to predict DWA performance a priori and DWAs must be tested in a pilot plant that can simulate the propane dewaxing process. Laboratory and analytical tests typically over predict DWA performance due to favorable laboratory conditions and inability to simulate the plant.

33.36 Asphaltene Contamination

The presence of asphaltenes in the feed to the propane dewaxer or in the propane will significantly reduce the filtration rate and must be avoided. Asphaltenes may be present in the heavy neutral due to entrain-

ment from the VPS section below the heavy sidestream drawoff. Contamination may occur if the lube deasphalting unit (LDU) and propane dewaxer share propane.

33.37 Regulatory Requirements

The manufacturer using DWAs must determine if an FDA-approved DWA is required in their product market. The number of DWAs meeting FDA technical requirements is small and these DWAs command a premium in the marketplace. The qualification of new DWAs is expensive and takes a long time. DWA chem-

istry type, molecular weight (M_w), molecular number (M_n), polydispersity ($PDI = M_w/M_n$), unreacted monomer concentration, and concentration in the final product are some of the major factors the FDA considers and the candidate must pass technical specifications in these areas in order to obtain approval.

33.38 Glossary

- **API:** American Petroleum Institute.
- **Aromatic:** An unsaturated ring compound having a basic six-carbon-atom ring with either a hydrogen atom or a chain joined to each carbon atom.
- **ASTM:** American Society for Testing and Materials.
- **ATF:** Automatic transmission fluid.
- **Base oil:** A base oil is the base stock or blend of base stocks used in API licensed oil (see API 1509).
- **Base stock:** A base stock is a lubricant component that is produced by a single manufacturer to the same specifications (independent of feed source or manufacturer's location), that meets the same manufacturer's specification, and that is identified by a unique formula, product identification number, or both (see API 1509).
- **Base stock categories:** Base stock categories/base oil categories. The American Petroleum Institute (API) has categorized base oils into five categories. Groups I, II, III and are manufactured from refined crude oil. Group IV are fully synthetic (polyalphaolefin) oils. Group V are all those not covered in groups I–IV.
- **Base stock properties:** Key base stock properties may include properties such as viscosity, volatility, viscosity index (VI), pour point, cloud point, color and Conradson carbon (CCR).
- **Base stock slate:** A base stock slate is a product line of base stocks that have different viscosities but are in the same base stock grouping and from the same manufacturer (see API 1509).
- **Batch:** Any quantity of material handled or considered as a unit in processing.
- **Batch treat:** A treatment of a limited quantity of material with chemicals to improve quality.
- **Blowback:** The term applied to blow gas usage. Some call *blow gas* by a *blowback* or *blowback gas* term.
- **Blow gas:** Gas used to *blow* the wax cake from the filter cloth by being applied under pressure beneath the cloth.
- **Bright stock:** A vacuum distillation tower bottoms that has been deasphalted and extracted or hydrotreated and probably dewaxed as a heavy base stock.
- **BSI:** British Standards Institution
- **Caulking grooves:** The U-shape piece of metal welded to the drum deck. The resultant *grooves* are used to *caulk* the filter cloth into place. Also, lips on the grooves are used to retain the grid on which the cloth rests.
- **CCR:** Conradson carbon residue. A laboratory test that indicates the coke forming tendency of an oil. The amount of the residue remaining after evaporation and pyrolysis of the oil. Equivalent to micro carbon residue (MCR) test.
- **CCS:** Cold cranking simulator. A test used to determine the low temperature performance of lubricants when cranking a cold engine powered only by the battery and starter motor.
- **Controlled chillers:** SSE using cold filtrate to cool the slurry.
- **Carryover:** Entrainment of heavy phase into the light phase and out with the raffinate solution (essentially solvent at the tower top).

- *Carryunder*: Entrainment of light phase that has not settled from the heavy phase and exits with the extract solution (essentially feed at the tower bottom).
- *Centistoke*: The worldwide unit of kinematic viscosity.
- *Coalescence rate*: Relative rate at which fine, small droplets form larger droplets, which settle faster, forming a clarified oil layer.
- *Continuous phase*: Heavy, NMP-rich phase that forms an unbroken stream through the treater.
- *Corrosion*: The gradual eating away of metallic surfaces as the result of oxidation or other chemical action. It is caused by acids or other corrosive agents.
- *Crystallization*: May be defined as a phase change in which a crystalline product is obtained from a solution.
- *Cut*: The portion or fraction of a crude oil boiling within certain temperature limits.
- *Cut point*: The temperature limit of a cut or fraction, usually but not limited to a true boiling point basis.
- *DAO*: Deasphalted oil: The extract or residual oil from which asphalt and resins have been removed by an extractive precipitation process called deasphalting.
- *DAU*: Deasphalting unit: A process for removing asphalt from reduced crude or vacuum residua (residual oil) that utilizes the different solubilities of asphaltic and nonasphaltic constituents in light hydrocarbon liquids, for example, liquid propane.
- *Density*: The mass of a unit volume of a substance.
- *Deck pipes*: Each segment is drained by a series of pipes located along side each caulking groove.
- *DILCHILL™*: DILution CHILLing. ExxonMobil process where chilled solvent is added stagewise to an agitated tower. Mixing, cooling and crystallization occur in the tower.
- *Dilution ratio*: The ratio of solvent to waxy raffinate feed (vol/vol).
- *Dispersed phase*: Light, oil-rich phase which *bubbles* through continuous phase, then settles, and repeats the process on each tray.
- *Distillate*: Product of distillation collected by passing vapors through a condenser.
- *DPC*: Double pipe chiller.
- *DPE*: Double pipe exchanger.
- *Drum*: The horizontal drum on which the filter cloth is applied to its circumference surface.
- *Dry Wax*: The solid component present in a waxy feed at a certain oil pour point if all oil were removed from it.
- *DWO*: Dewaxed oil.
- *Entrainment*: Entrainment is the carryover of liquid by the vapor phase. Liquid may be in the form of a spray, foam or mist.
- *EXOLFINING*: An ExxonMobil extraction process used to extract aromatics from lube feedstocks to improve the VI and quality of lubricating oil base stocks, integrated with hydrofining.
- *Extract*: In solvent refining processes, that portion of the oil which is dissolved in and removed by the selective solvent; the solvent rich phase. Contains a low percentage of oil that is typically high in aromatic content.
- *Extraction*: The process of separating a material, by means of a solvent, into a fraction soluble in the solvent and an insoluble residue.
- *Feed retention drum*: Feed solution hold up drum.
- *Feed solution*: Waxy feed plus warm propane.
- *FFR*: Feed filter rate ($(\text{m}^3/\text{day})/\text{m}^2$ of filter cloth). Refers to feed only.
- *Filter cloth blinding*: The term applied to the reduction in filter rate due to wax or ice particles plugging up the flow paths in the filter cloth.
- *Filter hood*: The top part of the filter outer enclosure.
- *Filtrate (or wet) port*: The section or nozzle on the master valve that collects filtrate from the vat slurry.
- *Filtrate*: Liquid product (oil plus solvent).
- *Final dilution*: The last increment of solvent added after the shock chillers.
- *Foots oil*: The soft wax melted or dissolved/washed away during wax deoiling. In the old days, it was the oil drawn from the bottom (foot) or a pan separator for wax formed in a wax *sweater*.
- *Fractionation*: Fractionation is the separation of light and heavy fractions in the distillation tower.
- *Furfural*: An aldehyde obtained from corn shucks, wheat, or oat hulls, used in an extraction process for removing aromatic, naphthenic, olefinic, and unstable hydrocarbons from a lubricating oil charge.
- *GCD*: Gas chromatographic distillation (GCD). Chromatography technique used to separate and analyze compounds that can be vaporized without decomposition. A simulated distillation GC analysis using a gas chromatograph with a nonpolar column to determine the boiling-point distribution analysis of petroleum fractions.
- *Haze*: Visible, uncombined or flocculated, wax or water in dewaxed oil.
- *Hot wash*: The technique or the hot solvent used to periodically melt and dissolve wax out of the filter cloth.
- *Hydrofinishing*: The final step in base oil manufacturing uses H_2 and a catalyst to saturate the molecules, break undesirable molecular chain struc-

- tures, and improve the stability of the oil by removing oxygen and color bodies.
- **Immiscible:** Two phases, one oil rich and one solvent rich. Normally not desirable in solvent dewaxing.
 - **Incremental dilution:** Refers to the addition of solvent in increment to the waxy raffinate feed as it flows through the heat exchanger equipment.
 - **Internal reflux:** Portion of the light phase that springs from the heavy phase due to lower temperature at treater bottoms, and recycles back up the tower in the dispersed phase.
 - **ISO:** International Standards Organization.
 - **Kinematic viscosity:** The ratio of the absolute viscosity of a liquid to its specific gravity at the temperature at which the viscosity is measured.
 - **L/S:** Liquid-to-solid ratio in the wax cake. The liquids consist of oil and solvent or liquids to solids in the filter vat.
 - **LCA:** Lube crude approval process. A lube crude selection process used by base stock manufacturers that includes detailed steps to qualify a crude for purchase by the manufacturing organization.
 - **LHU:** Lube hydrofining unit to improve color stability of lube oils using hydrogen.
 - **Lead pipes:** The pipes on the leading side of each segment as the drum rotates.
 - **LPS:** Low pressure steam.
 - **Lube oil volatility – NOACK:** ASTM D-5800. A test method that provides an indication of the evaporation loss of lubricants in high temperature service.
 - **Lube oil volatility – capillary GCD:** An alternative to ASTM test methods D-5800 and D-5480 (withdrawn in 2003). The lubricant volatility is measured at 371 °C by capillary gas chromatography.
 - **Lubricant:** Any substance interposed between two surfaces in relation to motion for the purpose of reducing the friction and/or the wear between them.
 - **LVPS:** Lubes vacuum pipestill.
 - **Master valve:** Trunnion valve, the stationary sectioned casting in contact with the rotating end of the drum (i. e., the wear plate) at which the lead and trail pipe manifolds are dead ended.
 - **MCR:** Micro carbon residue. A laboratory test to determine the amount of residue remaining after evaporation and pyrolysis under specified conditions. Equivalent to Conradson carbon residue test.
 - **MEK:** Methyl ethyl ketone or loose term for ketone dewaxing unit.
 - **MEK OIW test:** Oil content of wax using ASTM D921 (MEK solvent at –25 °F).
 - **MIBK:** Methyl isobutyl ketone.
 - **Miscible:** One homogeneous phase. Usually preferred in solvent dewaxing. Refers to oil and solvent mixture.
 - **Miscibility temperature:** Temperature at which solvent and feed are completely miscible – all feed dissolved in solvent – and there is no phase separation in treater tower or in dewaxer slurry.
 - **MPS:** Medium pressure steam.
 - **NMP:** *N*-methyl-2-pyrrolidone, a solvent used as an alternate to furfural and phenol for the extraction of lubricating oil fractions.
 - **Naphthene:** A group of cyclic hydrocarbons also termed cycloparaffins. Polycyclic members are also found in the higher boiling fractions.
 - **Naphthenic crudes:** Class designation of crude oils containing predominantly naphthenes or asphaltic compounds.
 - **Neutral:** A VPS distillate, extracted, and dewaxed, made into a base stock.
 - **Normal paraffin:** A straight chain hydrocarbon in which no carbon atom is united with more than two other carbon atoms.
 - **OIW:** Oil in wax.
 - **OPEX:** Operating expenses.
 - **Pale oil:** A petroleum lubricating or process oil refined until its color is straw to pale yellow.
 - **Paraffin-base crudes:** Crude containing paraffin wax and practically no asphalt or naphthenes.
 - **Paraffinic:** Describing the paraffin nature or composition of crude petroleum or products therefrom.
 - **Paraffins:** A homologous series of open-chain saturated hydrocarbons of the general formula C_nH_{2n+2} of which methane (CH_4) is the first member.
 - **Paraffin wax:** A colorless wax extracted from paraffin-base lubricating oils.
 - **PDU:** Propane dewaxing unit to remove wax from oil using propane as a solvent.
 - **PNA:** Polynuclear aromatic: A compound composed of two or more aromatic rings (see aromatic). These compounds are under close scrutiny since they are generally considered to be carcinogens.
 - **Polarity:** A measure of the asymmetric distribution of a molecule's electrical charge. $MEK > MIBK > H_2O$.
 - **Polyalphaolefins (PAO):** Alpha-olefins are polymerized to make a polyalphaolefin (PAO). In an alphaolefin the carbon-carbon double bond is between the first and second carbon atoms. PAOs are useful basestocks in some synthetic lubes. PAOs are categorized by API as group IV and are fully synthetic.
 - **Pour point:** The temperature at which the oil will no longer pour.
 - **Predilution:** Solvent addition occurring before the precoolers. Sometimes called primary dilution.
 - **Prechillers:** In propane dewaxing, shell and tube exchangers that chill the feed solution before batch chillers.

- **Raffinate:** In solvent-refining practice, that portion of the oil which remains undissolved and is not removed by the selective solvent; the solvent lean phase. Contains a low percentage of solvent and typically a low aromatic content oil.
- **Rectification:** Rectification is the removal of heavy material from the vapor phase.
- **RI:** Refractive index.
- **SAE:** Society of Automotive Engineers.
- **Saybolt universal seconds (SUS):** A measure of kinematic viscosity, expressed as the time in seconds for 60 ml of fluid to flow through a standard Saybolt universal viscometer at a specified temperature. ASTM method D-88 describes the method and apparatus.
- **Scale wax:** Wax with an oil content of 1–5%, for example, wax from a two-stage dewaxer.
- **Segment:** Each drum segment is made up of a pair of the caulking grooves running longitudinally on the drum deck with the grid in between.
- **Selectivity:** A measure of the ability of a solvent to separate compounds of different structure, for example, aromatics from paraffins from naphthenes.
- **Service factor:** A quantity that relates the actual on-stream time of a process unit to the total time available for use of the unit. Frequently a ratio of the number of actual operating days divided by 365.
- **Settling Rate:** The rate at which droplets of the dispersed phase rise through and separate from the continuous phase.
- **Shock chillers:** Double pipe exchangers (see SSE) that use propane or propylene as a refrigerant.
- **Shock chilling:** Rapid cooling rates ($> 2\%/min$) shock the slurry resulting in smaller crystals and lower FFR. Rapid uncontrolled crystallization, characterized by high nucleation rates producing very small average crystal size.
- **Slack wax:** Wax with an oil content $> 5\%$, for example, wax from one-stage dewaxer.
- **Solubility:** Degree to which the oil (mainly aromatics) dissolves in the NMP. This is a function of aromatic type and concentration, changes from one grade to another as well as for the same grade from one crude to another.
- **Solvent deasphalting:** A process for removing asphalt from reduced crude or vacuum residua (residual oil) which utilizes the different solubilities of asphaltic and nonasphaltic constituents in light hydrocarbon liquids, e.g., liquid propane.
- **Solvent neutral oil (SNO):** A paraffinic base oil that has been solvent refined, dewaxed, and finished and is ready to be used in blending or compounding.
- **SSC:** Scraped surface chiller: Usually a double pipe design of 6, 8, and 12 in diameter with internal scrapers to remove wax from the cold walls. Typically, a refrigerant such as propane, propylene, or ammonia is used on shell side. Used in conventional dewaxing.
- **SSE:** Scraped surface exchanger. Usually a double pipe design of 6, 8, 12 in diameter with internal scrapers to remove wax from the cold walls. Typically cold filtrate is used on shell side. Used in conventional dewaxing.
- **SSU:** See Saybolt universal viscosity.
- **Stability:** Resistance to chemical change.
- **Stripping:** Stripping is the removal of light material from the liquid phase.
- **TAN:** Total acid number.
- **Third phasing:** Immiscible condition in a dewaxer where you have two liquid phases and a solid (wax phase).
- **Trail (or lag) pipes:** The pipes on the trailing side of each segment as the drum rotates.
- **Trunnion valve:** Master valve: The stationary sectioned casting in contact with the rotating end of the drum (i. e., the wear plate) at which the lead and trail pipe manifolds are dead ended.
- **Typical lube processes:** Typical lube processes include: Lube vacuum distillation (VDU) or vacuum pipestill (VPS) to control the viscosity and volatility of the oil. Solvent extraction of the aromatics to control the viscosity index. Solvent dewaxing to control the pour point of the oil. Hydrofinishing to stabilize the oil.
- **Vat:** The bottom part of the filter outer enclosure into which the filter feed slurry flows.
- **Viscosity, dynamic:** Measure of the internal resistance to deformation caused by shear or tensile stress.
- **Viscosity index:** A measure of the change in viscosity with temperature; ASTM D-2270.
- **Viscosity, kinematic:** The ratio of the absolute (dynamic) viscosity divided by the fluid mass density.
- **VPS (VDU):** Fractionation equipment, a vacuum pipestill (VPS) or vacuum distillation unit (VDU) is used to distill atmospheric bottoms into gas oil or lube distillate cuts.
- **VTB:** Vacuum lower (VPS) bottoms, or vacuum residue or vacuum resid.
- **Warm-up:** A step in the batch chiller sequence during which the chiller internal metal wall is warmed in preparation of accepting feed, and avoiding shock chilling at the wall.
- **Warm solution drum:** Drum containing prechilled feed solution.

- *Wash*: Generally the term used for the cold solvent applied to the wax cake.
- *Wax cake*: Solid product consisting of, generally, 2–10 liquids (solvent plus oil) to solids content in the discharged wax cake.
- *Wax doctor knife*: The deflector blade that rides against the filter cloth or winding wire. The blade keeps the wax cake from falling off the drum back into the feed slurry after the blow gas dislodges the cake.
- *Wax, Refined*: Wax of, usually, 0.5–2% oil-in-wax produced from deoiling.
- *Wax, Scale*: Wax of, usually, 2–10% oil-in-wax produced from two stage dewaxing.
- *Wax Scroll*: The screw conveyor rotating in the wax trough. All scrolls in dewaxing service are the center-discharge type.
- *Wax, Slack*: Wax of, usually, > 10% oil-in-wax produced from one stage dewaxing.

Premium Lub

34. Premium Lubricant Base Stocks by Hydroprocessing

Stephen K. Lee, John M. Rosenbaum, Yalin Hao, Guan-Dao Lei

This chapter discusses the manufacture of premium lubricant base stocks using hydroprocessing technology. After a brief introduction about base stock demand and key base stock properties, we discuss the benefits of premium base stocks versus solvent-refined base stocks and how premium stocks help to meet the stringent specifications of automotive engine oils. The focus of this chapter is on the chemistry and processing of base stocks by modern refining technology, which includes hydrocracking, hydroisomerization, and hydrofinishing. Also included is a brief discussion of syngas-to-liquids (STL), also called gas-to-liquids (GTLs).

Base stocks are the core components for many lubricants and specialty products, including automotive engine oils, gear oils, industrial oils, turbine oils, greases, process oils, food-grade oils and medicinal oils. According to API 1509 Appendix E, a base stock is a lubricant component that is produced by a single manufacturer to the same specifications (independent of feed source or manufacturer's location); that meets the

same manufacturer's specifications; and that is identified by a unique formula, product identification number, or both. A base oil is a base stock or blend of base stocks used in an API-licensed oil [34.1]. The terms base oil and base stock are frequently used interchangeably in the industry. This is the case in this chapter. The specific functions for base stocks and additives in a lubricant oil are summarized in Table 34.1.

Fig. 34.1 Global base oils volume. Source: Lubes'n'Greases 2014 Lubricants Industry Factbook. Used with permission. May not equal 100 due to rounding [34.2]

Table 34.1 Functions of base oils and additives in a lubricant

Base oil contributions	Additive contributions
Viscosity grade	VI improvement
Low pour point	Corrosion resistance
High VI (Viscosity Index)	Low-temperature flow improvement
Stability	Dispersancy and detergency
Volatility	Oxidative and thermal stability
Solvency for additives	Antiwear improvement
	Extreme pressure improvement
	Friction modification
	Foam prevention

Total worldwide demand for lubricants is expected to rise only slightly for a number of years to come. As a result, the overall base oil demand is growing

slowly as well. Between existing plants, plant expansions, and new grassroots facilities, it is expected there will be adequate worldwide supply for the foreseeable future [34.2]. However, the demand for premium base stocks made from hydroprocessing is expected to continue growing significantly compared to base stocks made by solvent processing. API Groups II and III base stocks (hydroprocessed) are considered to be premium base stocks. Figure 34.1 shows the growth of premium base stocks globally. It increased from 21% of total base oil volume in 2005 to 42% in 2014 [34.2]. The growth of Groups II and III base stock volume virtually matches the decline in Group I (solvent-processed). Engine oils are by far the largest market for premium base stocks. Growth will be led by strong demand in the developing Asian countries, especially China and India.

34.1 Key Base Stock Properties

Some of the key base stock properties are viscosity, viscosity index (VI), pour point, volatility, and oxidation stability. A lube base stock must meet a viscosity specification within a narrow range, a maximum pour point specification, a volatility specification to limit the amount of low boiling molecules, and stability that is sufficient to meet the lubricant's required operating life.

Viscosity is the physical property that measures the fluidity of the base stock. Viscosity is a strong function of temperature. Two commonly used viscosity measurements are dynamic viscosity and kinematic viscosity.

Dynamic viscosity is the flow due to an applied mechanical stress. Cold-cranking simulator (CCS) viscosity at -25°C for engine oils and Brookfield viscosity at -40°C for automatic transmission fluids (ATF) are examples of dynamic viscosity measurements. The SI unit of dynamic viscosity is Pa s. The traditional unit

used is centipoise (cP), which is equal to 0.001 Pa s (or 1 mPa s). The industry is slowly moving to SI units.

Kinematic viscosity is the ratio of dynamic viscosity to density. The SI unit of kinematic viscosity is mm^2/s . The other commonly used units in industry are centistokes (cSt) at 40 and 100°C and Saybolt Universal Second (SUS) at 100 and 210°F . ASTM D445 (cSt) and ASTM D2161 (SUS) are the commonly used methods to measure kinematic viscosity. Conveniently, $1 \text{ mm}^2/\text{s}$ equals 1 cSt.

Typically, the naming of viscosity grades for neutral lube base stock, such as 100 Neutral and 600 Neutral, comes from the viscosity measured in SUS at 100°F . For the very heavy grades, such as 150 Bright Stock, the 150 viscosity is measured in SUS at 210°F .

Table 34.2 shows some typical viscosity grades for Groups II and III neutral oils.

Table 34.2 Typical base stock viscosity grades

Group II base stocks			
Grade	Kinematic viscosity at 100 °C (KV100), cSt	Kinematic viscosity at 100 °F, SUS	Mid-boiling point, °F
Light Neutral – LN (100N–110N)	≈ 4.0–4.2	≈ 100–110	≈ 750–760
Medium neutral – MN (220N–225N)	≈ 6.3–6.6	≈ 210–220	≈ 820–840
Heavy neutral – HN (600N)	≈ 11.8–12.2	≈ 530–580	≈ 930–960
Group III base stocks			
Grade	Kinematic viscosity at 100 °C (KV100), cSt	Kinematic viscosity at 100 °F, SUS	Mid-boiling point, °F
4 cSt	≈ 4.2–4.3	≈ 100–105	≈ 790–810
6 cSt	≈ 6.0–6.5	≈ 165–195	≈ 850–880
8 cSt	≈ 7.6–8.0	≈ 235–260	≈ 900–920

Viscosity index (VI) is an empirical number used to measure the change in the base stock's kinematic viscosity as a function of temperature. It is based on an arbitrary scale first developed around 1928. At that time, the best paraffinic lube oil (Pennsylvania-grade crude) was assigned a VI of 100 and the worst naphthenic lube oil (Louisiana-grade crude) was assigned a VI of 0. The higher the VI, the less relative change in viscosity with temperature. High-VI base stocks are desired for most of the lubricant applications, especially in multigrade automotive engine oils and other automotive lubricants subject to large operating temperature variations. In addition to the VI from the base oil, VI improver additives are used to improve the VI of the finished lubricant. These are called VI improvers (VIIs) or viscosity modifiers (VMs). ASTM D2270 is a commonly accepted method to determine VI.

Figure 34.2 shows the VI for various classes of molecules in the base stock boiling range. Normal paraffins have the highest VI, naphthenes (cycloparaffins) have intermediate VI, and aromatics the lowest. Isoparaffins have slightly lower VI than normal paraffins. However, they also have lower pour points, which make them preferred molecules for base stocks.

Pour point is the lowest temperature at which movement of the test specimen is observed [34.3]. It is one of the most important properties for base stocks as most lubricants are designed to operate in the liquid phase. Low pour point is usually desirable, especially in cold weather lubrication. Typical maximum pour point specs for conventional petroleum base stocks range from -9 to -18 °C.

Normal paraffins are the hydrocarbon molecules with the highest pour point. They must be removed by solvent dewaxing or catalytic dewaxing, or converted to isoparaffins by hydroisomerization for the base stocks to achieve the target pour points.

**Fig. 34.2** Viscosity index of various chemical molecules

ASTM D97 is the standard manual method to measure pour point. It is being gradually replaced by automatic methods, such as ASTM D5950 and ASTM D6749.

Volatility is a measurement of oil loss from evaporation at an elevated temperature. It has become a very important specification due to emission and operating life concerns, especially for lighter-grade base stocks. Volatility is dependent on the oil's molecular composition, especially at the front end of the boiling point curve. The efficiency of the distillation step in the base stock manufacturing process can have a large impact on volatility. The VI of a base stock can also greatly impact the volatility, as for a given viscosity grade, a highly paraffinic base stock (higher VI) will usually have a higher boiling range than a base stock with a lower paraffin content (lower VI).

Noack (ASTM D5800) is a commonly accepted method to measure volatility for automotive lubricants. The Noack test method itself simulates evaporative loss in high-temperature service, such as in an operating internal combustion engine.

Simulated distillation by gas chromatography (GC) is also used as an indicator of volatility by measuring the front end of the boiling point curve, e.g., % distilled at 700 °F. ASTM D2887, ASTM D6352, and ASTM D7213 are commonly used GC methods. In comparison to Noack, they are faster and have excellent precision. However, Noack is still the generally accepted volatility specification for automotive engine oils and thus for base stocks. This is because the majority of global base oil volume is consumed in automotive lubricants, and these lubricants generally have more demanding performance requirements than most industrial lubricants, so base stock manufacturers tend to focus their specifications around the automotive industry.

Flash point (ASTM D92) is another indicator of volatility as it measures the temperature at which there

is sufficient vapor of a specimen to ignite, which also reflects the front end of the boiling point curve. Flash point is a required safety specification for many base stocks.

Stability is a broad term to describe the base stock's resistance to chemical reactions under heat and/or light in both storage and operating conditions. It can be measured in terms of the base stock's appearance and estimated from chemical composition. Because stability of a finished lubricant is so strongly dependent on additives, most stability specifications are based on finished lubricant performance tests. That being said, base stock stability is a strong contributor to finished lubricant stability.

ASTM D1500 is a commonly used color specification. Most premium base stocks have a D1500 reading of less than 0.5 when they are fresh. An increase in D1500 is an indication of formation of oxidation products. Many base stock manufacturers have their own proprietary test methods to measure oxidation and storage stability of base oils.

34.2 Base Stock Categories

All base stocks used for automotive engine oils are divided into five general categories based on API guidelines (Table 34.3). Groups I, II, and III base stocks are manufactured from paraffinic crudes in refineries. Sometimes they are referred to as mineral base stocks or petroleum base stocks to be differentiated from synthetic base stocks manufactured from well-defined chemical compounds through specific chemical processes, such as polyalphaolefins (PAOs, Group IV). Group V base stocks include all other base stocks not included in Groups I, II, III, or IV, such as pale oils (naphthenic base stocks), which are manufactured from naphthenic crudes, and various kinds of synthetic base stocks.

Groups I, II, and III base stocks are distinguished from each other in terms of sulfur and saturate contents, and viscosity index. Group I base stocks, which are also called conventional base stocks, are produced with solvent refining technology. Group II and Group III base stocks, often referred to as premium base stocks in

the industry, are manufactured through hydroprocessing technology. Groups I and II base stocks are used in the vast majority of lubricants.

As a side note, a 1999 decision by the National Advertising Division of the Better Business Bureau declared that automotive lubricants made using Group III base stocks could be labeled *synthetic*. That council ruled that the very severe processing conditions required to make Group III base stocks, resulted in most of the molecules being created in the processing from molecules which were in the original crude. Furthermore, the performance of Group III lubricants could be formulated as comparable to that provided by PAOs. This has led to Group III lubricants being marketed as *synthetic* in most of the world.

In recent years, these categories for marketing purposes have been informally expanded into Group I+, Group II+, and Group III+ and Group IV+, with classification based primarily on different VIs:

Table 34.3 API base stock categories

Group	Sulfur (wt%)		Saturates (wt%)	VI
I	> 0.03	and/or	< 90	80–119
II	≤ 0.03	and	≥ 90	80–119
III	≤ 0.03	and	≥ 90	≥ 120
IV	All polyalphaolefins (PAOs)			
V	All stocks not included in groups I–IV (pale oils and non-PAO synthetics)			

- Group I+ (103–108 VI)
- Group II+ (111–119 VI)
- Group III+ (130+ VI for light neutral base stocks)
- Group IV+ (5–15 higher VI than conventional PAOs made strictly from 1-decene).

34.3 Why the Need for Premium Base Stocks?

Automotive engine oils are by far the largest market for base oils. Figure 34.3 shows the typical components of engine oils, which contain 75–90 wt% base oils.

The engine oil performance specifications have become more stringent due to requirements for lower emissions, longer drain intervals, and better fuel economy. This has resulted in the demand for better performance base stocks. These performance traits include:

- Lower base stock viscosity, which increases fuel economy by improving cold start performance and reducing friction in engines.
- Lower volatility (e.g., Noack), which reduces the loss of oil from evaporation and emissions. This is very important to prevent the oil from thickening and requiring addition of oil between changes, and thus reduces oil consumption. The thickening of oil in the crankcase can reduce fuel economy and impair lubrication and cooling of critical engine parts.
- Improved oxidative and thermal stability, which give longer drain intervals.
- Improved lubricant performance at low and high temperatures, which meet the needs of modern engine designs. Engine oils must allow engines to crank and pump oil at arctic temperatures, and also provide lubrication at high operating temperatures.

Moreover, there is an increasing trend to lower sulfated ash, phosphorus, and sulfur (SAPS) specifications for automotive engine oils to protect the exhaust catalysts. Due to their high sulfur content, Group I base stocks are less likely to be used in formulations designed to meet these specifications.

In the past, PAOs were used in formulation to achieve the stringent requirements listed above. PAOs have excellent performance characteristics as lubricant base stocks, including high VI, low volatility, superior low-temperature fluidity, and great oxidation stability. However, they are more expensive than mineral base stocks due to their higher raw material and processing costs. Modern hydroprocessed base stocks, after careful formulation, can often rival the performance of PAOs in many applications. Today's refiner, by using hydroprocessing technology, can economically manu-

This chapter focuses on the discussion of producing Group II and Group III base stocks using hydroprocessing technology. Production of Group IV and other synthetic base stocks are covered in Chap. 35 of this book by Wu et al.

facture high-quality base stocks (Group II/III) derived from crude oil and refinery process streams such as vacuum gas oils (VGO), unconverted oil (UCO) and deasphalted oil (DAO). In addition, raffinate, foots oil and slack wax produced in existing solvent base oil facilities are excellent feeds to make premium Group III/III+ base stocks using hydroprocessing. Wax from a gas-to-liquids plant is an excellent feed to manufacture exceptionally high-quality base stocks (Group III/III+) when fed to a hydrocracker followed by a wax hydrosomerization and hydrofinishing unit.

Figure 34.4 shows that when formulated properly, Group II and Group III base stocks are sufficient (and required) to produce automotive engine oil products that meet the most stringent specifications [34.4]. This figure provides the screening process that an engine oil formulator will use to identify suitable base stocks when designing a new automotive lubricant. The first two parameters to be considered are viscosity and volatility. For a multigrade engine oil, the viscosity the formulator will first focus on is the cold-cranking simulator viscosity (CCS, ASTM D5293). The lighter the base stock, the lower the viscosity – including the CCS. On the other hand, as the base oil gets lighter, the Noack volatility increases.

Each curve in Fig. 34.4 is constructed by blending two or more base stocks from a single base stock slate. For example, the left side of the green curve shows the blend properties for a typical Group II 100N blended with 220N in varying proportions, and the right side

Fig. 34.3 Typical components in automotive engine oil

Fig. 34.4 Base stock suitability for blending premium engine oils (after [34.4])

continues the curve by blending increasing percentages of 600N with 220N. Likewise the Group II+, Group III and Group IV (PAO) curves are derived by blending base stocks from those groups. As one moves from the upper right to the lower left, the VI (and blending power) of the base stock group increases. But so, of course, does the cost of the oils. (Note: blending power is not to be confused with thickening power, but is rather a function of the viscosity index of a com-

ponent in an engine oil blend. Higher VI components are required to meet the critical low-temperature viscosity specifications while also meeting tight volatility requirements.)

Putting the rectangular blending spaces together with the blending curves shows graphically the strategy of blending various base stocks together to hit the viscosity and volatility requirements of various engine oils. If a rectangle falls below a particular curve, then that base stock group cannot be used to blend the viscosity grade(s) shown in the rectangle. Thus, the formulator can quickly see that a 5W-20 engine oil cannot be blended with a Group I or a Group II base stock. However, most North American 5W-20s can be easily blended with Group II+, a Group III, a Group IV, etc. Also noteworthy is that a Group II 220N is very close to the 15W-40 rectangle. This is the reason that essentially all 15W-40 heavy duty engine oils (HDEOs) with modern high-performance claims use almost 100% Group II 220N in their base stock blends.

Because Group III/III+ base stocks are more available and cheaper, they have replaced PAOs in many lubricant applications, except where PAOs are required for extreme lubricant starting and operating conditions. Currently, PAOs account for less than two percent of the total global base oil capacity. Most synthetic lubricants are predominantly Group III/III+ based.

34.4 Lube Base Stock Manufacturing Technologies

Today, there are two primary refining technologies used to manufacture lubricant base stocks from crude oil. The conventional technology is solvent refining, and the modern technology is hydroprocessing. Both technologies include the following basic steps in the manufacturing process: vacuum distillation, VI upgrading, dewaxing, and finishing (Fig. 34.5).

In the vacuum distillation step, a crude oil long residuum (or atmospheric column bottom) is distilled in a vacuum column to produce lube VGO cuts and residuum. The VGO cuts are used to manufacture neutral oils and the residuum is used to manufacture bright stock. These cuts are distilled to the proper viscosities that are optimum for the desired base stock products.

Conventional solvent refining and modern hydroprocessing technologies are fundamentally different in terms of molecular transformation in the VI upgrading and dewaxing steps. No chemical reactions and molecular transformations take place in the solvent refining processes except in the final hydrofinishing step. Molecules that are not friendly for lubricant applications, e.g., aromatics and sulfur compounds with low VI and normal paraffins with high pour point, are re-

moved by various chemical and physical separation techniques. In the VI upgrading step, low-VI molecules are extracted with a solvent such as *N*-methylpyrrolidone (NMP), phenol, or furfural. The upgraded lube oil is called raffinate (or waxy base stock) and the highly aromatic byproduct is called extract. In the following dewaxing step, raffinate is chilled in the presence of a solvent mixture (methyl ethyl ketone (MEK)-toluene and methyl ethyl ketone-methyl isobutyl ketone (MEK-MIBK) being the most common) and vacuum filtered for wax removal to meet a pour point specification. Because a considerable amount of aromatics and heteroatom compounds remain in the finished base stocks, solvent refining makes only Group I base stock, except in the very few plants with hybrid processes. This will be discussed in Sect. 34.9.

In hydroprocessing, molecules in the VGO cuts are rearranged and selectively cracked and converted into base stocks. Hydroprocessing gives higher total base stock yield than solvent refining from the same feed stock. Moreover, it leads to Group II and Group III base stocks with much improved purity and performances. Detailed discussions on base stock manufacture through

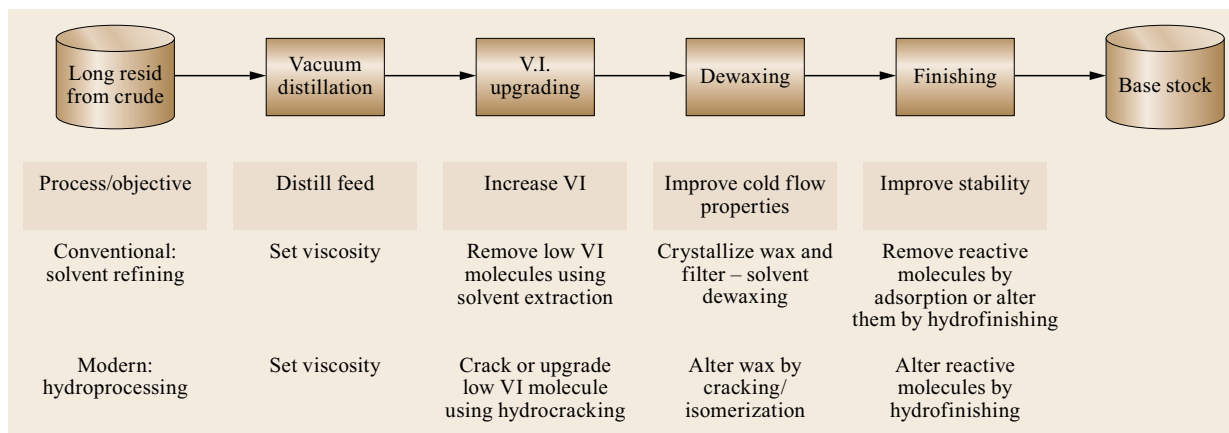

Fig. 34.5 Lube base oil simplified manufacturing steps

hydroprocessing technology are covered in Sects. 34.5–34.8.

Crude oil selection is critical for base oil economics. With solvent refining, the crude oil must have innate lube oil molecules to begin with. Therefore, a premium-grade crude oil, such as Arabian Light or other high-quality paraffinic crudes, must be used. The better the crude quality, the higher the lube stock yield. In contrast, refineries have much more flexibility to use a wider variety of crudes for base stock manufacture with hydroprocessing technology. This is one of the major advantages of hydroprocessing over solvent extraction technology. Hydroprocessing enables refiners to optimize crude selection around the entire refinery, not just around the base oil plant. Another advantage of hydroprocessing is that the byproducts are high value fuels while solvent processing produces a relatively low-value extract. It should be further noted that hydroprocessing frequently has lower capital and operating costs than solvent refining [34.5].

Bright stock is a very high viscosity base oil. Its major applications include automotive gear oils, marine lubricants, and heavy viscosity grade industrial oils. To manufacture bright stock, vacuum residuum must first be solvent deasphalted to obtain a deasphalted oil (DAO). Solvent deasphalting removes large, multiring compounds that cannot be handled by either the solvent extractor or the hydrocracker. Generally, propane is the

solvent used for deasphalting residuum. The DAO is then upgraded into a heavy base stock by either solvent processing (Group I bright stock) or hydroprocessing (generally Group II bright stock).

The majority of the world's bright stock supply is from solvent processing. With the demand for Group I neutral oils either declining or stagnant in all regions, bright stock capability has become a key economic driver to keep the solvent refining plants from rationalization. As the Group I plants with high operating costs continue to shut down, bright stock supply is expected to remain tight in the years to come.

Hydrotreating/hydrocracking DAO or a blend of DAO and VGO, followed by dewaxing and hydrofinishing produces a Group II bright stock with low levels of impurities. Group II bright stock offers a potential for high performance lubricants with its improved oxidation stability. However, due to its lower solvency, Group II bright stock cannot readily replace Group I base stock in many current formulations, especially for marine lubricants. Nevertheless, with advances in additive technology, formulations with Group II bright stocks are expected to be developed in the coming years because of the pressures for alternative bright stock supply and improved lubricant performance. Current Group II bright stock producers include IKC in Japan, SK in South Korea, Karamay in China, and IOCL in India.

34.5 All-Hydroprocessing Route for Lubricant Base Stocks

Lube hydroprocessing involves reactions of hydrocarbons and hydrogen at high pressure and moderate temperatures over various catalyst systems. The refinery processes to manufacture lube base stock using an integrated all-hydroprocessing route, as shown in

Fig. 34.6, consist sequentially of the processing steps hydrotreating/hydrocracking, catalytic dewaxing and hydrofinishing [34.6].

The purpose of the hydrotreater/hydrocracker is to upgrade the base stock to the target VI number. Cat-

Fig. 34.6 Simplified all-hydroprocessing flow scheme for base oils

alytic dewaxing is the step that converts the waxy, high pour point hydrocrackate into a wax-free product at a target pour point. Hydrofinishing is the final polishing step to improve color and stability by saturation of trace aromatics and residual polar hydrocarbons.

Chevron's Richmond Refinery Lube Oil Plant (Fig. 34.7) was the world's first all-hydroprocessing plant to manufacture lube base oil. This plant has been operating since 1984.

As mentioned in the previous section, an all-hydroprocessing route provides a refinery much more flexibility to manufacture premium base stocks from a larger variety of crude oils and feed stocks than a solvent plant. In addition, the performance of these base stocks is superior to those from a solvent-refined plant for engine oils and many other applications. These are the principal reasons why virtually all base oil plants built in the past 20 years use hydroprocessing.

Fig. 34.7 Chevron's Richmond Refinery Lube Oil Plant

Figure 34.8 shows a comparison of the impurity levels in Group I and Group II light neutrals. The Group II LN sample is essentially free of sulfur and nitrogen. The aromatic content is below 1 wt%. For engine oils, lower impurity levels will result in a longer-lasting lubricant, and the higher saturate levels will give better soot dispersancy and enable other additives such as detergents and wear inhibitors to function better. This is the case for most internal combustion engines, with the exception of those marine diesel engines that burn fuels with high asphaltene contents. Although Group II base stocks with proper additives can still work well in marine engine oils, Group I base stocks still have an economic advantage as they are better able to keep highly aromatic and

Fig. 34.8 Impurity levels in Group I and II base stocks (Ar and S, wt%; N, ppm)

polar compounds in solution with less detergent additives.

The all-hydroprocessing route also can make Group III base oils. This is done by increasing the severity of the hydrocracker operation to increase the VI of the base oil. Group III base oils via the all-hydroprocessing route have greatly improved oxidation stability and low temperature performance than conventional Group I base stocks. In addition to higher VI, they may exhibit better stability than Group II base stocks. Figure 34.9 shows the comparison of oxidation stability for the various classes of unadditized base stocks. The data is from a bench oxidation test designed to simulate a gasoline engine running at high temperature under high load. The time shown is the number of hours for the oil to consume a standard liter of oxygen. A longer duration means a higher quality and more stable base oil. The performance of Group III base stock in this test is close to the performance of PAOs, a big reason why lubricant

Fig. 34.9 Base oil oxidation stability tests.

* Data from Chevron proprietary oxidator test; longer time duration is better oxidation stability

companies are able to replace PAOs with Group III in some formulations [34.7].

34.6 Hydrotreating/Hydrocracking

Hydrocracking is the catalytic conversion process that converts heavy petroleum feedstocks (VGO, DAO, UCO, wax, etc.) into high-quality fuels and waxy base stock products. It is one of the two major heavy oil catalytic conversion processes used in modern refining, with the other being fluid catalytic cracking (FCC). There are two broad classes of reactions that take place in the hydrocracking process: (1) hydrotreating, in which impurities such as nitrogen, sulfur, oxygen, and metals are removed from the feedstock using base metal oxide catalysts; and (2) hydrocracking, in which carbon-carbon bonds are cleaved with hydrogen addition over bifunctional catalysts. When hydrocracking is used in a base oil plant, it is often referred to as lube hydrocracking, in comparison to fuel hydrocracking for the production of naphtha and mid-distillate fuels such as jet and diesel. Sometimes lube hydrotreating and lube hydrocracking are used interchangeably, which is the case for this chapter.

The lube hydrocracker does the following work to produce base stock hydrocrackates, which are the heaviest products from the hydrocracking reactions:

1. Increases the VI of the feedstock to the target VI.
2. Removes sulfur and nitrogen from the feedstock to produce a high-quality hydrocrackate to feed the isomerization dewaxer.
3. Saturates aromatics.

34.6.1 Hydrotreating and Hydrocracking Chemistry

Hydrocracking is the most severe step in the all-hydroprocessing process scheme. It usually consumes more hydrogen than the dewaxing and finishing steps combined. Some of the key reactions that occur in a hydrocracker include: hydrodesulfurization (HDS), hydrodenitrication (HDN), aromatic saturation, or hydrodearomatization (HDA), and hydrocracking/isomerization. They are summarized in Fig. 34.10 with increasing severity from top to bottom.

High sulfur content in the hydrocrackate is a poison to the noble metal catalysts in the catalytic dewaxing and hydrofinishing units and thus must be removed in the hydrocracker. During the HDS reactions, carbon-sulfur bonds in alkyl sulfides and thiophenes are broken readily through hydrogenolysis in the presence of base metal sulfide catalysts. The HDS reactions become much more difficult if the sulfur is hindered in substituted dibenzothiophenes, e.g., 4,6-dimethyldibenzothiophene. In this case, the molecule must be (at least partially) hydrogenated in order to free the sulfur atom from its aromatic ring and subsequently break the C-S bond. Deep HDS of a VGO feed reduces the sulfur content from roughly 1–3 wt% to less than 10–20 ppm in the waxy base stock.

Deep HDN faces the same dilemma as deep HDS. The rate-limiting step in the HDN reaction pathway

Fig. 34.10 Examples of chemical reactions occurring in a base oil hydrocracker

is the saturation of the aromatic ring. What makes this the slowest step is that the most refractory nitrogen molecules, such as substituted carbazoles, have the nitrogen atom embedded in the aromatic ring in a fairly inaccessible location [34.8]. As with sulfur, the aromatic ring containing the nitrogen atom must be saturated before the C–N bond can be broken. The nitrogen level is reduced to as low as < 2 ppm with the deep HDN. Nitrogen at an elevated level is a temporary poison that lowers the dewaxing catalyst activity, which will be discussed in detail later in this chapter.

HDA is a thermodynamically reversible process in which naphthenes can lose hydrogen to form aromatics if conditions are appropriate. Both hydrogen partial pressure and reaction temperature have a strong impact on the equilibrium constants. As the HDA reactions are exothermic, increasing reaction temperature would lead to higher aromatic contents at equilibrium. As higher temperature is required for the reaction to take place at a reasonable rate, aromatic saturation becomes a battle of kinetics against thermodynamics. If raising the reactor temperature decreases the product aromatic content, the reaction is described to be under *kinetic control*. Otherwise, it is under *thermodynamic control* [34.9]. Increasing hydrogen partial pressure can help to avoid undesirable thermodynamic control.

It is difficult to get total aromatics saturation as a hydrocracker because both the equilibrium and rate constants for the HDA reactions vary with aromatic types. Rates of saturation for monoaromatics are much smaller than those for diaromatics, which in turn are smaller than those for polycyclic aromatics (PCAs). Therefore, saturation of mono- and diaromatics are more

Fig. 34.11 Effect of temperature on aromatics at constant LHSV

favorable at a higher reactor temperature for a given hydrogen pressure. On the other hand, saturation of the PCAs are more favorable at lower temperatures because of the equilibrium constraint. Higher hydrogen pressure will favor the saturation of all types of aromatic molecules at a wider temperature range. Figure 34.11 shows that the hydrocracker reactor temperature drives the total product aromatics to a low level, but bumps up against equilibrium at high temperatures. At higher reaction temperatures, equilibrium competes against kinetics and dehydrogenation reactions become significant.

There are a couple of strategies to achieve near-complete aromatic saturation in an all-hydroprocessing lube plant. Building a plant that operates at a very high hydrogen pressure is one method. The very high hydrogen pressure results in a wider temperature range for the saturation of all aromatics. For example, with very high hydrogen pressure, as the temperature is raised to saturate the mono- and diaromatics, PCAs are also saturated to naphthenes. Building an all-hydroprocessing plant that operates at very high pressure, such as approaching 3000 psig, is very expensive, but in the early days of hydroprocessing, catalyst design expertise was limited and this was the only option aside from using solvent technology. A more cost-effective alternative is to design a lube plant to operate at a relatively lower pressure and do the aromatic saturation in two sequential temperature steps. The hydrocracker/hydrotreater and hydroisomerization dewaxer operate at higher temperatures and remove most of the mono- and diaromatics. The final-step hydrofinisher operates at a lower temperature and saturates the larger PCAs to improve the color and the oxidation stability of the base oil.

While HDS, HDN, and HDA convert impurities from the feedstock and modestly increase product VI,

Fig. 34.12 VI improvement with hydrotreating and hydrocracking reactions

ring opening reactions that occur during hydrocracking significantly improve product VI by converting low-VI PCAs and polycyclic naphthenes to naphthenes that have fewer rings and much higher VI (Fig. 34.12). However, the reaction does not always stop after ring opening. The paraffinic side chain attached to the original aromatic molecule can easily break off (dealkylation), resulting in molecules (side chains and ring fragments) that shift into the fuels boiling range. In addition, some molecules can shift to a lighter waxy base stock. The ideal lube hydrocracker would severely hydrotreat the feed to remove organic nitrogen and sulfur molecules to low levels and improve VI through HDA and ring opening reactions with no appreciable cracking of the base stock into light products (fuels and gas). In reality, the conversion in a lube hydrocracker is typically 30–40% for Group II base stocks made from a typical Arabian Gulf crude. A conversion level greater than 60% is generally required for Group III base stocks. The impact of hydrocracking conversion on VI of 700 °F+ hydrocrackate is shown in Fig. 34.13.

Through HDA, ring opening, and cracking reactions, lube hydrocracking not only increases hydrocrackate VI, but also lowers its viscosity (Fig. 34.14, Table 34.4). Its pour point remains in the positive domain due to the high paraffinic content. Most of the normal paraffins present in the crude are very difficult to crack and go through the hydrocracker unaltered. Hydrocrackate is thus a waxy base stock.

Fig. 34.13 VI improvement with increasing hydrocracker conversion – Arabian Heavy VGO

Fig. 34.14 Viscosity of hydrocrackate decreases as cracking conversion increases

Table 34.4 Summary of changes to base oil in the hydrocracker

Increase VI	Decrease viscosity
Reduce sulfur	Reduce nitrogen
Reduce aromatics	Increase naphthenes
Increase isoparaffins	Lower pour point
Produce transportation fuels	Reduce average molecular weight
Reduce carbon residue	Improve color

34.6.2 Crude Oil Selection for Base Stock Production

Hydrocracking permits the economic upgrading of VGOs with relatively low paraffin content, such as those from Alaskan North Slope crude, into base stocks. However, there are limits. Vacuum gas oils derived from very heavy refractory crudes oils cannot be economically used to manufacture base stocks. Figure 34.15 shows that VGO from San Joaquin Valley crude is essentially impossible to be upgraded to

Fig. 34.15 Different crude oils require different conversion level to make base oils (solvent dewaxed VI)

lube base stock even at very high conversion levels, using typical lube hydrocracking catalysts and conditions.

The conversion of the base stock boiling molecules to fuels boiling molecules is generally low when using high-quality lube crudes, but can be as high as 30–40% for Group II base stocks depending on the feed and operating conditions of the hydrotreater/hydrocracker. Kuwait and other good-quality Middle East crudes are excellent for manufacturing Groups II and III base stocks using hydroprocessing. Minas (Sumatran Light) crude is not the ideal crude to make Group II base stocks because of its high wax content and the base stock VI will be too high. However, it is good for Group III base stocks. Most Group III base stocks are produced from fuels hydrocracking operations where the cracking conversion of heavy molecules to naphtha, jet and diesel frequently exceeds 70–80%, and the hydrocracker bottom product is sent to hydroisomerization and hydrofinishing. This is discussed more in Sect. 34.6.4. It should be noted that laboratory data and proprietary correlations were used to obtain the dewaxed oil VI data shown in Fig. 34.15.

34.6.3 Hydrocracker Catalyst

The lube hydrocracking catalyst system consists of both hydrotreating (pretreat) and hydrocracking catalysts. The design of the best catalyst system is dependent on the properties of the feed stock and the product specifications. Hydrotreating catalysts are typically composed of oxides of Group VIII (either Ni or Co) and oxides of Group VI (either Mo or W) metals supported on alumina. The metal oxides are reduced and converted to metal sulfides in the sulfiding process, which are the active forms for the hydrotreating reactions. Different combinations of metal sulfides and their functions are summarized in Table 34.5.

Hydrocracking catalysts are dual function catalysts. The hydrogenation function is provided by similar metal sulfides as those in the hydrotreating catalysts, mostly Ni and W sulfides. The cracking or acid function is typically provided by solid acid components in the catalyst support. They could be amorphous silica-alumina, crystalline zeolite, or a mixture of them. High zeolite content cracking catalysts are generally not used for lube hydrocracking as they tend to over-crack the molecules to the fuel boiling range.

The catalyst system designed for lube hydrocracking is generally different from a catalyst system designed to make maximum fuels. It is extremely important to not only to have the right catalysts but also the right ratio of hydrotreating to hydrocracking components to meet specific production targets. Lube hydrocracking is designed to do deep HDS, HDN, HDA, and crack only as needed to achieve the target VI. Thus, preserving molecules in the base stock boiling range is critical for a lube hydrocracker. Figure 34.16 shows that using a fuels hydrocracking catalyst system for a lube hydrocracker application can result in a significant penalty for both lube oil yield and VI.

Table 34.5 Hydrotreating and hydrocracking catalyst components

Function	Component	Activity
Hydrogenation	Cobalt-molybdenum sulfides	HDS
	Nickel-molybdenum sulfides	HDS and HDN
	Nickel-tungsten sulfides	Aromatic saturation
Cracking ^a	Alumina	Very weak
	Amorphous silica-alumina	Moderate
	Zeolite (crystalline Si-Al) ^b	Very strong ^c

Points to remember:

^a Acidity is the key difference between hydrotreating and hydrocracking catalysts.

^b Zeolites offer high acidity, plus their unique crystalline structures are resistant to carbon deposition reactions that shorten catalyst life.

^c Too much zeolite, or the wrong types of zeolite, can over crack, resulting in higher production of fuels byproducts and lower waxy base oil yield.

Fig. 34.16 A lube-selective hydrocracking catalyst provides much higher VI and lube oil yield

34.6.4 Various Hydrocracker Process Configurations

There are a number of hydrocracker configurations used commercially. The most common ones are:

1. Single-stage once-thru hydrocracker (SSOT)
2. Single-stage with recycle hydrocracker (SSREC)
3. Two-stage recycle hydrocracker (TSR).

All three configurations are used for fuels and lube oil hydrocrackers. When designing a hydrocracker for maximum base oil production, SSOT is generally the preferred configuration (Fig. 34.17). The hydrocracker is run to a conversion level needed to make waxy base

stocks that meet the VI specifications after dewaxing and hydrofinishing.

There are a number of high-conversion fuels hydrocrackers (SSREC or TSR units) operating globally that draw a UCO (unconverted oil) stream as base oil feed stock. As shown in Fig. 34.18, the hydrocracker yields about 80–95% fuels, the primary product, and about 5–20% UCO, the side product. The UCO stream typically has very high VI and is used to manufacture Group III base stocks. It is fractionated in a vacuum still into waxy base stock cuts, which are subsequently dewaxed and hydrofinished into finished base stocks.

It should be noted that not all hydrocracker UCO streams are good for making base stocks. UCO drawn from a hydrocracker feeding VGO from low-quality crudes and cracked stocks (like coker gas oil or heavy cycle oil from an FCC) most likely will not be good for base stocks due to the high concentration of polycyclic aromatic coke precursors. Also, a UCO drawn from a near-full/very high conversion fuels hydrocracker may be difficult to convert to high-quality base stocks when it contains PCAs with seven or more condensed aromatic rings. These compounds may be generated in a hydrocracker from the polymerization of three- and four-ring aromatics found in the feed [34.10].

SSOT Hydrocracker Process Flow Diagram

Figure 34.19 shows a simplified process flow diagram for a SSOT lube hydrocracker. Oil feed is mixed with makeup (MU) and recycle H_2 and preheated in the reactor feed/effluent exchangers and reactor feed furnace. The oil-gas mix then enters the fixed bed, down flow reactor. There are multiple catalyst beds in the reactor. For larger capacity plants, there will be multiple reactors in series. Because the chemical reactions

Fig. 34.17 SSOT base oil hydrocracker for maximum base oil yield

Fig. 34.18 Fuels hydrocracker making base oils as a byproduct

Fig. 34.19 SSOT lube oil hydrocracker

(HDS, HDN, HDA and cracking) in the reactor are highly exothermic, H_2 quench gas is injected between the catalyst beds to cool and control the reactor temperature. The effluent leaving the reactor is cooled and then enters a series of separators (high pressure and low pressure separators – HPS and LPS) to flash separate H_2 gas from liquid oil. The gas from the recycle compressor (mostly H_2 and some hydrocarbons) is sent to the reactor as quench gas. The remaining

gas is recycled and injected with the makeup H_2 into the fresh oil feed ahead of the feed/effluent exchangers. The liquid product from the LPS is sent to the atmospheric and vacuum columns to be fractionated into fuels products and waxy base stocks. The waxy base stocks must be distilled to the proper viscosity and cut points. They are subsequently sent to the hydrosomerization or solvent dewaxing plant for pour point reduction.

Fuels Hydrocracker Making Waxy Base Stocks as a Side Product

As previously discussed, globally there are a number of hydrocrackers that make fuels as their main product but also make waxy base stocks as a side product. The fuels hydrocrackers can be any of the previously mentioned designs: SSOT, SSREC, or a TSR.

Figure 34.20 shows a SSREC design in which a UCO stream is drawn for waxy base stock production. Depending on the VI of the UCO, this stream can

be converted to Group II or III base stocks after dewaxing and hydrofinishing.

Figure 34.21 shows a TSR hydrocracker in which a first-stage UCO is drawn to make Group II or III base stocks, depending on the VI of the UCO. The second-stage UCO is typically used to make Group III base stocks. The UCOs produced in these units are fractionated in a feed preparation unit (FPU) vacuum column to the correct viscosity and cutpoints. Each fractionated waxy lube cut is then individually dewaxed (block

Fig. 34.20 Simplified SSREC fuels hydrocracker with base oil production

Fig. 34.21 Simplified TSR hydrocracker with base oil production

dewaxing) in the hydroisomerization dewaxer and hydrofinisher. A process option is to bulk dewax the entire UCO and then fractionate the dewaxed base oil into the desired viscosity grades. The merits of block and bulk dewaxing will be discussed in more detail in the dewaxing section.

34.6.5 Block and Bulk Base Oil Hydrocracker Operation

There are a couple of operating options to make waxy base stocks in a hydrocracker: block feed hydrocracking and bulk feed hydrocracking. There are pros and cons for each mode. The fractionation capability of the refinery's crude vacuum distillation unit, VDU, may have a large influence on which is the better mode. Sharply fractionated, narrow cut VGOs will provide the highest lube oil yield for a given feed. For an existing VDU in the refinery that has poor to mediocre separation efficiency, a capital expenditure to improve the VDU performance is money well spent, especially for a block operation mode. Also, new grassroots base oil plants are building high efficiency vacuum columns to prepare highly fractionated VGO feeds for the hydrocracker.

Block Hydrocracking

Figure 34.22 shows an example of a simplified flow scheme for block hydrocracking. The long residuum is fractionated in the VDU into three narrow lube VGOs plus a vacuum residuum. Each VGO cut must have the correct cut points and viscosity in order to make the desired base stock viscosity grades in the hydrocracker. The light, medium, and heavy VGOs make light neutral, medium neutral and heavy neutral oils respectively.

Block feeding each VGO will provide a primary base stock cut from the hydrocracker and possibly

a secondary base stock cut. For example, feeding a LN VGO can produce a waxy 100N (primary) and 60N (secondary). Feeding a HN VGO can produce a waxy 600N and possibly a small amount of lighter waxy base stock, depending on the boiling range of the HN VGO. However, the VI of the lighter base stock may be marginal in meeting the VI specifications because of VI droop. VI droop will be discussed in more detail later. Each of these primary base stock cuts are in turn blocked fed through the hydroisomerization dewaxer and hydrofinisher to make finished base stocks.

Note that the vacuum resid can be sent to a propane SDA plant to make feed for bright stock manufacture.

Bulk Hydrocracking

Feeding a broad-boiling-range VGO to a hydrocracker will result in multiple primary base stocks (of different viscosities) made simultaneously. In Fig. 34.23, a blend of the light and medium VGOs are fed to the hydrocracker to make waxy LN and MN base stocks simultaneously, and some light base stock such as a 60N. The ratio of the VGO blend will dictate the ratio of waxy LN and MN base stocks. Another scenario is to draw a combined light and medium VGO as a single VGO and feed it to the hydrocracker. This latter broad-boiling VGO will have a somewhat fixed ratio of LN and MN.

In Fig. 34.24, the medium and heavy VGOs are fed to make MN and HN waxy base stocks. In both scenarios, the hydrocrackate can either be fractionated into individual lube cuts (to a target viscosity) or fractionated into a broad-boiling base stock for dewaxing.

Advantages and Disadvantages of Block and Bulk Hydrocracking

The obvious advantages of bulk operation are fewer operating block changes on the hydrocracker with a sin-

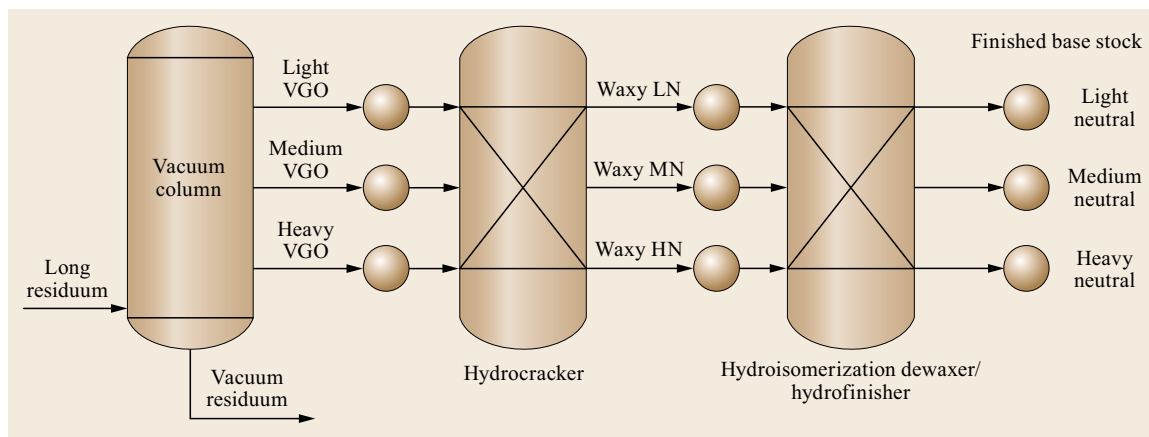

Fig. 34.22 Hydrocracker block feed operation

gle feed and possibly fewer and smaller intermediate tanks. However, there are some disadvantages. The hydrocracker vacuum column (Fig. 34.19) will be a more expensive and complex column to build and operate because at least two primary base stock draws are needed. An option is to not fractionate the lube hydrocrackate in the vacuum column, but to produce a wide-boiling waxy base stock fraction using a simple stripper. This wide-boiling fraction would then be bulk dewaxed followed by fractionation in a vacuum column to the various viscosity grades. Bulk dewaxing will be discussed in the dewaxing discussion.

It should be noted that for bulk hydrocracking the conversion must be sufficient to meet the target specifications of the limiting viscosity grade, which is generally the lighter grade. The VI and/or nitrogen level are usually the limiting specs for the waxy base stock. This will be better explained as we discuss VI droop. It could also result in much lower lube yield with VI giveaway.

With block hydrocracking, the unit is operated to meet the limiting specification(s) of a single waxy base stock grade instead of multiple grades. Very often, this is either VI or heteroatoms content, generally nitrogen. With the properties of only one base stock grade to achieve, this makes it easier to maximize/optimize the waxy base stock yield and base stock properties in the hydrocracker.

34.6.6 VI Droop

Because of the nature of bulk lube hydrocracking and due to the nonlinearity of the VI scale, the VI of the lighter base stock fraction will generally be lower than the VI of the heavier base stock fraction produced simultaneously. This has been referred to as VI droop and is explained in detail in a number of excellent articles [34.6, 11, 12]. In order to achieve the target VI for the lighter base stock, the hydrocracker must operate at a higher conversion, resulting in some

Fig. 34.23 Hydrocracker bulk feed operation – LN and MN block

Fig. 34.24 Hydrocracker bulk feed operation – MN and HN block

Fig. 34.25 VI droop in a hydrocracker feeding HVGO and making MN and HN base stocks – plant data

VI giveaway for the heavier lube cut. Thus, less total waxy base stocks are produced, and more fuels are made.

The VI droop between the adjacent base stock cuts typically ranges from two to ten VI numbers. The actual amount of droop depends on the viscosities of the adjacent base stock fractions, the hydrocracker conversion level and the feed VGO composition. Increasing the hydrocracker conversion generally results in a larger VI droop for a given feed. Also, increasing the severity (conversion of heavy molecules to lighter ones) results in more molecules cascading from the heavier to the lighter base stock fraction. The molecules that are converted to the lighter base stock fraction are frequently moieties with shorter alkyl chains and lower VI. Figure 34.25 shows commercial data in which the VI droop is about four to eight numbers for a hydrocracker feeding a broad-boiling-range HVGO to make MN and HN base stocks simultaneously.

Referring to Fig. 34.23, increasing the ratio of light VGO to medium VGO will directionally lower the VI droop between the LN and MN base stocks. This also holds true for the heavy block in Fig. 34.24 in which increasing the ratio of medium VGO to heavy VGO will directionally reduce the VI droop. The relationship between VI droop and feed VGO ratio generally must be determined experimentally or by a plant test run.

The parameters that affect the amount of VI droop in a bulk hydrocracker operation are:

- Blend ratio of LVGO:MVGO:HVGO, or boiling curve of the VGO feed
- Hydrocracker conversion level
- Distillation separation quality between the adjacent base stock cuts

Table 34.6 Typical hydrocracker process conditions

Process variable	Value
Pressure (psig)	1500–2500
Temperature (°F)	650–825
LHSV (1/hr)	0.5–1.2
Recycle hydrogen rate (scfb) ^a	3000–8000
Hydrogen consumption (scfb)	500–1800
Catalyst life (yrs)	2–3

^a scfb = std ft³/bbl feed

- Feed source (e.g., VGO, UCO, slack wax, raffinate, crude selection, etc.)
- Hydrocracker catalyst age.

34.6.7 Process Conditions

There are a number of process variables for designing a lube hydrocracker. The quality of the feed will dictate the process conditions for the hydrocracker design. A high-quality feed, such as Arabian Light VGO, will permit designing a higher reactor space velocity, while a poor-quality VGO from Alaskan North Slope crude will require a low reactor space velocity. Some typical process conditions are shown in Table 34.6.

These variables are interrelated in designing the hydrocracker. The reactor size (as determined by LHSV) must be designed to meet the desired catalyst run life for the design feed rate. There must be sufficient catalyst volume to make high-quality, on-specification base stocks throughout the entire run cycle. Generally, a 2–3 year run cycle is selected for the hydrocracker, although longer run cycles have been chosen. The catalyst operating temperatures at the start-of-run (SOR) and end-of-run (EOR) are defined and related to the reactor space velocity. The reactors and their internals must be designed properly to minimize reactor temperature maldistribution. The hydrogen pressure must be sufficient to make the desired product quality and control the catalyst fouling rate (coking) to meet the targeted run life. The recycle hydrogen rate must be set high enough to control the heat release in the reactor during normal operations and for potential temperature excursions and emergencies.

The hydrogen consumption in the lube hydrocracker will be a function of the feed properties (sulfur, nitrogen, and aromatics content) and the conversion level needed to achieve product VI. Generally, the more paraffinic the feed, the lower the hydrogen consumed in the process. The hydrogen consumption for a Middle East VGO is typically about 1000–1500 scfb of feed, depending on the conversion level.

34.7 Dewaxing

The pour points of the waxy base stocks coming out of the hydrocracker are lowered in the dewaxing step to meet the finished base stock low-temperature property specifications. This can be done by either physical removal of the wax or selective chemical reaction to alter or eliminate the wax. The wax is a mixture of hydrocarbons that separate out as a crystalline or semicrystalline solid material when the product is chilled, either alone or diluted by certain solvents. These hydrocarbons have the common feature of long normal paraffin chains. These chains can range from about 18 carbons to over 50 carbons long.

34.7.1 Current Dewaxing Technologies

The dewaxing technologies in commercial use today are solvent dewaxing and catalytic dewaxing. Solvent dewaxing is the conventional dewaxing technology. The wax in the waxy base stock is crystallized and precipitates when the solvent mixture, such as MEK and toluene, is chilled. It is then vacuum filtered to physically separate (extract) the wax from lube oil. A detailed discussion of solvent dewaxing can be found in other references [34.13, 14].

Catalyst dewaxing falls into two categories:

- Wax hydrocracking, referred to as conventional catalytic dewaxing
- Wax hydroisomerization.

Unlike solvent dewaxing, there is no slack wax byproduct from catalytic dewaxing. The byproducts are mostly LPG, naphtha and distillates. Refiners that want to continue to make refined and semirefined waxes must continue to use solvent dewaxing.

Figure 34.26 shows a simple schematic outlining the differences between solvent and catalytic dewaxing.

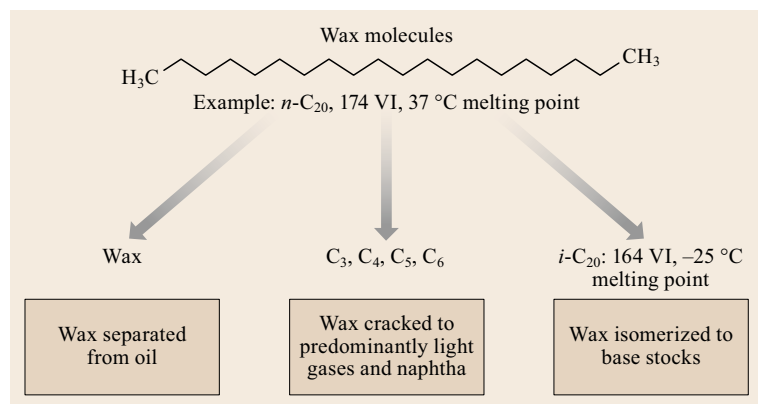

Fig. 34.26 Overview of dewaxing processes

34.7.2 Conventional Catalytic Dewaxing – Wax Hydrocracking

A number of catalytic dewaxing processes using wax cracking technology have been commercialized [34.13]. The most widely used was the Mobil Lube Dewaxing (MLDW™) process. ExxonMobil developed this technology in the mid-1970s as an alternative to using solvent dewaxing. The MLDW™ catalyst uses the ZSM-5 zeolite, a medium-pore zeolite, discovered in the late 1960s and patented by Mobil in 1972 [34.15]. The zeolite selectively cracks the undesirable wax while preserving the valuable base stock molecules. The primary cracking products include propane, butane, and light naphtha.

ZSM-5, as shown in Fig. 34.27, works on the principle of shape selective dewaxing. A constrictive, intersecting two-dimensional pore geometry ($5.4 \times 5.6 \text{ \AA}$ straight channel and $5.1 \times 5.5 \text{ \AA}$ sinusoidal channel) allows linear and the linear portions of some slightly branched alkanes to enter into the pore system while rejecting the low pour point, nonwaxy components (highly branched paraffins, naphthenes, and aromatics). The alkane molecules then get cracked to small hydrocarbons over the acid sites inside the zeolite pores.

Because of the shape selective nature of the ZSM-5 zeolite, it can withstand high nitrogen and sulfur levels in the waxy base stock. The large nitrogen and sulfur species cannot get deep inside the ZSM-5 pores and deactivate the zeolite. Therefore, the technology is robust and can be used to dewax a full range of raffinates ranging from spindle oil to bright stock from a Group I solvent plant, and all viscosity grades of hydrocrackate from a hydrocracker.

Depending on the operating pressure of the MLDW™, the dewaxing catalyst can lose activity from coke formation and carbonaceous deposits over time.

Fig. 34.27 ZSM-5 structure

Most of these contaminants form on the outside of the ZSM-5 crystals and plug the pore mouths. The catalyst is usually periodically reactivated with hot hydrogen gas stripping. The pressure of the MLDW™ units is generally designed between 500–3000 psig. The run length between hydrogen reactivation varies with the feed properties and operating pressure of the unit. A unit designed to operate at 2000 psig will run for years and not need a hot hydrogen reactivation. The ones designed around 500 psig will lose activity and must undergo periodic reactivation. The ZSM-5 zeolite was selected for the MLDW™ process because of its balance for wax reactant shape selectivity, reduced coking propensity, and resistance to poisoning from bulky nitrogen compounds [34.15].

Compared to solvent dewaxing, ZSM-5 removes more wax when achieving the same pour point on a common feed. The base stock yield is generally lower than solvent dewaxing, especially for the lighter viscosity grades such as LN and MN. However, the cold flow viscometrics for the formulated engine oils, such as cold crank simulator (CCS), mini-rotary viscosity (MRV), and scanning Brookfield viscosities, are better with base oil dewaxed with ZSM-5 because of more complete wax removal. In addition to wax molecules, some good base stock molecules, such as monobranched paraffins, may get cracked into fuels.

The VI of the ZSM-5 dewaxed base stocks can be 5–10 numbers lower than that of base stocks from solvent dewaxing, especially for the lighter grades. The high VI loss with the ZSM-5 catalyst can have a large ramification back to the solvent extractor and hydrocracker. Both of these units must operate at a higher severity to make up for the VI loss in the catalytic dewaxing step. Thus, for this type of catalytic dewaxing, there is an overall yield loss, which may be balanced out by less complex operations and better low-temperature performance for the base stocks. ZSM-5 performs better on heavy viscosity grades than lighter grades in terms of dewaxed oil yield and VI retention. For example, the dewaxed oil yield is higher for HN than LN. Also, the VI

losses on HN and bright stock are lower than for the LN and MN. In fact, the yield and VI for bright stock come close, or may even exceed that of solvent dewaxing as ZSM-5 is more selective for removing microcrystalline wax [34.15].

The wax cracking reaction causes the formation of a small amount of olefins. These intermediary olefins must be removed in the final hydrofinishing step to improve base stock stability. Hydrofinishing saturates all olefins and, depending on the pressure of the HDF, most aromatics. Catalytic dewaxing plants used for the manufacture of premium base stocks generally integrate catalytic dewaxing and hydrofinishing into a single plant with two reactors in series instead of two separate plants. This saves a considerable capital expenditure.

34.7.3 Hydroisomerization Dewaxing

In the early 1990s, a new approach emerged for catalytic dewaxing. A breakthrough technology was invented by Chevron named ISODEWAXING®. Instead of solely cracking wax into relatively low value LPG and light naphtha, the ISODEWAXING® technology converts wax into high value products, including base stocks, middle distillates, and naphtha, by hydroisomerization. Table 34.7 shows an example of how hydroisomerization provides a high-VI, low-melting-point base stock molecule.

Chevron commercialized their ISODEWAXING® technology at its Richmond California Refinery in 1993. This technology is currently licensed by Chevron Lummus Global, LLC. Since then, ExxonMobil developed their version of a hydroisomerization dewaxing technology, MSDW™ (Mobil Selective Dewaxing). It was implemented into their Singapore-Jurong lube oil plant in 1997 [34.16]. Shell Criterion also has a hydroisomerization dewaxing technology that is used in their GTL Pearl Plant in Qatar [34.17].

The hydroisomerization dewaxing catalysts are composed of proprietary zeolitic or molecular sieve materials and at least one noble metal. The zeolite or molecular sieve typically utilizes a one-dimensional pore geometry, which has better selectivity for limiting primarily paraffins with long-straight chains to enter the catalyst pores than ZSM-5 [34.18]. As depicted in Fig. 34.28, the n -C₃₀ molecule enters the catalyst pore and gets isomerized to a lower melting point isoparaffin molecule by adding one or two methyl branches or, in some cases, an ethyl branch. There are a number of isomers that can form inside the catalyst pores. The more branching, the lower the melting point. However, as the melting point decreases, the VI is also lowered with the added side chains. The amount of branching

Table 34.7 Isomerizing $n\text{-C}_{30}$ (triacontane) lowers the melting point and provides a branched lube oil molecule [34.19]

Formula	Structure	Melting point ($^{\circ}\text{C}$)	VI
$n\text{-C}_{30}\text{H}_{62}$ triacontane		66.5	195
$\text{C}_{30}\text{H}_{62}$ squalane		-38	117

**Fig. 34.28**

Chevron's shape selective ISODE-WAXING® Catalyst – paraffins isomerize in the pores with minimal cracking (only partial C_{30} molecules are shown in the diagram)

and side-chain length is a function of the pore geometry of the sieve and process conditions. A balance must be achieved to get the correct amount of branching to achieve the base oil target pour point and not lose too many VI numbers. The byproducts are predominantly high-quality liquid transportation fuels, i.e., naphtha and mid-distillates for the jet and diesel pools.

The ideal hydroisomerization dewaxing catalyst will have selective acidic molecular sieve sites and active noble metal hydrogenation sites for enhancing isomerization reactions and for catalyst stability. The acidity of the isomerization sites is less than that of ZSM-5, thus there is less cracking of the wax to lighter species, and more preservation of species in the base stock range. The presence of a strong hydrogenation metal to rapidly saturate the olefins produced in the isomerization reaction prevents coke formation in the catalyst. This strong hydrogenation function is critical to maintain the catalyst activity and stability. It also contributes to improve the base stock stability. Final base stock stabilization occurs in the hydrofinishing step. Modern hydroisomerization catalysts are designed such that the two functions, hydroisomerization and hydrogenation, work together in balance to achieve superior cold flow properties with high lube oil yield and VI retention.

The catalyst temperature needed to dewax a waxy base stock is a function of the wax content (wt%).

The higher the wax content, the higher the temperature needed to achieve the target pour point. For typical Group II base stocks made from Arabian Light VGO, the wax content increases as the base stock gets heavier, and so does the dewaxing temperature: LN ($\approx 9\text{--}12\%$ wax) < MN ($\approx 13\text{--}18\%$ wax) < HN ($\approx 20\text{--}25\%$ wax).

34.7.4 Hydroisomerization Dewaxing Catalyst Poisons

Hydroisomerization and hydrogenation sites in the dewaxing catalysts are sensitive to nitrogen- and sulfur-containing molecules. Nitrogen compounds are responsible for poisoning the acid sites on the zeolite or molecular sieve, which results in the deactivation of the dewaxing catalyst. Nitrogen poisoning is mostly reversible. The dewaxing activity can be recovered by hot hydrogen gas stripping or by introduction of a cleaner liquid feed. High levels of nitrogen in the waxy feed will require the dewaxing catalyst to operate at higher than normal temperatures, which may cause an increase in unselective cracking. It should be noted the recent new generations of hydroisomerization dewaxing catalysts are much more tolerant to feeds with higher nitrogen.

Sulfur compounds can passivate the noble metal in the dewaxing catalyst and inhibit the dewaxing reaction.

The sulfur content in the feed must be kept low to prevent damage to the hydrogenation function of the noble metal.

The waxy lube oil feed to the dewaxer ideally should have a nitrogen level of no more than a few ppm and a sulfur level of no more than 10–20 ppm. This is generally not a problem as the hydrocrackate and UCO leaving the hydrocracker are clean with extremely low nitrogen and sulfur levels.

34.7.5 Process Flow Diagrams

To save capital costs, hydroisomerization dewaxing and hydrofinishing reactors are generally included in the same reactor loop. However, there are scenarios in which it may be economical to have separate dewaxing and hydrofinishing reactor loops operating at different pressures. Examples of these scenarios are beyond the scope of this chapter. For this discussion, these plants will be referred to as an isomdewaxer/hydrofinisher. Hydroisomerization dewaxing and isomdewaxing will be used synonymously. The process diagram for a lube oil isomdewaxer/hydrofinisher is essentially the same as a conventional hydrotreater.

There are two operating options for catalytic dewaxing base stocks. They are *block* dewaxing (Fig. 34.29), and *bulk* dewaxing, (Fig. 34.30). Block dewaxing is defined as dewaxing a single primary viscosity grade at a time. The waxy base stock is a narrow boiling range oil of a single viscosity grade. For example, a refiner that makes 100N, 220N and 600N base stocks

will have three individual dewaxing blocks. The waxy feeds for each viscosity grade are fractionated at the hydrocracker vacuum column or a vacuum feed preparation unit (FPU) to the correct viscosities and boiling ranges before dewaxing. This was previously depicted in Fig. 34.19.

Bulk dewaxing is defined as dewaxing a wide-boiling-range waxy oil followed by vacuum fractionation of the dewaxed oil into multiple viscosity grades at the tail-end.

As shown in Fig. 34.29, the waxy base stock is mixed with makeup and recycle hydrogen gas and heated in the reactor feed furnace. The heated oil and gas enter the isomdewaxing reactor where the waxy base stock is dewaxed. The isomdewaxing reactor temperature is set to achieve the desired dewaxed oil pour point. The chemical reactions in the isomdewaxing reactor generates a small amount of heat from aromatic saturation and cracking. Interbed hydrogen quenching between the catalyst beds is needed to cool the reactor and control the reactions. The dewaxed oil exits the isomdewaxing reactor, is cooled in an interreactor feed/effluent heat exchanger (not shown in Fig. 34.29) by exchanging heat with the cold feed, and then enters the hydrofinishing reactor.

In the hydrofinishing reactor, the remaining aromatics are saturated to stabilize the base stock. The hydrofinishing reactor must be set at the proper temperature to saturate the last remaining aromatics. The heat release in the hydrofinishing reactor is very small. Generally, no interbed hydrogen quenching is required for the hydrofinishing reactor.

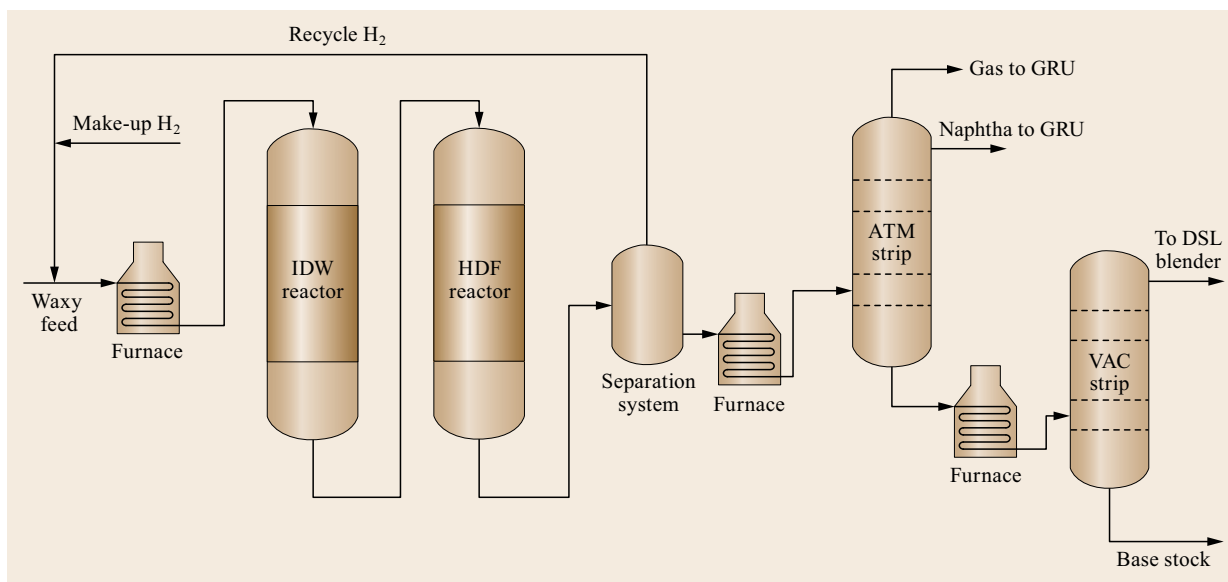

Fig. 34.29 Simplified process flow diagram for isomdewaxer/hydrofinisher – block dewaxing

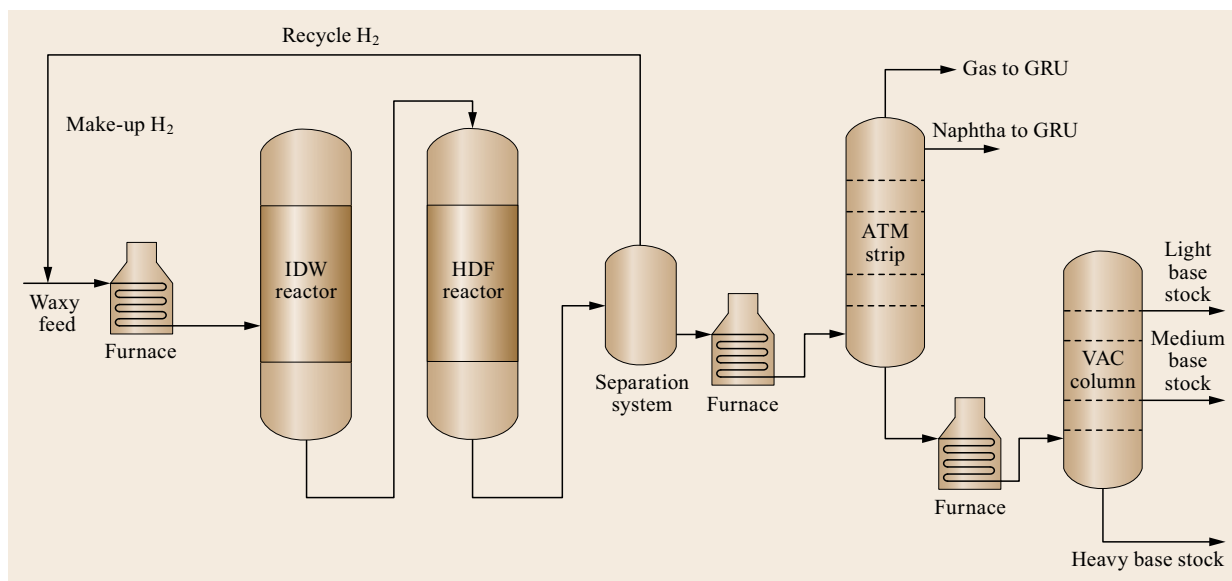

Fig. 34.30 Simplified process flow diagram for isom dewaxer/hydrofinisher – bulk dewaxing

The product exiting the hydrofinishing reactor then enters the separation system where hydrogen and light hydrocarbon gases are flash separated from the liquid oil. The liquid product is heated in the atmospheric furnace and enters the atmospheric stripper. Light gases and naphtha are removed overhead in the atmospheric stripper. The remaining product is heated in the vacuum furnace and sent to the vacuum stripper to separate the base stock and diesel.

The bulk dewaxer, as shown in Fig. 34.30, is essentially the same as the block dewaxer except the vacuum stripper becomes a vacuum column because of the need to boil up a greater percentage of the reactor effluent. The vacuum column fractionates the dewaxed oil into finished base stocks that meet viscosity specifications.

34.7.6 Bulk versus Block Dewaxing

There are a number of pros and cons with using bulk dewaxing compared to block dewaxing. The pros for bulk dewaxing include the following:

1. Less capital expenditure from:
 - a) Fewer and possibly smaller intermediate tanks
 - b) Less piping and other associated equipment
 - c) Possibly smaller reactors.
2. Simpler operation from fewer feed switches.
3. Smaller vacuum column in the hydrocracker or feed preparation unit.

The cons for bulk dewaxing include the following:

1. Less optimization of the viscosity grades to achieve the product specifications and the highest yield.
2. More complex vacuum column to fractionate the dewaxed oils to the target viscosities at the tail-end of the plant. This may be offset by item 3 in the pros.
3. Some VI loss in the lighter grade due to over-dewaxing.

The economics for bulk and block dewaxing needs to be properly evaluated before deciding which is preferred for a new lube oil plant. There can be a yield penalty with bulk dewaxing from not optimizing the product specifications. Figure 34.31 shows the pour

Fig. 34.31 Bulk dewaxing HN and MN – from Chevron data base

Fig. 34.32 Lube oil yield change and VI change versus pour point (after [34.20])

points for MN and HN with bulk dewaxing. The dewaxing reactor must operate at the temperature required to achieve the pour point target of the limiting oil that is HN. The MN is overdewaxed as its pour point is about 10–15 degrees lower than that of the HN. This leads to a lower MN yield in comparison to block dewaxing.

The amount of overdewaxing and potential yield loss between adjacent lube cuts depends on the feed properties and composition. Figure 34.32 shows the change in VI and yield for isomdewaxing a Group II 150N to various pour points. The yield loss is about 1 wt% for each 5 °C of pour point reduction for this particular product from block dewaxing. This can be different for other viscosity grades. The VI loss is about one VI number for each 10 °C reduction in pour point [34.20]. The yield and VI losses from over-dewaxing are not large from an absolute number standpoint. However, they can be significant when optimizing the finished base stock's volatility and cold flow properties for blending into premium engine oils as previously discussed in Sect. 34.3.

It should be noted that bulk dewaxing will result in a small amount of HN transitioning into MN from isomerization and cracking of wax, which is captured in

Table 34.8 Hydroisomerization dewaxing process conditions

Process variable ^a	Value
Pressure (psig)	1500–2500
Dewaxing temperature (°F)	600–700

Recycle hydrogen rate (scfb)	1500–5000
Hydrogen consumption (scfb) ^c	100–500
Catalyst life (yrs)	5–10+

^a Dewaxing and hydrofinishing reactors in series.
^b Dewaxing reactor only: oil volume rate/catalyst volume.
^c Includes both dewaxing and hydrofinishing hydrogen consumptions.

the final MN product. In block dewaxing, this portion of MN will not be captured as base stock unless the process distillation configuration is set up to do this.

Block dewaxing allows for optimization of the product specifications and yield for each grade of base stock. This can be especially important for the LN grades such as 100N and 150N. More interrelated specifications are required for these lighter base oils, including volatility (e.g., Noack), cold flow viscometrics (CCS, Brookefield, etc.), pour point, and VI. Block dewaxing makes it easier to meet all the specifications simultaneously, and provide the best base stock yield.

34.7.7 Process Conditions

The typical process conditions for dewaxing Groups II and III base stocks are shown in Table 34.8.

34.7.8 Comparison Between Solvent, Conventional Catalytic and Hydroisomerization Dewaxing

The technology transition from solvent dewaxing to conventional catalytic dewaxing to hydroisomerization dewaxing has been a dramatic evolution. The signifi-

Table 34.9 Comparison between solvent, conventional catalytic, and hydroisomerization dewaxing

Process/Item	Solvent dewaxing	Catalytic dewaxing	Hydroisomerization
Wax removal	Physical – wax crystallization and filtration	Chemical – wax cracking with shape selective catalyst	Chemical – wax isomerisation with shape selective catalyst
Product pour point	–10 to –15 °C	–10 to –50 °C	–10 to –50 °C
Yields	Base case	Same or lower	Same or higher
Drewaxed product VI	Base case	Generally 5–10 numbers lower	Generally 5–10 numbers higher
Byproducts	Slack wax	Gas, naphtha	Gas, naphtha, jet, diesel
Capital costs	Base (100%)	60–80%	65–85%
Operating costs	Base (100%)	50–60%	55–65%

cantly higher lube oil yield and higher retention of VI by the latest generation of hydroisomerization dewaxing catalyst has increased the efficiency and profitability for base stock manufacturers. Because base stocks are valued much higher than fuels, there is continuous, ongoing research by the technology licensors to improve the performance of their catalysts. Improvements in selectivity for more complete isomerization of wax to base stocks with minimum cracking to fuels is the major

goal of the catalyst researchers. As the catalyst performance improves incrementally by retaining more VI, the refiner is able to increase the yields in the hydrocracker and solvent extractor by running these plants at a lower severity.

Table 34.9 compares the various lube oil dewaxing technologies in terms of relative dewaxer yield, VI retention, byproduct slate, and capital and operating costs.

34.8 Hydrofinishing

The final processing step in the manufacture of premium base stocks is hydrofinishing. Without hydrofinishing, the residual aromatics in the base stock will oxidize, which results in oil darkening, sludge and varnish formation, and generation of corrosive compounds in engine and industrial oil applications. As previously discussed, a hydrofinishing reactor is generally included in the same reaction loop as the isomdewaxing reactor, giving a single, close-coupled hydroisomerization dewaxing/hydrofinishing plant. Today's modern hydrofinishing process virtually removes all polycyclic aromatics. This results in a dramatic improvement in color and high-temperature oxidation and storage stabilities.

34.8.1 Conventional Base Stock Finishing (Polishing) Process

Prior to the establishment of hydrofinishing as the final finishing step, base stocks were finished using sorbent beds of clay (Attapulgus clay was commonly used) or bauxite percolation treating to remove polycyclic aromatics. In the 1950s, lubricant formulators began to demand better quality base oils, and hydrofinishing

has progressively replaced adsorption treating for base stock manufacture. Besides providing superior quality base stocks, hydrofinishing is much more environmentally friendly than percolation adsorption treating, in which the exhausted clay must be thermally regenerated in a furnace or kiln to remove the adsorbed organic materials. After repeated regenerations, the clay loses adsorption efficiency and eventually must be replaced. The spent clay is a hazardous waste material requiring proper disposal.

34.8.2 Chemistry of Aromatics Saturation in Hydrofinishing

The chemistry and strategies for aromatic saturation were previously presented in the Hydrotreating and Hydrocracking Chemistry section, Sect. 34.6.1. Building a very high pressure hydrofinisher, say ≈ 3000 psig, will provide a wide temperature range to saturate all aromatics and overcome the thermodynamic equilibrium limitations. However, this is expensive. Thus, the two sequential temperature steps, as previously discussed, is the preferred strategy from a cost standpoint.

Fig. 34.33 Effect of HDF catalyst temperature on finished base oil qualities (after [34.21])

The hydrofinishing reactor is designed to run at lower temperatures, usually below 600 °F to saturate the polycyclic aromatics to naphthenes. Operating the hydrofinishing catalysts above 600 °F may work against saturating the polycyclic aromatics because of the thermodynamic equilibrium limitations, depending on the H₂ partial pressure and LHSV. This is depicted in Fig. 34.33 – the color of the base stock darkens at the higher HDF temperatures.

Today's modern noble metal hydrofinishing catalysts are so active that it is possible to saturate aromatics down to less than 1 wt%, and improve both color and oxidation stability significantly.

34.8.3 Hydrofinishing Catalysts

The early hydrofinishers were stand-alone units that typically fed Group I or Group II base stocks. The catalysts were base metal catalysts, such as Ni and Mo supported on alumina. Due to the catalysts' relatively low hydrogenation activity, the aromatics, sulfur and nitrogen levels of the hydrofinished base stocks were high when compared with today's all-hydroprocessing Group II and Group III base stocks.

Today's modern hydrofinishing catalysts contain noble metals and sometimes mixtures of noble metals, which provide deep saturation performance at low temperatures and low deactivation rate. These catalysts are significantly more active than the base metal hydrofinishing catalysts. The higher activity allowed

Table 34.10 Process conditions for lube oil hydrofinishing

Process variable ^a	Value
Pressure (psig)	1500–2500
Temperature (°F)	450–600
LHSV (1/hr) ^b	0.5–2.5
Recycle hydrogen rate (scfb)	1500–5000
Hydrogen consumption (scfb) ^c	50–500
Catalyst life (yrs)	5–10+

^c Hydrofinishing hydrogen consumption.

the hydrofinishing step to operate at temperatures in the 450 °F range, where the equilibrium thermodynamics favor more complete aromatic saturation. This enables GpII/III base oil plants to almost completely remove aromatics and make products with superior color (practically water-white) and excellent oxidation stability. Chevron's ISOFINISHING® catalysts and ExxonMobil's MAXSAT™ catalysts, among others, offer high activity for Group II and Group III base stocks. The catalyst life can be as long as ten years or more.

34.8.4 Process Conditions

The typical process conditions for hydrofinishing Groups II and III base oils using noble metal catalysts are shown in Table 34.10.

34.9 Integrating Hydroprocessing with Solvent Plants – Hybrid Plants

There are a number of existing base oil plants that use a combination of solvent processing and hydroprocessing. These plants generally started out as a solvent refining plant, and added a hydrotreating step to improve the base stock quality and/or debottleneck the lube plant. Figure 34.34 shows some of the more common lube oil manufacturing process configurations.

Adding a hydrotreating step following the solvent extractor produces a more saturated raffinate with higher VI and better quality. The raffinate hydrotreater makes it possible to increase raffinate yield and flow rates from the extractor, as the extractor does not have to make a raffinate that achieves final base stock property targets such as VI [34.22]. There are several examples of existing solvent Group I lube plants that added a raffinate hydrotreater to their processing scheme. This permitted them to make Groups II and II+ base stocks. ExxonMobil's raffinate hydroconver-

sion technology (RHC) is an example of this processing scheme.

An alternative to hydrotreating the raffinate is to insert a hydrotreater upstream of the solvent extractor. In this scenario, the VGO from crude oil is upgraded before entering the solvent extractor. Hydrotreating the VGO upstream of the extractor removes sulfur, nitrogen and saturate aromatics, making it easier to upgrade the VGO in the solvent extractor. In addition, the VI of the VGO can be significantly upgraded in the hydrotreater. The more severe the VGO hydrotreating, the higher is the raffinate yield from the solvent extractor. Generally, a high-severity hydrotreater (i. e., higher pressure) is required for this configuration, which may be more costly. An economic study is needed to understand which is the better option for a specific refinery. Locating the hydrotreater upstream of the solvent extractor is not as common as locating it after the solvent extractor.

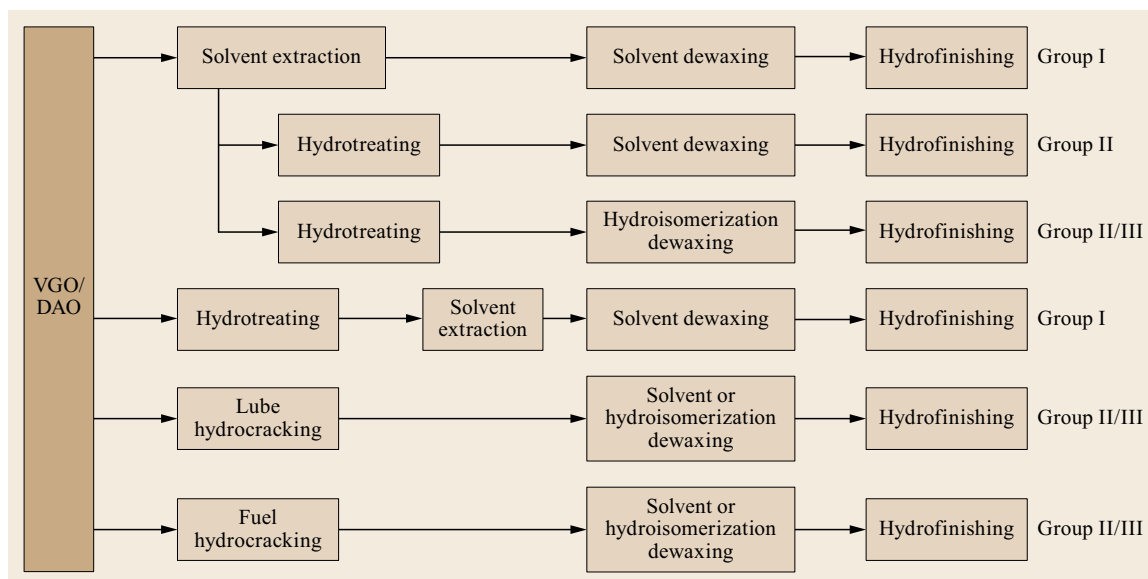

Fig. 34.34 Various base oil plant flow schemes

34.10 GTL Base Oils

Gas-to-liquid (GTL) is a process to convert natural gas or other gaseous hydrocarbons into longer chain hydrocarbon products, including fuels, base stocks, chemicals and wax. As shown in Fig. 34.35, a refinery process such as steam methane reforming (SMR), is used to convert natural gas into a mixture of carbon monoxide and hydrogen to make a synthesis gas. The syngas is then converted into paraffinic hydrocarbons over proprietary cobalt or iron catalysts in the Fischer–Tropsch (FT) process. The synthetic wax is subsequently upgraded using hydroprocessing to produce GTL fuels, naphtha, and base stocks. GTL base stocks are generally classified as Group III+. They are very-high-quality with virtually no contaminants, offering low pour point, low volatility, and high VI. Their performances are comparable to PAOs in many lubricant applications.

There are a total of five GTL plants globally:

1. PetroSA – Mossel Bay, South Africa
2. Shell – Bintulu, Malaysia
3. Sasol-Qatar – Oryx, Qatar
4. Shell-Qatar – Pearl, Qatar
5. Chevron-Sasol – Escravos, Nigeria.

Currently, the only two GTL plants that manufacture base stocks are Pearl, Qatar and Bintulu, Malaysia with capacities of 28 000 bpd and 1150 bpd respectively [34.23].

GTL plants are very expensive to build. They compete with LNG plants for monetizing natural gas. From an energy efficiency standpoint, LNG plants are more efficient. The carbon footprint of a GTL plant is high. The energy efficiency and large carbon footprint make

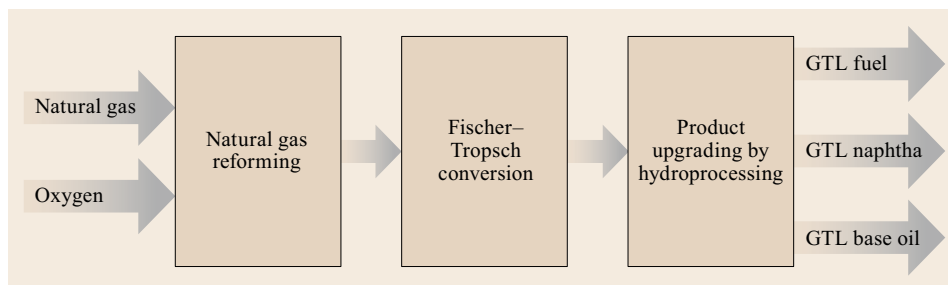

Fig. 34.35 GTL process scheme

GTL project economics challenging. A GTL plant becomes more attractive with low natural gas prices. There currently are a number of active GTL projects in development globally. Most of these projects are for

making liquid fuels. However, a project option to add hydroisomerization dewaxing to a GTL project is relatively simple and will permit manufacturing high-value Group III+ base stocks.

Synthetic Lub

35. Synthetic Lubricant Base Stock

Margaret M. Wu, Suzy C. Ho, Shuji Luo

Conventional lubricants are formulated using mineral base stocks, which are refined from petroleum and contain many chemical species. Although mineral base stocks serve general-purpose lubricants well, they cannot be optimized for specific performance features. Modern machines and equipment are increasingly designed to operate under more severe conditions, to require less maintenance, to have improved longevity and better energy efficiency. Sometimes, conventional lubricants based on mineral base stocks fail to meet these elevated performance requirements. Synthetic lubricants using tailored synthetic base stocks are designed to meet these higher performance needs and can provide superior performance and economic benefits over conventional lubricants.

In this chapter, we briefly discuss the history of synthetic lubricant development to understand the fundamental driving forces behind the use of synthetic lubricants, which have synthetic base stocks as the main components. The major part of the chapter is devoted to discussing the key synthetic base stocks, polyalphaolefins (PAO), esters and polyalkyleneglycols (PAG) – their chemistries, manufacturing processes, product properties, per-

formance features, major applications and advantages compared with mineral base stocks. Additional discussions on less widely used synthetic base stocks, such as alkylaromatics, polyisobutylene and phosphate esters, are briefly reviewed for completeness.

35.1 Background

At the beginning of this chapter, we briefly discuss the background and motivation for using synthetic lubricants, followed by reviews of the products and processes for synthetic base stocks produced from chemicals of well-defined structures and tailored to optimize specific properties and performance features. These synthetic base stocks are major and critical components used in the formulation of many synthetic lubricants. In this chapter, we use *synthetic base stock* to represent the base fluid and *synthetic lubricant* to represent the formulated, finished lubricant product.

Many mineral oil manufacturers and marketers promote the use of Group II+ and Group III base stocks in the formulations of *synthetic lubricants*. However, Group II+ and Group III base stocks are usually produced from crude oil by hydroprocessing or hydrosomerization as part of a refining operation [35.1]. Discussion of these hydroprocessed base stocks can be found in other chapters of this book. In this chapter, we review only those synthetic base stocks produced from chemicals of well-defined composition and structures.

35.1.1 Why Use Synthetic Lubricants?

Synthetic lubricants are used for two major reasons:

1. When equipment demands specific performance features that cannot be met with conventional mineral oil-based lubricants. Examples are operations at extremely high or low temperatures, stability under severe conditions etc.
2. When synthetic lubricants offer economic benefits for overall operation, such as reduced energy consumption, reduced maintenance.

Conventional lubricants are formulated using mineral base stocks which are derived from petroleum. Mineral oil contains many classes of chemical components, including paraffins, naphthenes, aromatics, heteroatom species etc. Its chemical composition is pre-determined by the crude source and oil refining processes that have limited ability to substantially alter the initial oil compositions to fully optimize the hydrocarbon structures. Mineral oils of such complex compositions are good for general-purpose lubrication; they are not optimized for specific performance features. The major advantages of mineral oils are their low cost and user's familiarity due to their long history. However, this paradigm is changing.

Modern machines and equipment are increasingly designed to operate under more severe conditions, to last longer, to require less maintenance, and to improve energy efficiency. Synthetic lubricants are designed to maximize lubricant performance to meet the high demands of modern machines and equipment, and to offer tangible performance and economic benefits.

35.1.2 What Is a Synthetic Base Stock?

Most lubricant formulations contain 80 to 98% of base stock, and the choice of base stock mostly determines the performance level of the finished lubricant. Recognizing this importance, the American Petroleum Institute (API) classifies lubricant base stocks into five major groups, Group I to V in Table 35.1, depending on their physical properties and chemical compositions.

Conventional mineral base stocks are derived from crude oil by refining processes and typically contain sulfur and nitrogen compounds as well as naphthenes. Generally, these heteroatom-containing compounds promote the formation of sludge. All may act as poisons for catalytic converters and/or metal corrosives, during operation. Synthetic base stocks are classified as either Group IV or V and do not contain the sulfur or nitrogen compounds seen in mineral base stocks thereby eliminating the reaction pathways to harmful species and leading to better performance.

Synthetic base stocks are produced from carefully chosen and well-defined chemical raw materials and by specific chemical reactions. These base stocks are designed to have properties that significantly improve performance features to meet specific equipment demands. The most commonly optimized properties are described below.

Viscosity Index (VI)

VI (viscosity index) is a number used to gauge oil's viscosity change as a function of temperature. Higher VI, indicating less viscosity change as oil temperature changes, is a desirable property. Group I and II base stocks of 4 cSt generally have VIs in the range of 85 to 110, whereas most synthetic base stocks of similar viscosities have VIs greater than 120.

Viscosity

Fluid viscosity is one of the critical properties for lubrication. In this chapter, all fluid viscosities stated are kinematic viscosities in cSt measured at 100 °C according to the ASTM D445 method. Very low-viscosity fluids (2–4 cSt) offer advantageous energy or fuel efficiency for machine operation. Very high-viscosity fluids offer special lubrication and wear protection. Mineral oil viscosity is usually limited to less than 40 cSt. In contrast, synthetic base stock can be tailor-made to 1000 cSt or higher while maintaining low-temperature performance.

Pour Point and Low-Temperature Viscosities

Many synthetic base stocks have low pour points, –30 to –70 °C, and superior low-temperature fluidity. Combination of low pour and superior low-temperature fluidity ensures oil flow to critical engine parts during cold starting, thus, offering better lubrication and protection. Mineral oils typically have pour points in the range of 0 to –20 °C. Below these temperatures, wax crystallization or oil gelation can occur, preventing the flow of lubricant to critical machine parts.

Thermal/Oxidative Stability

When oil oxidation occurs during service, oil viscosity and acid content increase significantly, leading to corrosion of metal parts, generating sludge and reducing efficiency. These changes also exacerbate wear by preventing adequate oil flow to critical parts. Although oil oxidation can be controlled by adding antioxidants, the intrinsic oxidative stability of a base stock is an important factor in preventing oil degradation and ensuring proper lubrication after the depletion of antioxidant or in long-term service. Many synthetic base stocks are designed to have improved thermal oxidative stability, to respond well to antioxi-

Table 35.1 Definition of API category I to V lubricant base stock

	(Description)	% Saturates	% Sulfur	VI
Group I	(Conventional, solvent refined) ^a	< 90	> 0.03	80–119
Group II	(Hydroprocessed) ^a	≥ 90	≤ 0.03	80–119
Group III	(Severely hydroprocessed or isomerized wax) ^a	≥ 90	≤ 0.03	≥ 120
Group IV	Polyalphaolefins			
Group V	All other base stocks not included in Group I, II, III or IV (e.g., esters, PAG, alkylaromatics, etc.)	–	–	–

^a Comments in parentheses are not included in the original API definition

dants and to resist aging processes better than mineral oil.

Volatility

Synthetic base stocks can be designed to minimize oil volatility. For example, polyol esters have very low volatility because of their narrow molecular weight distribution (MWD), high purity, high polarity, and thermal stability. Similarly, careful selection of raw materials and processing conditions can influence the volatilities of polyalphaolefins (PAO).

Other Properties

Including friction coefficient, traction coefficient, biodegradability, resistance to radiation etc. can be optimized through selection of base stock structures.

35.1.3 A Brief Overview of Synthetic Lubricant History

Significant commercial development of synthetic lubricants started in the early 1950s with the increased use of jet engine technology [35.2]. Jet engines must be lubricated properly in extremely high- and low-temperature regimes where mineral lubricants could not function adequately. Esters of various chemical structures were synthesized and evaluated. Initially, dibasic esters were used as base stocks. Later, polyol esters with superior thermal/oxidative stability, lubricity, and volatility were developed to meet even more stringent demands. These polyol esters are still in use today.

Another early application that demanded the use of synthetic lubricants came in the mid-1960s during oil drilling in Alaska where mineral oil lubricants solidified and could not function in the severe Alaskan

cold weather [35.1–3]. Initially, a synthetic lubricant based on an alkylbenzene base stock of excellent low-temperature flow properties was used in the field. This base stock was soon replaced by polyalphaolefins (PAO) base stock with better overall properties.

Research on PAO began at Mobil in early 1949 [35.4, 5]. The researchers recognized PAO's unique viscometric properties could be attained by proper selection of starting olefins and reaction conditions. In 1973, after many years of continuous improvements, Mobil Corporation introduced the first PAO-based synthetic automotive engine oil, Mobil SHC in Europe, followed by the fuel-saving Society of Automotive Engineers (SAE) 5W-20 Mobil 1 in the US. The product was a commercial success and subsequent generations of Mobil 1 continue to be the leading synthetic automotive crankcase lubricant today [35.6].

Since the early introduction of synthetic lubricants in automotive and industrial applications, many products from numerous companies followed. In 2011, the total synthetic lubricant consumption amounted to about 1.1 million metric tons/year, approximately 2.9% of the total lubricant volume [35.6]. Although the volume of synthetic lubricant is relatively small compared to conventional lubricants, synthetic lubricant represents about 10% of the total value of the global lube oil market. Furthermore, synthetic base stock is estimated to have grown by 3.5% per year from 2011 to 2016, much higher than conventional lubricant which is estimated to grow at less than 1% per year or remain flat [35.6]. In addition, the overall economic impact from synthetic lubricants is much larger than just the volume number alone, since synthetic lubricants improve energy efficiency, productivity, reliability, and reduce waste.

35.2 Overview of Synthetic Base Stocks

Of the total worldwide synthetic base stock volume, over 80% are represented by three classes of materials [35.7]:

- PAO (45%)
- Esters, including dibasic ester and polyol esters (29%)
- Polyalkyleneglycol (PAG) (13%).

Other smaller volume synthetic base stocks are alkylbenzenes, alkylnaphthalenes (ANs), polyisobutylenes, phosphate esters, and silicone fluids. With the exception of phosphate esters and silicones, all synthetic base stocks are made from basic petrochemicals including ethylene, propylene, butenes, higher olefins, benzene, toluene, xylenes, and naphthalene, as illustrated in Fig. 35.1.

As expected, the major producers of the synthetic base stocks PAO, esters, PIB (polyisobutylene), and alkylaromatics are integrated petroleum or petrochemical companies that also supply mineral oil base stocks and/or petrochemicals. PAG, phosphate esters, and silicone fluids are manufactured by chemical companies that produce these fluids on a much larger scale mainly for other applications. Their use as synthetic lubricant base stocks accounts for only a fraction of the total volume. Table 35.2 summarizes the major synthetic base stock producers [35.7].

Synthetic base stocks, being produced from well-defined chemical compounds by specific chemical processes, have higher raw material and processing cost and are generally more expensive than mineral oils. Table 35.2 lists the price of these synthetic base stocks relative to conventional Group I base stock [35.6].

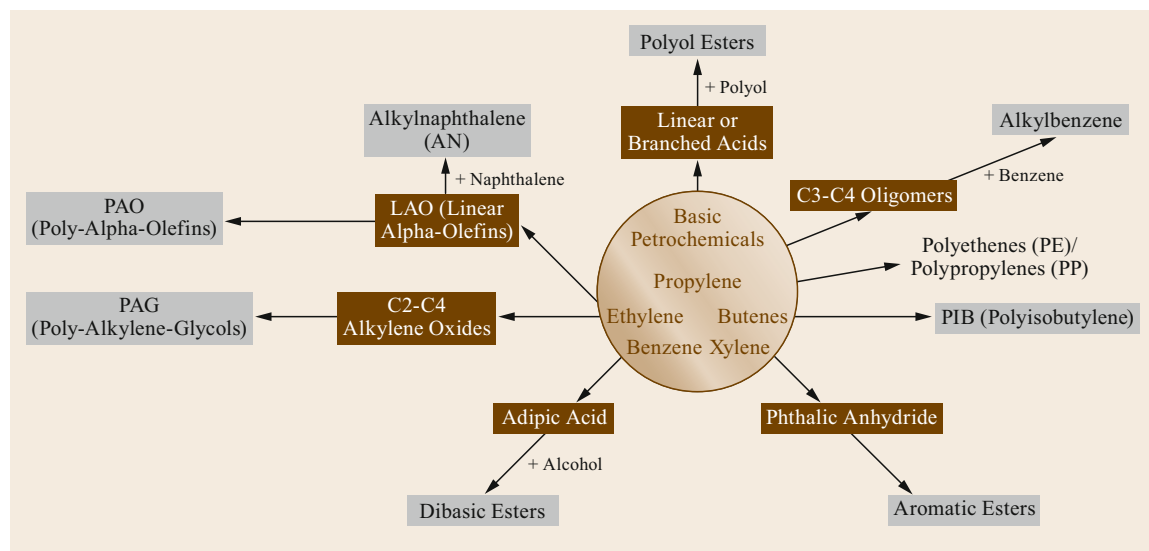

Fig. 35.1 Most synthetic base stocks are derived from petrochemicals

Table 35.2 Summary of major synthetic base stocks and producers

35.3 Synthetic Base Stock – Chemistry, Production Process, Properties, and Use

35.3.1 PAO

PAO is a class of base stock molecularly engineered to optimize viscosity index, pour point, volatility, oxidative stability, and other important lubricant base oil properties. PAO with viscosities of 2–150 cSt at 100 °C are currently produced and marketed commercially [35.8, 9]. The low viscosity PAO of 4–6 cSt account for more than 80% of the total PAO volume of 500 kta in 2010 [35.6]. The remaining are mainly medium to high viscosity fluids of 10–150 cSt.

Chemistry for PAO Synthesis

Historically, PAO is typically synthesized from 1-decene (Fig. 35.2). 1-Decene is produced from ethylene in an oligomerization process. This oligomerization process yields C_4 to C_{20} and higher linear alpha-olefins (LAO) according to the Schulz–Flory distribution [35.10]. 1-Decene is only one member of the many LAO products. Typically, 1-decene constitutes about 10–25% of the total LAO fraction, depending on the process technology. Recently, because of PAO's growth, 1-decene alone is not enough to meet demand. Other LAOs, especially mixtures of C_8 - and C_{12} -LAOs are also being used as starting materials for PAO synthesis.

In the typical PAO process, the linear 1-decene is polymerized using acidic Friedel–Crafts catalysts to give C_{20} , C_{30} , C_{40} , C_{50} , and higher olefin oligomers. Usually, C_{20} is too volatile for use as a high-performance base stock. It is removed by distillation or fractionation. The remaining fraction of C_{30} and

higher oligomers is further hydrogenated to convert the olefinic oligomers into fully saturated paraffinic hydrocarbons.

The degree of polymerization depends on the type of catalyst used and reaction conditions [35.11, 12]. Generally, BF_3 -type catalysts give a lower degree of polymerization. By careful choice of co-catalyst types and reaction conditions, the BF_3 process produces mostly oligomers of C_{30} to C_{50} range with fluid viscosities of 4–8 cSt. $AlCl_3$ -based catalysts are more suitable for the synthesis of higher viscosity PAO, 40–100 cSt because they produce oligomers with a higher amount of C_{60} , C_{70} and higher oligomers.

The choice of 1-decene as the starting material and the final base stock compositions were the results of extensive optimization. Early researchers at ExxonMobil systematically synthesized oligomers in the C_{30} to C_{40} range by BF_3 catalyst and compared their lubricant properties, as summarized in Table 35.3 [35.13].

These data show that the oligomers made from propylene, 1-hexene, and 1-octene have relatively low VI (70–106) and very high viscosity at -40 °C. This is because the oligomers have many short branches in the structures. Oligomers from 1-tetradecene have high VI but also have undesirable high pour points and are solid at -40 °C. Oligomers from 1-decene or mixtures of LAOs with an average branch length similar to 1-decene have the best combination of high VI, low pour points, and -40 °C viscosities.

Historically, the market dynamics of LAO supply and demand further drove the trend toward the use of 1-decene as a raw material [35.10]. Among all the ma-

^a By the ASTM D97 method

for LAO from the ethylene growth process (Fig. 35.2), C₆ and C₈ LAO were mainly used as co-monomer in the linear low-density polyethylene production; C₁₂ to C₁₆ LAO were mainly used in the production of linear alkylbenzene detergents; C₁₈ and C₂₀ LAO were used mainly in additive synthesis. 1-Decene was not in high demand for other chemical manufacturing. Its use as a raw material for synthetic base stocks made a perfect match. As PAO synthetic base stock grew, 1-decene supply became tight, and other LAO, such as C₈ and C₁₂, were successfully incorporated with 1-decene as the starting olefins for PAO production. Since 2001, the world's 1-decene supply has fluctuated with capacity as older plants have shut down and new technology has been developed to allow on-purpose production of specific LAOs such as 1-hexene, resulting in less side product LAOs [35.14, 15]. This fluctuation created uneven PAO growth rates, ranging from 3 to 7% per year, and sparked additional commercialization of mixed LAO base stocks [35.6]. Recent tight supply of LAO prompted the construction of new LAO facilities [35.6]. This new feed capacity is expected to sustain PAO growth.

The chemical composition of PAO from 1-decene is relatively simple. For example, a 4 cSt PAO is composed of ≈ 85% C₃₀ and ≈ 15% C₄₀ hydrocarbons. It has a narrow molecular weight distribution compared to typical 4 cSt mineral oils. The gas chromatogram in Fig. 35.3 shows that 4 cSt PAO has no low molecular weight components of less than C₃₀. In comparison, the mineral oil of same viscosity has many of these low molecular weight components which are highly volatile. They degrade oil volatility, flash and fire point. Therefore, PAOs outperform mineral oils by having low volatility and high flash or fire point.

Figure 35.3 also shows that the C₃₀ fraction of PAO is not a single compound but a mixture of many isomers. This is because the acidic BF₃ catalyst catalyzes the oligomerization reaction through a carbonium ion

intermediate which is well known to catalyze the isomerization of the double bonds, the backbone of the linear C₁₀ hydrocarbon chain, or the oligomer intermediates, thus, creating nonuniform connections between the monomers (Fig. 35.4). As a result, the PAO from the BF₃ process contains many isomers with different types of branching [35.16, 17]. This irregular branching is beneficial to imparting the very low pour point property for PAOs.

Manufacturing Process for PAO

Commercial production of PAO using a BF₃ or AlCl₃ catalyst generally involves a multistage, continuous stirred-tank reactor (CSTR) process [35.11, 12]. In early production technology, the catalyst was destroyed with diluted aqueous alkali after polymerization. More recent patents disclosed improved processes using BF₃ catalyst recycle to reduce catalyst usage, minimize process waste, and improve process economics [35.18].

Product Properties

The typical physical properties of some commercial PAO are summarized in Table 35.4 [35.8, 9]. PAO of different viscosity grades (VGs) and properties are available from different producers. Some PAO are produced with extra steps to meet specific performance criteria or to offer special performance advantages.

Comparison of PAO with Petroleum-Based Mineral Base Stocks

PAOs have different chemical compositions compared to mineral oil base stocks. The American Petroleum Institute (API) categorizes lubricant base stocks into five major categories, Group I to V, as shown in Table 35.1.

PAO is classified by itself as a Group IV base stock. Compared to Group I to III base stocks, PAO contains no naphthenes or aromatics, whereas Group I, II, and III base stocks contain different amounts of aromat-

Fig. 35.3 Gas chromatograph comparison of a 4 cSt PAO with a 4 cSt Group III base stock

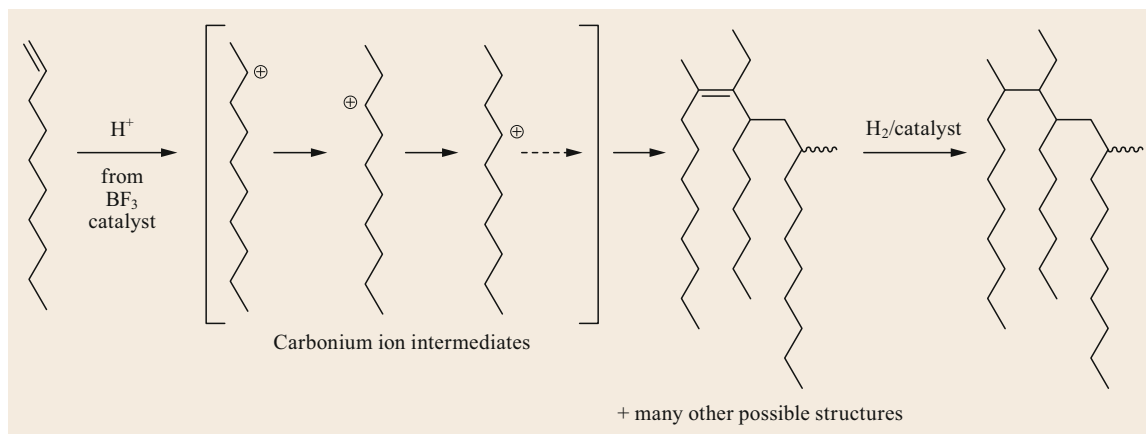

Fig. 35.4 Reaction chemistry responsible for the formation of many isomers in PAO synthesis using promoted BF_3 as the catalyst

ics ranging from < 1% to > 40% [35.19]. With the increasing presence of aromatics and/or naphthenes, oxidative stability and low-temperature properties of these fluids are typically degraded. Also, as shown earlier in Fig. 35.3, PAOs have discrete carbon numbers with relatively few low molecular weight fractions of lower than C_{30} hydrocarbons. In contrast, mineral base stocks contain significant amounts of these volatile, low molecular weight fractions. As a result, PAOs have lower volatility than mineral base stocks.

Table 35.5 compares the basic properties of low and high viscosity PAO versus Group I to Group III mineral oil base stocks. It is worth pointing out that the newer, next-generation PAOs have a wider range of viscosities and superior properties (see next section).

PAOs Have Superior Viscometric Properties Compared to Mineral Oil Base Stocks. Data in Table 35.5 show that PAO has higher VI and lower pour point than Group I and II base stocks. Compared to Group III

Noack volatility (wt%), by ASTM D5800 method	32	15	14	< 12	–	–	–
Aniline point (°C), by ASTM D611 method	100	113	118	119	97	160	> 170

base stocks, PAO has comparable VI, but much lower pour point and improved low-temperature viscosity as measured by Cold Crank Simulator (CCS) viscosity at -20 °C. In the same engine oil formulation, this lower CCS viscosity observed with PAO results in a wider SAE cross-grade (5W-40) than with Group III base stock (10W-40) [35.20]. The lower low-temperature viscosity translates into better fuel economy during the engine warm-up period.

PAO Has Lower Volatility. Data in Table 35.5 show that PAO has lower volatility than Group I to III base stocks. This lower volatility is the result of the uniform molecular structure that is composed of branched paraffins with a narrow molecular weight distribution relatively free of low weight-average molecular weight (Mw) hydrocarbons of less than C₃₀ (Fig. 35.3). Low volatility is advantageous for decreased oil consumption and reduced emissions.

PAO Has Excellent Response to Antioxidant Additive Treatment, Resulting in Better Oxidative Stability than Mineral Oil Lubricants. It has been demonstrated that the un-formulated PAO base stock treated with 0.5 wt% antioxidant resists oxidation for more than 2500 min in a standard rotating pressure vessel oxidation test (RPVOT) per the ASTM D2272 method. In comparison, similarly treated Group II and III base stocks start to oxidize much earlier in less than 800 or 1700 min, respectively [35.21].

**Fig. 35.5** Comparison of viscosity increase in ASTM sequence IIIIE engine test for fully formulated lubricants based on PAO versus Group III or I/II base stocks (after [35.20])

This oxidative stability translates into performance advantages in actual engine oil tests (Fig. 35.5) [35.20].

Figure 35.5 shows that a fully formulated engine oil with PAO has a much lower viscosity increase than with Group III or with Group I/II base stocks in a standard length, 64 h, ASTM sequence IIIIE engine test. In an extended-length, 256 h test, the viscosity increase for the PAO-based lubricant is still much less than the maximum increase allowable for this test. In contrast, Group III- or Group I/II-based

Fig. 35.6 Schematic representation of the molecular structures of mPAO versus conventional PAO made from 1-decene

engine lubricants become too viscous to measure. Because of this superior oxidative stability, PAO-based lubricants with performance advantages in fuel efficiency and oil consumption were reported in the literature [35.22].

PAOs Are Available in a Wide Viscosity Range. PAOs are available from 2 to 100 cSt at 100 °C. The high-viscosity PAOs maintain excellent VI and low pour point (Tables 35.4 and 35.5), in a manner that is superior to the highest viscosity mineral oil base stock – bright stock. High-viscosity PAOs are important as blend components with low-viscosity fluid to formulate high-viscosity-grade industrial oils. When used to blend with low-viscosity mineral oil, the high-viscosity PAO significantly improves the oxidative stability of the blended base stocks compared to using mineral bright stock [35.20].

PAOs Have High Aniline Point, Indicating Low Polarity. Table 35.5 shows that low-viscosity PAO has a higher aniline point than Group I mineral oils, 119 °C versus 100 °C. A more pronounced difference is observed for high-viscosity fluids (160 °C versus 97 °C). The higher aniline points of PAO mean that they are much less polar than Group I oils. Generally, lubricant additives and oil oxidation by-products are highly polar chemical species. They are not typically soluble in nonpolar fluids. As a result, additives and oxidation by-products have very poor solubility in PAO alone. To compensate for this, a polar co-base stock, such as ester or alkylnaphthalene, is usually added to the formulation to improve the solvency of PAO in a finished lubricant. These co-base stocks can also assist other performance features, such as seal compatibility and improved lubricity.

PAOs Possess Other Important Properties in Various Applications.

- Compatibility or miscibility with mineral oil at all concentration levels without phase separation or detrimental effects when cross-contamination occurs.
- Excellent hydrolytic stability.
- 10% higher thermal conductivity and heat capacity than comparable mineral oil, allowing equipment to run at lower temperature and improving wear performance [35.23, 24].
- Lower traction coefficients than conventional fluids, resulting in better energy efficiency for many industrial oil applications [35.8, 9].
- PAOs are nongreasy, have good skin feel, are non-irritant and noncomedogenic when used in the formulation of personal care products.

In summary, PAOs have superior VI, pour point, low-temperature viscosity, volatility, and oxidative stability and are available in a wider viscosity range compared to conventional Group I, II, or III mineral oils. Meanwhile, PAOs have poor solvency for additives due to their high hydrophobic/low polarity nature.

Recent Developments – SpectraSyn Elite – Next Generation PAO

Following the success of PAO, ExxonMobil Chemical Co. continues to develop new fluids with step-out performances [35.25–27]. In 2009, a new generation of PAO, SpectraSyn Elite was commercialized. SpectraSyn Elite is made from linear alpha-olefins using advanced metallocene catalyst technology, which produces polymers with a uniform, comb-like structure (Fig. 35.6). In contrast, conventional PAOs have short-chain branches due to the isomerizing nature of the

Table 35.6 Product properties of next-generation PAO – SpectraSyn Elite

Product	SpectraSyn Elite 65	SpectraSyn Elite 150
Kinematic viscosity 100 °C (cSt)	65	156
Kinematic viscosity 40 °C (cSt)	614	1705
Viscosity index	178	206
Pour point (°C)	−42	−33
Flash point (COC) (°C)	277	282
Specific gravity 15.6 °C	0.846	0.849

acidic catalysts, BF₃ or AlCl₃, used in their production processes (Fig. 35.4). The advanced metallocene catalyst technology enables production of high molecular weight PAOs with narrow molecular weight distribution. These structural differences are responsible for many of the properties and performance advantages for SpectraSyn Elite over other PAOs.

Table 35.6 summarizes the properties of commercial SpectraSyn Elite products [35.27]. Compared to conventional PAOs, SpectraSyn Elite mPAO have higher VI and lower pour points. They are available in higher viscosity ranges, up to 150 cSt. This unique class of fluid can be used in the formulation of automotive engine oil and industrial oil to provide improved shear stability, viscometric properties, and increased lubricant film thickness for better lubrication (see *Applications* below).

Overall, advantages for SpectraSyn Elite include:

- Wider viscosity range
- Improved shear stability for durability
- Higher viscosity index (VI) for low- and high-temperature performance
- Better low-temperature performance for increased flow in cold environments.

In addition to ExxonMobil Chemical Co., Chevron Phillips Chemical company introduced Synfluid high-viscosity mPAOs in the first quarter of 2011. The product is manufactured from a non-decene α -olefin feedstock (octene) using proprietary metallocene technology [35.6].

Applications

PAO is the workhorse base stock for most synthetic lubricants. Low viscosity PAO are used in high-performance synthetic automotive crankcase and gear lubricants, industrial oils and greases. High-viscosity PAOs have found great utility in high-performance industrial oils and greases. Both low- and high-viscosity PAOs are expected to grow at much higher rates than mineral oil base stocks in the future [35.6, 14, 15].

Synthetic Automotive Engine Lubricants. These consume the largest volume, \approx 50%, of all PAOs [35.6, 28–31]. They are typically formulated with 4–6 cSt PAO, ester or alkylated naphthalene and a balanced amount of additives such as antioxidants, antiwear additives, dispersants etc. Because of the choice of superior base stocks, the PAO-based synthetic engine lubricants have many performance advantages over mineral oil-based engine lubricants. These advantages are well documented in scientific and trade literature [35.28–31]. They include:

- Improved engine wear protection and durability
- Extended oil drain interval – less waste oil and reduced maintenance
- Improved fuel economy
- Better oil stability and hardware protection at high temperature
- Excellent cold-starting properties, low-temperature fluidity and pumpability – better low-temperature protection
- Better protection for the emission system due to low phosphorous and sulfur levels.

Many of these performance advantages are directly attributable to the intrinsically superior properties of PAO, such as high VI, low pour point, low-temperature fluidity, high oxidative stability, low volatility, and better lubricity.

The advantage of using synthetic engine oil is further supported by the fact that many automakers use synthetic lubricant as the *factory fill* lubricant for their high-performance cars. For example, in 2013, Mobil 1 synthetic engine oils were used as factory-fill lubricants for certain models of Corvette, Porsche, Mercedes-Benz, Nissan GT-R etc. [35.32].

PAO blended with mineral base stocks are also used in many partial synthetic lubricant formulations. In this case, PAOs are used as blending stocks to improve the volatility, high- or low-temperature viscosity, and oxidative stability etc. of the mineral base stocks.

Synthetic Industrial Lubricants and Greases. Synthetic industrial lubricants and greases formulated with PAOs are available in wider viscosity grades with improved performance because PAO base stocks are available in high viscosities with higher VI and lower pour point. For example, 150 cSt SpectraSyn Elite has 206 VI and a −33 °C pour point. In contrast, the highest mineral base stock is 40 cSt with 98 VI and a −18 °C pour point, which imposes limits on possible high-viscosity products or wide cross-grade products. Synthetic industrial lubricants have many documented performance and economic advantages over conventional lubricants [35.7, 33, 34]. For example, PAO-based in-

dustrial gear/circulation lubricants offer the following documented advantages:

- Energy savings, longer fatigue life, and lowered temperatures of operation due to lower traction coefficients
- Wider operating temperature range due to higher VI and better thermal-oxidative stability
- Reduced equipment down-time, reduced maintenance requirements, and longer oil life due to the excellent stability of PAO base stock.

When used as compressor lubricants, PAO-based lubricants have advantages due to their better chemical inertness and resistance to chemical attack. Some synthetic compressor oils are used in corrosive chemical environments, for example, in sulfuric acid or nitric acid plants. PAO-based lubricants are also used in refrigeration compressor applications due to their excellent low-temperature fluidity, lubricity, and generally wider operating temperature range.

When used in stationary gas turbines or wind turbines, PAO-based lubricants offer superior low-temperature performance and lubricant stability [35.25]. These performance features significantly increase the service life for these expensive turbines, and reduce equipment downtime and maintenance. PAO base stocks are approved for incidental food contact. When PAO-based synthetic lubricants are used in the gears of food-processing equipment, the lubricants provide excellent wear protection, extended service life, and reduced maintenance. Synthetic greases based upon PAOs are used in industrial equipment, aviation and automotive applications that take advantage of the wide operating temperature range, high degree of

stability, and other desirable properties and features offered by PAO base stocks.

The newer PAOs like SpectraSyn Elite 65 and 150 base stocks offer even more performance advantages. They are particularly suited for industrial lubricants requiring high stability under severe operating conditions. For example, when formulated into industrial gear lubricants of ISO viscosity grade (VG) 320, the lubricants based on SpectraSyn Elite 65 and 150 have significantly higher VI than the lubricant based on current PAO, SpectraSyn 100 (Fig. 35.7) [35.27]. Higher VI lubricants offer increased protection at high temperature while maintaining required performance level at low temperature. In another example, Fig. 35.8 shows that an ISO VG 460 circulating lubricant formulated with SpectraSyn Elite has much lower Brookfield viscosity at 0 °F (≈ -18 °C) and -20 °F (≈ -30 °C) than the similar lubricant based on PAO 100 [35.27]. This lower low-temperature viscosity is indicative of better lubrication function at low temperature or better energy efficiency. In addition, the new PAOs offer other advantages including outstanding shear stability and greater formulation flexibility.

PAO has found its way into personal care products such as shampoos, conditioners, and skin lotions because PAO provides emolliency, good skin feel, and is nongreasy and noncomedogenic. It is also used in off-shore drilling fluids because of its good lubricity. New applications for PAO are continuously emerging.

35.3.2 Dibasic, Phthalate, and Polyol Esters – Preparation, Properties, and Applications

Lard and vegetable oil, both ester-type compounds derived from natural sources, have been used as lubricants

throughout human history. After World War II, thousands of synthetic esters were prepared and evaluated as lubricant base stocks for jet engine lubricants [35.2].

General Chemistry and Process

Esters are made by reacting carboxylic acids with alcohols with elimination of water, as shown by the following equation

The reaction proceeds by heating the mixture to 150 °C or higher with or without a catalyst [35.11, 12]. Catalysts such as *p*-toluenesulfonic acid or titanium (IV) isopropoxide, are typically used to accelerate reaction rates. The reaction is driven to completion by continuous removal of water from the reaction medium. Sometimes, one component is used in a slight excess to ensure complete conversion. The final product is purified over an adsorbent to remove trace water, catalyst and residual acids and alcohols, all of which are detrimental to base stock quality. Commercially, esters are generally produced by batch processes.

The choice of acid and alcohol determines the ester molecular weights, viscometric and low-temperature properties, volatility, lubricity, as well as the thermal, oxidative and hydrolytic stabilities [35.35–39]. The structure-property relationships of ester base stocks are

**Fig. 35.9** Synthesis of adipate ester

well documented in the literature. Compared to PAO and mineral oil, ester fluids have a higher degree of polarity, contributing to the following unique properties:

- Superior additive solvency and sludge dispersancy
- Excellent lubricity
- Excellent biodegradability
- Good thermal stability.

Three classes of esters are most often used as synthetic base stocks – dibasic ester, polyol ester, and aromatic ester. Some basic properties of these esters are summarized in Table 35.7.

Fig. 35.10 Synthesis of polyol esters

Fig. 35.11 Cracking reaction mechanism for esters - β -H effect

Dibasic Esters

Dibasic esters are made from carboxylic diacids and alcohols. Adipic acid (hexanedioic acid) is the most commonly used diacid (Fig. 35.9). Because it is linear, adipic acid is usually combined with branched alcohols, such as 2-ethylhexanol or isotridecanols ($\text{C}_{13}\text{H}_{27}\text{OH}$) to give esters with balanced VI and low-temperature properties (Fig. 35.9). Dibasic ester is most often used as a co-base stock with PAO to improve solvency and seal swell properties of the final lubricants.

Polyol Esters

The most common polyols used to produce synthetic polyol ester base stocks are pentaerythritol (PE), trimethylolpropane (TMP) and neopentylglycol (NPG), (Fig. 35.10). By carefully choosing the degree of branching and size of the acid functions, polyol esters with excellent viscometric properties – high VI and very low pour points – can be produced (Table 35.7).

In addition to excellent viscometric properties, polyol esters have the best thermal resistance to cracking. This is because polyols lack β -hydrogen(s) adjacent to the carbonyl oxygen and thus cannot undergo the same facile β -H transfer reaction as the dibasic esters (Fig. 35.11) [35.35]. This cracking by β -H transfer leads to two neutral molecules and is a relatively low-energy process. Polyol esters can only be cracked by C–O or C–C bond cleavage, leaving two free radicals – a very high-energy process requiring extremely high temperature. Therefore, polyol esters are thermally stable up to 250 °C.

Among the three polyol ester types, the thermal stability ranking is

PE esters > TMP esters > NPG esters .

Aromatic Esters

Phthalic anhydride or trimellitic anhydride is converted into esters by reactions with alcohols as shown in Fig. 35.12. Phthalic anhydride is produced cheaply and in large volume from oxidation of *ortho*-xylene. The largest use of phthalate esters is in the plasticizer market. Only a small fraction of its production is consumed by the synthetic lubricants market. Phthalate esters generally have superior hydrolytic stability than adipic esters because the *ortho* di-ester groups are electronically less available and sterically more hindered [35.40]. However, they have lower VIs, 50–70, because of their high polarity and the presence of branched alcohol chains. They are used in special industrial oil applications where VI is not a critical parameter. Trimellitate esters are specialty products and relatively expensive. They are of high viscosity and usually are more resistant to oxidation than adipic esters.

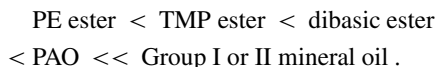

Fig. 35.12 Synthesis of phthalate and trimellitate esters

General Properties and Applications of Ester Fluids

Solvency and Dispersancy. Ester fluids are quite polar due to their high oxygen contents. They have high solubility for many commonly used additives. They also have high solubility for the polar acids and sludges generated by oxidation processes during service. This property makes ester-based lubricants *clean* compared to hydrocarbon-based lubricants, because of their better dispersancy and less sludge accumulation. Typically, low-viscosity ester fluids are soluble with nonpolar PAO base stocks. These properties make them excellent for use as co-base stocks with PAO in many synthetic automotive and industrial lubricants. Generally, 5–25% esters are used with PAO in finished lubricant formulations.

Hydrolytic Stability [35.40]. Hydrolysis of esters to give acids and alcohols is a facile reaction and can proceed at elevated temperatures in the presence of water. Hydrolysis of ester generates acid that can be very corrosive to metal components and can catalyze the base stock decomposition process. Therefore, hydrolytic stability of esters is an important issue. Much work has been carried out to improve the hydrolytic stability by varying the composition of acids and alcohols. Generally, esters made from aromatic acids or from more sterically hindered acids, such as 2-alkyl substituted acids or neo-acids, have improved hydrolytic stabilities. Proper branching of the acids protects the carbonyl ester function from the detrimental attack of water. The presence of an impurity, such as trace acid or metal, can catalyze the decomposition and hydrolysis of ester. Compared to PAO or alkylaromatic base stocks, ester hydrolysis is always an issue of concern in many lubrication applications.

Volatility. Ester fluids generally have lower volatility compared to PAO and mineral oil of comparable viscosities. A wt% volatility ranking for base stocks is as follows,

Lubricity. Polar ester fluids show mild boundary film protection at lower temperature. At lower temperature, esters interact with the metal surface via polar interaction, forming a chemisorbed surface film, which can provide better lubrication than the less polar mineral oil or nonpolar PAO. When esters decompose, they produce acids and alcohols. Higher molecular weight acids, can bind with the metal surfaces to form a film that can offer some degree of wear protection and friction reduction. However, none of these interactions are strong enough to persist when surface or oil temperature rises much above 100°C . At higher temperature, significant wear protection can only be achieved by the use of anti-wear or extreme-pressure (EP) additives. A drawback of the ester's high polarity is that esters can compete with a metal surface for polar additives, resulting in less efficient usage of anti-wear and EP additives. Therefore, in formulations using esters, it is important to choose the proper additives and concentration levels to obtain the full benefit of the lubricity from both the additives and esters.

Biodegradability. By carefully choosing the molecular compositions, esters of excellent biodegradability can be produced. Generally, esters from more linear acids and alcohols have better biodegradability [35.39].

Applications [35.41]. Esters, both dibasic and polyol esters, are used as co-base stocks with PAO or other

Fig. 35.13 Reaction scheme for PAG synthesis

hydrocarbon base stocks in synthetic automotive engine lubricants and industrial lubricants. Polyol esters are used in aircraft turbine oils due to their excellent thermal and oxidative stabilities, good lubricity, high VI, and excellent low-temperature properties ($< -40^{\circ}\text{C}$) [35.29]. Esters are also used in synthetic compressor oils for ozone-friendly refrigeration units. Because of their high biodegradability and low toxicity, esters are often the base oils of choice for many environmentally friendly lubricants or single-pass lubrication applications where ecological impact is critical [35.41].

Although ester chemistry has been studied extensively, new esters with unique performance improvements have continuously been reported in the literature [35.42, 43]. For example, esters with high stability were made from highly branched acids and polyols. Polyol esters formulated with ashless additives can be used as high-performance biodegradable hydraulic fluids.

35.3.3 Polyalkylene Glycols (PAG)

PAG is an important class of industrial chemicals. Its major use is in making polyurethanes. Outside of polyurethane applications, about 20% of the PAG is used in lubricant applications. Compared to PAO or esters, PAGs have very high oxygen content and hydroxyl end group(s). These unique chemical features give them high water solubility, high polarity, and excellent lubricity. PAG was first developed as fire-resistant, water-based hydraulic lubricants during World War II for military use [35.44]. Other applications such as textile lubricants, metal-working fluids etc. were developed subsequently to take advantage of their unique properties.

Chemistry and Process

PAGs are synthesized by oligomerization of alkylene oxides over a base catalyst with an initiator $R'OH$ (Fig. 35.13) [35.45]. When the initiator is water ($R' =$

H), the final PAG has two hydroxyl end groups. When the initiator is an alcohol ($R =$ alkyl group), one of the end groups is an alkoxy group (RO^{\ominus}). The most commonly used alcohol is *n*-butanol, although large alcohols have also been used for special applications. Phenol, thiols, or thiophenol are also used as initiators.

Ethylene oxide (EO), propylene oxide (PO), butylene oxides (BO), or combinations of these epoxides are used as starting materials for PAG syntheses. Longer chain alkylene oxides, such as butane oxide, hexene oxide or octene oxide, can be added to improve their compatibility with hydrocarbons. PAG with a wide range of viscosities, VIs, pour points, water solubilities and oil-compatibilities are produced by choosing the proper initiators, monomers, reaction conditions, and post treatments. The reaction is highly exothermic (22.6 kcal/mole) and heat removal is important to avoid side-reactions or broadening of the product molecular weight distribution.

Product Properties

Table 35.8 summarizes the typical lubricant properties of selected PAG produced from EO, PO, and BO with several different initiators [35.46].

EO-based fluids are typically waxy and have poor low-temperature properties. They have high water miscibility and are typically used to formulate water-based lubricants, especially fire-resistant hydraulic oil.

PO-based fluids are excellent lubricant base stocks with high VI and low pour point. They have lower solubility in water than EO-based fluids but are not oil miscible.

EO/PO-based fluids have a better combination of VI and low pour points than PO-based products. They are used as base stocks in industrial circulation/gear oils.

Pure BO-based PAG have improved oil solubility and are not less water-soluble. Recently, a wide range of oil-soluble PAG (OSP) base stocks have become available by co-polymerizing PO and BO [35.47].

Table 35.8 Lube properties of PAG fluids from EO, PO, and BO with different initiators

PAGs generally have excellent lubricity and low friction coefficients compared to mineral oil as shown in Table 35.9 [35.46, 48]. These properties result from the facile surface chemisorption of the oxygenate functions or through hydrogen bonding of the terminal OH groups with the metal surface.

Other unique properties for PAG include:

- Superior solvency – they dissolve additives, decomposition products, and sludges.
- Nonvarnishing and low ash – they leave little or no residue or carbon black upon decomposition.

Application

The major use of PAG is in industrial lube applications [35.48]:

- Fire-resistant hydraulic fluids. Water-soluble PAGs have fire resistancy, low toxicity, and excellent lubricity and anti-wear properties.
- Textile oils. PAG are nonvarnishing, nonstaining, and can be washed away with water.
- Compressor and refrigeration oils. Low solubility of many industrial gases, such as natural gas and ethylene, makes PAG suitable for gas compressor

applications. PAGs are compatible with new refrigerants (HFC-143a) and have excellent anti-wear properties.

- Metal working fluids. Some of the PAGs are nonvarnishing, have excellent lubricity, and anti-wear properties.
- Circulation/bearing/gear oil. Low friction coefficients and traction properties of PAG lead to lower operating temperature and energy consumption. They have good anti-wear properties and are low to nonvarnishing.

35.3.4 Other Synthetic Base Stocks

Polyisobutylene (PIB) fluids are produced by the oligomerization of isobutylene in a mixed C₄ stream over a BF₃ or AlCl₃ catalyst. PIBs are seldom used by themselves. They are typically used as blend stocks or as additives to increase lubricant viscosity. Table 35.10 summarizes the typical properties of selected PIB fluids [35.51]. The VI and pour points of PIBs are comparable to those of conventional mineral oil. PIBs usually have a lower flash point and decompose easily into monomer at 200 °C and higher. The advantages of PIB

are their high compatibility with most synthetic or mineral base stocks and their relatively low cost compared to other synthetic base stocks.

Alkylated aromatic base stocks include alkylbenzene and alkylnaphthalene. They are produced by the alkylation of benzene or naphthalene with olefins using Friedel–Crafts alkylation catalysts [35.49, 50]. Their typical properties are summarized in Table 35.11.

One unique feature of these alkylaromatic fluids is their very low pour points. Alkylbenzene was the first synthetic hydrocarbon used for engine lubricants in Alaska's oil production in the early 1960s because of its superior flow property at extremely low temperatures when mineral-based lubricants were frozen solid. Alkylbenzenes are mentioned in the patent literature as components for chlorofluorocarbon (CFC) or hydrochlorofluorocarbon (HCFC) refrigeration compressor oil. However, today, there is no reliable commercial supplier for alkylbenzene and it is rarely used in synthetic lubricant formulation.

In contrast to alkylbenzene, alkylnaphthalene (AN) is increasingly becoming an important class of polar synthetic base stock because of its many superior properties, especially its superior thermal, oxidative and hydrolytic stability [35.52]. Because of these outstanding stabilities, AN significantly improves lubricant service life and performance level when used to replace ester in the formulations of fully synthetic automotive engine lubricants or industrial lubricants. Figure 35.14 shows

Fig. 35.14 Turbine lubricant formulated with 10% AN has much better stability than similar lubricant formulated with 10% polyol ester in an oxidative stability test (ASTM D943 method)

the results from an oxidative stability test (ASTM 943 method) (or turbine oil stability test, TOST). In this test, the oil sample is heated at 95 °C with oxygen in the presence of water and an iron-copper catalyst. The amount of oil degradation can be monitored by periodically measuring the total acid number (TAN). This graph shows that an industrial turbine lubricant containing 10% AN has no change in acid number throughout the test duration of 3000 h. In contrast, lubricant containing 10% polyol ester suffers significant degradation

with increasing total acid number after 1000 h of the test.

Phosphate esters are produced from phosphorus oxychloride with various alcohols or phenols, or combinations of these hydroxyl compounds [35.53]. These fluids generally have good thermal and oxidative sta-

bilities and fire-resistancy. However, because of their high polarity, poor VI-pour point balance, facile hydrolysis [35.54], and inferior elastomer and paint compatibility, their use in general lubrication is limited. The major use for phosphate esters is in fire-resistant hydraulic oils.

35.4 Conclusion

Finished synthetic lubricants have significantly raised the performance level of automotive and industrial lubricants with the help of high-quality synthetic base stocks and high-performance additive technologies. Equipment builders, industrial users, and general consumers have benefited from the enhanced performances of synthetic lubricants such as reduced maintenance and waste, lower emissions and pollution, higher reliability and efficiency. As a result, finished synthetic lubricant is projected to grow at 4% per year by volume from 2013 to 2023 [35.55], a range considerably greater than for conventional lubricants. Although part of this growth is based on the availability of high-quality Group II or Group III base stocks which are also used to formulate finished synthetic lubricants, a significant part of this growth is based on synthetic base stocks described in this chapter. From 2011 to 2016, the worldwide demand for all synthetic base stocks was projected

to grow at 3.5% annually [35.28–31]. The growth for PAO base stocks may be slowed temporarily due to competition from Group II or III base stocks or from gas-to-liquid base stocks. Recently, high-performance PAO base stocks were projected to grow at 7% annually through 2020 due to their well-documented advantages such as greater efficiency, reduced maintenance, lower emissions, and longer service life and wider viscosity range [35.14]. Further into the future, to meet the escalating performance demand of new equipment, lubricant industry leaders are expected to respond by developing and marketing next-generation, high-performance base stocks and lubricants.

Acknowledgments. The authors would like to thank Alex Lee, Bruce Harrington, Kathy Cooper, Angela Galiano-Roth, and Wenning Han for their valuable comments on this chapter.

36. Catalytic Processes for Light Olefin Production

Genquan Zhu, Chaogang Xie, Zaiting Li, Xieqing Wang

Up to now, the major process for light olefin production has been thermal steam cracking. The diversification of feedstocks from heavy oil fractions to light hydrocarbons as well as methanol led to the development of catalytic processes. Differing from the radical mechanism for olefin formation by the thermal process, there are two reaction mechanisms for the description of olefin formation in the catalytic process: the carbocation mechanism for hydrocarbon cracking and the hydrocarbon pool mechanism for methanol to light olefin.

Deep catalytic cracking (DCC), developed by the Research Institute of Petroleum Processing (RIPP) of Sinopec, is a fluidized catalytic cracking process that uses a proprietary catalyst for the selective cracking of a wide variety of heavy feedstocks to produce light olefins. The catalytic pyrolysis process (CPP), also developed by RIPP of Sinopec, is an extension of DCC that gives an increased ethylene yield while keeping propylene production at a reasonable rate. The commercial units run worldwide showing the success of the development of these processes.

The key process features, the representative catalysts, and the performance of PetroFCC, Propylur, SuperFLEX, propylene catalytic cracking, olefins

catalytic cracking, olefins conversion technology, propane dehydrogenation, and methanol-to-olefins are also briefly introduced.

In future, for the production of light olefin, catalytic processing is the key step to integrate the refining and petrochemicals plants.

Consumption of petroleum in the transportation fuel sector is expected to show only a modest rate of growth in the near future. Fuel specifications are becoming increasingly stringent due to new environmental regulations and energy sources such as biofuel, and especially fuel cells for vehicles, which are becoming increasingly attractive as environmentally friendly alternatives. In the petrochemical sector, however, the consumption of hydrocarbon raw materials is expected to grow more rapidly. The building blocks for the petrochemical industry are mainly light olefins, principally ethylene and propylene, and aromatics, including benzene, toluene, and xylenes (BTX). Steam cracking has been the major source of light olefins and aromatics for more than

half a century. The proportions of different steam cracking feedstocks used worldwide are shown in Fig. 36.1. Naphtha is currently the dominant feedstock, accounting for 40–50% of the total. It is expected that ethane, associate gas, condensates, and methanol will dominate as the major feedstock because they are easier to obtain at a lower price. In North America and the Middle East, ethane and shale gas and associated gas already make up 70–80% of the feedstock for steam cracking. This threatens to induce an imbalance in the ethylene-to-propylene ratio in the overall output from steam cracking because typical ethane pyrolysis gives 79% selectivity to ethylene and less than 1% selectivity to propylene at 70% conversion, whereas

Fig. 36.1 Proportions of different feedstocks used in steam cracking

steam cracking of naphtha gives approximately 30% ethylene and 15% propylene. It is predicted that by 2020, the annual demand for ethylene and propylene will be 170 and 115 Mt respectively (a propylene-to-ethylene ratio of 0.68). The propylene stream from refineries currently accounts for one third of the total supply, and it is clearly necessary to develop new ways of increasing propylene production. A variety of new processes for modifying the propylene-to-ethylene ratio are emerging, such as transformation or product shift by isomerization, hydroisomerization, metathesis, interconversion, skeletal isomerization, and catalytic cracking.

Increasing the integration of petroleum refining with petrochemicals is an inevitable tendency not only for economic and environmental reasons but also because of an increasing reliance on deep upgrading of

crude oil. Statistics show that reserves of heavy crude are much larger than those of conventional crude, and deep upgrading of heavy crude for both refining and petrochemicals is attracting more and more attention from scientists and engineers. Integration will also lead to a rational development of both refinery product slates and petrochemical building blocks.

In the manufacture of the key building blocks for petrochemicals, i. e., ethylene, propylene and other olefins as monomers for polymerization, and BTX as the basic raw material for various synthetic pathways, thermal steam crackers currently still predominate. Catalytic processes such as fluid catalytic cracking (FCC), alkylation, isomerization, catalytic reforming, and hydroprocessing play a decisive role in the production of clean fuels and lubricants in refineries. The integration of refining with petrochemicals leads to the optimization of all the processes involved, and the development of processes with an adjustable ratio of ethylene-to-propylene production is now becoming possible. It can be expected that catalytic processes will play an increasingly significant role in the production of light olefins, especially when the feedstock for light olefins becomes diversified. Besides heavy or low grade oil, light hydrocarbon byproducts from refining and petrochemical plants, methanol and biomass are utilized to produce light olefins and aromatics in different catalytic processes. With the large-scale application of natural gas and shale gas, an agile portfolio of solutions is required to produce light olefins efficiently. This chapter introduces the latest progress toward the aim of increasing propylene production in FCC and related processes for light olefins.

36.1 Fundamentals of the Cracking Mechanism for Light Olefin Production

There are two routes for the production of light olefins by catalytic cracking, which differ according to whether heavy or light hydrocarbons are employed as feedstock. When heavy hydrocarbons are used, they undergo primary cracking. Light hydrocarbon feedstocks are byproducts from refining and petrochemical plants i. e., C₄ and C₅ fractions of relatively low added value, which are suitable for further cracking to ethylene and propylene. The reaction pathways involved for the two types of feedstock differ to some extent.

The complex composition of heavy feedstocks means that a large number of reactions can take place, both in parallel and consecutively, on the catalyst. The relative rates of the various reactions, taken together with the relative ease of the formation of various carbo-

cations from the parent molecules, lead to a bewildering array of possible reaction pathways. The matter is complicated by the presence of a variety of active sites on the heterogeneous catalysts. These sites not only differ in their acid strength but also in their nature. A variety of reactions of carbocations can take place on these acid sites, including cracking, isomerization, hydrogen transfer, alkyl transfer, and C–C bond formation as well as coke formation. Cracking reactions of large molecules tend to predominate, however.

In the FCC process using heavy feedstocks, light olefins are probably produced by the secondary cracking of primary olefins in the FCC naphtha fraction. The reaction proceeds readily over Zeolite Socony Mobil-5 (ZSM-5) zeolite-containing catalysts. It is widely ac-

cepted that olefin cracking over catalysts with Brønsted acidity involves the initial protonation of the double bond to form a tricoordinate carbenium ion, with subsequently scission of a carbon–carbon bond in the beta position, to form a free olefin and a smaller carbenium ion.

Anderson et al. [36.1] recently attempted to predict the optimum zeolite-based catalyst for the selective cracking of naphtha-range hydrocarbons by the pathway proposed by Haag and Dessau in 1984. According to this mechanism, light olefins are produced from alkanes via *protolytic cracking*, in which alkanes are protonated to form carbonium ion transition states that can undergo either C–C bond cleavage, yielding alkanes (including methane and ethane), or C–H bond cleavage, yielding dihydrogen and carbenium ions. These carbenium ions subsequently form alkenes via the back-donation of a proton to the zeolite. The formation of ethylene is probably via this pathway.

Weitkamp et al. [36.2] introduced a classification of carbenium ion beta scission processes. The process where the carbenium ions before and after scission are both tertiary is denoted as type A. Type B1 scission refers to the reaction of a secondary ion to give a tertiary ion, while type B2 involves a change from a tertiary to a secondary ion. Type C involves the conversion of a secondary ion to another secondary ion, and type D involves the transformation of a secondary ion to a primary ion. Buchanan [36.3] added an additional category of primary-to-tertiary ion transformation, designated as type E. Although the beta scission of primary carbenium ions can produce ethylene, the formation of other types of carbenium ions, which mostly produce propylene by terminating the reaction pathway, is more likely.

Cracking of the second category of feedstock – light hydrocarbons such as C₄ olefins – is likely to involve a bimolecular process and probably proceeds via initial oligomerization to form C₈ species, which then undergo

further cracking to form light olefins. Both the study of C₄ saturates and that of Wakui et al. [36.4] showed that butanes are difficult to crack directly. They must first be dehydrogenated to form butylenes, which are then consecutively cracked following the usual olefin reaction pathways.

It should be noted that, in addition to Brønsted acid sites, Lewis acid sites also play an important role in olefin production, although in fact these two types of acid sites can be interconverted at high temperatures. In general, heating the zeolite catalyst to a high temperature results in a loss of Brønsted acidity with a corresponding increase in Lewis acidity. This alters the activity and selectivity of the zeolite in favor of a high light olefin yield. We have found that it is of great importance to maintain an optimum Lewis-to-Brønsted (L/B) ratio in order to maximize ethylene yield under severe operating conditions.

Table 36.1 shows that when ZSM-5 zeolite is modified by treatment with silver (samples AGZ-1 and AGZ-2), both the number of Brønsted and Lewis acid sites increase, but the increase in the number of Lewis sites is much more marked. By using these zeolites as catalysts for the cracking of heavy oil at 650 °C, substantially higher yields of ethylene and propylene can be obtained compared with the reaction over quartz as a representative inert solid. Furthermore, increasing the number of acid sites, especially Lewis sites, leads to an enhanced ethylene yield. Our experimental data are summarized in Table 36.2.

Corma et al. [36.5] postulated that on highly dealuminated zeolites, the cracking reactions take place on extra-framework aluminum sites following a radical-type pathway, which will give more C₁ and C₂ hydrocarbons, mostly ethylene. The mechanism for the cracking reactions we observe at 650 °C (results shown in Table 36.2) may involve either carbenium ion or radical ion intermediates, but this still has to be determined.

The conversion of methanol-to-olefins (MTOs) over acidic zeolites (HZSM-5) or zeotype materials (HSAPO-34) has become an increasingly important catalytic process both in modern natural gas and coal chemical industries. HSAPO-34 was derived from (2x1x1)CHA supercell (24T), in which all Si atoms were substituted by P and Al atoms alternatively, and one P atom then is replaced by a Si atom to generate one Brønsted acid site per cage [36.6]. Due to its complex

AGZ-2	0.27	2.80	8.99	12.77	0.70	21.76

nature, the MTO reaction mechanism is still a hot area of dispute. It was traditionally believed that the MTO reaction proceeds through the hydrocarbon pool mechanism, and methylbenzenes (MBs) are the predominant hydrocarbon pool species. However, by extensive periodic density functional theory (DFT) calculations in the HSAPO-34 catalyst, Wang [36.7] proposed that olefins themselves rather than MBs are likely to be the dominating hydrocarbon pool species. A full reaction network is established, as depicted in Fig. 36.2, and the routes to produce olefins, alkanes, and aromatics are formulated. They find that light olefins such as ethene and propene are mainly produced through the scission of cracking precursors (carbenium ions, alkoxides, and higher olefins), and which are formed by the methylation of lighter olefins. The distribution of these cracking precursors as the number of carbon atoms in the pores of catalysts influences the product selectivity from the reaction point of view. A decrease trend in the cracking energy barriers is observed with the carbon atom number of cracking precursors. Hydride transfer between two olefins results in the formation of alkanes and dienes, and the latter are likely to be the precursors to forming aromatics, subsequently leading to the deactivation of catalysts.

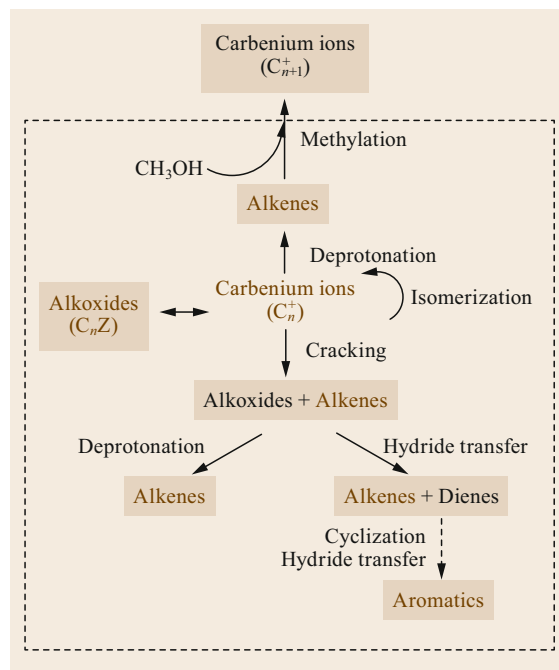

Fig. 36.2 Reaction network of the MTO conversion in acidic zeolites. (After [36.7])

36.2 Catalysts

In the FCC process, it is generally accepted that after vaporization the large molecules of heavy hydrocarbons undergo cracking on both the surface of the Y-zeolite and on the surrounding silica-alumina matrix as a primary reaction. The smaller molecules thus formed permeate into the pores of the Y-zeolite and reach the active sites of the catalyst where the desired catalytic cracking reactions take place. Great efforts have been made to redesign the catalyst formulation as well as to improve the process of catalyst manufacture in order to optimize the yield of light olefins.

As far as the improvement of catalyst formulation is concerned, there are two approaches to the goal of enhanced light olefin yields in the FCC process: incorporation of ZSM-5-containing additives into conventional FCC host catalysts or reformulation of the catalysts, especially for olefin production.

Both of these methods have their advantages and disadvantages. Mixing the conventional FCC catalyst with ZSM-5-containing additives gives the advantage of flexibility in fluid catalytic cracking unit (FCCU) operation according to changes in the market demand for gasoline or olefins. The disadvantage is the difficulty in providing the pore size distribution gradient in the mixed zeolite catalyst, which gives the desired

ratio of light olefins as products of primary cracking and secondary cracking. Furthermore, according to the accepted reaction mechanism, the intermediates from primary cracking should first be desorbed from the acid sites of the main catalyst and then enter the pores of the ZSM-5-containing additive. In the course of this migration, the intermediate species can undergo some undesired reactions. As a result, the yield of light olefins may be adversely affected. From the viewpoint of the physical properties of a mixed catalyst in an FCCU, the two kinds of solids should be closely matched in the density and attrition index in order to keep their relative proportions constant over time. This necessitates a careful choice by the user of both host catalysts and additives.

An especially formulated catalyst for maximizing the yield of light olefins can be tailored in light of the feed properties and target products by optimizing the composition of a mixture of different performances of zeolites. The pore-size distribution of the matrix should be such as to allow access to the large molecules of the feedstock, whilst the incorporation of large-pore Y-zeolite favors intermediate molecule formation and mesoporous ZSM-5 favors the production of light olefins. The gradient in the pore-size distribution allows

ready access to a series of reactants of different molecular sizes. Furthermore, the acidity of catalytic materials, as well as their strength and density, can be adjusted to give predominantly light olefins.

Modification of ZSM-5 is crucial if olefins are to be produced under much more severe operating conditions than those employed for conventional FCC. In the RIPP of Sinopec, there has been a long-term program aimed at enhancing the hydrothermal stability and selectivity of ZSM-5.

It is well known that the incorporation of rare earth cations can greatly improve the hydrothermal stability of Y-zeolite. *Shu et al.* [36.8] have reported the incorporation of rare earth ions into the ZSM-5 structure by a seeding method in which an REY-zeolite (Y zeolite modified by RE) is dispersed in a gel containing Si, Al, Na sources and water, and the mixture converted into an MFI-type zeolite (a kind of zeolite with mesopore). The resulting ZSM-5 zeolite containing rare earth ions was further modified under hydrothermal conditions and the final catalyst, denoted ZRP-1 (ZSM-5 modified by Fe), has outstanding hydrothermal stability as shown in Table 36.3.

Luo et al. [36.9] have reported the modified MFI-type zeolite ZSP (ZSM-5 modified by P and Fe), which was formed by the treatment of ZSM-5 with phosphorus and transition metal ions. When ZSP is used as the catalyst for *n*-C₁₄ cracking at 520 °C, the yield of propylene is increased compared with that obtained over the ZSM-5, as indicated in Table 36.4.

It was found that the introduction of phosphorus into the ZRP series of zeolites further stabilized the crystal structure and was successful in reducing dealumination at high reaction temperatures allowing a large

fraction of the acidity, and hence activity, to be maintained. Based on this experience, a modified MFI-type catalyst CEP-1 [36.10, 11] was developed by RIPP, especially for the catalytic pyrolysis process (CPP) with the aim of giving high activity and selectivity for light olefins under severe operating conditions. The hydrothermal stability of the catalyst is shown in Table 36.5.

The stability of carbenium ions decreases in the order tertiary > secondary > primary, meaning that the yield of ethylene is generally much less than that of propylene. *Zhang et al.* [36.12] found that by adjusting the acid type, acid strength, and acid distribution, the ratio of ethylene-to-propylene can be altered in favor of ethylene. A modified MFI-type zeolite PMZ (ZSM-5 zeolite modified by Fe and alkaline earth metal) was formed by the treatment of ZRP-1 with alkaline earth metal ions. When PMZ is used as the catalyst for middle distillate cracking at 520 °C, the ratio of ethylene-to-propylene is increased, compared with that obtained over the ZRP-1 precursor, as indicated in Table 36.6.

It should be noted that in addition to the catalytic carbenium ion pathways for light olefin production, thermal reactions involving free radicals are also a sig-

nificant source of ethylene and indeed predominate at higher temperatures. Table 36.7 gives a comparison of

the impact of such thermal reactions on the yields of ethylene and propylene at different temperatures.

36.3 New Technology

In the last few decades, great efforts have been made to produce light olefins by catalytic processes in order to achieve a rational utilization of heavy feedstocks or petrochemical byproducts. Some papers in this area presented at the 17th World Petroleum Council (WPC) drew considerable attention from both academic and industrial researchers. A variety of very promising processes have been developed, and some have already been commercialized. All of the new catalytic processes aim to tackle the problem of low propylene-to-ethylene ratio caused by the recent feedstock change for steam crackers.

36.3.1 Deep Catalytic Cracking

Deep catalytic cracking (DCC) [36.10, 11, 13, 14] is a new fluidized catalytic cracking process using a proprietary catalyst for the selective cracking of a wide variety of heavy feedstocks to give light olefins. The process, developed by RIPP of Sinopec, has been commercially proven with ten units built since 1990, seven in China and the others in Thailand, Saudi Arabia, and India. The DCC-I process is similar to that of conventional FCC with a modified reactor consisting of a riser plus fluidized dense bed. The dense bed at the end of the riser results in a longer residence time at a high catalyst-to-oil ratios, favoring the secondary cracking of primary intermediates, which is thought to enhance propylene production at the cost of gasoline yield. In the DCC-II system, the dense bed is removed in order to allow

flexibility in propylene and gasoline yields according to market demand. Table 36.8 shows a comparison of the key features of DCC with those of conventional FCC.

The experience accumulated over decades in four refineries and one petrochemical complex has shown that light olefin yields are greatly dependent on the feedstock properties as detailed in Table 36.9. Daqing paraffinic feedstock gives the highest propylene and isobutylene yields, with 23.0 and 6.9 wt% respectively. For intermediate base feeds, propylene yield is more than 18 wt% for DCC-I and 14.4 wt% for DCC-II operation with an FCC naphtha yield near 40 wt%.

The DCC gasoline fraction is rich in BTX, especially xylenes. Table 36.10 lists the BTX content in the DCC naphtha fraction and DCC 75–150 °C light gasoline range. Recovery of BTX from the narrow cut for petrochemical applications is economically viable.

A DCC unit with the capacity of 4600 kta has been put into commercial operation since May 2009 at Saudi Aramco-Sumitomo Chemical at their Rabigh, Saudi Arabia site. The production rates are 225 kta ethylene and 950 kta propylene. The DCC unit was integrated with the ethane steam cracking unit for recovering the ethylene.

The reactor of conventional DCC is a riser plus fluidized dense bed, which can enhance propylene production and can also bring out higher dry gas and coke yields due to the lower catalyst activity and an unreasonable temperature gradient in the DCC reactor. In order to improve the selectivity of the desired

products, RIPP has developed a DCC-plus process, which can optimize the temperature and catalyst activity gradient along the reactor by introducing high temperature and activity catalysts into the fluidized-bed reactor through the second riser. A series of experiments for DCC-plus technology was carried out on the pilot plant unit [36.15]. The experimental results showed that as compared with DCC technology, the yields of liquid petroleum gas (LPG), propylene, and butylenes in DCC-plus process were enhanced significantly at the same time the yields of dry gas and coke were reduced.

A DCC-plus unit with the capacity of 1200 kta has been put into commercial operation since February 2014 at the CNOOC Hainan Dongfang Petrochemical Corporation limited.

The ethylene in the DCC dry gas can be recovered by means of cryogenic separation through integration with the steam cracking. On the other hand, the ethylene in the DCC dry gas can be converted into styrene, and some units have been put into commercial application in China.

It has been clearly demonstrated that increasing propylene production, even at the expense of gasoline yield, is a commercially economic proposition in an integrated refining-petrochemical complex.

36.3.2 Catalytic Pyrolysis Process (CPP)

The CPP [36.16], also developed by RIPP of Sinopec, is an extension of DCC that gives an increased ethylene yield while keeping propylene production at a reasonable rate. The key features of this process are as follows:

- A new catalytic material has been developed that reduces the activation energy required, thus allowing the reaction to be carried out at a significantly lower temperature compared with that required for steam cracking, and also favors the production of light olefins.
- The catalyst possesses excellent hydrothermal stability and attrition resistance.
- The operating conditions for CPP are more severe than that for residue fluid catalytic cracking (RFCC) to an extent that allows it to be operated in existing idle RFCC units without the risk of damage to the fabric of the plant.
- The heat required for the cracking reaction can be provided by burning coke in the regenerator, making the reaction fully self-supporting.
- An especially designed stripper located between the regenerator and reactor removes the flue gas carried over from the regenerator.
- Since the reaction temperature is higher than for conventional RFCC, a postriser quench has been introduced for heat recovery as well as termination of secondary reactions in order to prevent further thermal degradation of the target products.

Commercial trial runs were successfully completed in early 2001 at the PetroChina Daqing Refining and Chemical Co. using a revamped DCC unit with a capacity of 80 kta. Three sets of conditions were employed:

1. Mode 1 for the maximum propylene yield
2. Mode 3 for the maximum ethylene yield
3. Mode 2 – intermediate between the two.

Feedstock properties, product distribution, and major operating parameters can be seen in Tables 36.11–36.13. Across the three modes, the combined yield of ethylene and propylene ranges between 34 and 38 wt%, and the total yield of $C_2=C_4$ olefins is around 45 wt% in each case. The ethylene-to-propylene ratio can be adjusted by the variation of the operating conditions.

Table 36.11 Feedstock properties

We suggest that in order to optimize the use of crude oil as a petrochemical feedstock, a combination of steam cracking and CPP may be the best choice, as depicted in Fig. 36.3.

Key economic data for a CPP plant with the integrated steam cracker are shown in Table 36.14. Based on 500 kta of ethylene produced by CPP and 1000 kta of ethylene produced by steam cracking, the estimated net product revenue is 450 \$ MM/a.

A CPP unit with the capacity of 500 kta has been put into commercial operation since June 2009 at Shenyang Chemical Group Shenyang Paraffin and Chemical Company.

The plant producing ethylene and propylene from the Daqing atmospheric residue was composed of three parts: CPP system, ethane-propane tubular-cracking furnace, and pyrolytic gas purification and separation system. The flow diagram for this plant is shown in Fig. 36.4. The atmospheric residue is cracked in the CPP system's reactor, and the reactor effluents are cooled in the postriser quench and flow into the fractionator and direct cooling tower to be separated into cracked gas, naphtha, and LCO. The cracked gas is compressed and pumped into the pyrolytic gas purification and separation system to obtain poly-

ethylene and propylene at the same time; the aromatics content in cracked naphtha is 82.46 wt%.

Since July 2014, a CPP unit with a capacity of 1500kta has been put into commercial operation at Yanchang Petroleum.

36.3.3 PetroFCC

The PetroFCC [36.18–21] process is licensed by UOP LLC and features RxCat technology. The process gives high yields of propylene, light olefins, and aromatics for petrochemical applications, from feedstocks that can include conventional FCC feeds and higher boiling or residual feeds. The feed comes into contact with the blended catalyst in the riser under very severe pro-

cessing conditions. The blended catalyst consists of the regenerated and coked catalysts.

The PetroFCC process uses a high-conversion, short-contact time reaction zone that operates at elevated reactor riser outlet temperatures and low partial pressures. It also incorporates a relatively high level of a shape-selective zeolite catalyst additive with a selected standard FCC catalyst as the balance. The PetroFCC process incorporates UOP's Optimix feed distribution system, vortex separation system (VSS), vortex separation technology, advanced fluidized (AF) spent catalyst stripping technology, and RxCat technology to enhance light olefin and/or aromatics production. RxCat is a key differentiating technology of the PetroFCC process when compared to alternate technology.

The PetroFCC process employs several measures to improve the yield and selectivity of propylene and lower the yield of dry gas:

- The PetroFCC catalyst has two components. The first component comprises a large-pore zeolite, such as a Y-type zeolite. The second component involves medium- or small-pore zeolites, such as ZSM-5 or ST-5, which have high coking resistance.
- The riser inlet temperature is reduced to about 620 °C by cooling the regenerated catalyst with the recycled coked catalyst. The ratio of the catalyst-to-feed can be increased to an extent without any adverse influence on the heat balance in the unit.
- The residence time for the feed in contact with the catalyst in the riser is less than or equal to 2 s. The

short residence time ensures that the target products are not further converted to undesired products. The diameter and height of the riser should be varied to give the desired residence time.

- To enhance light olefin production, low hydrocarbon partial pressures (70–210 kPa(a)) and elevated temperatures (540–620 °C) are employed.
- A second riser, which shares a common regenerator with the primary riser reactor, is provided for re cracking the naphtha-containing higher olefins.

The expected yield patterns for a typical vacuum gas oil (VGO) in a conventional FCC unit and a PetroFCC unit are compared in Table 36.15.

36.3.4 Propylur

The Propylur process [36.22–24] converts low-value light hydrocarbons enriched in olefins into petrochemicals such as propylene and is based on a shape-selective heterogeneous zeolitic catalyst of the ZSM-5 type.

The feedstock for the Propylur process can be C₄ cuts, Raffinate I, Raffinate II, or a gasoline fraction. Naturally, a feedstock with high olefin content is more favorable. Compounds such as paraffins, cycloalkanes, and aromatics are rarely converted when they pass through the reactor. The diolefin content should be limited to approximately 1.5% in order to reduce the formation of gum and coke during the reaction.

The Propylur reactor is an adiabatic fixed bed type, similar to that employed in a Claus unit. The operating temperature is approximately 500 °C and pressure is 100–200 kPa. The hydrocarbon partial pressure is reduced by diluting the feedstock with steam in order to shift the equilibrium toward the desired product (propylene). This also minimizes coking and gum formation. The reaction is endothermic and requires additional heat.

By cooling the reactor effluent, the steam is condensed and then separated together with some gasoline

Table 36.15 Yield patterns of conventional FCC and PetroFCC units

Component (wt%)	Conventional FCC	PetroFCC
H ₂ S, H ₂ , C ₁ , and C ₂	2.0	3.0
Ethylene	1.0	6.0
Propane	1.8	2.0
Propylene	4.7	22.0
Butanes	4.5	5.0
Butylenes	6.5	14.0
Naphtha	53.5	28.0
Distillate	14.0	9.5
Fuel oil	7.0	5.0
Coke	5.0	5.5

byproducts. The remaining vapor is compressed in order to allow C₃/C₄ separation at reasonable temperatures. Most of the C₄+ fraction is recycled to the reactor to increase the ultimate propylene yield and a portion of C₄+ is sent to the plant's furnace section to prevent excessive buildup of C₄+ paraffin recycle. Further separation of the C₃ fraction can be done in the ethylene plant. The single-pass propylene yield is 40–45%, and the ethylene yield is 10%. The ultimate yield of propylene is 60% and that of ethylene is 15%, with the butylenes recycled.

The catalyst lifetime is predicted to exceed 15 months based on the laboratory pilot-plant experience. The catalyst can be regenerated off-stream in situ by burning the coke deposited on it by controlled combustion with a nitrogen cycle and small air makeup.

When integrated with an ethylene plant, the Propylur plant can give increased propylene-to-ethylene ratios in a steam cracker. The typical yields of different products from the Propylur process are shown in Table 36.16.

36.3.5 SUPERFLEX

The SUPERFLEX process [36.25–31] is a proprietary technology patented by ARCO Chemical Technology, Inc. (now Lyondell Chemical Co.), and is exclusively offered for license by Kellogg Brown and Root (KBR). It uses an FCC system with a proprietary catalyst to convert low-value feedstock with high olefin content to petrochemical products such as propylene and ethylene.

The feedstock can be olefin-rich light hydrocarbons in the carbon range C₄–C₈, and the ideal feedstocks are C₄ and C₅ streams generated in the steam cracker. Diolefins and acetylenes in the feedstock can be partially hydrogenated to olefins, or the diolefins extracted for other petrochemical applications. Other possible feedstocks are MTBE raffinate-2, aromatics plant raffinate and refinery streams that are rich in olefins, such as light naphtha from an FCCU, coker or visbreaker. Refinery streams do not require pretreatment or hydrogenation of dienes – there is no limit on feed aromatic or diene content.

The SUPERFLEX FCC system is similar to that of a conventional FCC unit and consists of riser reactor, regenerator vessel and units for air compression, catalyst handling, flue gas handling and feed and effluent

Table 36.16 Typical yields from the Propylur process

	Typical yields (wt%)	
	Single pass	C ₄ recycle
Propylene	40–45	60
Ethylene	10	15
Butylenes	30	

heat recovery. The SUPERFLEX system should be integrated into an ethylene plant in order to minimize capital investment, with the feedstock obtained directly from the steam cracker and shared common product recovery. The cooled reactor effluent can be processed in a nearby existing ethylene plant recovery unit. Alternatively, the effluent can be processed in a partial recovery unit to recover recycle streams and olefin-rich streams concentrated for further processing in a nearby ethylene plant.

The SUPERFLEX process operates at approximately 500–700 °C and 100–200 kPa, and so it converts paraffins and naphthenes along with olefins. This allows it to operate in a total recycle mode and to produce higher yields of propylene and ethylene. The propylene-to-ethylene ratio is about 2 : 1 (wt/wt).

The conditions involve low hydrocarbon partial pressures, high temperatures, and low per-pass conversions in order to favor propylene production. The catalyst is very robust, and there is no need to pretreat for typical feed contaminants, such as sulfur, water, oxygenate, or nitrogen in feeds. The typical ultimate light olefin yields after the C₄–C₅ recycle operation are listed in Table 36.17. FCC light naphtha would make 30% propylene and a lesser amount of ethylene, whereas a typical C₄-raffinate-1 (butadiene has been extracted) yields half as much propylene and about the same amount of ethylene.

KBR also presents SUPERFLEX as a means of greatly increasing the production of propylene in a refinery by integrating it with the company's MAXOFIN process. When the two processes are synergistically combined to form a dual-riser version of SUPERFLEX, it is called SUPERFLEX plus.

36.3.6 Mobil Olefins Interconversion (MOI)

Mobil olefin interconversion (MOI) was developed by the Mobil Oil Corporation and converts light hydrocarbons containing C₄–C₇ olefins to more valuable light olefins by contacting the feed with a catalyst containing Mobil ZSM-5, which provides the acid activity and shape selectivity needed to help promote oligomerization, cracking, and disproportionation while limiting

coke formation and the production of polynuclear aromatics and dry gas [36.32].

The feedstocks will typically be low-value refinery or petrochemical streams, such as steam cracker byproducts rich in C₄s, which have poor propylene selectivity when recycled to the steam cracker. The feedstock can include raffinate, FCC naphtha, coker naphtha, and steam cracker pyrolysis gasoline, as well as synthetic chemical streams containing sufficient amounts of C₄–C₇ olefins. Dienes, sulfur, nitrogen, and oxygenates in the feeds are preferably selectively hydrotreated prior to the conversion process. However, feeds with low levels of dienes, sulfur, nitrogen, metal compounds, and oxygenates can be processed directly from FCC units, cokers, or steam crackers without any pretreatment.

The process uses a dense fluidized bed and the hydrocarbon feed containing the C₄–C₇ olefins is continuously passed through the bed under conversion conditions in the presence of the catalyst. The catalyst is continuously circulated between the fluidized bed and a regenerator. The fluidizable catalyst can transfer heat from the latter to the former, thereby helping to supply some of the thermal needs of the conversion reaction, which is endothermic. The operation of the process is similar to that of conventional FCC.

The dense fluidized-bed conversion conditions include temperature in the range 540–650 °C and pressure from 0.10 to 0.45 MPa, catalyst-to-oil weight ratio of 0.1–10, and a weight hourly space velocity (WHSV) of 1–10 h⁻¹. Because the catalyst used in the process has lower cracking activity relative to conventional FCC catalysts, a higher temperature compared with that for conventional FCC may be used in order to achieve a higher conversion to the desired light olefins.

The catalyst in MOI contains only ZSM-5 without any large-pore zeolites. The ZSM-5 preferably has a high initial silica/alumina molar ratio and is modified by phosphorus and metals such as gallium.

The products from MOI include light olefins such as propylene and ethylene. A higher yield of propylene is produced than is usually obtained in conventional catalytic cracking processes utilizing a ZSM-5 additive. The propylene-to-ethylene weight ratio is related

Table 36.17 SUPERFLEX product yields from various feeds^a

Yields (wt%)	C ₄ raffinate-1	Partially hydrogenation C ₅ S	FCC LCN	Coker LN
Dilute ethylene (C ₂ and lighter)	26.6	31.7	25.1	11.6

C ₆ + gasoline	17.9	18.6	31.7	22.9

^a The yields resulted from recycled C₄ and C₅

to the conversion and feed but almost always exceeds 3.0. The combined yield of ethylene plus propylene is about 20–30 wt%. Propylene purities of 85 wt% or greater can be achieved. In addition, only relatively small amounts of aromatics such as BTX are produced.

Table 36.18 shows the products obtained from the processing of FCC C₅–C₇ naphtha containing 51 wt% olefins and steam cracker byproduct using a single pass and a recycle configuration of the MOI process. Recycle of C₄ and C₅ olefins is used to increase ethylene and propylene yields. As shown in Table 36.18, conversion to propylene is higher with the steam cracker feed since it contains more olefins.

The use of MOI in the processing of C₄ steam cracking byproduct (typically 40% butadiene) results in the highest propylene yield. This option is compared in Table 36.19 against various upgrading alternatives. Hydrotreating is used in three of these options to either selectively convert butadiene to butylenes or to convert all of the butadiene and butylenes to butanes.

36.3.7 PCC (Propylene Catalytic Cracking)

The ExxonMobil PCC process [36.33–35] is a new fluid solid naphtha-cracking process to convert naphtha olefins to light olefins, such as propylene, which employs an optimum catalyst, reactor design, and patented combination of optimum operating conditions to achieve a high degree of reaction selectivity.

The feed can be obtained from cat naphtha, coker naphtha, and steam cracker's C₄s and pyrolysis gasoline. The largest source of olefinic feedstock molecules is cat naphtha, which contains 20–60% olefins. Most of the linear cat naphtha olefins are converted to light olefins, and at the same time an increased octane and reduced olefin content naphtha are produced by the concentration of higher octane aromatics, plus isomerization, and some additional aromatics formation.

A fluid solid reactor-regenerator configuration is designed for large-capacity units. Feed naphtha is preheated and is injected into the reactor of a fluid solids reactor-regenerator system. The hot, regenerated catalyst contacting the preheated feed supplies the necessary sensible heat to complete preheating the feed to reaction temperature, and supplies the heat of reaction. These fluid solids systems can use ZSM-5-containing fluid solids catalysts. In this way, coke made on the catalyst when cracking naphtha is low, therefore, a means to provide supplemental fuel to burn in the regenerator to supply the necessary sensible heat and heat of reaction is required. The regeneration of catalyst provides the flexibility to process a variety of feeds, which can contain diolefins, aromatics, or heavy ends to a certain degree.

Reactor effluent is cooled and vapors are compressed for product recovery. Once-through yields of ethylene and propylene typically are in the range of 10–20 and 30–40 wt% on feed olefin content, respectively. The propylene's concentration ranges from

Table 36.18 MOI yields when treating FCC and steam cracker products

conversion and high selectivity toward the desired product. Regeneration is required because of coke formation on the dehydrogenation catalyst. PDH provides 85 wt% propylene and small amounts of hydrogen and ethylene byproducts, which can be used as fuel for the PDH process. Paraffin dehydrogenation reaction chemistry, although quite simple from a stoichiometric point of view, is very complex due to its strongly endothermic nature and significant conversion limitations caused by thermodynamic equilibrium. Side reactions include the cracking of hydrocarbons and hydrogenolysis, as well as oligomerization, cyclization, hydrogenation of olefins, deep dehydrogenation, and eventually the formation of coke and tar laid down on the catalyst, which requires frequent catalyst regeneration.

Two main catalytic systems have been identified and commercialized for light-paraffin dehydrogenation, the first being supported chromia catalysts (i. e., chromia on alumina support), which are doped with alkali metals to add alkalinity and suppress unwanted side reactions, and the second supported platinum or platinum-tin catalysts, with different support materials. These materials include alumina or zinc-/calcium-aluminate, and potentially further modifiers such as alkali metals, again to reduce the acidity of the support and suppress side reactions. Today, both catalyst systems are used in commercially available PDH processes (i. e., chromia catalyst in Lummus CATOFIN and platinum-tin catalysts in UOP Oleflex and Uhde's STAR process).

With the dehydrogenation reaction being favored by high temperatures and low hydrocarbon partial pressures, all commercially available technologies keep the

process temperature at or below approximately 650 °C, because higher temperatures would lead to a significant increase in side reactions and therefore a decrease in the selectivity of the main reaction for propylene production. Furthermore, the most significant side reactions are not limited by thermodynamic equilibrium. As a result, the higher retention times required to achieve higher per-pass conversions also have a strongly negative impact on propylene selectivity. At the same time, partial pressure is kept low by applying absolute pressures slightly above atmospheric pressure or even under vacuum, or by using a diluent to reduce the hydrocarbon partial pressure. As a result of these considerations, all the technical processes for PDH have limited conversion in the range of 32–55%, with selectivities to propylene in the range of 87–91 mol%. As the significant amount of coke laydown leads to a fairly quick deactivation of the catalyst (i. e., in the range of minutes to a few days), different reactor systems are applied to account for the regeneration needs. Continuous systems applied are moving-bed systems and fluidized-bed systems. Discontinuous (fixed-bed) systems applied are heated fixed-bed systems (as in Uhde's STAR process) and adiabatic fixed-bed systems.

Product work-up sections for all the PDH technologies are very similar, as the side products, and therefore the separation tasks are also similar. When comparing different PDH technologies, several key components need to be evaluated to find the differences and advantages of one technology over the other. Table 36.20 lists certain data generally available in the industry for commercial PDH technology.

Table 36.20 PDH process technology parameters

	UOP oleflex	Uhde STAR process	Lummus CATOFIN
Catalyst	Pt–Sn on alumina	Pt–Sn on zinc-/calcium-aluminate	Chromia on alumina

36.3.11 Methanol to Olefin Process

The MTO process converts methanol to light olefins [36.47–50]. The process provides greater selectivity to ethylene and propylene versus C₄+ by-products.

The ethylene and propylene are produced from a dimethylether (DME) intermediate in the MTO process. Some byproducts such as butylenes and other higher olefins are also produced. The MTO reaction is exothermic. The coke deposited on the catalyst can be removed by combustion with air in a catalyst regenerator system in order to prolong the active life of the catalyst.

The MTO process utilizes the highly selective met-alloaluminophosphate molecular sieve catalyst, which is based on SAPO-34. The main olefin products are ethylene and propylene, but the catalyst is rapidly deactivated by aromatic coking. An alternative catalyst is the medium-pore zeolite ZSM-5 in the MTP process. In this case, the main olefin product is propylene, and the deactivation of the catalyst caused by aromatic coke is slower, but significant quantities of C₅+aromatic byproducts are formed.

In the MTO or MTP process unit, the methanol and DME come into contact with the catalyst in the reactor and are converted into light olefins. Residence times are very short and the reactor operates in a stable steady-state in the vapor phase at temperatures between 350 and 600 °C and pressures between 0.1 and 0.3 MPa. In

the process, the catalyst is deactivated by coke accumulation, and a part of the catalyst is transferred to the fluidized-bed regenerator in order to restore its activity.

Polymer-grade ethylene and propylene can be produced from the reactor effluent by a series of purification steps. The results from an MTO demonstration plant show that the conversion of methanol is 100%, selectivity to ethylene is above 40%, and selectivity to propylene is close to 40%. Table 36.21 lists certain data generally available in the pilots of MTO and MTP technologies.

A DMTO unit with a capacity of 500 kta ethylene and propylene has been put into commercial operation since January 2011 at Shenhua coal to olefin project in Baotou, China. And an SMTO unit with a capacity of 600 kta ethylene and propylene has been at final inspection and acceptance since January 2014 at Zhongyuan Petrochemical Co. Ltd. In the near future, 15 units with a capacity of about 10 000 kta ethylene and propylene will come on line in China.

In the MTO and MTP processes, a considerable quantity of light olefins such as butylenes and pentenes are also produced while acquiring ethylene and propylene. Discovering how to convert these light olefins into ethylene and propylene effectively will promote the profitability of the MTO and MTP process. So some new processes such as SMTO+OCC, UOP MTO+OCP, MTO+OCT, MTO+SUPERFLEX, and MTO+Omega have also been developed.

36.4 Prospects

The production of ethylene and propylene is one of the cornerstones of the petrochemical industry and developments in this area are key to progress in the industry as a whole.

According to reliable forecasts, the world's recoverable conventional oil resources amount to 310 billion tons [36.51] while nonconventional oil resources (including extra-heavy oil, oil sands, asphalt, and oil shale) total 400–700 billion tons. It is predicted that the output of conventional crude oil will be peak in 2030, and by 2060 the production of conventional and nonconven-

tional crude oil will reach 6.54 billion tons. Refineries will face the tough task of upgrading more heavy oils, not only for clean fuels, but also for the provision of petrochemical raw materials.

Olefin production technology can be separated into noncatalytic and catalytic processes. Nowadays, conventional pyrolysis of light hydrocarbons, a noncatalytic process, plays the dominant role in ethylene production and there have been significant advances in reaction selectivity through innovative designs as well as in energy saving. Catalytic processes have been de-

veloped rapidly in recent decades in an effort to extend the range of possible feedstocks in a variety including heavy hydrocarbons, byproducts from refineries and petrochemical streams and natural gas, as well as coal to olefins. Principal issues to consider in the selection of olefin technology for a grassroots plant or a revamped refining-petrochemical complex with expanded capacity are feedstock optimization, byproduct slate and markets, capital return, and environmental constraints. Many of these issues are site-specific, especially feedstock supply, which varies considerably from region to region. Feedstock preparation for olefin plants mainly involves the limited modification of the hydrogen-to-carbon ratio, either by hydrogen addition or carbon rejection. By virtue of the shortfall in light fraction supply as feedstock, integration of a steam cracker with FCC-modified processes, such as DCC, CPP, or PetroFCC is generally the best choice. Such a combination means making full use of crude by coupling a noncatalytic with a catalytic process.

To comply with the current or probable future clean gasoline specifications, the aromatic content as well as the olefin and sulfur content should be strictly limited. In order to increase the isoparaffin content of the gasoline pool, *Chen* [36.52] has proposed a new clean refinery system with the production and upgrading of light olefins at its heart. He proposed that the production of light olefins by catalytic hydrotreating be coupled with high-temperature catalytic cracking and upgrading of light olefins based on isomerization, oligomerization, and hydration or etherification. All of these processes lead to the manufacture of clean fuels and high-quality synthetic lubricants. *Furtado Ramos* [36.53] has also proposed that light olefins are a valuable raw material for the petrochemical industry, as well as for producing high-quality gasoline through alkylation, isomerization, and etherification.

Catalytic processing for the production of light olefins is the key step in the future towards the integration of refining and petrochemicals plants.

Polyolefins

37. Polyolefins

David Fiscus, Antonios Doufas, Sudhin Datta

The petroleum refining industry produces small fractions of volatile olefins in addition to transportation fuels such as gasoline. In aggregate, these olefins represent very large quantities because of the huge scale of the primary refining industry. The availability of these olefins has given rise to a worldwide polyolefin industry which makes most of the common rubbers and plastics in use today. These olefins are converted to high polymers by the process of polymerization. The polymers span an unexpected range of thermal and mechanical properties. The introduction and the acceptance of these polymers arise from continuous innovation which improves the properties for use. The introduction of new fabrication processes allow the utilization of novel methods to produce forms with typical densities at or below 1.00 gm/cc, leading to lightweight materials.

37.1 Olefin Feedstocks and Derived Polymers

37.1.1 Olefin Feedstocks

The feedstocks that are widely used for making polymers are described in Table 37.1. Most of the feedstocks are olefins and are derived as by-products of petroleum refining processes. These feedstocks are converted to polymers by the process of polymerization. Only a few polymers derived from these feedstocks are considered in this section, it is however exemplary that even for this small subset there are a number of manufacturing processes which lead to polymers and a larger number of fabrication processes for making products containing these polymers. The introduction and the acceptance of these polymers arise from continuous innovation to improve both properties and applications. The introduction of a new fabrication process allows the utilization of novel methods to produce forms with typical densities at or below 1.00 gm/cc, leading to lightweight materials.

37.1.2 General Polymerization Processes

A *polymer* (from Greek poly = many and meros = units) is a substance composed of macromolecules

Table 37.1 Olefin feedstocks

Olefin monomer	Chemical formula	Boiling point (°C)
Ethylene	C ₂ H ₄	−104
Propylene	C ₃ H ₆	−48
Butadiene	C ₄ H ₆	−5
Styrene	C ₈ H ₈	145
Isobutene	C ₄ H ₈	−7

built by covalently joining at least 50 monomer segments. The word polymer was introduced in 1832 by Jons Jacob Berzelius for substances that may have identical chemical composition but differ in molecular weight (MW) [37.1]. A polymer's chemical composition relates to the relative amounts of the constituent monomers while its molecular weight describes the number of monomers it contains and thus represents molecular size. Unlike typical discrete small molecules, polymer samples typically contain a distribution of molecular sizes arising from a corresponding distribution of individual molecular weights. This distribution of molecular weights is usually expressed as a number average or weight average value. A polymer's average molecular weight is an important factor in determining its performance and utility.

The polymerization of a petroleum-derived olefin monomer is dependent on the availability of double bonds, where the carbon atoms share both σ and π electrons. The π bonds can be broken under the influence of an external polymerization catalyst in a polymerization process and the result is the formation of two new σ bonds which link the monomers together at the expense of two π bonds. This process is highly exothermic. The representative polymerization of ethylene to polyethylene (PE) liberates 3.34 kJ/gm of heat. This chain growth process, repeated many times, leads to industrial polymers typically containing between 1000 and 15 000 monomer units. There are always three reaction steps in a polymerization:

- Initiation
- Propagation
- Termination.

Polymerization of high molecular weight polymers requires the propagation rates to be many times larger than the termination rates. Polymerization reactions can take place in a homogeneous phase such as bulk or solution or in a heterogeneous phase such as particle

forming or emulsion. A particularly common embodiment of the latter process for polyolefin thermoplastic is gas-phase polymerization where semicrystalline solid polymer is condensed from a gaseous mixture of olefins.

37.2 Polymerization Mechanism

37.2.1 Free Radical Polymerization

In free radical polymerizations, the homolytic dissociation of the π electrons in the double bond constitutes the initiation reaction. Dissociation occurs due to heat, light, electron transfer, or reaction with free radicals derived from agents such as peroxides. These agents initiate the polymerization. The most frequently used initiators are chemical electron transfer redox systems and free radical generation from peroxides. The initiation of the polymerization is followed by multiple propagation steps, where the polymer chain grows through stepwise addition of monomer molecules, until the polymerization reaction is terminated. Initiation, propagation, and termination are not temporally correlated but are each statistical time-dependent phenomenon. Thus, the lengths and composition of the chains do vary because of differences in degrees of polymerization, resulting in different distributions of molecular weight. The growing polymer chain can react with chain transfer agents whereby the current macromolecule is deactivated and a new polymer chain is initiated. Chain transfer reduces the molecular weight and modifies the branching character of the polymers. Thus, these modifications control the technological properties of polymers, such as processability. Free radical copolymers can be made by the copolymerization of two or more monomers. This follows the same pattern as the homopolymerization except that monomer radicals can be formed by all of the different monomers present. As a limiting example, one type of polyethylene (low density) is typically made by free radical polymerization [37.2]. In general, free radical polymerization leads to arboreal polymers with a mixture of short-chain branches (e.g., C_1 to C_6) and long-chain branches (e.g., up to several hundred carbon atoms). The architecture of the long-chain branches is similar to that of the polymer's backbone.

37.2.2 Ionic Polymerization

In ionic polymerization, electron pairs are asymmetrically allocated to the active polymerization intermediates to lead to anionic or cationic species. These initiators start the polymerization, which then propagates

as a chain reaction. While in a free radical polymerization, the initiator radical transfers the uncharged free radical to a monomer molecule, in ionic polymerizations, there is a transfer of charge from the initiator ion to the monomer. At the start of the polymerization, the initiator ion transfers the π -electrons of a monomer molecule to one or the other carbon atom, depending on the charge. Subsequently, the initiator attaches to the monomer, which then becomes the new initiator, attaching an additional polarized monomer molecule to form a growing polymer ion.

A cationic polymerization can be initiated by Bronsted or Lewis acids (e.g., H_2SO_4 , $AlCl_3$, BF_3), requiring typically, small amounts of cocatalyst, such as water or alcohol. Anionic polymerization initiators are most commonly alkyl lithium compounds. Since the activation energies for the initiation reactions are often significantly smaller for ionic than for free radical polymerizations, these polymerizations can often be carried out at low temperatures. Chain transfer reactions can also occur with cationic polymerizations. However, as the polymerization temperature is lowered, these reactions become less frequent and thus ionic polymerizations at low temperatures lead to high molecular weight polymers. Under these conditions, chain transfer reactions are almost eliminated with anionic polymerizations leading to very narrow molecular weight distributions. These polymerization sites are active even after all monomers are incorporated leading to *living polymers* that are capable of further growth on addition of fresh monomer. Block copolymers can be produced if a different kind of monomer is added partway through the polymerization process.

37.2.3 Coordination or Metal Complex Polymerization

In coordination polymerization reactions, the initiator is a metal complex, attached to the growing end of the polymer chain, and the chain reaction progresses by the insertion of monomer molecules into this complex. The most commonly used initiators are the Ziegler–Natta catalysts. These are reaction products of organometallic group I to III elements, and transi-

tion metal salts of group IV to VIII elements. Typical examples of Ziegler–Natta catalysts are mixtures of aluminum alkyls and halides of titanium, cobalt, nickel, vanadium or tungsten. The catalytic activity of these transition metal compounds may be due to their ability to form coordinate bonds with unshared pairs of π -electrons from olefins or dienes. This ability allows the catalysts to exchange one type of bond for another, and this exchange is the pertinent feature of the propagation (or insertion) reaction step at the transition metal ion. In contrast to both free radical and ionic polymerization as a monomer unit enters the polymer chain which is always connected to a metal center, it is possible to have a definite stereochemistry for this insertion to lead to a sterically controlled chain propagation, leading

to sterically configured (e.g., isotactic or syndiotactic) polymers.

These polymerization processes typically produce linear polymers. The catalysts determine the resin's chemical composition, the sequencing in copolymers, and molar mass distributions. For example, the linear low-density polyethylene produced using chromium and Ziegler–Natta catalysts have minor amounts of low-molecular-weight waxes and high-molecular-weight high-density components in conjunction with the predominate component, which has an intermediate density and molecular weight. Single-site catalysts produce resins with more uniform chemical composition and molar mass distributions than those produced using the chromium and Ziegler–Natta catalysts.

37.3 Polymerization Processes

37.3.1 Bulk Polymerization

In this process, the polymerization occurs in the pure, liquid, or gaseous monomer without solvent being present. The heat of polymerization is dissipated through refrigeration across the wall of the reactor or by evaporation followed by condensation of the liquid monomer. The first synthetic polymers nearly a 100 years ago were made in a bulk polymerization process.

37.3.2 Solution Polymerization

In solution polymerizations, the monomers are dissolved in a solvent which also acts as a solvent for the polymer. In solution processes, polymerization occurs at a temperature above the melting temperature of the polymer in hydrocarbon solvents, like cyclohexane or paraffinic hydrocarbon. The reactors are typically small continuous stirred tank reactors. The catalyst, reactants, and solvent are continuously added to the reactor. The solution is continuously removed from the reactor and the polymer recovered by removing the solvent. During polymerization the viscosity of the reaction medium rises with both the concentration of the polymer in solution and its molecular weight of polymerization, this limits the extent of polymerization as the viscosity of the solution becomes a limiting criteria. Solution polymerization is however an excellent process for polymerizing different monomers into the same polymer. The polymer content in steady state in solution is about 35% by weight for low molecular weight resins and less for higher molecular weight polymers. The reactor temperatures range between 120 and 300°C. The

reactor pressures range between 360 and 1500 psi. The residence time of the polymer in the reactor ranges between 1 and 30 min. The resin's molecular weight is controlled by the reactor conditions (temperature and pressure) or by adding transfer agents to the reactor. The process allows for short transition times between grades.

37.3.3 Suspension Polymerization

In suspension polymerization a liquified monomer is used as the medium and the other polymerization ingredients are added to it. In this process, polymerization occurs in the hydrocarbon medium at a temperature below the melting temperature of the polymer: thus the polymer is essentially insoluble. Typical reaction mediums are propane, isobutene, isopentane, and hexane. The catalyst, reactants, and solvent are continuously added to the reactor. The resulting high polymer is insoluble in the monomer, and remains suspended as a slurry in the reaction medium. The suspension/slurry is well agitated to prevent reactor fouling, i.e., the resin from sticking to the reactor's walls and limiting heat transfer. The slurry is constantly removed from the reactor and the polymer recovered by removing the solvent. Slurry processes are conducted in stirred tank or slurry loop reactors. In suspension polymerizations, the viscosity of the reaction medium increases only fractionally with either the increasing molecular weight or increasing weight fraction of the polymers. Thus, polymers with very high molecular weights can be made by this process with a high degree of conversion as well as a high concentration of polymer in the slurry ($\approx 60\%$ w/w). The polymer molecular weight is con-

trolled by controlling the reactor conditions or adding chain transfer agents to the reactor [37.3].

37.3.4 Emulsion Polymerization

Emulsion polymerization is an important example of free radical suspension polymerizations where water-insoluble monomers form water-insoluble polymers as latex. Emulsifiers or surfactants are required to maintain this morphology. The latex contains hydrocarbon droplets with a diameter of about 10^{-4} cm. Polymerization occurs within these suspended hydrocarbon latex particles. Compared to homogeneous polymerization the suspension or emulsion process has the following advantages:

- The continuous water media promotes easy removal of heat of polymerization.
- The diffusion of monomers into the latex is faster than polymerization, leading to uniform composition.
- The process is capable of a wide range of polymer viscosity.

37.3.5 Gas-Phase Process

In 1968, Union Carbide commercialized a fluidized-bed gas-phase process for polymerization utilizing low

temperatures and pressures. In this process, reactants, nitrogen, and catalyst are fed into a cylindrical reactor with constant and turbulent agitation in a flowing gas stream where polymerization takes place. The reaction components as gases and a diluent gas, typically nitrogen, are introduced into the bottom of the reactor through a distribution plate. The catalyst is added to the reactor above the distribution plate. The polymer particles that form are fluidized by the incoming gas stream. The polymer is continuously withdrawn from the reactor and recovered. The unreacted monomer and comonomer are separated and returned to the recycle stream. The gas-phase process is a very versatile process with low capital cost and broad polymer capability. These characteristics have made it the most widely used process for manufacturing polyethylene resins [37.4]. The inter-comonomer versus intra-comonomer distributions in resins produced in gas-phase processes are less uniform than those in resins produced in solution processes because of the differences in the mass transfer and reaction kinetics of the two processes.

Current gas-phase reactors have an L/D ratio of about 7. The reactor temperatures range between 60 and 110 °C, preferably less than about 80 °C. The reactor pressures are between about 200 and 500 psi. The residence time of the polymer in the reactor is several hours. The production rates are in excess of twice those obtained in the other processes [37.5].

37.4 Postpolymerization Process

Processing polymers has three component parts: the intimate mixing of ingredients, the fabrication of these mixtures, and a postfabrication annealing/vulcanization step for property enhancement. Ingredients can consist of low molecular weight additives as well as other polymers. Fabrication consists of shaping the mixtures to form fibers, sheets, laminates, and composites that are useful. In most processing applications there are additional, quiescent steps of heat treatment involved referred to as ageing, annealing, or vulcanization to induce irreversible physical or chemical changes in the polymer for better properties or durability.

37.4.1 Mixing Equipment

Addition of a portion of nonpolymeric ingredients, to improve the properties of polymers arises from the addition of fillers, plasticizers, protectants or vulcanizing agents, largely promoted by the need for tires [37.6]. The first internal processing equipment was by Werner & Pfleiderer GmbH [37.7]. The first enclosed batch

internal mixer with a ram closure was, and still is based on the subsequent design by *Banbury* [37.8]. This elliptical design with clamshell housing containing cooling–heating channels and bottom drop is largely the basis of commercial batch mixers to this day. The only major innovation was the invention of intermeshing rotor internal mixers by *Cooke* [37.9]. This allows high shear stresses to be applied to the compounds between the rotors as well as between the rotor and the mixing chamber wall. The Banbury internal mixers have industry standard performance. In comparing two-flight and four-flight rotors in Banbury design internal mixers *Cho* et al. [37.10] have showed the superior mixing ability of the latter rotors.

These batch mixers were soon supplanted by continuous mixers having similar mixing elements. The earliest description of a continuous mixer was by *Pfleiderer* [37.11] where two nonintermeshing counter-rotating shafts with sigma blade mixing elements and intermediate conveying screw sections were described. More sophisticated machine devices for mastication,

compounding, and blending include single-screw devices such as List's Buss Kokneter [37.12] and those with intermeshing counter-rotating kneading pumps such as from *Leistritz* and *Burghauser* [37.13]. In the last 50 years the development has been exclusively on twin-screw machines which are better continuous mixers. The concept of a self-wiping corotating twin-screw extruder dates to the beginning of the twentieth century with an intermeshing twin-screw extruder that was developed in 1939 by *Colombo* [37.14]. Several of these machines were purchased by IG Farbenindustrie and applied for polymer mixing and polymer dewatering [37.15]. This was followed by developments which are incorporated largely unchanged in today's continuous twin-screw extruders such as twin-

rotor kneading disc block mixing [37.16] and the twin-screw devolatilizer [37.17]. However, alternate designs of continuous mixers also evolved in parallel. An example of this is the nonintermeshing counter-rotating twin-screw extruder by *Farrell* [37.18], which has rotors consisting of screws feeding Banbury-like rotors. It has been widely used in the compounding and polymerization industries.

Modeling the performance and flow, both in individual modules and in composite modular machines [37.19] can predict fill factor and pressure and temperature profiles along the screws. Many efforts have been made to simulate the flow in individual modules of the machine as well as composite models of the mixing and metering section near the machine exit [37.20].

37.5 The Structure of Polymers

37.5.1 Monomer Insertion

Olefins can react in various ways in a polymerization and thus yield polymer molecules with significantly different structures. These differences arise from intrinsic *cis-trans* insertion of olefins during insertion and 1, 2 versus the less common 1, 3 or 1, 4 insertion. Specific conditions under which the polymerizations are carried out determine these insertion procedures. In addition to this insertion isomerization during polymerization various forms of stereoisomerization in the insertion of the monomer can also lead to differences in the polymer. Stereoisomerization is reflected in the geometry of the relationship of adjacent or nearby monomer units. In the case of polymerization catalyzed by coordination catalysts an additional isomeric form of insertion is in the mutual relationship of the adjacent monomer units. These differences lead to differences in tacticity from a *meso* to racemic structure in a pendant group.

37.5.2 Monomer Sequence in Copolymers

In copolymers an important difference is the repeat unit sequence. The statistical control of this sequence and sequence length is measured by the reactivity ratio $r_1 r_2$. This measure quantifies the statistics of the catenation sequence of the two monomers with low values indicating an alternating sequence while high values indicate a propensity to homologation. Copolymerization using several different monomers can lead to differences in the sequence distribution of monomers in the copolymer depending on the polymerization process [37.21]. Reactivity ratio values predict the statistics of the sequencing of the different monomers. This is exemplified

below in a hypothetical copolymer of A and B monomer units for certain limiting cases:

- $r_1 r_2 = 0$: Monomer sequence is strictly alternating since there are no A-A or B-B linkages and the polymer is -A-B-A-B-A-B-A-B-A-B-A-B-. Homopolymerization of either monomers is absent and the composition of the polymer is independent of the monomer feeds.
- $r_1 r_2 = 1$: Monomer sequence is completely random and determined by the feed composition and there are A-A or B-B linkages and the polymer is -A-B-A-A-B-A-B-B-B-A-B-. Homopolymerization of either monomers is present.
- $r_1 r_2 = \infty$: Monomer sequence is strictly a homopolymerization of two monomers since there are only A-A or B-B linkages and the polymer is -A-A-A-A-A-A-B-B-B-B-B-B- if a single A-B linkage is allowed kinetically. Homopolymerization of either monomers is present and the composition of the polymer is independent of the monomer feeds.

37.5.3 Molecular Weight and Molecular Weight Distribution

The distribution of molecular weights determines in great measure the processability of polymers. Polymers with a narrow molecular weight distribution soften only in a very limited range of temperatures, which has a negative influence on mixing processes. Because of their easy processing characteristics and better filler distribution, it is desirable to have polymers with a broad molecular weight distribution, where the low molecular weight portions behave somewhat like plasticizers.

If the molecular weight is too high, the processing of the resin is difficult because of the high viscosity. Such products either have to be degraded in molecular weight (*masticated*) prior to use, or they have to be extended with appropriate amounts of plasticizer. The latter improves the processability and it reduces the price of the product.

Today, very high molecular weight polymers, in particular rubbers which are extended with oil are commercially useful since in many cases the limited plasticizer extension does not impair the mechanical properties of the vulcanizate. A very high molecular weight-based polymer with a high tensile strength is used for this purpose, and the oil extension only reduces the processing viscosity to a practical level. Without oil extension the high strength properties of the base polymer cannot be exploited. Since the tensile behavior depends, amongst others, on the length of the primary polymer molecule, low molecular weight polymers are typically prone to mechanical failure.

37.5.4 Linearity and Branching

There are additional structural elements of the polymer molecule, such as linearity, short- or long-chain branching, and crosslinking (gel), which have a considerable influence on the processability as well as on the mechanical property spectrum. In most instances branching is welcome for processing advantages but gels are not since they lead to both optical and mechanical defects.

37.5.5 Mechanical Properties

The performance of a plastic part is greatly influenced by its resin's molecular architecture (molar mass, chemical composition, and long-chain branch content) and morphology (arrangement of crystalline and noncrystalline material) as fixed by the way the part is formed. All else being equal, a part's performance reflects that of its resin(s). A resin's stiffness increases with an increase in its density, while its strength and toughness (tear and impact resistance) increase with an increase in its molecular weight. The performance of resins is the same in all directions, i. e., isotropic. In general, extrusion and molding causes parts to be anisotropic – perform differently in one direction relative to another. Thicker parts are stronger than thinner parts.

A resin's strength is determined using a tensile test – a mechanical test measuring a material's response to an applied load/force. This test characterizes a resin's deformation behavior (elongation, deformation, and failure), allows comparing the performance of different resins, and determines how a resin's molec-

ular architecture affects its performance. Typically, an isotropic material of known dimensions (length and cross-sectional area, for example) is clamped by two *grips* with a known separation distance. One grip is moved away from the other grip, which is fixed. The force/energy required to separate the grips is transferred to the test specimen. The applied force is plotted against the distance the specimen deforms. The plot is called a load–displacement, stress–strain, or force–elongation curve (see the discussion below). The energy imparted to and dissipated by materials can be determined from these curves. This strain energy is proportional to the energy the materials dissipate during impact and tear testing.

Tensile tests are typically used to characterize a resin's stiffness, yield performance, plastic deformation/necking behavior, and ultimate properties.

Stiffness

Under a load, a polymer elongates reversibly until the applied force or elongation exceed threshold values, where upon the resin yields and deforms plastically, as discussed below. A resin's reversible elongation prior to yielding is referred to as stiffness. Stiffness describes a resin's resistance to deforming by elongation or bend processes. A material's stiffness is quantified as the ratio of the force required to elongate a sample reversibly to the amount the sample elongates under that load. A resin's stiffness is usually determined using up to the first 3% of its stress–strain curve.

Yield

The yield reaches a local maximum in the stress–strain curves for semicrystalline polymers. The local maximum becomes more pronounced as the resin's density increases, the strain rate of the test increases or the temperature at which the testing is conducted decreases.

Plastic Deformation/Necking

After yielding, semicrystalline polymers typically deform plastically: irreversibly and nonuniformly by thinning in the directions perpendicular to applied forces for several hundred percent without rupturing. The material thins over part of its length to form a constriction or *neck* in which the stretch is large and the sample's cross-sectional area is decreased relative to its initial cross-sectional area, while the rest of the sample is slightly stretched without a significant change. The constriction or *neck* can stabilize and travel along the material during tensile testing. As it travels, more of the sample is drawn into the necked region. This necking continues until the stretched region reaches the resin's natural draw, at which point no more sample is drawn into the necked region.

Ultimate Performance

Stretching a semicrystalline polymer beyond its natural draw results in irreversibly but uniformly drawing the necked region until the sample fails. This uniform stretching is called strain hardening, and the material's engineering strain increases with an increase in its engineering stress. The ratio of the material's force to elongation during strain hardening is referred to as its ultimate modulus. A linear resin's ultimate modulus and performance increase with an increase in the resin's molecular weight [37.22].

A stress-strain curve can be used to determine the energy dissipated by materials in a variety of tests and end-use applications. Simply stated, the energy a material dissipated during a tensile test is a measure of the energy it dissipates during other tests (tear and impact) and in end-use applications. Load-displacement curves allow one to determine the amount of work required to deform resins, i. e., the amount of energy consumed by resins under tensile testing conditions (strain rate and temperature). Increasing the amount of energy a resin consumes during a tensile test increases its strength and mechanical performance. Plastics dissipate energy differently at different strain rates with the energy dissipated at high strain rates being proportional to that dissipated at low strain rates. Low strain rates are used in tensile testing, while high strain rates are used in tear and impact testing. Increasing the amount of energy a resin consumes during a tensile test increases its strength, toughness, and mechanical performance like tear and impact resistance.

As mentioned above, extrusion and molding can create anisotropy in materials. The orientation causes

the material's tensile curves to deviate from those of corresponding isotropic materials. Increasing orientation shifts the material's tensile curve to appear like that of a higher molecular weight material. In this way, orientation alters the energy-absorbing capabilities of materials; increasing it in one direction and decreasing it in another.

Tear and Impact

In addition to strength, other key mechanical properties of resins are tear and impact resistance, i. e., the resin's toughness. Tear resistance is the tendency of a test specimen to resist the growth of a cut when the specimen is in tension. Increasing the strain energy in the direction of the test specimen perpendicular to the direction of the cut increases the specimen's tear resistance. Impact resistance is the tendency of a test specimen to resist a sudden impact. Balancing the strain energy in all directions of the test specimen increases its impact resistance.

In addition to the above, a resin's toughness, particularly its impact resistance, increases with an increase in the uniformity of its composition distribution and, for semicrystalline polymers, lamella thickness. Higher α -olefin comonomers (1-hexene and 1-octene) increased the toughness of polyethylene compared to lower α -olefins (propylene and butane). Increasing the size of the comonomer increases the amount of tie chains in a resin with the increase decreasing as the length of the chain increases. Further, a resin's toughness increases as the lamella become smaller, i. e., thinner and shorter. Smaller lamella convert into amorphous material more easily than larger lamella.

37.6 Synthesis and Processing of Polyethylene

37.6.1 Polyethylene

Polyethylene is a semicrystalline thermoplastic polymer made by polymerizing ethylene alone and with comonomers to form either linear chains or three-dimensional networks of polymer chains [37.23]. Ethylene is readily available from natural gas and as a by-product to the refining of crude oil into gasoline, fuel oils, lube oils, and industrial chemicals. Ethane is present in natural gas and as a by-product of the refining processes and is cracked to give ethylene. The forecast is for natural gas, which costs a fraction of crude oil (e.g., from shale), to provide the majority of ethylene for the foreseeable future. The comonomers are derivatives of ethylene, most of which are termi-

nal α -olefins, or more rarely, cyclic olefins or dienes. Most commercial polyethylene resins contain more than 2000 mer while those used for structural applications contain greater than 4000 mer. A resin's chemical composition is an important factor in determining its properties. Decreasing the comonomer content in a resin increases its stiffness at the expense of its toughness.

Polyethylene is the most widely used plastic with global annual consumption exceeding 80×10^3 MT/yr and growth rate increasing, depending on the source, in the high to low double digits per annum. It is clear that growth in developing economies exceeds that in the more mature regions. Polyethylene obtained its lead position in the plastics industry because of its cheap feed

stock, ease of manufacture and conversion into inexpensive articles of commerce having superior performance in applications, such as film, automotive, transportation, medical, electronic, computer, consumer product, packaging, coating, pharmaceuticals, pipe, conduit, tubing, foams, durable goods, and wire and cable. More than half of all polyethylene resins go into film applications.

Polyethylene resins are produced by over 30 major companies in over 35 countries using one of four manufacturing processes:

- High pressure
- Solution
- Slurry
- Gas-phase processes.

The various manufacturing processes make polymers with similar composition but different molecular architectures and thus properties. These differences are in both processing during fabrication (extrudability and drawability) and mechanical properties (stiffness, tensile strength, tear resistance, and impact resistance). The high-pressure processes employ exclusively free radical chemistry to produce resins that are slightly easier to process compared to those produced using the other processes which employ catalysts (Ziegler–Natta, chrome and single-site catalysts). These metal-catalyzed processes produce resins with superior mechanical properties. Each catalyst produces slightly different resins leading to the coexistence of all of these manufacturing processes.

37.6.2 Historical Perspective

Between 1890 and 1898, crystalline, high-density polyethylene was being made in laboratories via diazo methane polymerization [37.24]. In 1933, ICI in England started experimental work to produce polyethylene. In 1935, this work resulted in producing polyethylene using oxygen as the free radical initiator, followed in 1937 by the first high-pressure pilot plant and in 1939 by commercial production of low-density polyethylene. In 1940, BASF in Germany developed a high-pressure tubular reactor to produce high-pressure polyethylene resins, referred to as low-density polyethylene (LDPE) resins. The characteristic structure of LDPE resins is long-chain branches.

Using lower pressures, the Phillips slurry process alleviated some safety issues associated with high-pressure processes, and increased the production rates of polyethylene resins. This process, unlike the high-pressure process yielded linear resins with improved

physical properties over LDPE. Further, these processes allow one to control the amounts and types of comonomers incorporated into the polymer by addition of comonomer to the reactor. The development of new polyethylene resins centers on using dual metallocene catalyst systems in gas-phase reactors to provide tailored resins having both superior processability and toughness: easy processing with a superior balance of lifting ability, stiffness, tear resistance, and impact resistance. Commodity grades will be produced by gas-phase processes. Specialty grades will be produced by the other processes (high pressure, solution, and slurry).

The tubular process is different from the autoclave process, although both processes utilize free radical chemistry and have similar operating characteristics: pressures ranging between 2 and 50 kpsi (179–219 MPa), and temperatures ranging between 120 and 300 °C. Development of lower pressure processes for manufacturing polyethylene began in the late 1940s. These low-pressure processes alleviate some safety issues associated with the high-pressure processes, employ catalysts that increased the production rate for making resins, and yield linear resins with improved physical properties over the LDPE resins. The low-pressure processes operate at pressures less than 1.5 kpsi (10 MPa), temperatures less than 300 °C, and are conducted in solution, slurry, and gas-phase equipment. The chromium, Ziegler–Natta, and metallocene catalysts employed provide linear resins while introducing various amounts and types of comonomers into the polymer. The linear resins have improved physical properties over the LDPE resins. The comonomers are introduced and controlled by the amount of comonomers added to the reactor.

Currently, commercial grades of polyethylene resins are referred to as:

- Low-density polyethylene (LDPE)
- Linear low-density polyethylene (LLDPE)
- High-density polyethylene (HDPE)
- Very low-density polyethylene (VLDPE)
- Ultrahigh molecular weight polyethylene (UHMWPE).

These collectively ... *have bulk densities ranging between about 0.915 and 0.96 g cm⁻³, melting temperatures between 100 and 136 °C, and crystallinities between 40 and 90% ...* [37.25] (Table 37.2).

VLDPE resins or plastomers contain more than 10% by weight comonomer and can contain up to about 35% by weight comonomer. Plastomers incorporate the qualities of elastomers, such as rubber-like properties,

Table 37.2 Classification and properties of polyethylene resins

Classification	Density (g/cc)	Comonomer content (wt%)	Typical peak melting point (°C)	Crystallinity (%)	M_w (D)	Introduction
HDPE	> 0.95	< 2.5%	130–135	70–90	–	1957
LLDPE	0.91–0.95	< 10%	115–125	35–60	–	1965
LDPE	0.91–0.92	< 10%	108–115	45–65	–	1933
VLDPE	0.86–0.90	10–35%	–	20	–	–
UHMWPE	≈ 0.94	> 35%	N/A	–	> 3×10^6	–

into polyethylene resins. Specifically, elastomers undergo a permanent thinning in a direction perpendicular to an applied force with the extent of thinning in-

creasing with the applied load, but the resins recover a significant portion of their original shape once the applied force is removed.

37.7 Polyethylene Process and Catalysts

37.7.1 High-Pressure Low-Density Polyethylene

In high-pressure polyethylene manufacturing processes polyethylene resins are made in liquid ethylene at temperatures above the polymer melting point. Only about 30% of the ethylene is polymerized using a free radical initiator. The resin's molecular weight is controlled by regulating the reactor's pressure and temperature, and by using chain transfer agents. The polymerization is highly exothermic leading to temperature rises that if not controlled can result in reactor instabilities. The high-pressure processes are conducted in autoclave and tubular reactors which produce resins with densities between 0.920 and 0.927 g/cc. The crystallinity of the resins is between about 50 and 60%. Autoclave processes give resins with higher proportions of long-chain branches and greater amounts of low molecular weight components compared to the tubular process. In general, higher pressures lead to higher molecular weight resins, while higher temperatures increase branching in the resin. In these free radical processes, ethylene can be copolymerized with a wide range of comonomers, such as vinyl acetate and acrylates.

37.7.2 Chromium Catalysts

After World War II, Phillips Petroleum and Standard Oil Company of Indiana developed transition metal catalysts supported on metal oxides to polymerize ethylene into linear polyethylene in hydrocarbon liquids. In 1951, Phillips Petroleum used silica-supported chromium trioxide catalyst to produce a high-molecular-weight high-density polyethylene resin. The current Phillips slurry loop process pro-

duces resins with a broad range of molecular weights and densities greater than 0.95 g/cc.

37.7.3 Ziegler–Natta Catalysts

Ziegler–Natta catalysts are combinations of a transition metal catalyst (typically titanium tetrachloride) and organometallic activator (typically an aluminum alkyl). In 1953, commercial Ziegler–Natta catalysts were developed to make high-density polyethylene resins at atmospheric pressure and ambient temperature. Karl Ziegler began development of the Ziegler–Natta catalysts in 1940 using triethyl aluminum. Development of the Ziegler–Natta catalysts allowed increased incorporation of comonomers to densities below 0.92 g/cc. The early Ziegler–Natta catalysts were unsupported. In the 1960s, Ziegler–Natta catalyzed linear low-density polyethylene resins were commercialized.

37.7.4 Supported Catalysts

In the 1970s supported catalyst systems were developed. Ziegler–Natta catalysts were supported on magnesium chloride. Union Carbide supported chromium catalysts on other materials than the metal oxides that Standard Oil Company of Indiana used. These supported systems make the active centers of the catalysts more accessible to monomers which dramatically improves the catalyst's efficiency, meaning the catalyst does not have to be removed from the resin [37.26, 27].

37.7.5 Metallocene Catalysts

In the 1990s, Exxon and Dow Chemical Companies commercialized metallocene catalysts that produce low

density and plastomers. These catalysts have a single active site, unlike the chromium and Ziegler–Natta catalysts that have multiple active sites as discussed above. The metallocene resins are composed of one population of resin instead of a mixture of resins. The metallocene resins lack the low molecular weight waxes and high-molecular-weight high-density components inherent in the conventional linear low-density polyethylene resins.

Current efforts to develop metallocene-catalyzed resins centers on producing tailored resins having both superior processability and toughness:

- Easy processing with a superior balance of lifting ability
- Stiffness
- Tear resistance
- Impact resistance.

37.8 Structure of Polyethylene

37.8.1 Morphology

Conceptually, the solid state of polyethylene resins can be represented as composites of crystalline (lamella) and noncrystalline or amorphous materials. The crystalline material, called lamella, consists of orderly arrangements of the ethylene sequences in the polymer chains. Lamella form in a resin's melt spontaneously, via a process called self-nucleation, when the ethylene sequences in one or more chains align next to each other. Van der Waals forces cause the sequences to bond together to form nuclei that subsequently grow by addi-

tion of polymer chains via ethylene sequences of similar length to the lamella's thickness. A resin's morphology is determined by both its chemical structure and how it is processed. For example, the speed with which the resin is cooled greatly influences its morphology. During quiescent crystallization, lamella grow into larger space-filling structures, called super molecular structures with the most common type of structure being a spherulite – a ball-like structure [37.28]. Polyethylene spherulites can have diameters up to between 10 and 20 μm . These structures do not form when the resin is rapidly cooled, a process called quenching.

37.7.6 Combined Processes

All the manufacturing processes discussed above have particular advantages. Combining different processes can provide materials that exploit the advantages obtained from each process individually. Specifically, the different manufacturing processes can be tied together.

37.9 Polyethylene Processing

37.9.1 Processing

The semicrystalline nature of polyethylene resins enables the resins to become pliable and flow above a specific temperature and then return to a solid form on cooling below that temperature. These attributes make polyethylene resins thermoplastics. These attributes also allow easy and inexpensive conversion of polyethylene resins into usable parts. Polyethylene parts are formed by melting a polyethylene resin, molding the melt into a shape, and cooling the molten shape to below the resin's melting point, i.e., cooling the molten shape into a solid. In this way, thermoplastics can be extruded and molded into different articles of commerce. Thermoplastics can also be re-extruded and remolded.

Polyethylene is converted into end-use products by a variety of extrusion and molding methods such as film extrusion, sheet extrusion and fiber extrusion, blow molding, injection molding, and coating methods designed for specific product applications. In addition, there are two specialty fabrication methods: rotational molding and compression molding. The method selected to make parts is determined by the shape/dimension of the parts to be made, the applications of the parts, and the molecular weight of the resin used.

Extrusion

In the extrusion processes, polyethylene resins are melted in a plasticating extruder which is composed of heated barrels containing an Archimedean type screw.

The length-to-diameter ratios (L/D) of the extruders range from about 18 : 1 to about 30 : 1. The extruder's L/D ratio is determined by the quality of its products and the type of resin used. High-quality products require higher L/D screws of 24 : 1 to 30 : 1, which provide more extensive mixing of the melt. Medium-quality products employ screws with L/D ratios of about 20 : 1. Low-quality products employ screws with L/D ratios of at most 20 : 1. Additionally, extruders with L/D ratios of 24 : 1 or greater are typically smooth-bored extruders. Shorter extruders are typically grooved feed extruders, and are used to process higher density resins. The melts in these latter extruders have short time-temperature histories.

The extruder barrel and screw are divided into three sections, each providing a different function: advancing, melting, and mixing the melt. At the mouth of the extruder, the feed zone moves the resin along the barrel, and raises its temperature to near its melting point. The resin is a solid at the beginning of this section, but becomes a mixture of molten and solid resin by the time it reaches the end of the feed zone. The movement of the screw drags the pellets near the surface of the barrel across the barrel's surface which causes frictional heating to melt the resin. After the feed zone, the compression zone of the extruder further heats the melt bed by forcing it against the barrel. The compression forces needed are generated by reducing the depth of the flights in the screw. The melt phase changes from predominately solid to completely liquid over this section of the extruder. Once the resin is completely melted it is mixed or homogenized within the metering zone of the extruder. The depths of the flights in the metering section of the extruder are shallower than those in the other sections of the extruder, and are of uniform depth over the length of the mixing sections. The metering zones typically contain an advanced mixing section near the tip of the extruder to intensively shear the melt. Resin advancing within the extruder pressurizes the melt and enables extrusion from the extruder to an extrusion die or head which molds the melt into its final shape before being quenched to a solid product.

Blown Film

In blown film fabrication, the molten pressurized resins pass from an extruder to a die that redirects the melt 90° around a die pin to form a tube which is typically directed vertically upward. The tube is subsequently expanded in both the direction of extrusion (machine direction, MD) and transverse to that direction (transverse direction) by a process similar to inflating a balloon except the inflated melt resembles a tube. The expan-

sion causes the melt to become thinner in the direction perpendicular to both the film's machine and transverse directions, i.e., through the film. As the molten tube expands, it cools, begins to solidify, and eventually crystallizes. When the melt begins to crystallize it becomes opaque and the dimensions of the tube are fixed.

Polyethylene blown films are used in form-fill-and-seal applications, food packaging applications, shrink film applications, and thin-film applications like liners. Examples of form-fill-and-seal applications include heavy duty sacks such as resin bags, mulch bags, gravel bags, lawn and garden bags of different kinds, and bags for cement-like products. Polyethylene films are also used in flexible food packaging applications such as freezer films used to package frozen foods and ice. Freezer films are used to package vegetables, potato products, fish and seafood, meats, and ready meals. Other examples of flexible polyethylene film products are bread bags and fresh produce packaging. Nonfood packaging applications include shrink films such as shrink bundling films, industrial shrink film, retail shrink film, stiff high-clarity shrink film, pallet shrink film, collation shrink film, and light-duty shrink film.

Cast Film

In cast film fabrication, the molten resin is extruded vertically onto a chilled drum via a flat or coat hanger die that spreads the melt out to form a thin molten sheet or curtain. The curtain of molten resin is drawn in the direction of the extrusion (machine) direction by rotating the chilled drum. The drum quickly cools the melt and causes it to solidify. Cast polyethylene films are typically less than 1 mil thick and are used in stretch warp to unitize materials for shipping.

Blow Molding

In blow molding, the molten resins pass from an extruder to a forming head that redirects it 90° around a die pin within a manifold. The melt exits the head vertically downward in the form of a parison, which resembles a thick-walled hollow tube or pipe. The parison's length is matched to that of a clam shell mold that is closed around it. The mold seals the bottom of the parison and air is injected into the top of the parison forcing the resin against the mold. Inflating the parison expands the resin and thins its wall. Contact with the mold shapes and cools the thinned resin to produce the final blow-molded article. After being cooled, the mold is opened to collect the article as a product. This extrusion blow-molding process is used to make rigid packaging for dairy products and fruit juices, wa-

ter bottles, 55 gal drums, stadium seating, gas tanks, and beams as examples.

Sheet Extrusion and Thermoforming

In sheet extrusion and thermoforming, the molten pressurized resin is passed from an extruder to a flat or coat hanger die that spreads the melt out to form a molten sheet similarly to the sheet formed in cast film fabrication. However, in sheet extrusion and thermoforming operations the sheets can be very thick, 3 mm to greater than quarter of an inch and are extruded horizontally. They are not drawn in either the extrusion (machine) or transverse directions and are slowly cooled as they travel down a conveying system. The resultant thick flat sheets are cut to length and moved to the thermoforming stations, where they are heated and then brought into contact with a mold to form the final parts. The molding can be accomplished via draping the molten sheet over a male or female mold and then applying a vacuum or pressure to force it against the mold. Additionally, the molten sheet can be sandwiched between male and female molds. Sheet extrusion and thermoforming is used to produce large panels, housings, enclosures, truck bed liners, small rigid cups used in food packaging and pails as examples.

Wire and Cable

In wire and cable applications, the molten pressurized resins pass from an extruder to a cross head die that directs the melt's flow 90° around a die pin through which the wire and cable is pulled.

Pipe Extrusion

In pipe and tubing extrusion, the molten resin is extruded through an annular die to form a tube which passes through a sizer to fix the part's final dimensions before being quenched. The quenched tube is cut to length. These processes produce pipes up to a couple of meters wide with wall thicknesses up to inches.

Fiber Spinning

In fiber spinning, the molten pressurized resin is passed to a multiport die equipped with spinneret. The molten extrudate is caught in the high-speed air jet of the spinneret that elongates and cools the melt into a fiber.

Injection Molding

In injection molding, the molten pressurized resin is forced into the mold at very high pressure to form it

into a final shape that is quenched producing the molded part. Unlike in other processes, the screw serves a secondary function as a ram to fill the mold with the molten resin. Specifically, the barrel of the extruder is significantly longer than the screw. The screw is operated until the barrel is full of molten resin. Then, the screw is advanced forward and pushes the molten resin into the mold. After the mold is filled, the screw is returned to its original position to refill molten resin from the extruder. The temperature of the mold cycles between that of the melt and the quench temperature. After cooling, the mold is opened and the part collected. When foaming agents are included in the resin, the final part can be foamed. Injection molding is used to make small appliance housings, small electronic housings (telephone handsets, electrical switches, television cabinets, etc.), crates, medical devices, automotive dash boards, and bottle lids/closures, for example.

Injection Blow Molding

In injection blow molding, the injection-molding and blow-molding operations are combined.

Rotational Molding

In rotational molding, or rotomolding, polyethylene powder is introduced into a mold. The mold is closed, moved into an oven which is typically gas fired and rotated both vertically and horizontally. The powder melts and is flung onto the walls of the mold by centrifugal force where it forms a skin. The mold is removed from the oven, cooled, and the product collected. When the proper additives are included in the resin, the final part can be crosslinked. Rotomolding is used to make simple rigid hollow structures that can be processed further into final products, like children's toys, traffic cones and posts, canoes, and trash containers. It's most often used for very large articles and specialty products usually made in small quantities.

Compression Molding

In compression molding, polyethylene powder or resin is introduced into a square mold and then pressurized while being heated. After being heated with a specified time-temperature-pressure protocol, the formed part is cooled and collected. Parts are typically cut from the collected part, which is typically in the form of a sheet. Compression molding is typically used in making parts from resins that cannot be extruded, for example, ultra-high molecular weight polyethylene resins.

37.10 Synthesis and Processing of Polypropylene

37.10.1 Background

Polypropylene (PP) is a semicrystalline thermoplastic polymer made by polymerizing propylene, in the presence of catalysts which lead to isotactic or meso insertion of the pendant methyl groups of the propylene. This polymer is tough, hard plastic which can be shaped and fabricated by a variety of processes. Catalysts leading to a random racemic with meso mixture of soft, partly crystalline polypropylene are not the subject of this section. Polymerization may be by propylene itself leading to homopolypropylene or with other comonomers typically ethylene or other α -olefins, such as 1-butene, leading to random copolymers. In contrast to most other thermoplastics, the manufacture of polypropylene often also includes a variant in the propylene mixture with inclusion of ethylene and/or other α -olefins to be polymerized to form a copolymer which is a rubber. This rubbery copolymer is a distinct polymer compared to the polypropylene and exists within the matrix of

polypropylene as a separate phase. The mixture is often referred to as impact copolymer polypropylene (ICP) or heterophasic copolymer (HECO). The intent behind making these rubber-modified mixtures is improvement of the impact properties of the polypropylene at the expense of a reduced stiffness. A recent review summarizing the developmental history of ICPs and presenting options for the in-reactor design of these polymers and their modification by compounding with elastomers and fillers or reinforcements after polymerization can be found in *Gahleitner et al.* [37.29].

Polypropylene is a very useful plastic with an global annual consumption exceeding 53 MT/yr in 2012 making it the most produced single thermoplastic material [37.30], and a growth rate exceeding 9%. The reason polypropylene obtained its position in the plastics industry is the cheap feedstock derived from the refining of petroleum, and the ease of manufacture and conversion into inexpensive articles of commercial use.

37.11 Polypropylene Process and Catalysts

37.11.1 Polymerization Processes

Polypropylene is typically made with a single highly evolved titanium trichloride (TiCl_3)-based polymerization catalyst (Ziegler–Natta). The evolution of the catalysts over the last 60 years has led to greater tacticity or stereo regularity of the polymer. Increasing tacticity relates to higher stiffness and melting point of the polypropylene. The most recent evolution in the polymerization of propylene has been the discrete organometallic catalysts derived from metallocene which makes the polymer with a different error signature in terms of tacticity than the evolved Ziegler–Natta catalysts. A review highlighting the major evolutionary steps made in polyolefin catalyst systems in terms of productivity and possibilities to control the molecular architecture of both polypropylene and polyethylene can be found in *Gahleitner et al.* [37.31]. A comprehensive description of catalyst systems used for PP can be found in *Polypropylene Handbook* [37.32].

Most 1st-generation PP was produced commercially using Ziegler–Natta catalyst systems in a semi-batch slurry process (Montecatini and Hercules) with hexane or heptane as the diluent to suspend the crystalline polymer particles, remove the heat of polymerization, and dissolve the amorphous polymer fraction. The crystalline polymer product was separated from

the diluent by filtration or centrifugation and then dried [37.32]. Amorphous (atactic) polymer dissolved in the diluent was separated by evaporation. Slurry technologies require a section for the recovery of the diluent and segregation of the amorphous polymer, leading to extra costs in investment and operation of the plant. They are rarely used commercially today for the production of PP. The advances in catalyst technology (e.g., high yield and high stereospecific catalysts) and the continuous need for improved product performance have led to the development of new polymerization processes (typically bulk or gas phase) that are more cost effective than the early slurry processes. Polypropylene polymerization lines have been constructed with increased capacity, from about 5 kt/yr in the early 1960s to over 400 kt/yr today [37.30]. New products, such as ultrahigh melt flow rate (MFR) homopolymers and high melt flow, high impact copolymers can only be produced using advanced catalysts and processes [37.32].

Polypropylene is made commercially today with a variety of licensed polymerization processes [37.32] including:

- Novolen (NTH)
- Unipol (Dow)
- Spheripol (LyondellBasell)

- Hypol (Mitsui)
- Borstar (Borealis)
- Innovene (BP) etc.

Such processes eliminate the use of hydrocarbon diluent by using either liquid or gaseous monomer as the polymerization medium. Contrary to the slurry operations, in such processes, the removal of catalyst and atactic polymer are unnecessary.

The first commercial gas-phase propylene polymerization process was developed by BASF in the late 1960s [37.32]. The Novolen technology involves vertical stirred gas-phase reactors operating at pressures above 20 bar and temperatures of 70–90 °C [37.33]. Originally the design was that of a stirred autoclave with a bottom-mounted helical stirrer maintaining uniform conditions in the polymer bed. This stirrer is designed to convey the particles up the reactor wall and let them fall down through the center of the bed. The special design of the agitation system is considered to be responsible for forming sub segments in the reactor. By this it is claimed that the reactor behaves like a cascade of a large number of continuous feed stirred tank reactors (CSTRs) [37.30]. Unreacted monomer is condensed and recycled through an external heat exchanger to remove the heat of polymerization. By using mechanical agitation rather than fluidization to provide mixing, gas recirculation is minimized. Initially, the Novolen technology was used with a single reactor for the production of homopolymers. However, in the late 1970s, ICPs were produced with Novolen technology using two reactors in series.

The use of gas-phase fluidized-bed reactors for olefin polymerization was pioneered by Union Carbide with the development of the Unipol process for polyethylene in the late 1970s. The Unipol process was adapted for the production of PP in 1985 by incorporating Shell high-activity catalysts (SHAC) [37.32]. One feature of this Unipol process is the large fluid-bed reactor with a wider upper section that serves to separate the fluidized polymer from the recirculating gas. One reactor is required for the production of homopolymer or random copolymers; a second smaller reactor is used in series for the production of the ethylene-propylene rubber for impact-modified copolymers. The heat of reaction is removed by cooling with external water through a heat exchanger. Recycled propylene can thus be cooled to its dew point, allowing some liquid monomer to be fed in homopolymer production (condensing mode operation). The polymerization temperature is around 65 °C with operating pressures of 30 bar in the homopolymer reactor and 20 bar in the copolymer reactor. Plant capacities of Unipol PP plants are typically about 200 kt/yr [37.32].

Processes using liquid monomer as the polymerization medium are divided into two categories: those using continuous stirred reactors and those using loop reactors. Such processes are often used to produce homopolymer PP or random copolymer PP with less than about 5% ethylene [37.32]. However, processes using liquid monomer are not suitable for the production of the rubber phase of impact copolymer PPs due to the solubility of the rubber in the liquid monomer. Consequently, impact (heterophasic) copolymer polypropylenes today are mostly made with a hybrid process. In this process, the homopolymer or random copolymer matrix is made first in the liquid phase followed by copolymerization in the gas phase for the dispersed rubber.

The Spheripol process is the dominant hybrid process licensed by LyondellBasell. Roughly one third of today's world PP production is based on Spheripol technology [37.30]. In this process, catalyst components and monomers are fed into a loop reactor for homopolymerization as shown in Fig. 37.1. Operating conditions are typically in the range of 60–80 °C and 35–50 bar [37.34]. The use of spherically shaped catalysts with narrow particle size distribution in combination with the high liquid velocities avoids reactor fouling. Because of the large surface-to-volume ratio for loop reactors, the heat removal capacity is high and enables high specific outputs up to 450 kt/yr [37.32]. Upon exiting the loops, the PP slurry is depressurized and flashed at a pressure that allows for recycle of the vaporized monomer. External cooling water is used for cooling and condensation of the monomer mixture, which are required for gas-phase copolymerization. Impact copolymers are produced by using the granules made in the above process in a trailing fluidized-bed gas-phase reactor to produce ethylene-propylene rubber imbedded in the homopolymer spheres from the preceding loop reactors [37.32]. Typical operating conditions of the gas-phase reactor do not exceed 100 °C with a pressure of about 15 bar.

Borealis Borstar PP is another example of a hybrid process, where a combination of loop and gas-phase reactors in series is used for the production of homopolymer and random copolymer followed by one or two fluidized-bed gas-phase reactors for the production of rubber in the case of impact copolymers. The loop reactor of the Borstar process operates under sub- or supercritical conditions (80–100 °C and 50–60 bar pressure) resulting in increased hydrogen and comonomer concentration without the formation of gas bubbles.

Mitsui's Hypol first-generation process is an example of a hybrid process, where Montedison–Mitsui high yield, high stereospecificity catalysts and liquid propy-

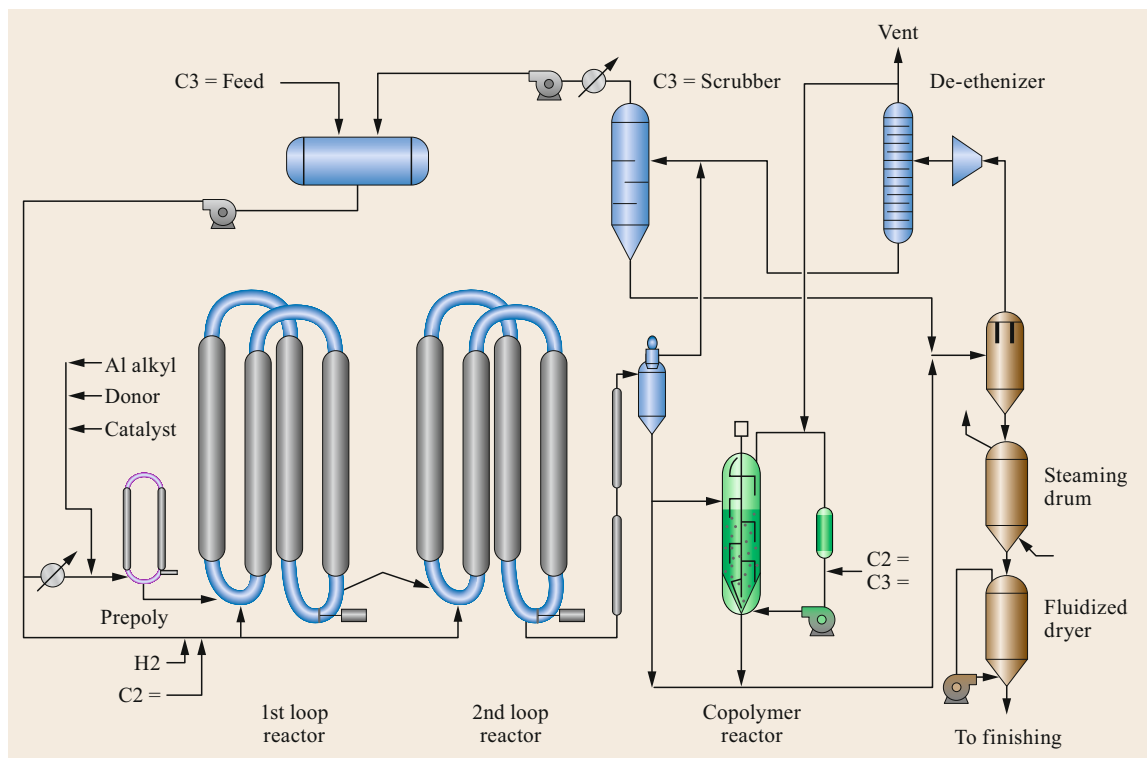

Fig. 37.1 Schematic of a polypropylene and impact copolymer polymerization process

lene are fed in a series of continuous stirred reactors (bulk polymerization), followed by gas-phase polymerization in a fluidized-bed reactor for the production of impact copolymer polypropylenes [37.32]. The latest generation of the Mitsui Hypol II process has replaced the continuous stirred tank reactors with a loop reactor configuration for homopolymer production.

The BP innovene process technology is based on a horizontal mechanically agitated multistage gas-phase reactor [37.35]. This process was commercialized by Amoco in 1979 for the production of homopolymer using TiCl_3 catalyst. The reactor design of the BP innovene process, where the polymer passes from one baffled zone to another, behaves as a series of stirred reactors providing a narrow overall residence time distribution [37.32]. As a result, polymer particle size and copolymer composition distributions can be significantly narrowed compared to those from single-stage stirred reactors. Additionally, molecular weight distributions can be broadened with the innovene process by varying the hydrogen feed to each section to produce a wide range of molecular weights. The residence time per reactor is typically 1 h. The reaction conditions are 65–85 °C for the homopolymer reactor and a pressure in the range of 25–30 bar. Producing the ethylene–propylene rubber in a sec-

ond gas-phase reactor can make heterophasic (impact) copolymers.

In the late 1980s, Basell developed the Catalloy technology which is a gas-phase, fluidized-bed process for the production of ex-reactor polypropylene-based blends [37.32]. Catalloy consists of three fluidized-bed reactors in series utilizing spherical-form controlled-morphology catalysts able to synthesize a wide range of polymer structures including homopolymer polypropylene and ethylene–propylene rubber. A unique feature of the Catalloy process is that each reactor can operate at its own temperature, pressure, gas composition and level avoiding cross contamination and allowing for accurate control of the desired amount of each polymeric phase [37.32]. Catalloy is targeted towards the specialties markets and as such the commercial plants are relatively small. The biggest Catalloy plant was built in 1997 in Moerdijk/The Netherlands with a capacity of 180 kt/yr.

In the early 2000s, Basell commercialized Spherizone, an innovative propylene gas-phase process. Spherizone consists of a multizone circulating reactor (MZCR) with two or more distinct zones, each operating under its own peculiar flow dynamic regime [37.32]. This reactor concept builds on the riser-tube design known from fluid catalytic cracking. The Spherizone

technology consists of two interconnected reaction zones, a riser and a downer, separated by a cyclone. In the riser (the first reaction zone) the gas velocity is high with the first zone acting as a fast-fluidized bed [37.30]. In the connected cyclone the polymer particles are separated from the gas, which then enter the second reaction zone (downer). The two sections of the reactor can be operated at different concentrations of hydrogen and comonomer, allowing for the production of bimodal composition polymers (in terms of molecular weight and/or comonomer concentration/type). This is achieved by introduction of a liquid or gas propylene stream on the top of the downer just below the polymer level, so that the riser gas is replaced by one with a different composition [37.28]. The fast circulation of the growing polymer particles between the different reaction zones makes the residence time per pass in each zone one order of magnitude smaller than the overall residence time. This leads to a very good homogeneity of the final product even for bimodal compositions [37.30].

37.11.2 Extrusion and Finishing Processes

The polymer made during the polymerization process is typically in granular or powder form and in most cases has to be converted into a stabilized pellet via the use of an extruder process. The direct sale of nonstabilized or (mostly) spray-stabilized PP where the antioxidant is sprayed on the surface of the granules of PP powder is rather limited [37.30]. In the 1990s, Himont (currently LyondellBasell) assumed that the spherical particle PP powders resulting from 4th-generation catalysts and the Spheripol process would be suitable in nonpelletized form for large parts of the PP market. Applications with powders are largely limited to rotomolding, melt-blown fiber spinning, and use as support for liquid additives like peroxides [37.30]. In particular, really low MW (high melt flow rate) PP used for melt-blown fibers (MFR on the order of 1000–1500 dg/min) is really difficult, if not impossible, to pelletize with current extruder/pelletizing technology due to the extremely low melt viscosity polymer *oozing out* from the die plate. Other alternate processing schemes have been proposed e. g. continuous mixer technology [37.32] for finishing of polypropylene, however they are rather limited commercially. Twin screw extruders coupled with underwater pelletizing system are almost universally used today to make pellets of polypropylene.

The type of extruder most often used in modern PP plants is the twin-screw corotating and fully intermeshing extruder due to its high flexibility and mixing/dispersion efficiency. Werner and Pfeiderer (Coperion), Japan Steel Works, and Kobe Steel are among the

lead manufacturers of twin-screw extruders. A typical L/D (screw length over diameter) of the extruder is 24–27, although a 32 L/D is used when devolatilization is required for the particular PP finishing process. During the extrusion process, different additives (usually in solid form) are fed directly at the extruder hopper without any significant premix with the PP powder. Typically, additives are added to the PP powder up to a level of 1 wt% (and most often in the range of ≈ 0.03 –0.5 wt%) on commercial extruders including primary and secondary antioxidants for polymer stabilization, UV stabilizers, nucleators, clarifiers, antistatic agents, slip and antiblocking agents etc. In special compounding processes, fillers, elastomers or other reinforcements can be mixed with PP pellets at concentrations of about 1–40 wt% [37.30].

A common practice in the PP industry is to use a postreactor reactive extrusion process. These modify the molecular weight (MW) and molecular weight distribution (MWD) of the resin produced in the reactor – which is often referred to as the *native* polypropylene. One example of PP reactive extrusion is the so-called visbreaking or controlled rheology (CR) process via the use of organic peroxides such as 2,5-di(*tert*-butylperoxy)-2,5-dimethylhexane [37.36, 37]. In the visbreaking process, the peroxide forms peroxy radicals, which attack the tertiary carbon items on the polymer backbone to form radicals. During the extrusion process, under the heat for a given residence time, the radicals undergo chain-scission reactions. The radicals abstract almost exclusively the tertiary hydrogen of the polypropylene. Since each tertiary carbon in the melt is equally likely to be abstracted, the longer polymer chains are more likely to be reacted. The unstable carbon centers are responsible for free radical chain *breakage* to form two lower molecular weight polymers in a process known as *chain scission* [37.32]. As a result, the visbreaking process lowers the weight-average molecular weight (MW) (thus increasing the PP melt flow rate MFR) and narrows the MWD (reduced Mw/Mn, where Mw is the weight average molecular weight and Mn is the number average molecular weight). In large-scale manufacturing plants, visbreaking allows the production of a multiplicity of grades from one reactor setting (one PP powder) with significant cost savings. Organic peroxides are usually added in liquid form to the extruder section where they can be premixed with the PP powder or, more typically, sprayed onto the pellets. The location for this addition is very close to the feeding screw elements in the hopper or in some cases, at the barrel feeding section. The visbreaking process can, in principle, be done in all kinds of PP including homopolymer, random copolymers, and impact (heterophasic) copolymers.

The visbreaking agent may be an organic peroxide, wherein at least a methyl group or higher alkyl or aryl is bound to one or both oxygen atoms of the peroxide. The visbreaking agent may also be a sterically hindered peroxide, wherein the alkyl or aryl group associated with each oxygen atom is at least a secondary carbon or a tertiary carbon. Nonlimiting examples of sterically hindered peroxides (*visbreaking agents*) include 2,5-bis(*tert*-butylperoxy)-2,5-dimethylhexane, 2,5-dimethyl-2,5-bis(*t*-butylperoxy)-hexyne-3,4-methyl-4-*t*-butylperoxy-2-pentanone, 3,6,6,9,9-pentamethyl-3-(ethylacetate)-1,2,4,5-tetraoxy cyclononane, α,α' -bis(*tert*-butylperoxy) diisopropyl benzene, and mixtures of these and any other secondary- or tertiary-hindered peroxides. As mentioned previously, a preferred peroxide is 2,5-bis(*tert*-butylperoxy)-2,5-dimethylhexane also known by the trade name Luperox 101 or Trigonox 101. Another common peroxide used as a visbreaking agent for polypropylene is di-*t*-amyl peroxide most commonly known by the trade name DTAP. Alternatively, the free radical initiator may include a diazo compound or any other compound or chemical that promotes free radicals in an amount sufficient to cause degradation.

The narrower MWD resulting from the CR process is particularly desirable in fiber spinning or cast film processes because the long chains resisting uniaxial deformation are preferentially reduced in molecular weight during this process. Therefore, in the case of fiber spinning, the spinnability (ability to produce fibers without or with a minimum amount of fiber breaks and with a fiber diameter of the order of 1 μm or even less) is significantly increased. While stiffness for reactor grades of PP (with broad MWD) increases with increasing MFR (lowering MW), it remains constant or is reduced for CR grades [37.30]. Additionally, transparency and surface gloss are improved via the visbreaking process.

37.12 Polypropylene Fabrication

Polypropylene (PP) is a thermoplastic material of great technological importance with a diversity of industrial applications including fibers, nonwoven spunbonding, injection molding, thermoforming, automotive compounding, film, foam extrusion, blow molding, and many others. A look at the global distribution of PP applications shows that the extrusion segments, including films and fibers but also coating and pipe extrusion, accounts for slightly more than 50% of the total volume, while injection and blow molding makes up less than

Pelletization can be achieved in strand form or in underwater systems. In a strand-cut pelletization process, several melt strands from the die plate are quenched in water for solidification and then chopped by high-speed cutters into 2–5 mm long cylinders. Strand-cut pelletizers are typically used for lab or semicommercial-scale extruders, while on the manufacturing scale underwater pelletizers are most often used. In underwater pelletizing systems, high-speed knives rotate against the extruder die plate to cut off short lengths of the molten extrudates. The insulated die plate is immersed in water which solidifies the lens-shaped pellets and also transports them to a sieving and drying device. Gala is a lead manufacturer of underwater pelletizers. While nitrogen has to be used for powder conveyance up to the extruder, air can be alternatively used for pneumatic pellet transport afterwards. *Neubauer* et al. [37.38] discussed the fundamental properties governing the underwater pelletizing process and confirmed their findings based upon actual observations during process and mechanical troubleshooting of high-capacity pelletizing systems. As the polymer melt becomes less elastic and less viscous (both properties reflected in the *Deborah* number), the ductility of the material increases, requiring relatively larger strains for the polymer to rupture (fracture). Therefore, the ability to obtain sharp and good cuts diminishes [37.38]. *Neubauer* et al. [37.38] reported that decreasing the cutting distance, increasing cutting velocity, increasing polymer viscosity, and increasing specific capillary flow rate all increase the cutting stresses being applied and help the polymer rupture as a brittle material versus a ductile material. This in turn makes the cutting process less difficult, thereby improving the overall performance of the underwater pelletizer. A description of common PP cut defects and a troubleshooting guide for their avoidance can be found in *Crumb* [37.39].

50% of the consumption [37.30]. A general trend towards material substitution has allowed PP to grow by replacing more costly polymers like polycarbonate (PC) and acrylonitrile–butadiene–styrene terpolymers (ABS) but also *traditional* materials like glass and metal.

A short description of some key PP fabrication processes is given below. For more details or descriptions of other processes, the interested reader is referred to [37.30, 32] or Handbook of Polypropylene and Polypropylene Composites [37.40].

37.12.1 Polypropylene Rheology and Process Instabilities

The rheological properties of PP are important because of the breadth of fabrication processes to which PP is subjected covering both extensional (e.g., fiber spinning, film extrusion) and shear (e.g., injection molding, extrusion/compounding) flow kinematics. A series of PP resins have been studied both in shear and extensional flow [37.41] and found to have a nonlinear correlation between the melt strength and fundamental shear flow properties including low-frequency loss tangent, crossover frequency and zero shear-rate viscosity. The study also modeled both the extensional (rheotens) and shear flow rheometric experiments with kinetic theory based on constitutive equations, demonstrating very good fitting and predictive capability. A comprehensive summary for the significance of melt strength was provided in several polymer processes, with the rheotens behavior of a variety of PP melts primarily from an experimental point of view [37.42]. A correlation of melt strength of several PPs with their sagging resistance in thermoforming processes was demonstrated [37.43].

High melt strength (HMS) refers to a melt that becomes stiffer and stronger (strain hardening) with an increase of the strain rate. Polymers with long-chain branches such as LDPE exhibit good melt strength or strain-hardening behavior. HMS PP is particularly useful in applications like blow molding, film blowing and thermoforming, where resistance of the melt to deformation for enhanced process stability or sagging under the influence of gravity become important. The melt strength of PP can be improved by increasing the average molecular weight, broadening the molecular weight distribution, and introducing long-chain branching (LCB). Different routes of producing HMS PP with introduction of LCB including irradiation of the polymer chains or by means of chemical, free-radical initiators (e.g., organic peroxides) are described in Polypropylene Handbook [37.32].

A principal problem in the extrusion of polyolefins is the phenomena of extrudate distortion, commonly known as melt fracture and wall slip [37.44]. Melt fracture usually appears when the wall shear stress exceeds a critical value, typically 0.13–0.15 MPa for polypropylenes [37.45]. Most of the previous studies on melt fracture of polymers examined the behavior of various types of polyethylenes (HDPE, LDPE, and LLDPE) and are summarized in *Hatzikiriakos and Migler* [37.44]. However, little is known about this phenomenon in the processing of PP and the relevant literature is summarized in this section.

37.12.2 Melt Fracture

Bartos [37.46] studied the melt fracture behavior of a series of polypropylenes to examine the critical conditions for the onset of extrudate distortions. He found that melt fracture occurs at a critical value of 8.5 MPa with a *melt fracture* number, which is defined as

$$N_{MF} = \frac{\eta_0 \dot{\gamma}_C}{PDI},$$

where η_0 is the zero-shear viscosity, $\dot{\gamma}_C$ is the critical shear rate for the onset of melt fracture, and PDI is the polydispersity index. *Kamide et al.* [37.47] reported a critical value of 10.9 MPa, while *Barnett* [37.48] found a critical value of 10.4 MPa for other series of polypropylenes. It would be desirable to have this information in terms of a critical shear stress, which unfortunately is lacking in these papers. *Ui et al.* [37.49] also studied the melt fracture behavior of a number of different polymers at various temperatures, including polypropylene. The flow curves obtained were smooth without any discontinuity similar to those found by *Kazatchkov and Hatzikiriakos* [37.45]. Such discontinuities are commonly observed in the flow curves of high-density and linear low-density polyethylenes. The type of melt fracture obtained for PP was fairly regular with a sharp transition from a smooth to a gross fracture appearance. Thus, small-amplitude periodic distortions which are obtained in the extrusion of linear low-density polyethylenes were not obtained for PP. Finally, *Ui et al.* [37.49] found that melt fracture occurs at a critical value of the wall shear stress in the range of 0.1–0.13 MPa, independent of temperature (180–260 °C), which is in agreement with findings reported by *Kazatchkov and Hatzikiriakos* [37.45]. The melt fracture of PP was also addressed in [37.50–53]. *Huang and Tao* [37.50] studied the melt fracture, shear rheology, extensional rheology, and die swell behavior of a fractional PP resin. They reported critical shear stresses for the onset of melt fracture ranging from 0.13–0.2 MPa, in agreement with other reported data in the literature. Finally, *Baik and Tzoganakis* [37.54] studied the melt fracture of a series of PP materials prepared by controlled rheology peroxide reactive extrusion. They found that PPs exhibit only gross melt fracture in agreement with other reports. They also reported that the critical shear stress for the melt fracture onset increases with decreasing molecular weight and polydispersity, and correlations have been developed between the critical stress values and the polymer polydispersity and shear compliance.

37.12.3 Wall Slip

It is known that molten polymers slip no matter how small the applied shear stresses [37.55]. Polypropylene was also found to obey this rule. Specifically, *Kazatchkov* and *Hatzikiriakos* [37.45] studied slip phenomena in the case of molten PPs using the Mooney technique in capillary flow. While diameter dependence was not observed directly via the Mooney technique, the authors explained that this is due to significant viscous heating. *Rosenbaum* and *Hatzikiriakos* [37.56] used a numerical technique to correct for the effect of viscous heating in order to calculate the slip velocity of PPs. *Mitsoulis* et al. [37.57] also studied the effect of slip on the flow of a branched polypropylene melt by using a visualization technique to directly deduce slip. Finally, *Kazatchkov* and *Hatzikiriakos* [37.45] carried out experiments in both sliding plate and capillary rheometers for a PP melt to determine the conditions for the onset of slip, surface and gross melt fracture.

37.12.4 Processing Aids

Athey et al. [37.58] and *Rudin* et al. [37.59] studied the melt fracture of a molten polypropylene and added a small amount of fluoropolymer to the resin to suppress this phenomenon. They found that this additive provided some benefits in the extrusion process such as reduction in extruder power and die pressure. *Kazatchkov* and *Hatzikiriakos* [37.45] also used a fluoropolymer-based processing aid to suppress the melt fracture phenomena in polypropylene. They reported that the presence of the fluoropolymer coating on the polymer–wall interface (i) improved the processability of polypropylene and (ii) significantly decreased the wall shear stress implying that it is a strong slip promoter. Melt fracture, shear rheology, extensional rheology, and die swell behavior of a fractional PP resin have been studied by several authors. *Huang* and *Tao* [37.50] studied this for capillary flow while *Baik* and *Tzoganakis* [37.54] studied the melt fracture of a series of PP materials prepared by controlled rheology peroxide reactive extrusion. *Kazatchkov* and *Hatzikiriakos* [37.45] carried out experiments in both sliding plate and capillary rheometers for a PP melt to determine the conditions for the onset of slip, surface and gross melt fracture.

37.12.5 Extrusion Surging

It has been reported that PP resins process on single-screw extruders at specific output rates that are about

30% less than those of linear low-density polyethylene (LLDPE) and that PP has a greater tendency for flow surging instabilities than LLDPE [37.60, 61]. In a single-screw extruder, the output rate is determined by the combined effectiveness of solid conveyance, melting, and melt metering [37.62]. Any imbalance of these three mechanisms can induce extrusion instability such as flow surging which is defined as the oscillatory variation of the output rate of the extruder under a given set of conditions. For PP, this has been attributed, among other factors, to the high melting temperature, high crystallinity, and low pellet compressibility of PP over other polymers. *Doufas* et al. [37.63] studied through experiments the extrusion instability surging phenomenon of a PP melt in a single-screw extruder with different screw designs and extruder conditions and found that a barrier screw yields considerably more stable extrusion performance relative to a metering screw.

37.12.6 Compounding and Blending

The modification of PP after the polymerization process via extruder compounding/blending plays a major role in enhancing the range of properties of PP compounds and blends. Besides the twin-screw extrusion and finishing processes to make pellets from powder/granules coming from the reactor discussed above, compounding is used for blending of PP pellets with fillers and elastomers/plastomers to create thermoplastic olefin (TPO) compounds with targeted stiffness/impact balance and other mechanical properties. A typical TPO formulation is 70 wt% ICP, 10 wt% talc, and 20 wt% plastomer (e.g., Engage of Dow Chemical Company or Exact of ExxonMobil Chemical) [37.64, 65]. HDPE additions in PP have been found especially suitable for the reduction of stress whitening or scratch sensitivity [37.30].

In the case of TPO compounding, special mixing elements/kneading blocks are used to maximize mixing and dispersion. For example, the Farrel kneader possesses a big blending chamber for adding EPR (ethylene–propene rubber), EPDM (Ethylene–propylene–diene terpolymer) and other elastomers in the form of bale, while the Buss cokneader allows a more gentle dispersion of glass fibers by combining rotating and pulsating melt movements [37.30]. Modifications of mechanical properties as well as shrinkage and thermal expansion are possible through the addition of fillers and reinforcements of mostly mineral nature. The respective effects are determined by the properties of the base polymer as well as by the quantity and nature of the filler [37.30, 66]. Talc with an average particle size of 0.6–10 μm is the most commonly

used filler, while calcium carbonate, kaolin, wollastonite, and mica are used to a lesser extent.

37.12.7 Fibers and Nonwovens

Fiber formation is one of the most demanding and delicate PP-fabrication processes because it requires the highest possible quality and consistency resin to enable production of very thin fibers (sometimes on the order of 1 μm) without occurrence of any breaks. Most often, PP fibers are produced via melt spinning, a process in which the polymer melt is extruded through a spinneret comprising a plurality of die holes (typically 0.3–0.8 mm in diameter) and the resulting extrudates are simultaneously cooled (via air flowing perpendicular to the filaments) and uniaxially stretched (either via mechanical or aerodynamic means) with an equivalent take-up speed in the range of 1000–5000 m/min. With the combination of extensional deformation, cooling, and flow-induced/enhanced crystallization (FIC), fibers are produced on the order of 1–20 dpf (denier per filament; where denier is grams of fiber per m^2) or equivalently about 10–55 μm .

A description of the melt-spinning process and fundamentals can be found in *Denn* [37.67] and *Ziabicki* [37.68]. A mathematical model for melt spinning with a two-phase constitutive/microstructural model for FIC that can be used for industrial product and process development is described in *Doufas et al.* [37.69]. Model validation in the case of PP melt spinning with on-line Raman crystallinity data and fiber tension measurements is discussed in *Patel et al.* [37.70] and *Paradkar et al.* [37.71]. As mentioned previously, narrow MWD (e.g., via peroxide visbreaking) enhances the spinnability performance stabilizing the spinline relative to both random disturbances and draw resonance [37.72, 73]. Overall, at a given MW (MFR) and spinning conditions, the fiber tensile strength (tenacity) increases and the elongation to break decreases [37.73, 74].

The three most common fiber-spinning processes for PP are:

- Continuous filament (CF)
- Bulk continuous filament (BCF)
- Staple fiber (SF) [37.30].

Because the holes in the die (spinneret) are quite small (0.3–0.8 mm), low melt viscosity is important. Therefore, high melt (die) temperature (230–280 $^{\circ}\text{C}$) and relatively high MFR (10–30 dg/min) are used. A relatively large extruder is usually equipped with a manifold to distribute a high throughput of molten

PP to a bank of 8–20 spinnerets. Each spinneret is equipped with a separate gear pump to regulate output through the spinhead, a filter pack supported by a *breaker plate* and the spinneret plate within the head [37.32]. The number of holes in the spinneret plate determines the number of filaments in a yarn and is typically in the range of 50–500. The holes can have round, annular, or rectangular patterns to help with good distribution of the quench airflow.

For the CF process, a *long spinline* is preferred which can combine spinning and finishing stages as well as out-of-line drawing options [37.30]. An air cooling gap of 2–5 m is needed between the die plate and the wind-up roll. Line speeds up to 1000 m/min at the spinning stage, increasing to 3000 m/min during solid drawing over hot rolls, call for complex and expensive haul off, drawing, and wind-up sections [37.30]. CF yarns typically range from 40–2000 denier (filaments ranging from 1–20 dpf) with spinning speeds ranging from 800–1500 m/min. The product is preferably sold as continuous yarns or tows having no texture or crimp. It can be used as is or textured and combined with other yarns [37.32]. PP BCF yarns are used mainly in carpet face yarns and upholstery fabrics. The BCF process is mostly used for carpet face and upholstery yarns and characterized by the addition of a *bulking* step after spinning or spinning and orientation [37.30]. The bulking or texturizing at 140–160 $^{\circ}\text{C}$ in a jet with compressed air has a similar effect as the crimping process used for other textile fibers, causing fibers to have a wavy to curly structure for higher volume. While the MFR range is the same as for CF (10–30 dg/min), broader MWD and higher crystallinity can give advantages for the BCF process [37.30].

37.12.8 Spunbond Nonwovens

In a spunbond process, filament spinning and web forming are integrated into a single process. Filament extrusion (from molten polymer), filament drawing (orientation of polymer molecules), filament laydown (collection of filaments on a screen or porous belt to form the fabric) are operations that are simultaneously controlled. A schematic of a spunbonding nonwoven process is given in Fig. 37.2.

The spunbonding process typically utilizes a slot drawing technique as described by *Geus* [37.75] and *Balk* [37.76]. Filament formation can be achieved with one large spinneret having several hundred holes. After exiting the spinneret, the molten filaments are quenched by a cross-flow air quench system, then pulled away from the spinneret and attenuated (drawn) by high-pressure air to an equivalent take up speed of up to

Fig. 37.2 Schematic for a spunbond nonwoven process for polypropylene

about 5000 m/min. There are two methods of air attenuation, both of which use the Venturi effect. The first draws the filament using an aspirator slot (slot draw) which runs the width of the machine. The second method draws the filaments through a nozzle or aspirator gun. Web-like structures are consolidated/bonded to form a nonwoven fabric. Thermobonding is the most usual technique to consolidate webs, while other techniques such as needle punching, chemical bonding, or water jetting may also be used [37.32]. In the case of thermobonding, the fabric is passed between heated calendar rolls to bond the fabric at points covering about 20 to 40% of its area in order to increase fabric integrity and strength. The choice of resin influences the bonding temperature window. A wide bonding temperature is desirable for the best combination of operability and properties.

The typical PP resin is homopolymer PP of 25–40 MFR with narrow MWD (e.g., achieved by visbreaking of a Ziegler–Natta resin and/or use of metallocene catalyst). The narrow MWD specifically improves spinnability and provides higher orientation (thus fiber tenacity) during the high drawdown of these fibers. Fine fibers on the order of 10–20 μm are formed. The advantages of finer fibers are improved fabric uniformity and better barrier properties. In fact, for the same base-weight nonwoven fabric (g/m^2 of fabric), the finer fabric leads to a greater number of filaments per unit area leading to enhanced uniformity and coverage. Following bonding, a topical finish can be applied to the fabric to make it hydrophobic, hydrophilic, antimicrobial, or antistatic, as desired. After bonding and treating, the fabric is slit into rolls of desired widths and lengths. PP spunbond nonwovens are used for a wide range of articles, such as, disposable hygiene goods including diapers, sanitary napkins, training pants, adult incontinence products, hospital gowns, baby wipes, moist towelettes, cleaner cloths, filters, geotextiles, furnishings and carpet backing.

37.12.9 Melt-Blown Nonwovens

In the melt blowing (MB) fiber process, a high temperature, high velocity gas (air) stream, impinging on the molten polymer stream as the polymer extrudes from the small capillary in the melt-blowing die, rapidly attenuates the filament from 500 μm diameter at the capillary down to diameters as small as 0.1 μm . This process occurs in about 200 μs over a distance of a few cm [37.32]. Die design is the key to producing a quality product efficiently. The major advantage of the MB process is that it can make very fine filaments and produce very lightweight fabrics with excellent uniformity. As a result, MB achieves soft fabrics with excellent barrier properties, meaning effective filtration characteristics and resistance to penetration by aqueous liquids. The melt-blown fabrics are poorer in tensile strength especially compared to spunbond fabrics. However, the finer filaments of the melt-blown fabrics provide better moisture barrier properties, and the optimum fabric is a laminated combination of spunbond and melt-blown fabric layers: spunbond for strength and melt-blown for barrier properties [37.32]. Typically two or three spunbonded (S) layers are combined with two or three melt-blown (M) layers, e.g., SSMMS is an example of combined nonwoven construction.

Melt blowing requires a very high MFR (> 200 dg/min up to about 1500 dg/min) to obtain the finest possible fibers. Some melt-blowing manufacturers purchase 35 MFR homopolymer PP and carry out peroxide-assisted (visbreaking) degradation during extrusion to achieve the required MFR. Commercial resins with MFR in the range of 400–1500 dg/min are available with the 4th-generation catalyst technology eliminating the need for peroxide visbreaking. Higher MFR resins allow lower melt and air temperatures resulting in energy savings. As with the spunbond nonwovens, MB fibers require narrow MWD for production of very thin fibers with enhanced orientation.

37.12.10 Unoriented/Low-Orientation Films and Sheets

Depending on the fabrication process employed, PP can be processed into film and sheets ranging in thickness from 5–2000 μm and converted further into a wide variety of products [37.77]. The more common processing step is film casting with an extrusion from a slit die onto a (relatively) cold roll. The so-called *chill roll* is kept at temperatures between 15 and 80 °C by liquid cooling or heating, depending on the polymer processed and its final destination [37.30]. If the film is applied directly after solidification in this step, in which only a limited degree of orientation in machine direction is achieved, cast film is produced which typically covers a thickness range of $\approx 30\text{--}300\ \mu\text{m}$. The rapid cooling leads to films of low crystallinity with excellent clarity, which can be influenced in performance both by a choice of polymer and additive package and by variation of the processing conditions [37.78]. Applications of these films are as diverse as bags for shirts and other textiles, stationery pocket pages for photos and collectibles and hard candy twist wrap [37.32]. For cast film, PP of MFR of 7–20 dg/min is typically used with preferably narrow MWD (e.g., visbroken grades). Film can be run from the chill/take-up roll further through a calendar-like arrangement of rolls for solidifying and annealing, and roll-stack films are produced with a primary thickness range of 300–2000 μm [37.30]. These films or sheets are primarily used for thermoforming applications described later.

37.12.11 Thermoforming

In the thermoforming process sheets of polypropylene are formed into complex shapes by a pressure-assisted die process. A variety of methods can be used depending on the desired shape and dimension. Both in-line and off-line processes are applied with two essential steps, heating and shaping, the former mostly by infrared irradiation and the latter either by mechanical force, air pressure, or vacuum. Thermoforming is the only film processing segment where nucleation is applied to a significant extent [37.79]. Thermoforming has the advantages of relatively low forming pressures, low mold costs, production of multilayer structures, and low-cost fabrication of large parts [37.32]. Critical process issues in thermoforming include sheet quality, thickness uniformity of formed parts, dimensional stability, part reproducibility, and regrind use. For thermoforming, PP with MFR of about 1.5–4 dg/min are typically used [37.30] and high melt strength is desirable to improve processability by reducing sagging [37.80]. A more detailed description about cast film and ther-

moforming processes is available in *Gahleitner* and *Paulik* [37.30] and *Pasquini* [37.32].

37.12.12 Oriented Films

Biaxially oriented PP (BOPP) processes are the most popular methods for manufacturing PP packaging films [37.32]. BOPP films can be made with two methods: the tubular process and the tenter process. Tubular (or double-bubble) is less capital intensive than the tenter process but requires more labor. Film thicknesses range from 8–50 μm , while line outputs are usually in the range of 100–550 kg/h. In the bubble process, a thick-walled tube is extruded downward from an annular die over a water-cooled large-sized mandrel and quenched further in a water bath. This is the first *bubble*. The tube is about 0.3–1.5 mm thick, i.e., 30–40 times thicker than the final product. Taking care to avoid putting a hard crimp in the sides of the flattened tube, it is reheated to a temperature of 140–160 °C and is then oriented in the second *bubble* by inflating it to about 7–8 times the tube diameter. Simultaneously, the tube is stretched in the machine direction. Cooling of the bubble during stretching aids in thickness as well as in uniformity and process stability. A substantial increase in crystallinity occurs during the bubble biaxial deformation resulting in a strain-hardening effect on the film which also improves thickness uniformity [37.32]. Because of the strain-hardening effect, the tubular process can manufacture very high-quality films with excellent gauge control, although minor bands of thickness, known as gauge bands, may still occur. For more information about postprocessing of BOPP film made with the tubular process, the reader is referred to *Propylene Handbook* [37.32].

Tenter is the most common process for production of BOPP because of its lower variable costs resulting from very high output rate and wider availability of this technology over the bubble process. Film ranging from 13–33 μm is produced with widths of 3–10 m at line speeds up to 300 m/min and output rates of over 3600 kg/h. The primary market for 13–25 μm film is for snack food packaging. Films of 25–30 μm are used primarily in adhesive tape constructions [37.32]. Extruders ranging in diameter from 110–300 mm are used in the tenter process [37.32]. The primary extruder melts the resin and transfers it to a secondary, usually larger, extruder that homogenizes the melt and precisely meters it to the die. The unoriented sheet is extruded from a flat sheet extrusion die with a die gap of 1.5–3 mm and a chill roll system is often used. A single, large diameter roll partially submerged in a water bath or two large chill rolls set at 20–30 °C are typical. As with flat film extrusion, an air knife and edge pinning

are used to provide intimate contact between melt and chill roll [37.32]. Downstream, the sheet is reheated to 125–150 °C by means of heated S-wrap rolls and then passed between closely spaced differential speed rolls to achieve machine direction (MD) orientation with restrained width. The lengthened and thinned sheet is cooled and passed to the tenter section of the line. The temperature in each oven section is controlled precisely to within 0.5 °C. At the desired temperature, the tenter chain diverges and stretches the sheet to the desirable film width. Oven temperatures range from 150–170 °C. In order to stabilize the molecular orientation achieved during stretching and increase heat stability (reduction in shrinkage), a heat-set stretching process can follow the stretching process [37.32]. The film is cooled, and the clips are released prior to edge trim, treatment (optional), and winding.

Contrary to the tubular process, in the tenter process the film generally undergoes sequential orientation (two-stage method). In the tenter process, extruded film is first drawn in the MD 4- to 6-fold, and then in the width or cross direction (CD) by about 7- to 10-fold with a total thickness reduction ratio of 40 : 1 to 55 : 1 [37.32]. Consequently, the extruded sheet can range from 0.6–3 mm in thickness. There are also available simultaneous biaxial stretching units, where machine and cross stretching are performed simultaneously. The two orientation methods (bubble and tented process) produce generally different physical film properties. Tubular film has balanced properties (MD versus CD), while the higher draw in the CD gives the tented films higher stiffness and strength in that direction. However, modern tenter lines can produce films with practically isotropic properties [37.32]. BOPP films are characterized by a much higher orientation, stiffness, gloss, and transparency in comparison to cast films. While in the packaging area, the low water vapor permeability and the excellent optical appearance are especially appreciated, the high mechanical and thermal resistance make BOPP also suitable for electrical capacitors.

PP resins with MFR values of 1.5–4 dg/min are used for BOPP with a relatively broad MWD to have sufficient melt strength and strain hardening for enhanced stability during stretching. The PP film resins have appropriate amounts of antiblock and slip additives to allow good film handling in production and high-speed converting operations downstream [37.32]. The BOPP film area is largely dominated by PP homopolymers and random copolymers with ethylene, but for sealing layers terpolymers with ethylene and butene are also used [37.30]. Impact copolymers are limited mostly to nontransparent applications with low-temperature toughness requirements, unless special polymer designs are applied which allow a combination of transparency

and toughness (e.g., *interpolymer* concept) with high propylene content in the EPR phase [37.32].

37.12.13 Injection Molding

Injection molding is a cost-effective fabrication process widely used for production of three-dimensional PP parts including rigid packaging containers and housewares, caps and closures, appliances and hand tools, medical articles and pharmaceutical packaging systems, consumer/industrial, etc. In injection molding, polymer (typically in pellet form) is softened, melted, and conveyed with a single screw. The melt is pushed through a runner system into a cavity or multiple cavities of a mold. The mold is cooled and eventually the solid parts are ejected and stacked. In thin-wall injection molding (TWIM) for rigid packaging container applications, the thickness does not usually exceed 25 mil and could often be considerably less than that [37.40].

Successful injection molding requires adequate product design, mold or tool design and construction, machine design and operation, and resin selection [37.32]. All these phases of product and process development and optimization frequently use computer-aided engineering (CAE) techniques. In particular, finite element analysis (FEA) can be used to simulate almost every mechanical and thermal condition such as static loads, impact events, thermal dilatation and creep, vibration and response to oscillatory loads, among others [37.30]. Thus, the design, dimensions, and thickness of injection-molded parts can be optimized. Details about injection-molding principles and design can be found in Injection Molding Handbook [37.81].

A typical range of PP MFR used for injection molding is 1–100 dg/min [37.30]. Increasing the MFR allows filling thin and narrow cavities over longer distances, however, the impact strength is greatly reduced. Use of random or impact copolymers can enhance impact strength. However, stiffness, heat resistance, and transparency, if targeted, will in turn be compromised. For TWIM, a typical reactor-based PP grade is approximately 35 dg/min MFR, although MFRs up to about 100 dg/min are used to permit more wall thinning and source reduction (downgauging). Both reactor and CR (Control rheology: a process of reducing molecular weight and molecular weight distribution of isotactic polypropylene (iPP)) PP resins are used, although reactor resins are generally more desirable for injection molding for two reasons. The broader MWD of a reactor resin over CR results in more shear thinning enhancing processability and a reactor resin has better organoleptics (taste and odor transfer characteristics) because of the absence of by-products of peroxide decomposition [37.40].

Typical PP injection-molding conditions are as follows [37.30]:

- Melt temperature T_m : 200–265 °C
- Injection pressure P_{inj} : 50–150 MPa
- Injection speed v_{inj} : 100–400 mm/s
- Mold (wall) temperature T_w : 30–60 °C.

Lower T_m will be used for higher MFRs, and lower levels of T_w for thinner parts. Molding machines for thin wall injection molding (TWIM) require fast injection speeds and high platen opening and closing speeds. Injection times of less than 0.20 s can be achieved for TWIM and cycles can vary between 7 and 20 min [37.32].

During PP injection molding, the formation of crystalline superstructures including shear-induced skin-core layers [37.82] affects both the solidification speed and the mechanical strength of molded parts. The presence of broad MWD resins containing a high molecular weight tail generally favors skin layer formation. Semicrystalline PP exhibits higher shrinkage and greater tendency for parts warpage than amorphous materials such as polystyrene (PS) and ABS. The resulting crystalline structure during injection molding determines the in- and post-parts shrinkage and anisotropy. Linear postmolding shrinkage of PP is 1.0–1.5%, of which 85% occurs within the first 24 h [37.30]. Distortion or warpage in molded products results from anisotropic shrinkage and both reflect internal stresses and crystal orientation. Higher MFR and/or narrow MWD typically reduce shrinkage and warpage of

parts [37.83]. Shrinkage and warpage can also be controlled by proper choice of processing conditions and part design. In general, the combination of resin attributes (e.g., M_w and MWD) and parts design and processing conditions affect the final parts properties.

A problem often encountered in injection molding of ICPs or thermoplastic olefin (TPO) compounds for long automotive parts is the formation of tiger marks. Tiger (flow) marking is defined as a viscoelastic melt flow instability that typically occurs in relatively long injection-molded parts, where alternate dull and glossy regions occur beyond a certain distance from the gate (onset distance to flow marks). Tiger marking is highly undesirable due to unacceptable appearance of the molded parts. Tiger marking fundamentals have been described in the literature [37.65, 84, 85]. It was found that the enhancement of melt elasticity at low shear rates effectively prevents the occurrence of flow marks on the molded parts [37.84]. As described in [37.64], a certain class of ICPs and TPOs with a high viscosity ratio (> 4) between ethylene–propylene rubber (EPR) and matrix phases (iPP) was reflected in a low value of loss tangent at 0.1 rad/s at 180 °C in a small-angle oscillatory shear (SAOS) experiment. These also exhibit either no tiger marks or significantly delayed onset of tiger marking. The ICP compositions made with a bulk/gas reactor process (nonslurry, solvent free) also exhibited significantly reduced amounts of gels/fish eyes despite the high viscosity ratio between matrix and rubber phases leading to excellence appearance and paintability of the molded parts [37.64].

37.13 Synthesis and Processing of Elastomers

37.13.1 Elastomer IUPAC Nomenclature

IUPAC nomenclature of elastomers is rigorous. It divides the materials into elastomers and rubbers, differing principally in their degree of crosslinking to create insoluble materials as well as hydrocarbon materials whose accepted acronyms end with M or R, corresponding to whether they are saturated in the backbone (M) or contain residual unsaturation (R). Nonhydrocarbon materials have spe-

cial designations such as Q for silicones. The common elastomers derived from petroleum which are described in this section are summarized in Table 37.3 [37.86].

Table 37.3 Common elastomers derived from petroleum

BR	Butadiene rubber (BR) (polybutadiene)
EPDM	Ethylene–propylene–diene terpolymer
IIR	Isobutylene–isoprene rubber (IIR) (butyl rubber)
SBR	Styrene–butadiene rubber (SBR)

37.14 Polybutadiene (BR)

37.14.1 Synthesis

The earliest polymerization of butadiene was with alkali metals in a bulk polymerization process. This technology using metallic sodium led to the development of the Buna grades. These early efforts were a technical demonstration without much commercial success. Subsequent efforts using either Ziegler coordination catalysts or alkyl lithium catalysts to produce solution polymers have led to a greater success in making BR. BR is composed of butadiene units which are joined by 1,4-addition (mostly in *cis*-1,4, but also *trans*-1,4-conformation) as well as by 1,2-addition. These geometric and stereo isomeric forms of monomer insertion lead to different polymeric properties ranging from amorphous to crystalline. The largest proportion of the globally produced BR is obtained by solution polymerization. The initiators used are primarily coordination catalysts, namely titanium [37.86], cobalt [37.87], nickel, and neodymium compounds [37.88]. Anionic polymerization using alkyl lithium compounds is also widely used since the BR rubber made in this process is structurally dissimilar to that obtained by the coordination polymerization. While with coordination catalysts the butadiene units in BR add linearly in greater than 92% *cis*-1,4-configuration, the alkyl lithium catalysts yield a BR with an intermediate *cis*-1,4-content and a higher 1,2-structure. The free radical emulsion polymerization in water of butadiene (emulsion or E-BR) yields a less uniform BR which although of great historical significance is not widely used today. However, a variant of this process where the polymerization is conducted as a coordination polymerization modification using a RhCl_2 catalyst in emulsion yields a predominantly *trans*-1,4-BR. The principal catalytic processes and thus the corresponding isomers of BR are listed below:

- **Titanium:** Originally, Phillips used titanium tetraoxide and aluminum tris(isobutyl) as catalysts. These formulations have now evolved to produce modified titanium catalysts to yield a BR which is easy to process.
- **Cobalt:** According to a process developed by Goodrich, CoCl_2 , Co-bis(acetylacetonate) or Co-bis(octanoate) in combination with diethyl aluminum chloride or ethylaluminum sesquichloride is used as catalyst [37.89].
- **Nickel:** A Bridgestone process [37.90] uses initiators such as Ni-bis(naphthenate)/boron trifluoride/ethylene oxide/aluminum trialkyl as a catalyst for the production of BR.
- **Neodymium:** A new Bayer development leads to a neodymium-based BR with high *cis*-1,4-content and correspondingly favorable mechanical properties in tread and sidewall compounds for car and truck tires due to improved fatigue resistance, abrasion resistance, and lower heat build-up compared to the conventional BR grades. Similar work has also been reported from the Chinese Academy of Sciences in Chanchung.
- **Lithium:** A process developed by Firestone uses alkyl lithium catalysts for the production of BR. The polarity of the solvent has a great influence on the microstructure and the vinyl content. The latter can be adjusted by the use of ethers or tertiary amines [37.91].
- **Alfin:** A process developed by Morton [37.92] for the production of BR with so-called Alfin catalysts, is an interesting specialty process with unique chemistry and polymer products. This catalyst consists of sodium salts of organic alkoxides in conjunction with sodium chloride. The polymerization is carried out in aliphatic hydrocarbon solvents. Contrary to the other processes, this process produces BR with high *trans*-1,4-content, and extremely high molecular weights. A unique facet of this polymerization process is that the high molecular weights persist through a range of process conditions including changes in the catalyst concentration.

37.14.2 Structure of BR and Its Influence on Properties

The average molecular weight of commercial BR grades is in the range of 250 000–300 000, corresponding to ML (1+4) Mooney viscosities at 100 °C of 35–55. The macrostructure of BR grades and the molecular weight distribution directly affects the properties and processability of the rubber both in the formation of compounds and the fabrication of the final article. These structural features depend on the polymerization process. Anionic lithium BR usually has a very narrow molecular weight distribution which leads to both poor processing and cold flow. Broader molecular weight distribution coordination polymerized BR is better. Broadening of the molecular weight distribution can be achieved using coupling or extensive branching which by extending the relaxation times leads to the same benefits in processing. With Li-BR, these branching reactions can be carried out by copolymerization with the difunctional monomer, divinyl benzene. Dramatic changes in the molecular weight distribution

are done with a coupling reaction. This coupling reaction uses an agent such as silicon tetrachloride or divinylchloride [37.93] and inorganic acid chlorides, such as POCl_3 , SOCl_2 , or S_2Cl_2 [37.94]. These very high molecular weight BRs are used for the production of oil-extended rubbers. Long-chain branching results in reduced cold flow, longer mixing cycles, better filler distribution, higher green strength, and higher extrusion rates.

Catalysts influence the microstructure of BR, and thus the vulcanized properties. The higher the *cis*-1,4-content of BR, the lower is its glass transition temperature T_g . Pure *cis*-1,4-BR grades have a T_g temperature of about -100°C , while commercial grades with about 96% *cis*-1,4-content have one below -90°C . Pure *cis*-1,4-BR has a subambient melting point and do not exhibit strain crystallization at room temperature. The glass transition temperature of BR rises monotonically as the concentration of 1,2-structure (vinyl content) increases. The tendency towards crystallization is determined by the 1,2-content.

37.14.3 Compounding and Vulcanization of BR

BR is mostly used in blends with natural rubber (NR) or SBR. Compared to BR alone, these blends in similar applications can be used with higher filler loading, higher extrusion rates, and higher green tensile strength. These attributes lead to lower cost and faster throughput in the manufacturing process. BR can be easily blended with all nonpolar diene rubbers. The blend ratio depends on the desired result, and ranges from about 30–50% for the BR elastomer.

The tensile strength of vulcanizates from BR with high *cis*-1,4 is much lower than desirable and cannot be used by itself in tires. However, blends with other rubbers show extremely low T_g with acceptable mechanical strength. These blends have a particularly high abrasion resistance, good low temperature flexibility, and

high resilience. Dynamic properties, such as heat generation during flexing and resistance to cracking, are also improved in general-purpose rubbers when they are blended with BR.

37.14.4 Uses of BR

- *Tires*: Over 90% of the total BR production is used in tires. The use of BR for specific tire components has changed in recent years due to the advances of radial tires. Originally BR had been widely used in tread compounds to improve the abrasion resistance. In radial tires, this rubber has found greater use in carcass, sidewall, and bead compounds because the tread of a radial tire already has an intrinsically higher abrasion resistance than that of bias tires. In winter tire treads, however, BR still plays an important role because of the improved ice traction.
- *Technical rubber goods*: In these products, and particularly in shoe soles or conveyor belting compounds, BR is preferred for its high abrasion resistance. Compounds containing BR also have improved flow properties, and for this reason, BR is recommended for compounds which are processed by injection molding. Successfully proven uses of BR are in compounds for shoe soles, bumpers, roll covers, conveyor belts, transmission belts, pads for chain tracks, shock absorber pads, and other products which require a reversion-resistant compound.
- *Liquid-reactive BR grades*: BR grades with a low molecular weight and reactive end groups (so-called telomers or reactive liquid polymers) can be converted into elastomers through a reaction with other suitable compounds in conventional methods for converting liquid polymers.
- *Impact modifiers for plastics*: Li-BR is used in considerable quantities as a modifier to improve the impact resistance of plastics.

37.15 Styrene–Butadiene Rubber (SBR)

37.15.1 Synthesis

In 1929, in a series of seminal experiments based on anionic polymerization and copolymerization of dienes and styrene, Tchunkur and Bock discovered that mixtures of butadiene and styrene can be copolymerized in emulsion [37.95]. These were called Buna S and had improved vulcanized properties compared to BR and were thus more widely accepted. Continuing re-

search and development lead to development of chain transfer agents for control of molecular weight and the development of redox initiators which allowed a reduction of the polymerization temperature as well as the development of easily processed SBR rubbers which still retained the excellent vulcanization characteristics [37.96]. Commercial production of emulsion SBR started in Germany in 1937, followed closely in 1942 in the United States as Government Rubber-Styrene. This

genesis led to the development of a very large commercial, worldwide SBR manufacturing industry based mostly on redox-initiated emulsion SBR with a growing amount of anionic or coordination solution SBR where the properties are more discretely variable. The styrene content in SBR ranges usually from about 23 to 40%. Since coordination catalysts have become available, stereospecific SBRs have also been produced in solution processes. An additional recent development is the block copolymers, composed of BR and PS blocks made by sequential anionic copolymerization of styrene and butadiene. These block polymers though isomers of SBR do not share the same properties. At room temperature, the styrene blocks separate into discrete phases, resulting in a physically crosslinked network structure and thermoplastic elastomers (TPEs).

In emulsion polymerizations, the rubber is obtained as latex which can be either used as such or further processed to yield solid rubber. The preferred emulsifiers for the dispersion of monomers during polymerization are, for instance, mixtures of sodium salts from fatty and rosin acids [37.97]. The ratio of butadiene to styrene is typically 76 to 23% by weight. The free radicals required for the initiation step are obtained by the reaction of iron(II) salts with *p*-menthane hydroperoxide or pinane hydroperoxide. *tert*-Dodecyl mercaptan is most frequently used as a chain modifier. With some SBR grades, extender oils and/or carbon black are added at the end of the polymerization stage. For oil extension, the rubber is usually produced to significantly higher molecular weights [37.98]. The oil, which is added to the latex, and which is recovered with the rubber from the latex, acts as a plasticizer during processing.

Solution copolymerization of butadiene and styrene in aliphatic or aromatic hydrocarbon solvents, using alkyl lithium catalysts produces the corresponding solution SBR [37.99]. Because of differential reactivity, the butadiene monomer polymerizes first, followed by the styrene, thus blocks of these monomers are found in the copolymer. Statistically random copolymerization occurs in the presence of modifiers such as ethers or tertiary amines. Although the overall composition of block copolymers and random copolymers can be the same, their physical properties differ significantly. Anionic polymerization is a living process which can be used to make multiblock butadiene and styrene block polymers by sequential and staged addition of monomers.

37.15.2 Structure of SBR and Its Influence on Properties

Emulsion SBR (E-SBR) is commercially available in ML (1+4) Mooney viscosities at 100 °C ranging from

30 to about 120, which correspond to average molecular weights of about 250 000–800 000. Emulsion SBR's differ in the amount of long-chain branching, thus in their processing and tensile characteristics, depending on the temperature of the polymerization. This emulsion process yields a rubber which may contain extremely high molecular weight gels, and their elimination requires a specific staged mode of addition of the chain transfer agent. Emulsion SBR's made by redox process at low temperatures have less long-chain branching and thus different processing characteristics than those made at a higher temperature with better tensile properties. At an equivalent viscosity, the low-temperature emulsion SBR can be more easily processed and form a smooth surface which is a consideration for tires. In the low-temperature redox polymerization SBR the butadiene component has, on average, about 9% *cis*-1,4-, 54.5% *trans*-1,4- and 13% 1,2-structures. At a 23.5% bound styrene level, the glass transition temperature (T_g) of SBR is about –50 °C. As the styrene content in the SBR increases, the glass transition temperature rises with loss of elastomeric properties like elastic recovery and resilience. However, the higher styrene content SBR also has an improvement in processability (extrusion rate, green strength, surface smoothness). Depending on the quantity of styrene in the butadiene chains, it is possible to adjust anywhere between these two extremes.

This rubber is supplied as gum, or extended with oil or carbon black, and can usually be processed directly. Since SBR cannot be readily masticated, the viscosity of the available material is of special importance regarding its processability. Low molecular weight SBR polymers are easily processed on rubber machinery, incorporate fillers and oil more readily, and can be fabricated by extrusion and calendaring. However, the higher molecular weight SBR rubbers have better green strength, and also accept higher filler and oil loadings.

Solution SBR affords entirely different structural, macrostructure, and butadiene insertion profile compared to emulsion SBR with a wide control using different catalysts and modifiers. By choosing appropriate polymerization systems and conditions, it is possible to custom-make solution SBRs with a wide range of specific properties. Solution SBR with a higher 1,2-content and thus a higher amount of pendant vinyl groups has largely the same effect on the polymer properties as the styrene with respect to T_g and interaction with fillers. Both lead to increase of T_g and the choice of concentrations of styrene and 1,2-butadiene units in the property of SBR rubbers can be tailored to suit the specific application. The spectrum of relaxation times of the rubbers is controlled by the breadth of molecular

weight distribution. This can be adjusted through the branching reactions. Solution SBR grades with a random distribution of styrene units are very similar to the emulsion polymers in composition except for the greater preponderance of the *cis*-1,4-structure and a narrower molecular weight distribution accompanied by less long-chain branching than the emulsion polymers. In segmented or blocky solution SBR, these polymers exhibit two distinct T_g at -85°C for the polybutadiene block and $+75^\circ\text{C}$ for the polystyrene block.

37.15.3 Compounding and Vulcanization of SBR

SBR can practically be blended with all nonpolar rubbers over the whole range of blend concentrations. Blends with BR or NR are of great importance in tire applications. In this example, the BR improves, for instance, the abrasion resistance and the hysteresis of the vulcanizates. Blends of SBR with polar rubbers, such as natural butyl rubber (NBR), are restricted to those NBR grades with low acrylonitrile.

Mechanical Properties

The tensile properties of E-SBR vulcanizates depend in great measure on the type and amount of filler in the compound. Gum vulcanizates have only poor tensile properties since the rubber lacks self-reinforcing qualities, and they are therefore of little interest. Instead, reinforcing fillers are usually required in SBR compounds. At optimum loadings with reinforcing carbon blacks, it is possible to reach virtually the same level of excellent tensile properties for SBR as for NR vulcanizates, but the tear resistance of the SBR vulcanizates is still inferior. The elastic properties of

E-SBR vulcanizates are also poorer than comparable ones of NR. The compression set of the vulcanizate, which is important for many applications, depends on the compound formulation, the cure conditions, and the specific test method. Through proper compounding and at optimum cure, it is, however, possible to obtain very low values of compression set for E-SBR vulcanizates.

Dynamic Properties, Aging Resistance, and Abrasion Resistance

E-SBR vulcanizates show surprisingly effective dynamic fatigue resistance, aging resistance, and heat resistance, surpassing NR vulcanizates. Without antioxidants the SBR vulcanizates are, however, not resistant to weathering and ozone degradation. Sulfur-free and low-sulfur vulcanization systems play an important role as well, and this also applies to NR. The heat resistance of optimized E-SBR vulcanizates allows service temperatures to be about 20°C higher than those for NR vulcanizates. E-SBR vulcanizates formulated with reinforcing fillers give a superior abrasion resistance than comparable ones from NR, which accounts for their predominance in passenger car tire treads. Since the E-SBR vulcanizates are so durable, they have replaced NR in many applications. The dynamic properties of E-SBR are inferior to those of NR, therefore, E-SBR vulcanizates give a higher heat buildup in dynamic applications. However, since they have a better heat resistance, E-SBR vulcanizates can also tolerate higher service temperatures. Nevertheless, in thick-walled rubber products, heat can build up because of the poor thermal conductivity of rubber, and this can lead to temperatures in excess of those tolerable by E-SBR vulcanizates.

37.16 Ethylene–Propylene Rubber (EPR/EPDM)

Polyethylene containing enough incorporated alpha olefin such as propylene can be essentially amorphous since the presence of statistically incorporated comonomer reduces both the melting point and the extent of the crystallinity. These amorphous materials are elastomeric and are thus resilient and recover from deformation over a wide range of temperatures. These resulting ethylene-propylene monomers (EPMs) do not contain unsaturation and can only be crosslinked to rubbers with peroxides. The incorporation of a third monomer during copolymerization of ethylene and propylene leads to sulfur-vulcanizable elastomer. The third monomer is a diene which retains one of the double bonds after polymerization as a pendant reactive

site. The terpolymers are EPDM which can be vulcanized using agents, depending on the reactivity of the double bond or atoms adjacent to them such as allylic hydrogens.

37.16.1 Synthesis

EPM and EPDM made by copolymerizing ethylene, propylene, and optional diene with Ziegler–Natta catalysts started in 1963. The majority of commercial EPM grades contain about 40 to 80% by weight corresponding to 45 to 85 mol% of ethylene, and the most important polymers contain about 50 to 70 mol%. The polymers at the higher end of the ethylene composi-

tion have some polyethylene-type crystallinity and are not amorphous. While many compounds are classified as dienes to make EPDM, commercial rubbers contain one of only four dienes. The choice of a suitable monomer depends on many criteria [37.100]. Firstly, the two double bonds of the diene should have different reactivities so that one will copolymerize with the second remaining unreacted in the polymer chain, enabling it to be used in subsequent vulcanization reactions. The other requirement is a high reactivity of the second double bond in sulfur vulcanization reactions.

These dienes are nonconjugated and in the final EPDM the retained double bond that did not participate in the Ziegler polymerization process is present as a pendant sidegroup to the main polymer chain. The four dienes are:

In commerce single-site catalysts such as vanadium or modern metallocene catalysts are used. The vanadium catalysts are formed in situ from a combination of VCl_4 and $VOCl_3$ along with the activating component $Al_2(ethyl)_3Cl_3$ or $Al(ethyl)_2Cl$. In the most common solution polymerization processes, the solvents are aliphatic hydrocarbons such as pentane or hexane. In suspension polymerization processes, an excess of propylene serves as the medium.

The key structural variations in the synthesis determine the properties of EPM and EPDM (in parenthesis, below):

- Composition: Ratio of ethylene and propylene (amorphous or semicrystalline)
- Co- or terpolymer (EPM or EPDM)
- Type and concentration of monomer (vulcanization kinetics, mechanical properties)
- Solution and suspension polymerization (highest obtainable molecular weight)
- Molecular weight distribution (processability)
- Oil extension (price).

37.16.2 Structures of EPM and EPDM and Their Influence on Properties

Sequence Distribution

Copolymers, which contain between 45 and 60 ethylene, are completely amorphous and are not self-reinforcing. At higher ethylene contents of 70–80%, the polymers contain long ethylene sequences, which are crystalline or crystallizable under deformation. These partially crystalline domains form thermally reversible physical crosslinks, which appear as high modulus prior to crosslinking.

Viscosity and Processability

The processability, which is both the ease of compound formation as well as fabrication of the final object prior to vulcanization, depends on their molecular structure [37.101]. Typically, a narrow distribution is adequate for average carbon-black dispersions, and a broad distribution for applications requiring excellent carbon-black dispersion. The molecular weights of most commercial grades are between 200 000 and 300 000 and the corresponding ML (1+4) Mooney viscosity at 100 °C lies between about 25 and 100.

Degree of Unsaturation

Since in both EPM and EPDM the polymer backbone is completely saturated having excellent resistance to oxygen and ozone even at elevated temperatures, EPM and EPDM vulcanizates are environmentally stable. The vulcanization properties, including rate and state of cure of EPDM, depend on the amount and type of double bonds from the monomer.

37.16.3 Compounding of EPM and EPDM

Blending EPM or EPDM with other polymers [37.102] improves the ozone resistance of other diene rubbers, such as BR and SBR. Since covulcanization of the components is difficult but highly desirable for high-ENB-EPDM grades, where ENB is 5-ethylidene-2-norbornene, the use of highly reactive accelerators or peroxides is common. EPDM grades with low unsaturation or EPM can also be used in blends with saturated polymers. Examples are blends of EPM or EPDM with polyolefins, sometimes already precrosslinked, to produce *thermoplastic elastomers* (TPE). The EPM or EPDM blend components also act as elastomeric modifiers to improve the impact strength, and since the modifiers have to be very elastomeric and often precrosslinked with peroxides, EPDMs are preferred in this application over EPMs.

Vulcanizing Agents

While EPM can only be crosslinked with peroxides, EPDM can use peroxides or sulfur. The methyl groups in polypropylene inhibit crosslinking reactions with peroxides, instead, they lead to chain scission. However, copolymer with 50 or greater mol% of ethylene can be crosslinked with peroxide. The termonomer also has an influence on the peroxide cure. For cable insulations, EPDM is frequently crosslinked with high-energy radiation as well. In this process no chemical curing agent is required. However, by using specific coactivators, a given degree of crosslinking can be obtained with a reduced dose rate. With sulfur cures, the required amount depends on the type and amount of termonomer in the polymer.

37.16.4 Processing of EPM and EPDM

Only compounds from low Mooney EPM or EPDM grades can be mixed on open mills. Therefore, EPM/EPDM compounds are almost exclusively mixed in internal mixers, and preferably by the so-called *upside down* technique. Since the EPM/EPDM is reversion resistant, high cure temperatures are generally used.

37.16.5 Properties of EPM and EPDM Vulcanizates

Mechanical Properties

The level of mechanical properties depends considerably on the type and amount of fillers in the compound. Optimized vulcanizates have lower levels of tensile properties as SBR. The mechanical properties of the partly crystalline, high ethylene content EPDM grades are particularly high, reaching the level of those for NR vulcanizates. Tear resistance, particularly at high temperatures, also compares with that achieved by NR vulcanizates. A wide range of hardnesses can be obtained with EPM or EPDM vulcanizates.

The elastic properties of EPM or EPDM vulcanizates are by far superior to those of many other SR vulcanizates, but they do not reach the level obtained with NR vulcanizates. The resistance to compression set of EPM or EPDM vulcanizates is surprisingly good, and this particularly applies to ENB-EPDM with a high ethylidene-norbornene (ENB) concentration, which is cured with either peroxides or sulfur in a highly active accelerator system. Compression set of sulfur-cured EPDM vulcanizates increases very rapidly with increasing temperatures in contrast to

peroxide crosslinked EPDM which remain relatively stable.

Dynamic Properties

The dynamic properties and the dynamic fatigue resistance of EPDM vulcanizates are also very good, comparable to those of SBR vulcanizates. This applies particularly to sulfur-cured vulcanizates.

Heat and Aging Resistance

The resistance to heat and aging of optimized EPM and EPDM vulcanizates is better than that of SBR or NBR vulcanizates. It is comparable to that of sulfur-cured IIR vulcanizates. Peroxide-cured EPM can, for instance, be exposed for 1000 h at 150 °C without significant hardening. The heat resistance of sulfur-cured EPDM vulcanizates is somewhat poorer. Therefore, because of the higher heat resistance of peroxide cures, combined with a very low compression set, this cure system is also widely used for EPDM. Under normal use conditions an oxidative degradation of the vulcanizates will not take place. The ozone resistance is also excellent. Even after an exposure for many months to ozone, the vulcanizates are not deteriorated. The ozone resistance of peroxide-cured EPM grades is best, followed by sulfur-cured EPDM. The ozone resistance of EPDM vulcanizates is still superior to that of CR and IIR. The resistance to weathering is also excellent, and follows the ozone resistance.

Resistance to Swelling and Chemicals

EPM and EPDM vulcanizates have an excellent resistance to chemicals. They are not attacked, and if so, only slightly, by dilute acids, alkalis, acetone, alcohol, and hydraulic fluids. Concentrated inorganic acids harden or destroy the vulcanizates. This is in contrast to the swelling resistance in aliphatic, aromatic, or chlorinated hydrocarbons. Since they are nonpolar, EPM and EPDM vulcanizates swell considerably in these media.

Electrical Properties

The electrical insulating and dielectric properties, or the breakdown and corona resistance, of EPM and EPDM vulcanizates are all excellent. In these respects, one should, however, differentiate between EPM and EPDM. EPM vulcanizates exhibit the best behavior. The electrical properties of these vulcanizates are also good at high temperatures and after heat aging of the vulcanizates. Because EPM and EPDM vulcanizates absorb little moisture, their electrical properties suffer minimally when they are submersed in water or buried underground.

37.17 Butyl (IIR) and Halobutyl Rubber

Isobutylene–isoprene rubber (IIR) is based on the BASF process of 1931 for making polyisobutylene. Standard Oil of New Jersey (now ExxonMobil) Chemical developed the commercial method for producing IIR in 1943. IIR consists of 97 to 99.5 mol% isobutylene and 0.5 to 3 mol% isoprene which provides the double bond required for sulfur vulcanization. More recently, chlorinated and brominated butyl rubbers (CIIR and BIIR, commercially known as chlorobutyl and bromobutyl) have also been produced to provide interfacial vulcanization of IIR and general purpose rubber (GPR) in tires.

37.17.1 Synthesis

IIR is produced by a cationic copolymerization of isobutylene and isoprene in methyl chloride suspension with AlCl_3 as a catalyst. The polymerization is conducted at -100°C with small amounts of water or HCl as cocatalysts. This low polymerization temperature is required to obtain high molecular weights for IIR. During the polymerization, which progresses to high conversion, high molecular weight IIR precipitate in discrete particles (precipitation polymerization), which are then separated from unreacted monomer and solvent, before drying. Cationic polymerization processes are dependable and reproducible only if the monomer is extremely pure. More recently, instead of AlCl_3 , $\text{Al}(\text{alkyl})_2\text{Cl}$ has been used as catalyst with a hexane solvent at higher polymerization temperatures of -40 – -50°C . This is a solution polymerization process which still leads to sufficiently high molecular weights [37.103].

37.17.2 Structure of IIR and Its Influence on Properties

Macrostructure

The average molecular weight of IIR is about 300 000–500 000, corresponding to ML (1+4) Mooney viscosities at 100°C of about 40–70. The molecular weight distribution of IIR is relatively broad most probably due to the inhomogeneous polymerization conditions.

Microstructure

The isobutylene monomer units polymerize predominantly in a head-to-tail arrangement, and the isoprene units are built into the polymer chains in *trans*-1,4-configuration.

Unsaturation

The largely saturated backbone of IIR contributes to its good resistance to oxidative and ozone degradation by

chemicals, while its density and chain dynamics determine the key attribute of low gas permeability. Among elastomers IIR is notable in having the lowest gas permeability and is thus principally used for air retention in tires and closures. The double bonds in the chain which are residues from isoprene permit sulfur vulcanization. At low levels of unsaturation, this vulcanization is slow. With increasing levels of unsaturation, vulcanization rates increase, but at the expense of thermal and chemical stability.

Blends

Since IIR cures relatively slowly, it does not covulcanize with other diene rubbers. For certain applications, blends with CIIR and chloro sulfonated rubber (CSM, up to 25% by weight) are used. CIIR and BIIR are important as blend partners with other diene rubbers.

37.17.3 Properties of IIR Vulcanizates

Mechanical Properties

With reinforcing fillers [37.104] very high tensile strengths can be obtained in IIR vulcanizates, corresponding to those of GPR vulcanizates. The vulcanized compounds characteristically exhibit very small rebound at room temperatures. Normally, IIR vulcanizates can be produced in hardnesses up to Shore A 85. For harder vulcanizates the use of resins or blending with CSM (up to 25% by weight) is recommended. As with other rubbers, the compression set of IIR vulcanizates depends primarily on the degree of vulcanization, and on the type and amount of filler and softener used in the compound formulation. In spite of the low rebound and stiffening of the vulcanizates at lower temperatures, the brittleness point is very low at -75°C .

Heat and Aging Resistance

The heat resistance of IIR vulcanizates, especially those cured with phenolic or halogenated phenolic resins, is excellent. Sulfur vulcanizates of IIR, however, have considerably poorer heat resistance compared with that of sulfur-cured EPDM vulcanizates. Because they contain a limited amount of unsaturation, IIR vulcanizates have an excellent resistance to weathering and ozone degradation.

Permeability

Vulcanizates from IIR have very low gas permeability, which is even lower than that of vulcanizates from high nitrile NBR.

37.17.4 Uses of IIR

The main applications of IIR are in cable insulations and jacketing, inner tubes of tires, inner liners of tubeless tires, curing bladders, pharmaceutical stoppers (mainly resin cured), and roofing membranes. However, tire treads based on IIR have not performed successfully.

37.17.5 Synthesis CIIR and BIIR

On adding chlorine or bromine to IIR in an inert organic solvent, a rapid electrophilic substitution reaction occurs, whereby one halogen atom is added per isoprene unit, mainly on the allylic positions [37.105]. Thus, only a relatively small number of halogen atoms are incorporated into the polymer chain. An addition of a pair of halogen atoms across the double bond hardly occurs. With chlorine, one obtains CIIR, and with bromine, BIIR:

- *Structures of CIIR and BIIR and their influence on properties:* Compared with IIR, the halogenated

IIRs have two advantages: the cure reactivity of the double bond is enhanced by both the halogen atom and allylic halogen structure. As a result, improvements occur in vulcanization rates, the states of cure, the reversion resistance, and interfacial covulcanization with other diene rubbers.

- *Compounding of CIIR and BIIR:* In addition to sulfur and phenolic crosslinking, crosslinking with ZnO or diamines is possible. BIIR gives faster vulcanization rates, and for the same cure systems, it gives a higher state of cure. Since with ZnO alone, the cure state is often inadequate, it is frequently used together with sulfur or sulfur donors.
- *Properties of CIIR and BIIR vulcanizates:* The properties of the CIIR and BIIR vulcanizates are better than those of IIR vulcanizates, such that BIIR vulcanizates have an even lower gas permeability, better weather and ozone resistance, higher hysteresis and better resistance to chemicals than the IIR parent.

37.18 Conclusion

Polymers derived from petroleum although composed of only a few major unsaturated building blocks occupy an increasing portion of the landscape and comprise of polymers which span the range of thermoplastics and elastomers. The efficiency of their manufacturing processes and the scale of the production of the monomers enable these polymers to be the biggest volumes in their respective fields. In addition, for these polymers their utility is greatly increased by the ease of the forma-

tion of binary or multicomponent blends. These blends, which typically have properties intermediate between the thermoplastics and the elastomers, are easily made by melt mixing. It is undoubtedly true that as the types of petroleum extricated changes in the future the nature of monomers available will change but the variety of petroleum-derived polymers ensures that under most conditions and scenarios this will continue to a productive and vibrant part of the economy.

Biomass to L

38. Biomass to Liquid (BTL) Fuels

Gary Brodeur, Subramanian Ramakrishnan, Chang Samuel Hsu

We introduce a strategy for biomass fractionation and refinery co-processing. Some of the leading conversion technologies are reviewed, including pretreatment-hydrolysis (for 2nd-generation biofuels), gasification and Fischer-Tropsch (FT) synthesis, pyrolysis, and aqueous phase reforming (APR), along with some of the current challenges for commercialization. The main objective is to give an overview and recommendations in regard to the co-processing of biomass oil with crude oil that includes some of the developed technologies, as well as providing a new theoretical approach to the co-utilization of these raw materials. This new approach utilizes biomass to undergo 2nd-generation conversion processes where it is fractionated into relatively pure streams of soluble cellulosic/hemicellulosic sugars and residual solid lignin (non-sugar) fractions. The cellulose/lignin fractionation would also facilitate the development of new-generation characterization schemes to reduce interference between sugar and non-sugar components. Upgrading and reforming techniques such as gasification and Fischer-Tropsch (FT) synthesis, pyrolysis, or aqueous phase reforming (APR) can then be adopted for use with these fractions to generate feedstocks such as bio-oils that resemble those used within a petroleum refinery. If treated properly these

biomass-derived oils have been shown to resemble crude-derived oil feeds and when supplemented in large quantities to process feeds can produce equivalent fuels and chemicals to that of petroleum crude oil. Consequently, dependence on fossil fuels will be reduced, among other advantages such as a reduction in greenhouse gas (GHG) emission, while still utilizing in-place technologies and with lower capital investments compared to earlier generations of biofuels.

Long-term success for a sustainable, clean energy source will require a new approach to the current biofuels trend that has focused on a comprehensive makeover of a billion-dollar industry, invested with trillions of dollars' worth of infrastructure and distribution networks, while having been completely integrated into our society. The goal should not be to merely replace the energy technologies that have been developed over time, but to supplement the feedstock (crude oil) with a cleaner and more sustainable resource that has similarities with regards to chemical make-up (e.g., biomass oil). The challenge with the current technologies lies

with the ability to break down the biomass, *cost effectively*, into its basic monomeric units and gaseous forms so that components may be upgraded or reformed into feedstocks that resemble those used within a petroleum or petrochemical refinery.

Recently, there has been a migration of research and technology from a petroleum foundation towards a more green (or alternative) approach to the energy and chemical industry. Environmental concerns are at the forefront of this need to transfer to a more carbon neutral platform in addition to economic and political backing providing a substantial push. The United States

Department of Energy (US DOE), among other national and international agencies, have laid out a goal to accelerate biomass-to-energy conversion research in order to make biofuels both possible and practical within the coming years [38.1]. There are a variety of pathways that are being considered for alternative routes including solar, wind, geothermal, etc., but the route that will be considered in this overview will be the biomass-to-liquids (BTL) fuel production pathway and how this method can be integrated into the current infrastructure of petroleum refineries.

The biomass used to generate biofuels can cover a broad range of materials that include: food crops (1st-generation biofuels), nonfood crops or nonedible portion of food crops (2nd-generation biofuels), and microalgae (3rd-generation biofuels). The 1st-generation biofuels have achieved a certain degree of success in terms of commercialization, especially under government subsidies or mandates. The bioethanol derived from corn and sugarcane, for example, is unable to replace gasoline completely without major modification to the internal combustion engine, and subsequently, must be blended with gasoline in order to be used within existing engines. Recently introduced biobutanol, which has a heat content close to gasoline and less water affinity, can be blended with gasoline at higher concentrations than bioethanol. Biodiesel produced from animal fats and vegetable oil has performed well in diesel engines, especially when blended with petroleum-derived diesel. However, all of the potential sources for 1st-generation fuels are associated with sustainability and affordability concerns, owing to the fact that they inherently compete with food sources considered to be limited in many regions of the world. The 3rd-generation biofuels that are currently under development have potential issues related to long time scales due to the slow growth-rate of the algae along with the need for an incredibly large photosynthesis area to support the large quantity of feedstock used to generate the extracted oils. Economic removal of excess water presents another challenge for algal fuel production.

The 2nd-generation biofuels can be categorized as a variety of products, namely: agricultural wastes (e.g., corn stover, sugarcane bagasse, etc.), municipal wastes, pulp milling by-products, recycled vegetable oils, as well as true feedstocks generated from under- or non-utilized forestry biomass. In essence, biomass is associated with such things as waste streams, pure feedstocks, recycled materials, as well as some materials that have not found a dedicated use. A large portion of biomass is in the form of lignocellulosics, which is a composite material particularly well suited for energy applications due to large-scale availability,

low costs, and the environmentally benign production. Many of the energy production and utilization cycles based on lignocellulosic biomass have low or near-zero greenhouse gas (GHG) emissions on a life-cycle basis [38.2–4]. This is owed to the fact that the CO₂ produced through the use of these fuels is utilized by the growth of other biomass. An added benefit of these new conversion routes is the generation of new employment opportunities in dwindling economies by consolidating and amplifying agricultural economy through energy crop cultivation as well as reinforcing long-standing industries such as sugar, paper, and forestry that can work synergistically with these conversion technologies.

A much overlooked concept that should increase the popularity of utilizing these biomass feedstocks is the idea of use within a fully integrated biorefinery, much like what has already been developed within petroleum refining [38.5, 6]. Biomass material can potentially integrate itself within existing petroleum refineries and be utilized as a feedstock for many of the products that petroleum has created a monopoly over. The integration could be considered as the 4th generation of biofuels as GHG emissions produced are reduced by sequestration techniques over standard refinery operations and biomass fuel production routes alone. This approach would not only be able to help alleviate the fuel industry but also that of plastics, chemicals, and other products that are derived from petroleum.

The primary obstacle impeding the more widespread production of energy from biomass feedstocks is the general absence of low-cost technology for overcoming the recalcitrance (difficulty to break down) of these materials. Currently, there are only a few lignocellulosic conversion methods that have been looked at for implementation into an adapted refinery. These include the generation of electricity by way of combustion, thermochemical treatment (gasification and/or pyrolysis), biochemical treatment, and a combined physicochemical treatment conversion pathway. A variety of chemicals, temperatures, and pressures are used separately or in combination with any of these processes to pretreat the feedstock and then break down the structures of the lignocellulosics into their monomeric, oligomeric, or gaseous forms so they can be further converted or upgraded into a usable product. Formation of these products can take the form of energy (heat and electricity), fuels (solid, liquid, or gaseous), and/or chemicals and materials. This paper will outline some of the technologies that are currently being investigated, along with a more detailed analysis of the utilization and implementation of gasification and pyrolysis into a fully integrated biorefinery (green refinery), and how these processes can be linked with current petroleum and petrochemical refineries.

38.1 Lignocellulosic Biomass

Before breaking down a complex material such as lignocellulosic biomass something must be known about how it is formed and what the structure is comprised of. Lignocellulose has three primary constituents which are cellulose, hemicellulose, and lignin, with smaller quantities of extractives, proteins, and inorganic materials. The largest of the constituents, cellulose, is a homopolymer composed of *D*-anhydroglucopyranose units (repeated glucose units), linked together by β -(1 \rightarrow 4)-glycosidic bonds. The cellulose chains are packed into microfibrils, stabilized by extensive hydrogen bonds (Fig. 38.1) [38.7]. These fibrils are attached to each other by hemicelluloses (amorphous polymers of various sugars) as well as other polymers such as pectin, and then encased by lignin. Hemicellulose is composed of mainly pentoses (xylose and arabinose) and hexoses (mannose, glucose, and galactose). Lignin is an amorphous polymer whose attributes include providing rigidity to the plant cell wall and resistance to microbial attack. The cellulose microfibrils present in the hemicellulose-lignin matrix are often associated in the form of bundles of macrofibrils.

Necessary information that could prove more important when dealing with some of the thermochemical processes is the ultimate analysis of various feedstocks that could be used (Table 38.1).

The ultimate analysis of the biomass materials is the chemical composition (e.g., carbon, hydrogen, oxygen content) of the feedstocks. A major factor that must be kept in mind during processing, as will be discussed later, is the oxygen content of these materials and its effect in various processing routes, especially when looking into integration within a refinery.

^a Processed biomass includes: shredded currency, demolition wood, furniture waste, and wood yard waste [38.8].

38.2 Biomass Processing Routes

There are a few processing routes with regard to the break down of the lignocellulosic biomass into one of many potential products. The three routes that will be discussed herein are: (1) pretreatment-hydrolysis, (2) biomass-to-liquid (BTL) fuels via gasification and Fischer–Tropsch (FT) synthesis, and (3) pyrolysis. A schematic representation of these conversion routes along with the potential pathways that can be implemented for the production of biofuels can be seen in Fig. 38.2 [38.9].

In the pretreatment-hydrolysis route the recalcitrance of the biomass material is first reduced through some type of available pretreatment, followed by hydrolysis of the polymeric sugars into an easier-to-handle soluble fraction. This fraction can then be further treated by means of fermentation, dehydration, or hydrogenolysis to produce liquid fuel substitutes such as hydrocarbons or alcohols. Gasification has been looked at in conjunction with Fischer–Tropsch synthesis, combined as the Biomass-to-Liquid (BTL) fuel process, in order to gasify the feedstock and subsequently convert the gases formed into liquid fuels. Finally, pyrolysis will convert the biomass into a liquid fraction known as bio-oil that can be upgraded to hydrocarbon fuels by a variety of catalytic reactions, as well as having the potential to supplement various streams within a petroleum refinery.

38.2.1 Pretreatment–Hydrolysis Pathway (Route 1)

Ultimately, three distinct hurdles (Steps 2, 3, and 4 in Fig. 38.3) must be considered with this type of con-

version pathway that converts the lignocellulosic feed into a usable product, most notably ethanol and butanol, via biological processes. First, there must be some type of (1) pretreatment of the raw material to disrupt the fibrous structure by which the cellulose and hemicellulosic polymers will be made more accessible to be broken down into their monomeric sugars. This digestible lignocellulosic material can then be (2) hydrolyzed (acidically or enzymatically) into the individual subunits of the polymers or fermentable sugars. The fermentable sugars are then converted by one of the (3) oxygenate or alcohol formation pathways, such as fermentation in which microbial *bugs* are used to convert the sugars to products, such as alcohols [38.10].

The current bottleneck lies with the high cost of hydrolysis, owing to either the cost of enzymes or capital investment associated with acid hydrolysis. Currently, enzymatic hydrolysis is the preferred conversion route due to its ability to be specifically tailored to various feedstocks and the low operation costs linked with the reactors. Lowering the enzymatic loadings through the use of higher severity pretreatments without degradation of the feed is the focus of many research groups. The maximization of sugar production at the lowest possible cost can open up multiple routes for hydrocarbon/oxygenate formation [38.9–12].

The strategy that has recently received attention is the idea of fractionating the lignocellulosic biomass into its individual components so as to convert the material into the desired products more effectively [38.13–15]. Fractionation techniques have been used extensively in the pulp and paper industry in order to purify

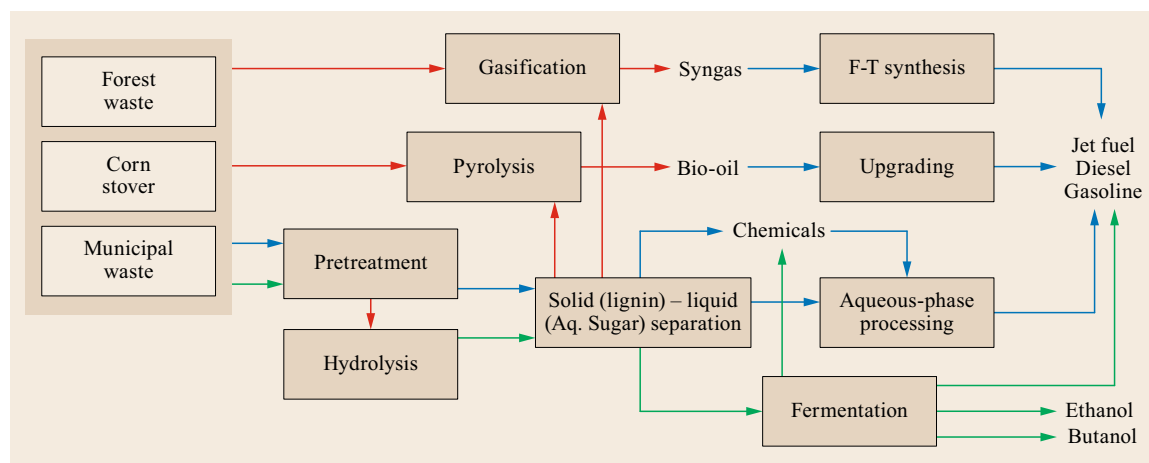

Fig. 38.2 Routes for the conversion of lignocellulosic biomass into liquid fuels. *Red arrows* refer to thermal routes, *green arrows* refer to biological routes, and *blue arrows* refer to catalytic routes (adapted from [38.7])

Fig. 38.3 Processing of 2nd-generation biofuels from biomass via the biological route

the cellulosic components of the feedstock, while the residual fraction is mostly burned to generate energy by combustion. However, this method does not effectively utilize the remaining biomass, making upwards of 70% of the total feedstock. These residual solids could potentially be used as feedstocks for gasification or pyrolysis where the material can be upgraded into higher value products.

38.2.2 Biomass-to-Liquid (BTL) Fuels (Route 2)

The BTL fuels route can be described almost equivalently to the much older technology of coal-to-liquids or gas-to-liquids (GTLs) conversion. These techniques involve the gasification of the feedstock, whether that is coal, gas, or biomass, followed by Fischer–Tropsch

(FT) synthesis for the production of liquid hydrocarbons.

Gasification

The idea of gasification has been around since the mid-19th century where it was originally utilized to convert coal to coal gas (or *town gas*) for lighting and heating purposes, and was used until just after WWII. Recently, the gasification pathway has shifted to producing more synthetic liquid chemicals and fuels through the use of integrated conversion operations. A relatively new approach to the utilization of gasification technology has been developed for use with biomass as a possible clean energy route with a lignocellulosic feed. This method preferentially converts organic-based carbonaceous material (e.g., biomass) into synthesis gas (*syngas* – a mixture of mainly CO and H₂) through the

use of high temperatures and the addition of a precise amount of air (or pure oxygen), and to a lesser extent, steam.

One of the attractive features of gasification is the fact that almost any biomass material can be used in this processing route; other routes such as ethanol or biogas production for example, can only use a select type of biomass material. This is due to the process's ability to break down the biomass into a gaseous form as opposed to the intermediates (monomeric sugars) required with the 1st-generation biofuels. A simplified scheme for which solid waste products (or potentially any carbonaceous material) are converted through a downdraft-type gasification system is shown in Fig. 38.4. The syngas produced from this system must first be treated to remove sulfur, nitrogen, and particulates before it can be further converted via FT synthesis. The generation of carbon-based co-products by gasification can be used for chemical upgrading or fertilization in soils (as 4th-generation biofuel production to provide a negative carbon budget in air), limiting waste generation. It is estimated that one ton of carbon (tar or char side-products) produced within this process scheme is equivalent to roughly 3–3.5 t of CO₂ that would normally be released by incineration, greatly reducing GHG emissions when implemented [38.16].

A more concrete definition for gasification would be the partial combustion (or partial oxidation, POX) of a solid fuel (biomass) that takes place at tempera-

tures of roughly 1000 °C in the presence of a controlled amount of oxygen. Complete combustion of the solid fuel will generally produce N₂, water vapor, CO₂, O₂, as well as small amounts of particulate matter considered harmful to both the atmosphere and humans. The *controlled* partial combustion of the biomass produces a preferred mixture of carbon monoxide (CO) and hydrogen (H₂) with traces of methane (CH₄) as well as some unwanted side products such as tars and chars, the latter being products of incomplete combustion. The key to a gasifier design is to create a situation in which biomass is reduced to charcoal and subsequently converted to syngas while also limiting the build-up of ash within the reactor. There are four unique processes (reaction zones) that can be considered to take place within a desired gasification process: dehydration, pyrolysis, combustion, and reduction. The break down of the biomass moving through these zones is illustrated in Fig. 38.4.

During the first stage (zone 1) of gasification the water is removed from the biomass feed (having a moisture content of roughly 10–30 % w/w) at temperatures of up to 200 °C, driven by the heat released from the lower zones of the gasifying unit. This is a necessary step as the water within the biomass can drive unwanted reactions during the following steps of gasification due to the presence of the molecular oxygen within the water. High oxygen content in biomass reduces the energy density of the material and for this reason must be removed (similar to the reasoning for the removal

Fig. 38.4 Simplified schematic of a downdraft gasification unit along with some appropriate reactions and pathways

of oxygen in crude oil for petroleum transportation fuel production) in the form of either CO₂ or H₂O.

This dehydrated material is then mixed with a gas flow stream where it begins the process of pyrolysis (devolatilization). In this stage, the biomass is converted to large quantities of tars and gases containing carbon dioxide, as well as some methyl alcohols, as the carbonaceous particles are heated up at temperatures ranging from 280–500 °C. Although the gasification process is not necessarily synonymous with pyrolysis, it should be noted that pyrolysis will always occur to some degree within a gasifying reactor generating various condensable hydrocarbons as the material moves from the lower temperature zones to the higher temperature *gasifying* zones. Volatiles are released during this stage while the residual solids form the product char. The material properties of the products and the composition of the char formed during this particular step is highly dependent on the properties of the carbonaceous material that is being supplied to the system and will determine what type of gasification reactions these intermediate products will undergo. The possible reactions that occur during a gasification process can be seen in Table 38.2.

Combustion begins as the volatile products and char begin to react with O₂ to form CO₂ and CO, releasing heat for the subsequent gasification reactions. These reactions are effectively limited in this zone of the reactor by controlling the input rate of O₂. This limited flow of oxygen to the system will increase the amount of py-

rolysis that occurs in the zone above as the oxygen is consumed initially by the product from pyrolysis (char) that falls from the pyrolysis zone [38.18].

Gasification reactions will be introduced through the combined oxidation and reduction paths in which the carbon sources from the preceding zones are converted to the desired syngas. Solid-phase oxidation reactions will take place at temperatures ranging from 700–1000 °C where heterogeneous reactions (Table 38.2) between oxygen and the residual solid carbon fuel falling through the reactor form CO and H₂, as well as other by-products. As stated previously, another positive consequence of these reactions is the addition of heat that is necessary for processes within the system. The reduction reactions taking place will require high temperatures (up to 1100 °C) and consume the energy in the system, reducing the heat. Reduction reactions (Table 38.2) such as the Boudouard reaction, water-gas (WG) reaction, water-gas-shift (WGS) reaction, and the methane production reaction (Boudouard and WG preferred) will convert the available carbon to CO and CH₄ with the appropriate reacting material.

It is important to note that there is no distinct separation between the various zones throughout a gasification unit, but an overlap from one zone to the next. These zones may also vary in their order within the reacting system depending on where the air is fed, as well as the configuration of the gasifier. There are several configurations that have been used, most notably: updraft (air fed below gas outlet), downdraft (air fed above gas out-

let), and cross-draft gasifiers (air fed at same level as the gas outlet). *Warnecke* [38.19] provides an extensive review of the various configurations of gasifiers along with their advantages and disadvantages.

Downdraft gasifiers are preferred when dealing with feedstocks such as wood and biomass residues as they tend to be smaller in scale, more affordable, and the tar that is developed during the process has a greater chance of being broken down as it descends through the combustion and reduction zones [38.19, 20]. Some of the other advantages and disadvantages of the various configurations have been highlighted in Table 38.3. Various geometrical configurations within a downdraft gasification unit (straight, single throat, or double throat) are also used depending on the application or feed [38.21].

Research has indicated that many parameters will affect the preferential production of syngas over the less-desired producer gas (mixture of CO, H₂, CO₂, CH₄, C_xH_y, and N₂). If producer gas is to form it can be further converted to syngas through other processes such as reforming or tar cracking, but this would add another costly operation step to an already complex process system. The controlling parameters of syngas production to note include the utilization of pure oxygen versus air feed, temperature range, particulate size, system pressure, residence times, as well as the feedstock to be used [38.9, 20]. The production of syngas from biomass for FT synthesis is normally associated

with high temperature, high oxygen content, small particle sizes, high pressure, and low residence times.

Co-firing of biomass with coal has been of recent interest in order to maximize the extent of the water-gas-shift reaction. *Kumabe* et al. observed that when a ratio of 0.5 (coal to biomass) was used, a maximum extent was observed [38.22]. If a further increase of the biomass ratio was introduced, an increase in the amounts of syngas and CO₂, along with decreases in char, tar, and H₂ were seen. Conversely, CO and hydrocarbon concentrations were left unchanged [38.23].

Syngas has the ability to be used in a variety of processing schemes for a variety of products. Some of the more common conversion routes are FT synthesis, combined heat and power (CHP) technologies, hydrogen production, catalytic synthesis of methanol (and other alcohols), and fermentation to ethanol. The catalytic synthesis of methanol is an interesting option for use with syngas due to the ability of methanol to be used for a range of products such as formaldehyde, dimethylether, and acetic acid. Methanol can also be converted to gasoline when used as the feedstock for methanol to gasoline (MTG) processes [38.24, 25]. FT synthesis however, will be the only option explained in-depth within the confines of this discussion.

Fischer–Tropsch (FT) Synthesis

FT synthesis is a technology that refers to the conversion of syngas to liquid hydrocarbons using a transition

Table 38.3 Advantages and disadvantages of various gasifiers (after [38.18])

Gasifier type	Advantage	Disadvantage
Updraft	<ul style="list-style-type: none"> ● Small pressure drop ● Good thermal efficiency ● Little tendency towards slag formation ● No carbon in ash 	<ul style="list-style-type: none"> ● Producer gas production ● Poor reaction capability with heavy gas load ● Relatively long time required for startup of internal combustion engine ● Great sensitivity to tar, moisture, and moisture content of fuel
Downdraft	<ul style="list-style-type: none"> ● Flexible adaption of gas production to load ● Small-scale applications ● Low sensitivity to charcoal dust and tar content of fuel 	<ul style="list-style-type: none"> ● Design tends to be tall ● Not feasible for very small particle size of fuel ● Producer gas production
Cross-draft	<ul style="list-style-type: none"> ● Short design height ● Very fast response time to load ● Flexible gas production 	<ul style="list-style-type: none"> ● Very high sensitivity to slag formation ● High pressure drop
Fluidized	<ul style="list-style-type: none"> ● Large-scale applications ● Feed characteristics ● Direct/indirect heating ● Can produce syngas 	<ul style="list-style-type: none"> ● Moderate tar yield ● Higher particle loading
Circulating fluid	<ul style="list-style-type: none"> ● Large-scale applications ● Feed characteristics ● Can produce syngas 	<ul style="list-style-type: none"> ● Moderate tar yield ● Higher particle loading
Entrained flow	<ul style="list-style-type: none"> ● Can be scaled ● Potential for low tar ● Can produce syngas 	<ul style="list-style-type: none"> ● Large amount of carrier gas ● Higher particle loading ● Particle size limits

metal catalyst. The products that are formed from this process (depending on the type of catalyst used – iron (Fe) and cobalt (Co) being predominant) can include transportation fuels (diesel or jet fuels) as well as higher value chemicals (waxes, lubricants, alcohols, etc.). The FT process can involve a variety of chemical reactions that produce multiple hydrocarbon molecules, however, primary reactions forming species with the formula $C_nH_{(2n+2)}$ (alkanes) are preferred. A block diagram of this FT synthesis pathway and the generalized products that form from the reactions can be seen in Fig. 38.5.

In order to avoid the production of methane ($n = 1$) the process temperature is normally kept below 400°C while pressures are kept in the range of $\approx 150\text{--}580$ psi. Lower temperature synthesis ($\approx 200\text{--}240^\circ\text{C}$ with Co catalyst) will yield high molecular waxes while higher temperatures ($\approx 300\text{--}350^\circ\text{C}$ with Fe catalyst) will yield low molecular weight olefins [38.26].

The generation of unreactive gases, short- and long-chain paraffins, olefins, and alcohols can all occur within the FT process. Paraffins produced tend to be straight-chain. However, the distribution of chain lengths (ranging from C_1 up to C_{50}) formed tends to be quite large. A positive fact to note with the production of these chains is that the chains will be predominately sweet (sulfur free) with low aromatic content, and can be further converted to automotive fuels through cracking, isomerization, or reforming. A route that has been taken to avoid the large distribution of chain lengths is to produce a more waxy material (larger carbon chains; $> C_{30}$) that can then be cracked into the diesel range by hydrocracking followed by purification using standard petroleum refining techniques. As an example, it has been shown that the syngas that has been converted during this process can be used as a feedstock for the generation of diesel and jet fuels using proprietary techniques developed by companies such as Syntroleum, Rentech, among others.

One of the major hurdles that accompanies BTL fuel processing is the fact that the syngas feed for FT synthesis must be free of impurities as the catalyst system is highly sensitive and is easily deactivated. Multiple, complex purification steps must be used in order to separate the unwanted species such as tars, volatile species (NH_3 and HCl), sulfur compounds, fine particles, and ashes that normally accompany the syngas produced. The volatile stream derived from biomass gasification will also have a much lower H_2/CO (≈ 0.5) ratio than what is normally preferred (≈ 2) during FT synthesis [38.9]. Consequently, the gas stream is usually co-fed to an intermediate reactor with water in order to increase the H_2/CO ratio (WGS reaction). Steam reforming may also be used in order to adjust

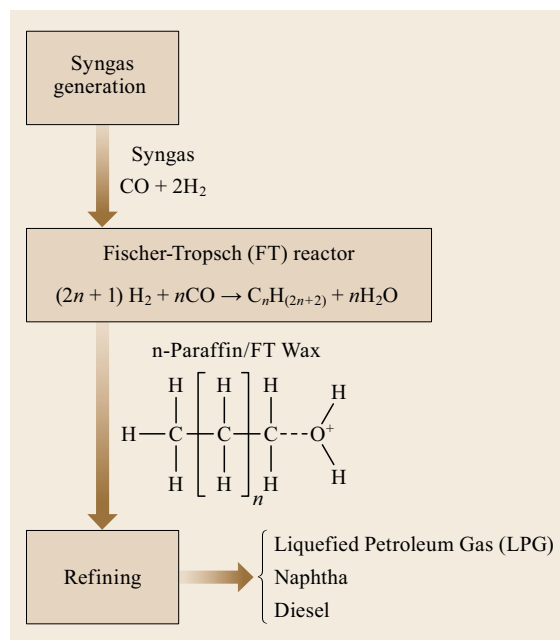

Fig. 38.5 FT synthesis schematic

the H_2/CO ratio if the CH_4 content is high. This reaction will convert CH_4 and H_2O to CO and H_2 (Table 38.2).

One example of a multistage gasification unit for biofuel production that is able to utilize a variety of biomass feedstocks is a process developed by Choren. Although this process has had difficulties becoming completely commercialized, it has shown the potential to be expanded upon and optimized in order to be fully functional. In this process, the biomass is first reduced in size, followed by dehydration, before being sent to a relatively low-temperature ($400\text{--}500^\circ\text{C}$) gasifier that forms the carbonization gas (syngas) along with tar and coke (solid state). This gas is then partially oxidized in a combustion chamber at high temperatures ($> 1400^\circ\text{C}$) with a precise amount of oxygen during coke addition, increasing the yield of CO and aiding in the break down of the material. After cooling, particulates that are not completely converted to gas are separated, followed by stripping of chlorides and sulfides. The gas stream will then be ready for FT synthesis and ultimately, fuel production [38.27].

Liu et al. [38.28] has shown evidence with performance and cost analysis that the co-generation of FT liquid fuels using coal alongside lignocellulosic biomass can be produced *cost effectively*. These synthetic fuels provide lower GHG emissions and capital investments than a standard fossil fuel power plant implemented with CO_2 capture. Fuels co-generated are also able to be produced cheaper than through a typical 1st-generation biofuels facility. The analysis shows that

it is possible to develop a scaled up biomass-derived FT fuel production facility with some further commercial optimization.

38.2.3 Pyrolysis (Route 3)

Pyrolysis differs from gasification by the fact that there is no air (specifically O₂) present during the break down of the carbonaceous material. The products that are formed during pyrolysis will also differ from that of gasification. However, the processes do show some similarities due to the overlap in reactions taking place. A lack of gasification within a pyrolysis reactor is usually never possible, as complete absence of oxygen is usually impossible as well as the fact that some oxygen is released from biomass during the reactions taking place. Consequently, some gasification occurs during pyrolysis just as some pyrolysis occurs during gasification. The desired product from pyrolysis is the liquid pyrolysis oils (bio-oils) that rapidly condense from the vapors released. Some other less desirable products will also form as solid residues containing carbon and ash, as well as producer gases.

In order to produce the bio-oil during processing, fast pyrolysis is preferred that utilizes moderate temperatures ($\approx 450\text{--}600\text{ }^\circ\text{C}$) at relatively high heating rates ($< 2\text{ s}$) followed by rapid quenching [38.29, 30]. Slow pyrolysis will produce char rather than bio-oil as the main product. Moisture content should also be strictly controlled, as too little moisture will simply form dust; conversely, too much moisture will form gases, owing to the presence of oxygen from the breakdown of compounds such as water, promoting gasification.

Pyrolysis Oil (Bio-Oil)

Pyrolysis oil (bio-oil) is a dark brown, viscous liquid product that is obtained from the pyrolysis of biomass. This bio-oil has a large variation of components dependent on pyrolysis conditions and the composition of the feedstock. A variety of highly oxygenated compounds make up the bio-oil and can be broken down into groups as acids, alcohols, aldehydes, esters, ketones, and aromatic species, along with some unreacted polymeric carbohydrates and lignin fragments [38.31–33]. The typical components of pyrolysis oil is shown in Table 38.4.

The highly complex bio-oil mixture is chemically unstable and can be altered or even degraded during storage due to thermal equilibrium shifts. The quality of the bio-oil is also highly dependent on the starting feedstocks and the pyrolysis reaction conditions need to be tailored to the characteristics of the feed [38.34]. It

Table 38.4 Typical component of pyrolysis oil (Bio-oil)

Component	(wt%)
Water	27
Ether-soluble organics (aldehydes, ketones, lignin monomers)	25
Volatile acids (mainly acetic)	5
Ether-insoluble organics (anhydrosugars, anhydro-oligomers, hydroxyacids)	28
Lignin derivatives, polymerization products and solids	15
Extractives (<i>n</i> -hexane soluble organics)	4

Table 38.5 Comparison of elemental composition of biomass-derived bio-oil and conventional crude oil (after [38.34, 36, 37])

Element (wt%)	Bio-oil	Crude oil
C	55–65	83–86
H	5–7	11–14
O	28–40	< 1
S	< 0.05	< 4
N	< 0.4	< 1

has been shown, however, that if the reaction conditions were tailored to each specific feedstock, the resulting compositions will have similar collections of cyclic hydrocarbons [38.35].

A comparison of the elemental compositions of bio-oil and crude oil has been made, shown in Table 38.5. Some observations can quickly be noted when comparing the elemental compositions of the two oil products. The conventional crude oils have extremely low oxygen content in comparison to the biomass-derived bio-oils that are intended to be co-fed. The high oxygen content within the biomass system can be attributed to the oxygenated functional groups that are prevalent within biomass. It is also estimated that roughly 15–30% of the components of the bio-oil is made up of water because of the high moisture content of the original biomass and the dehydration of the biomass that takes place during hydrolysis [38.38]. Accordingly, the high oxygen and water contents in the biomass-derived bio-oils will lower the heating values (half of that of hydrocarbon fuels) of the oil, and will also cause the streams to be immiscible when co-fed with petroleum-derived oils. For this reason, the products from pyrolysis must first be upgraded via hydrotreatment before being integrated into a petroleum refinery. This is similar to what petroleum-derived oils encounter when hydrotreatment is needed to remove impurities such as nitrogen and sulfur. In the case of biomass-derived bio-oils, however, the hydrotreatment will be used to remove oxygenated compounds.

38.3 Biomass Oil and Petroleum Oil Co-processing

Biomass oils co-processed with petroleum cuts is a novel idea that has been formulated to overcome many of the hurdles that have been realized when developing processing routes that strictly use biomass for fuel production. If the pretreatment-hydrolysis route was simply used in conjunction with a fermentation-type process that converts the soluble sugars to alcohols many alterations would need to occur if the ties with petroleum were to be severed. The trillions of dollars that have been invested in infrastructure such as refineries, vehicles, and transportation networks would all be lost or have to be renovated. Work is still being conducted with regard to the thermochemical routes such as gasification and pyrolysis and being able to implement those technologies in more industrialized locations, as many undesired products are generated during the formation of the desired products.

In order to overcome these disadvantages it is theoretically possible to combine some of the newly developed technologies with the already-in-place petroleum infrastructure to develop biomass/crude co-processing. The idea would be to fractionate the biomass into its respective constituents (cellulose, hemicellulose, and lignin) and preferentially convert the materials by either liquefaction or catalytic conversion techniques. The products generated can then be combined with streams within the in-place petroleum or petrochemical refineries. The fact that biomass, once broken down, or pre-hydrotreated, has a very similar chemical composition and structure to the intermediate feed streams within a refinery makes this quite feasible.

This *co-processing* technique has the ability to add large quantities of feed to an already existent refinery stream with relatively low input in terms of capital costs as well as having a lower environmental impact compared to that which is normally synonymous with fossil fuels production. There are several options that can be used for co-processing that utilize the pretreatment-hydrolysis route, thermochemical route (gasification or

pyrolysis), or even a combination of the two, to generate a feedstock that can be supplemented into the refinery operations.

Fogassy et al. [38.39] has developed a representative reaction scheme (1) for the removal of oxygen in the bio-oil, forming the products CO₂, CO, C, and H₂O.

During this processing route a mixture containing 80 wt% vacuum gas-oil (VGO) and 20 wt% hydrodeoxygenated bio-oil was processed in a fluidized catalytic cracking (FCC) unit. The majority of the oxygen within the material was said to be removed in the form of CO₂ and H₂O by means of decarboxylation and dehydration reactions [38.39]. The impact of this release of CO₂ and CO that is produced during the co-hydrotreatment of petroleum gas oil and lignocellulosic biomass oil has been investigated and it was shown that it can be attributed to some inhibition within the hydrodesulfurization and hydrodenitrogenation reactions [38.40].

Elliot et al. [38.35] have shown that they can dramatically increase the C/O ratio (Table 38.6) over the course of various treatments of bio-oils that could be co-fed into a refinery. The lowest severity treatment, simply hydrotreating the bio-oil (A), focused on low temperatures with a palladium-on-carbon catalyst. The next two treatments made efforts to maximize the C/O ratio. In the first of these cases (B), the oil phase products of the hydrotreated bio-oil were subjected to hydrocracking, where lower pressures and higher temperatures were applied with a sulfide-form catalyst as opposed to directly hydrocracking the bio-oil products. In the second case, nonisothermal hydroprocessing (C) involves a low-temperature hydrotreatment followed by a high-temperature hydrocracking of the bio-oil products without an intermediary product phase separation

Table 38.6 Ultimate analysis of biomass feed (mixed wood, corn stover, oak, and poplar) and biomass-derived bio-oils, as well as three types of treatment: (A) Hydrotreated bio-oil, (B) Hydrocracked bio-oil, and (C) Nonisothermal hydroprocessed bio-oil (after [38.35])

Ultimate analysis (wt%)	Biomass feed		Bio-oil (Moisture free)		(A) Hydrotreatment		(B) Hydrocracked		(C) Nonisothermal hydroprocessing	
	Average	+/-	Average	+/-	Average	+/-	Average	+/-	Average	+/-

N	0.5	0.4	0.6	0.5	1.3	1.1	0.4	0.2	0.2	0.2
S	0.1	0.1	n/a	n/a	0.1	0.1	0.0	0.0	0.0	0.0
C/O	0.93		1.81		5.33		174		202	

processing step. Work is ongoing with regards to optimization of the hydrodeoxygenation, catalytic cracking, and reforming techniques that would enable fully functional integration of the bio-oils into the refining process.

Al-Sabawi et al. [38.41, 42] reviewed co-processing of petroleum-derived and biomass-derived oils to produce clean transportation fuels via FCC [38.41] and hydroprocessing (such as hydrotreating and hydrocracking) [38.42]. The effect of biomass feedstocks on process operations, catalyst performance and deactivation, and product yield and quality were discussed. Even with the added benefit of the ability to use existing refining infrastructure and configurations that offer both economic and environmental advantages, many technical challenges remain. These include the low thermal stability of the bio-oil, compatibility of co-fed feedstocks, effects of the formed water on catalyst activity and stability, corrosion, mass and heat transfer properties, as well as quality and performance of fuels. Thermal stability is one of the biggest issues – the material cokes rapidly under reaction conditions or even in preheaters before reaching the reactor.

38.3.1 Aqueous Phase Reforming (APR) – Virent

Virent has developed reaction schemes for the conversion of sugars such as xylose and sucrose into hydrocarbons when utilizing their proprietary catalyst technologies [38.43]. These sugars can be derived from a multitude of biomass feeds by way of the pretreatment-hydrolysis technique, as has been noted. An efficient fractionation technology will be imperative for moving this technology further as it would be preferable to deal with a purified sugar source during these catalytic reactions. The following representative pathways (38.2) and (38.3) are used by Virent for the conversion of sugars, particularly xylose and sucrose, to hydrocarbons

As seen, the xylose $\text{C}_5\text{H}_{10}\text{O}_5$ sugars can be converted to branched C_{12} hydrocarbons and used as a product such as jet fuel, while the sucrose $\text{C}_{12}\text{H}_{22}\text{O}_{11}$ can be converted to the high-octane xylene (C_8) that can be used in gasoline blending [38.42]. The overall process that is in development consists of a multistage conversion for production of gasoline-range hydrocarbons: aqueous phase reforming (APR) of the carbohydrate sugars (glucose, xylose, etc.) and hydrolysates,

catalytic conversion, and fractionation into purified gasoline products. There are a multitude of reactions that are occurring during the APR process that include:

- Reforming to generate hydrogen
- Deoxygenation reactions – dehydration (alcohols), decarbonylation (ketones/aldehydes) and decarboxylation (acids/esters)
- Hydrogenolysis
- Cyclization.

Accordingly, the products formed can be further upgraded using a modified ZSM-5 catalyst to generate a high-octane gasoline, similar to that of the petroleum-derived reformat stream. What makes this processing ideal is the functionality of the products that are developed and the fact that these *drop-in* fuels can potentially replace over 90% of the products that come from a barrel of crude oil. Relatively little infrastructure will need to be implemented and almost none will need to be altered or replaced for the processing of the sugars (i. e., glucose via cellulose; primarily xylose, along with smaller quantities of arabinose, mannose, glucose, and galactose via hemicellulose – see Sect. 38.1) derived from biomass. This is because of the similar chemical compositions of the fuels derived from biomass to that of petroleum-derived fuels along with the in-place technologies that have the ability to upgrade these intermediary chemicals into the necessary feeds for refinery integration.

38.3.2 Pretreatment-Hydrolysis/ Thermo-conversion Co-processing

Now, a basis has been set for the idea of breaking down biomass material into purified fractions and then converting or upgrading these fractions through one of the aforementioned processing techniques. We can begin to think about how this can be done. A fractionation scheme that is currently in development utilizes a dual treatment of a lignocellulosic waste stream followed by enzymatic hydrolysis of that waste which is able to theoretically separate the majority of the constituents into three streams [38.44]. In applying this method, the biomass is first fractionated then the various thermochemical conversion techniques can be applied to upgrade these fractions individually where the products will begin to be representative of the crude streams within a petroleum refinery. It is at this point, that the biomass-derived oils and gases could potentially be co-processed with the streams within a refinery. An introduction of these methods will be discussed, followed by a generalization of the conversion method and results.

The first of the pretreatments is a dilute sulfuric acid (DA) treatment that is considered a well-established pretreatment technology within the biomass research community. This method of treatment has been extensively reviewed and refined by several groups and has been established as being able to not only enhance the ability of enzymatic hydrolysis, but also solubilize the majority of the short-chain hemicellulosic structure while leaving the long-chain cellulosic and lignin structures relatively intact for further processing due to the low severity of the treatment [38.10, 45–47]

Next, *N*-methyl morpholine *N*-oxide (NMMO) is used as a solvent to dissolve the DA-treated biomass for a short period of time (< 3 h) followed by an antisolvent regeneration step that will wash away the solvent and precipitate the biomass out of solution. The utilization of NMMO as a pretreatment is a relatively new technique, although it has been used predominately to treat purified cellulose within the fiber industry for several decades by generating Tencel fibers. The effects of this solvent on the lignocellulosic structure of biomass has been of recent interest. What has been discovered is the fact that NMMO is able to effectively and

efficiently decrystallize the cellulosic fibers and swell the lignocellulosic structure to increase the accessible hydrolyzable area for enzymatic attack. The result is that multiple groups have shown that the treatment of biomass with NMMO is able to enhance the rate of hydrolysis of cellulose by fungal enzymes [38.48–51]. However, the point of this discussion is the synergistic utilization of these two treatments to enhance the fractionation and conversion capabilities so that they can enhance the generation of intermediary products where one of the aforementioned conversion techniques will be employed to generate a feed ready for co-processing with crude oil.

The purified product streams generated from this dual treatment (dilute acid with NMMO treatment, or DAWNT) can be fractionated as follows: soluble hemicellulosic sugars (mixture of pentoses and hexoses), soluble cellulosic sugars (mainly glucose – hexose), and a residual solid lignin fraction according to the process design shown in Fig. 38.6. Fractionation is not new to biomass conversion practices, but the idea of a fractionation after enzymatic hydrolysis due to the highly digestible substrate may be considered a novel

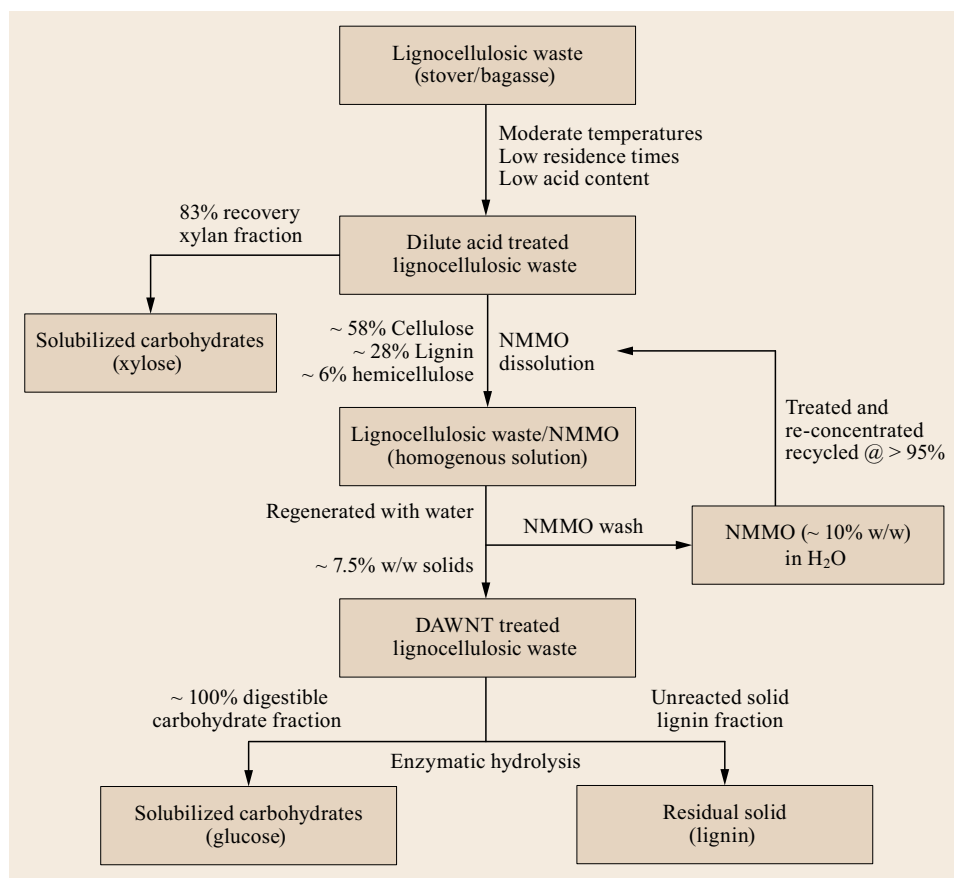

Fig. 38.6 Dilute acid with NMMO treatment (DAWNT) processing of lignocellulosic wastes (after [38.44])

technique. The DAWNT (dilute acid with NMMO treatment) method that uses this type of methodology can be summarized by the following criteria:

- DA Treatment [38.46]
 - $\approx 83\%$ of the hemicellulosic sugars will be solubilized and separated
 - Composition of processed solids: 58% cellulose, 28% lignin, and 6% hemicellulose
- NMMO Treatment [38.10, 44, 52, 53]
 - Unaltered solid composition
 - Highly digestible cellulosic fractionation
- NMMO swells cellulosic fibers enhancing enzymatic digestibility
- NMMO processing can be done at short time scales due to effects based solely on dissolution that occur rapidly due to the initial DA treatment
 - NMMO can be recycled at a rate of $> 95\%$ while keeping the same treatment efficiency
- Enzymatic Hydrolysis [38.10, 44]
 - $\approx 100\%$ cellulosic conversion to soluble sugars within 48 h at low enzyme concentrations (10 mg_{C_{Tec2}}/g_{glucan} enzyme loading)

- The remaining hemicellulosic fraction will also be converted here
- Residual solid lignin fraction and liquid sugar fraction can be easily separated.

This process is currently in development, but one can start to think about the potential applications when moving forward. Solubilized glucose, generated after enzymatic hydrolysis can easily be purified and used with either current 1st-generation conversion techniques or implemented into catalytic reforming processes, such as APR. The solubilized hemicellulosic-derived sugar fraction that is separated during the first treatment can potentially be used in an APR process, as was explained previously. The residual solid lignin fraction can be used in a thermo-conversion process such as gasification or pyrolysis after the solids are extracted post hydrolysis. If the pyrolysis route was to be used, bio-oil could be formed followed by mixing with the vacuum gas oil stream within a refinery process. Consequently, each of these methods will convert the starting biomass material into a usable hydrocarbon fuel, while utilizing the majority of the feedstock.

38.4 Conclusion

The majority of the conversion methods discussed here are still in their infancy and have not yet been fully investigated or refined. What can be taken away from this discussion is the fact that it is possible to convert biomass into a usable hydrocarbon fuel through co-processing without the need to convert the already in-place infrastructure and addition of significant capital investment to build independent continuous units (biorefineries). This is highly favorable over other alternative energy routes that would require alterations to an established billion dollar industry as well as an already developed trillion dollar infrastructure, but can simply be subsidized with biomass oil as a feedstock.

There appears to have been no significant breakthrough in 2nd-generation biomass-to-liquid processes in recent years [38.54]. Fractionation of biomass into digestible cellulosic sugars for fermentation and insoluble lignin for pyrolysis/gasification followed by Fischer-Tropsch and co-processing with petroleum oils might provide an alternative for further process development. Cellulose/lignin fractionation would also facilitate the development of new generation characterization schemes for detailed molecular compositional analyses of feedstock, process streams, and products of biofuel/chemical production.

39. Renewable Diesel and Jet Fuels

Henrik Rasmussen

Hydroprocessing offers great potential for producing renewable diesel compatible with existing infrastructure and engine technology. This chapter discusses the catalyst technology and the process technology required to convert renewable feed sources such as triglyceride-based vegetable oil, used cooking oil, animal tallow and algae oils into transportation fuels.

	References	1140

As a consequence of the general concern about fossil fuel resources and global warming from CO₂ emissions, the use of alternative, sustainable sources of energy for transportation has been increasing. Despite the growth in renewable fuels production, so far there has been little integration into existing petroleum refineries. There are two different classes of green fuels, namely first-generation *biofuels* and second-generation *renewable fuels*.

The two main biofuel products used in transportation fuels are bioethanol blended in gasoline and FAME (fatty acid methyl ester) used in or as diesel. FAME is a mixture of esters produced from chemical reactions between alcohols (typically methanol) and a renewable feedstock (typically a triglyceride-based compound). There are, however, several compatibility issues with the properties of FAME and the specifications of diesel, including a poor stability and filter plugging issues when blending FAME into the regular diesel fuel. For these reasons, only limited volumes of FAME can be blended into the fossil diesel fuel pool.

What is renewable diesel? The definition is a synthetic diesel fuel, produced from a renewable source that meets the ASTM D975 specifications for diesel fuel. Haldor Topsøe has commercialized a number of plants using our hydroprocessing technology desig-

nated HydroFlex for the production of renewable fuels such as diesel and jet fuel. In this process, the renewable organic material is reacted with hydrogen at elevated temperatures and pressure in a catalytic reactor. The obvious advantage of hydroprocessing compared to the use of FAME biodiesel is the fact that the final products, simple paraffins, from this simple process are the same components as those already present in fossil diesel.

Most of the existing FAME biodiesel can be characterized as first-generation biodiesel since it relies on the vegetable seed oils normally entering the human food chain; thus, this type of fuel may lead to escalating food prices and shortage of food supply. In contrast, renewable diesel from hydrotreating may be produced from a broad variety of sources, including waste animal fats and vegetable oils, but also from tall oil from the paper and pulp industry, pyrolysis oils, and other nonedible materials. The hydroprocessing of these feedstocks to renewable diesel utilizes the same types of catalysts as presently used for processing of fossil diesel streams to meet governing environmental specifications. Thus, a coprocessing scheme where fossil diesel and renewable feedstocks are mixed and coprocessed is possible, producing a clean and green diesel meeting all ASTM D975 specifications. The hydrotreating

Table 39.1 The advantages of renewable diesel over biodiesel

Property	Renewable diesel	Biodiesel	Advantages of renewable diesel
Storage stability	Months/years	Weeks	Easier to handle and distribute
Hydroscopic	No	Yes	Easier to handle and distribute
Cetane number	75+	48	Better blend stock
Energy content per volume	98–100% of fossil ultralow sulfur diesel (ULSD)	≈ 92% of fossil ultralow sulfur diesel (ULSD)	6–8% higher mileage per gallon

may also take place in a dedicated standalone unit that produces 100% renewable drop-in diesel. The new feed components, however, give rise to new reactions and to the formation of new byproducts, resulting in a series of challenges we have addressed by using optimized

catalysts and process design in our HydroFlex technology.

Table 39.1 compares some characteristics of renewable diesel and biodiesel, highlighting the advantage of renewable diesel over biodiesel.

39.1 Processing Renewable Feeds: Consequences for Hydrotreating

The refinery hydrotreaters play an important role in the production of transportation fuels. Before introducing even minor amounts of biomaterial into a diesel hydrotreater, it is important to know the implications and how all potential risk factors can be mitigated.

Virtually all naturally occurring oxygen-containing species are much more reactive than the sulfur compounds in fossil fuels. The challenge in industrial operation is mainly to control the very exothermic reactions and the large amounts of hydrogen consumed, which require higher makeup hydrogen rates and larger quench gas flows even when coprocessing smaller amounts of renewable feedstocks. Thus, the refinery hydrogen balance must be checked and the unit feed capacity may be lower than when only processing fossil diesel. The depletion of hydrogen from the treat gas, combined with high temperatures, directionally leads to accelerated catalyst deactivation and pressure drop buildup. To control these factors, tailor-made catalysts and a careful selection of unit layout and reaction conditions must be employed.

Another challenge is the often quite high content of contaminants such as phosphorous, sodium, and calcium. This may cause rapid pressure drop buildup and catalyst deactivation unless proper specialty guard beds are designed to prevent pressure drop buildup and to protect the downstream catalysts. When process-

ing other feed types, such as tall oil or vegetable oils with a high content of free fatty acids, severe corrosion of pipes and other equipment upstream of the reactor may take place if not properly addressed in the design.

High amounts of propane, water, carbon monoxide, carbon dioxide, and methane are formed as byproducts of the hydrotreating reactions. These gases must be removed from the loop either through chemical transformation, by a gas cleaning step (e.g., an amine wash), or more simply, by increasing the purge gas rate. If not handled properly, the gases will form buildup in the recycle gas loop and reduce the catalyst activity.

Due to these quite severe challenges, the present industrial practice involving coprocessing of fossil oil and renewable organic material is usually limited to blends with less than 5 vol.% renewable diesel. However, Haldor Topsøe has developed solutions to all of these issues that will result in a better economy of the coprocessing scheme and allow the proportion of renewable organic material in the feed to be increased up to 50 vol.% or more.

It is also possible using the HydroFlex technology to design the hydrotreating unit configuration and a catalyst system to process 100% renewable fuels; that is done commercially in a number of units around the world.

39.2 Renewable Diesel: Feeds, Products and Reaction Pathways

The purpose of hydrotreating biologically derived (i. e., renewable) feedstocks on an industrial scale is to produce hydrocarbon molecules, typically boiling in the diesel range, which are directly compatible with existing fossil-based diesel and which meets all current specifications for ULSD in ASTM D975. With the introduction of feedstocks stemming from renewable sources, new types of molecules are introduced with a significant content (10–15 wt%) of oxygen present. These molecules must be properly hydrotreated to eliminate the oxygen and contaminants.

Although a great variety of renewable feeds exist, the hydrotreating to produce diesel-type molecules is somewhat simplified by the fact that the chemistry of vegetable oils and animal fats is rather similar and based on triglycerides with a structure as shown in Fig. 39.1.

Since the paraffins produced from the fatty acid chains boils in the normal diesel boiling range, this means that a diesel hydrotreater is the preferred unit for coprocessing most feeds. Unlike fossil feedstocks, the content of sulfur and nitrogen species is very low in these feedstocks, thus the catalytic activity required for sulfur conversion (HDS) to make ULSD is reduced when coprocessing renewable feeds.

To investigate how the triglycerides react under typical hydroprocessing conditions, a pilot plant test with a NiMo catalyst was conducted using a blend of 75 vol.% Middle East straight-run light gas oil (SR LGO) and 25% rapeseed oil. Rapeseed oil is a triglyceride of fatty acids, mainly C₁₈ to C₂₂ acids. The conversion of triglycerides was confirmed to be 100%. Furthermore, yields of CO (0.6 wt%), CO₂ (1.2 wt%), and CH₄ (0.1 wt%) were observed. The total liquid product was analyzed by gas chromatography, and the results are shown in Fig. 39.2. The total conversion of rapeseed oil is confirmed by the fact that all high-boiling components (at retention times > 35 min) are not present in the product. Instead, four normal paraf-

Fig. 39.1 Examples of some triglyceride structures in renewable feedstocks. 9c-18:1 is *cis*-9 oleic acid and 9c12c-18:2 is *cis*-9,12 linoleic acid

fins are formed with carbon chain lengths of 17, 18, 21 and 22 atoms respectively.

The conversion mechanism consists of several steps. The double bonds and the triglyceride are hydrogenated by one of at least two distinct reaction pathways (Fig. 39.3). The first pathway involves a complete hydrogenation. This pathway is usually called hydrodeoxygenation, or simply the HDO pathway. The other pathway involves a decarboxylation step, which means that CO₂ is split off.

The byproduct formation of both carbon dioxide and water influences the propagation of two additional reactions (also shown in Fig. 39.3); the reverse water gas shift (WGS, CO₂ + H₂ → CO + H₂O) and the methanation (CO + 3H₂ → CH₄ + H₂O), which will impact the overall hydrogen consumption.

Figure 39.4 shows gas chromatograms (GC) of liquid products from hydrotreating tests with 100% rapeseed oil as feed. The rapeseed oil is from a different source than that described above for the coprocessing test and consists mainly of C₁₈ fatty acids and minor amounts of C₁₆ fatty acids. The three catalysts were tested under identical conditions, but as Fig. 39.4 shows, the product distributions are quite different. Catalyst A converts the triglyceride mainly by the HDO route, producing mainly *n*-C₁₈. When using catalyst B, the HDO route is only slightly favored over the decarboxylation route, whereas catalyst C almost exclusively produces *n*-C₁₇ – the characteristic decarboxylation yield. The key is that Haldor Topsøe can catalytically control the reaction pathway, and by using the hydroprocessing catalyst A, we can increase the

Fig. 39.2 Simulated distillation chromatogram of feed (blue) and product (red) from a pilot plant test of 25% rapeseed oil coprocessing. All rapeseed oil is converted into predominantly four normal paraffins with chain lengths of 17, 18, 21 and 22 respectively

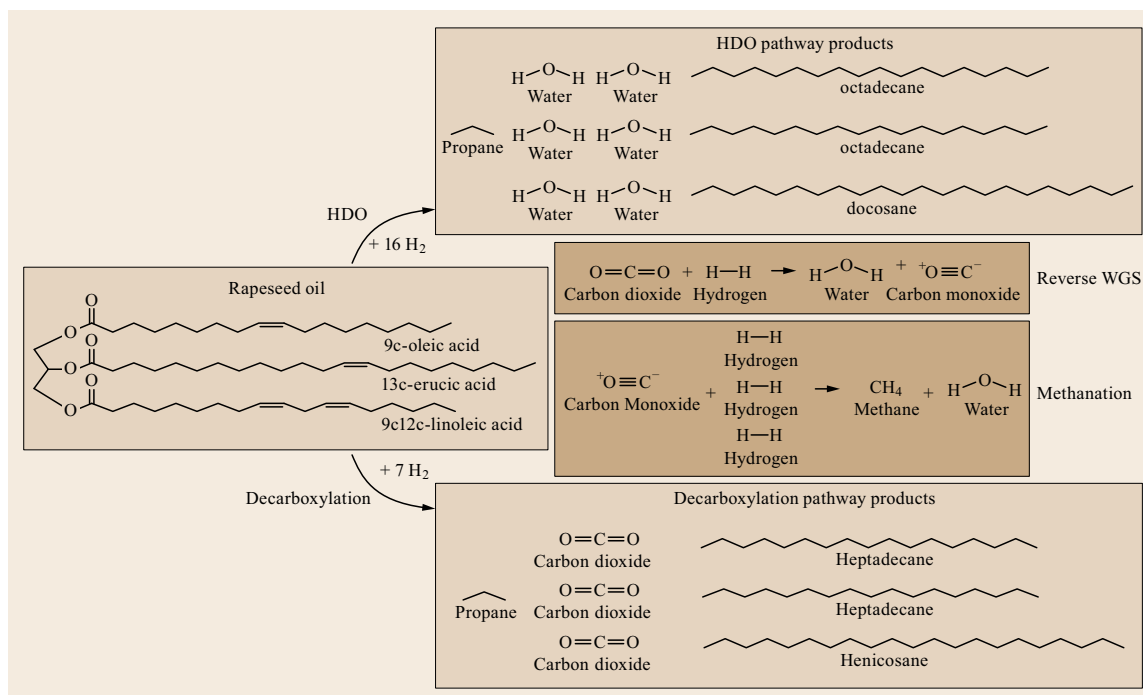

Fig. 39.3 Reactions occurring during the hydroprocessing of rapeseed oil

Fig. 39.4 Gas chromatograms of products from hydrotreating of 100% rapeseed oil. Large peaks at retention times of approximately 6 and 7 min are *n*-C₁₇ and *n*-C₁₈ respectively. The three catalysts have very different selectivities towards the decarboxylation and HDO pathways

liquid yield of diesel by about 4–5% because of the production of C₁₈ rather than C₁₇, which furthermore minimizes the CO₂ production.

The ability to control the reaction pathway away from the decarboxylation route and selectively toward the hydrogenation route will have advantages and disadvantages:

- Higher liquid diesel yield, which will have a very significant impact on the overall unit profitability.
- Practically eliminating the formation of CO₂, which also minimizes the formation of CO via the reverse

water gas shift reaction, which furthermore minimizes the methanation reaction.

- Higher recycle gas purity. Recycle gas purge is reduced. This is especially important in the coprocessing scenario because a lower hydrogen partial pressure (lower hydrogen purity) will impact the catalyst desulfurization abilities.
- Minimizing the formation of carbonic acid reduces the risk of corrosion in the downstream equipment.
- In a grassroots unit processing 100% renewable feedstock, the lack of CO₂ formation means that the amine scrubber can be eliminated. This will

- obviously reduce the installed cost for the plant and significantly increase the return on investment (ROI).
- In a coprocessing plant, the amine unit may become the limitation, because if CO_2 is formed, it will reduce the amount of H_2S that can be removed originating from hydrotreating the organic sulfur species in the conventional crude. Consequently, the feed rate of conventional crude barrels has to be reduced resulting in a reduced profitability from the asset.
 - The hydrogenation route typically consumes more hydrogen than the decarboxylation route, as can be seen in Fig. 39.3. This will result in a slightly higher operating cost when looking at the hydrogen only.

The higher cost of hydrogen, when utilizing the hydrogenation route, is easily justified due to many other advantages with this reaction route over the decarboxylation route, as described above.

39.3 Development of Catalysts for Conversion of Renewable Feeds

The complex reaction mechanism and the new challenges related to hydrotreating of renewable feeds must be taken into account when designing catalyst systems. If a catalyst is chosen that is not designed or tailor-made to handle coprocessing, the result may be poor desulfurization, hydrogen starvation, accelerated catalyst deactivation, and pressure drop buildup – depending on the amount and quality of the renewable material. Furthermore, the hydrotreated product may not meet the required targets for cold flow properties. The catalyst design for this service should, therefore, be based on solutions that address all of the challenges mentioned. In response to the challenges associated with the processing of renewable feedstocks, Topsøe has introduced a number of dedicated catalysts for the hydrodeoxygenation (HDO) of renewable feeds and isomerizing dewaxing catalysts for cold flow property improvement. In combination with specialized graded bed catalysts and conventional ULSD catalysts, these new products will extend the cycle length and ensure that an on-spec product with a renewable component is achieved without any operational problems. These

catalysts may be employed in both coprocessing and standalone units processing 100% renewable feeds.

These catalysts have already been employed in more than 15 industrial units, making renewable drop-in fuels in both coprocessing and neat (standalone 100% renewable) operating mode. Figure 39.5 shows the pressure drop in an industrial ULSD hydrotreater, which after two years of operation started to coprocess 3–5 wt% of vegetable oil. The original Haldor Topsøe catalyst loading was designed only for hydrotreating of a fossil feedstock, and when the refiner introduced the renewable feed, it was evident that the pressure drop increased quite dramatically. The pressure drop continued to increase, and as a result, the refiner was limited in how much renewable feed could be processed. At the next opportunity for a shutdown of the hydrotreater, the special optimized renewable fuels catalysts from Haldor Topsøe were installed. As illustrated in Fig. 39.5, with Haldor Topsøe catalysts, the pressure drop was low and stable while processing biofuels. In fact, the pressure drop was at the same very low level as before the introduction of renewable feeds [39.1, 2].

Fig. 39.5 Pressure drop development when coprocessing vegetable oil with and without Haldor Topsøe biofuel catalyst

39.4 Choosing the Right Main Bed Catalyst when Coprocessing

In the coprocessing scenario, the hydrotreater still needs to convert all the organic sulfur in the fossil diesel barrels to H_2S to be on-spec, so it is of utmost importance that the desulfurization (HDS) activity is maintained in the unit. In order to investigate the impact of a renewable fuel in a coprocessing mode, a number of pilot plant tests were conducted using both a nickel-molybdenum (NiMo) hydrotreating catalyst and a cobalt-molybdenum (CoMo) hydrotreating catalyst.

The first set of bars in Figs. 39.6 and 39.7 represents the HDS and HDN baseline activities when processing a 100% fossil light gas oil (LGO). The second set of bars represents the pilot plant test where the LGO is mixed with 15% rapeseed oil and tested at the exact same process conditions as when operating with pure LGO. The data clearly shows that the HDS and the HDN activity of the CoMo catalyst is severely inhibited by the rapeseed oil, but the NiMo catalyst is practically unaffected. In order to determine what component of the rapeseed oil is causing the severe inhibition, we

performed a third pilot plant test processing pure LGO with 1 vol.% CO mixed in the hydrogen treat gas. The data from this test is represented in the third set of bars in Figs. 39.6 and 39.7. The inhibition of the CO is very similar to the inhibition observed with coprocessing 15% rapeseed oil, which strongly indicates that the formation of the CO_2 , and consequently the CO formed via the reverse WGS reaction, is causing the inhibition. However, the NiMo catalyst is not affected by the CO in the recycle gas. This is clear evidence that a NiMo-type catalyst should be used as the main bed catalyst for the desulfurization of the fossil diesel when coprocessing. Even in the case where Topsøe's selective catalysts, which are going via the hydrogenation route, are used in the top of the reactor, we still recommend using a NiMo catalyst below these specialty catalysts. We want to prevent any inhibition issues in case the top part of the bed is poisoned to an extent that allows unconverted triglycerides to reach deeper into the bed, where the normal hydrotreating catalyst is located.

Fig. 39.6 The inhibition effect of CO on a CoMo hydrotreating catalyst on desulfurization (HDS) and denitri-fication (HDN) activity

Fig. 39.7 The inhibition effect of CO on a NiMo hydrotreating catalyst on desulfurization (HDS) and denitri-fication (HDN) activity

39.5 Simplified Process Diagram

Haldor Topsøe has designed both grassroots renewable fuels units, as well as revamping existing hydrotreating units, to process sustainable fuels in coprocessing mode for 100% renewable feedstock. In the revamp case, we aim to utilize as much as possible of the existing equipment and the process layout can have a number of different configurations. In the grassroots scenario, we have the freedom to design the optimal process layout.

Figure 39.8 represents a typical process configuration of a grassroots renewable fuels unit. The unit consists of three reactors for hydrotreating. The lead reactor will be loaded with high void and active hydrotreating ring-shaped catalysts to minimize pressure drop buildup. The second reactor will have more demetallation (HDM) catalysts and typically some main bed HDO catalysts in the bottom part. The third reactor

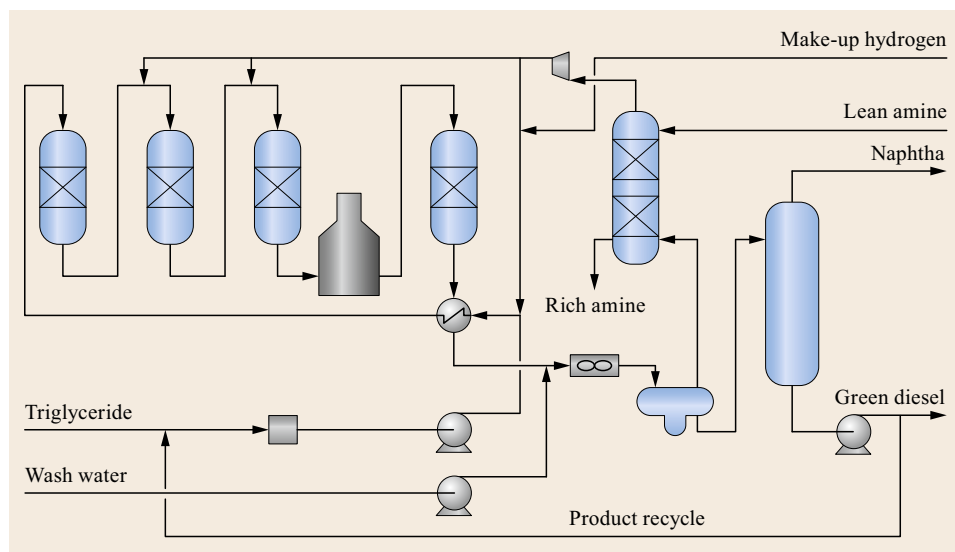

Fig. 39.8 Simplified process flow diagram for a grassroots renewable fuels unit for co-processing or 100% renewable feedstock

will be loaded with mainly HDO catalysts. Once the catalyst trains have converted the feedstock to long chain C_{17} – C_{22} , it is heated up before going through the fourth reactor for dewaxing – in other words, cold flow property improvement. The last reaction step can be eliminated if the renewable diesel product is used as blend stock in a larger fossil diesel pool, but is required if the renewable diesel is sold as a drop-in fuel.

In the case of a coprocessing unit, it is in most cases necessary to install an amine scrubber to remove the H_2S generated during the hydrotreating reactions. However, if the unit will be processing 100% renewable feedstock (standalone unit) and utilizing the catalyst selective for the hydrogenation route, the amine scrubber can be eliminated in the design, thus,

significantly reducing the equipment and installation cost.

Hydroprocessing units for renewable diesel will also typically be designed with product recycle used to quench the temperature rise in each reactor. This is especially important if processing 100% renewable feedstock as the temperature rise can be as high as $500^\circ F$ ($260^\circ C$), which is not manageable without a large amount of recycle used as a heat sink. The need for product recycle in a coprocessing unit will depend on the amount of renewable processed in the unit.

If the main purpose of the unit is to make a renewable jet fuel, the last reactor will also contain a hydrocracking catalyst to convert the long chain molecules into the jet boiling range and naphtha.

39.6 Catalysts for Dewaxing of Renewable Diesel

The most effective way of improving the cold flow properties of diesel fuels is catalytic hydrodewaxing. This technology improves the cold flow properties by selective isomerization to slightly branched paraffins. The hydrodewaxing catalysts are zeolitic-based, and they either selectively isomerize or crack mainly the normal paraffins. An inherent property of all dewaxing-type catalysts is the formation of smaller amounts of lighter products, mainly the formation of naphtha and some C_1 – C_4 gases.

Haldor Topsøe's dewaxing catalysts are sulfidic catalysts supported on an acidic carrier able to operate in a sour environment. Both have medium-high

HDS and HDN activity, and thus the reactor volume loaded is not lost in terms of desulfurization and hydrogenation capacity, when used in coprocessing mode. The hydrogenating activity will give slightly higher hydrogen consumption, which results in improved product properties such as lower density and higher cetane number. The dewaxing catalysts can advantageously be loaded close to the outlet of the reactor, thereby permitting the dewaxing function to be effectively switched on or off by temperature control in the last bed by use of quench and reactor inlet temperature control as illustrated in Fig. 39.8. To make use of the dewaxing function during wintertime oper-

ation, the reactor temperatures are simply increased. During summertime operation, the temperature inlet of the dewaxing catalyst is reduced by reducing the firing of the upstream furnace and/or by increasing quench.

The above plot in Fig. 39.9 illustrates that the cold flow properties of the diesel fuel can be improved by either cracking the molecules or by isomerizing normal alkanes into branched molecules. Cracking of the molecules, when producing diesel, should be minimized, as it will reduce the diesel yield and cetane number, and will produce jet and naphtha instead. Significant improvement in cold flow properties can be obtained through isomerization with only 1- or 2-branching as illustrated in Fig. 39.9.

Fig. 39.9 Diesel dewaxing based on isomerization and cracking

39.7 Conclusion

Hydroprocessing of renewable diesel offers a unique opportunity to produce a sustainable hydrocarbon transportation fuel completely compatible with existing fuel infrastructure and engine technology. The process is very versatile in terms of feed type and thus offers great potential for future operation on e.g., algae oils or other high-yield feedstocks that cannot be used for human consumption.

Haldor Topsøe's HydroFlex technology and catalysts for both standalone 100% renewable feedstocks and coprocessing schemes with fossil fuels for the production of jet and diesel fuels are commercially proven. Haldor Topsøe's selective catalysts and unique technology will offer better diesel and jet yields, significantly improving the profitability of renewable fuels projects.

40. Small Scale Catalytic Syngas Production with Plasma

Adam A. Gentile, Leslie Bromberg, Michael Carpenter

The production of syngas has been desired for nearly a century as a starting point towards an effort to achieve the synthesis of higher-energy liquid fuels. Methods that are utilized for obtaining syngas have undergone profound technological transformations over the years. The formation of plasma is one such concept capable of energizing molecular chains through dielectric manipulation in order to excite electrons and form radicals. Many types of plasma configurations exist under a range of variable parameters such as pressure, temperature, current, power intensity, and physical structure. Nonthermal plasma in conjunction with catalysis is a relatively new concept that takes a more subtle approach that eliminates the intensive energy requirement while maintaining high conversion efficiency. The technology and process presented in this book chapter will encompass a hybrid plasma/catalysis (PRISM) system having the ability to ionize and reform any vapor phase species with a focus on short to long chain hydrocarbons. The apparatus promotes reactions that would otherwise be disadvantageous from either a high activation energy standpoint or from the yield of unfavorable side products. Catalytic partial oxidation (CPOX) using a low-energy, nonthermal plasma is capable of nearly perfect conversion of a carbonaceous starting material into clean, homogeneous, hydrogen-rich syngas.

This chapter documents work done on small- to mid-scale plasma enhanced catalysis for platform-flexible fuel reformers in an effort to improve conventional (i. e., internal combustion) vehicle operation as well as the commercial standard reformation efficiency. Although industry has been focusing on methane, the system performs as a cost-effective method in the production of hydrogen-rich, process-ready syngas from any carbonaceous source/feedstock.

There exist several applications of stationary and onboard hydrogen production:

- Supplementation and augmentation of hydrogen into internal combustion engines (ICEs) for improved operation and pollutant elimination
- Diesel PRISM fuel reformation for after-treatment application
- Onboard hydrogen generation for fuel cell power production
- Clean-burn electrical generation (turbines, gen sets)
- Liquid drop-in fuel production.

The chapter is organized as follows: First, an introduction of plasma and its different forms and attributes are defined in Sect. 40.1. The primary reaction of interest is partial oxidation (POX) and this, along with the micro- and macrokinetics of the PRISM process in terms of theory, will be described in detail in Sect. 40.2. Section 40.3 details the experimental process from start to finish with a broad overview of operational perspec-

tive. In Sect. 40.4, we expound on a discussion of the data including process challenges, areas of improvement, and future development. Some of the synergistic effects of plasma over typical gas-phase processes can be found in Sect. 40.5, which leads to the conclusion of how and why plasma-assisted POX in a catalytic environment is a viable and cost-effective technology.

40.1 Plasma

40.1.1 Introduction

There are many different paths that lead to the production plasma, which is universally known as the fourth state of matter and also the most abundant state present in the universe. Some generally known devices and methods of generating plasma include the plasmatron, plasma jet or torch, spark, corona discharge, electrical or gliding arc, and glow discharge. For our purposes, plasma is regarded as a collection of freely charged particles in random motion that is, on average, electrically neutral [40.1]. Typically generated from a gaseous phase, application through an electrical field induces a temporary condition of a plasma state regardless of bulk medium temperature. Additional ways to accomplish this include, but are not limited to, a radio frequency (RF) treatment or a microwave treatment of the gas in a strong electromagnetic field. When utilized to augment a reaction, plasma adds substantial beneficial factors to the molecular interactions and kinetics of the reaction at hand.

Breakdown and Ionization

The standard gas molecule is stable in an environment when at or near a state of equilibrium with its surroundings. As intensive and extensive properties change, molecules begin to lose their stability. Electron movement rapidly increases and ionization is achieved when electrons gain enough energy to remove themselves from their respective orbitals unbound from their normal position within or around the molecule. Ionization

may also be achieved when temperatures rise beyond a distinct threshold level of the molecule. With less difficulty than applying extreme amounts of heat, ionization can be reached inside an electrical field supplied by an adequate voltage source. This approach causes a dielectric *breakdown* of the gas molecule into plasma consisting of charged species (electrons, ions, radicals) and neutral species (atoms, molecules, and excited particles). The plasma thus becomes a highly energetic state of matter characterized by an elevated electrical conductivity [40.2]. Strongly bonded molecules like hydrocarbons such as methane (CH_4) in a plasma-induced state have been documented to disassociate ($\text{C}_1\text{H}_4 \rightarrow \text{C}_1\text{H}_{[x<4]} + \text{H} + \text{H}_2$) then quickly recombine into intermediate compounds such as C_2H_2 , C_2H_4 , and C_2H_6 [40.3]. This can be achieved and maintained as long as the methane is exposed to the electrical field. The intermediate molecules are a short-lived species and will reform back into methane if not converted while yielding some amount of molecular hydrogen.

Generation of Plasma Field

Multiple methods exist to produce a viable plasma field, the most practical being two electrodes in close enough proximity supplied with a voltage creating an arc of electricity, or plasma, through the air gap between the electrodes. This can be seen in Fig. 40.1b using parallel conductive plates. The power supply drives the current between the conductive electrodes ionizing the gas flowing through it. Pressure plays an important role for the generation of the field. At pressures below

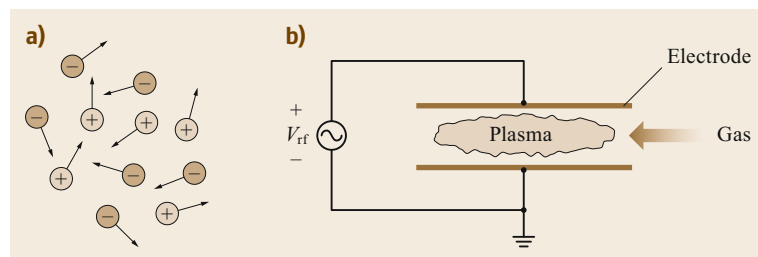

Fig. 40.1 (a) Visual of excited ion motion that makes up plasma. (b) Simple plasma discharge apparatus (after [40.1])

atmospheric and above vacuum, the electrical energy required to create a plasma field arc or glow discharge is reduced to a minimum. The augmentation of the dielectric strength of vacuum by matter and pressure is the primary function for sustaining the plasma field.

Another factor in field generation refers to the geometry of the electrodes. Industrially, these can vary from sharp singular points to infinitely long plates to annular arrangements physically similar in appearance to concentric pipe heat exchangers. In the case of processing gas, the annular apparatus is highly efficient and isolates the system from the surrounding environment. It is difficult to classify and analyze the plasma generated from an external electromagnetic field because of the inconsistent nature of the ionized particles. The generated plasma is on a very short time and space scale (10^{-7} – 10^{-9} s) as the excitation weakens, dissipating quickly upon departure from the applied electrical source. If not utilized properly, the plasma will return to a stable gaseous ground state.

Stability and Equilibrium

Plasma requires constant treatment via an external energy source in order to maintain its phase stability, making it a short-lived species at ambient conditions. In a continuous process, it's wise to consider the placement of the plasma generating field in order to optimize overall system efficiency. Ionization and dissociation are a requirement for the existence of plasma, but these induced conditions also cause a fluctuation in equilibrium. Plasma density, also defined as electron or ion density (n_i), is the number of free electrons per unit volume. Ion density can be used to determine the degree of fractional ionization (x_{iz}) of plasma represented by the equation

$$x_{iz} = \frac{n_i}{n_g + n_i}$$

where n_g is neutral gas density. If the degree of ionization is ≈ 1 then the plasma can be considered fully ionized and if $x_{iz} \ll 1$, the plasma is weakly ionized. No matter how minute the presence of ionization in the gas phase, plasma characteristics still show to some degree [40.3]. Threshold levels for ionization exist during excitation of a gas-phase substance and depending on the amount of energy applied, different charged and neutral molecules will be produced that are of overall equal constituents to the original gas molecule. These excited forms consist of rotational excitation, vibrational excitation, disassociation, and full plasma ionization. Rotational and vibrational excited states are generally considered impractical for most processes due to their low threshold energy (< 2 eV) and short

lifetimes (nanoseconds) [40.1]. Electrical field energy is directly proportional to electron energy responsible for greater molecular decomposition from the electron-impact dissociation and ionization reactions. As an example, bonding energy of most hydrocarbons is between 3–6 eV. This range expresses C–H and C–C bond strength varying from molecule to molecule of any hydrocarbon in general. C–H bonds are stronger and closer to 6 eV in strength than that of C–C bonds, which reach the lower interval of 3 eV in strength. An electron-volt (eV) is energetically equivalent to about 1.6×10^{-19} J (Joules). The following electron-impact reactions of methane show the threshold energy barrier necessary to achieve specific levels of plasma excitation [40.3]:

- Vibrational excitation

- Dissociation

- Ionization

Methane is a highly stable compound and, as a result, requires more energy to break the threshold barrier than most other hydrocarbons. This data can be used as an initial guide for determining the necessary energy requirement for any intended plasma application. Threshold levels affecting plasma stability lead to one possible reason as to why the plasma state is almost never in chemical or physical equilibrium with its surroundings. Since the discharges are electrically driven and weakly ionized, the applied power preferentially heats the mobile electrons while the heavy ions exchange energy through collisions with the background

gas [40.1]. At or below ambient pressure, the ion temperature (T_i) representing the overall temperature (T) is typically much less than the electron temperature (T_e). An immense amount of energy is required for neutral species and charged species to be in thermal equilibrium with each other ($T_e = T_i = T$). This is known as hot plasma and the requirement differs from element to element where, for example, a temperature of 20 000 K must be reached for complete thermal ionization of helium while around 4000 K is needed for cesium [40.1]. When not in thermal equilibrium ($T_e \gg T_i$), the phase state is considered cold plasma meaning that the overall temperature (T) of the plasma is at least equal to the ambient system process temperature.

40.1.2 Types of Plasmas

As stated before, there exist many different types of plasma, both natural and conventional (Fig. 40.2). The focus of this chapter is on one form of conventional plasma used in a reformation process; it is still worthwhile, however, to note other types. For instance, most plasma is naturally occurring in the universe from stars and interstellar matter. An example of hot plasma, also known as thermal plasma, is the Sun's surface or a bolt of lightning. A neon light can be considered nonthermal plasma or cold plasma. This classification depends on temperature, electronic density, and level of energy of the medium [40.2].

Conventional plasma is synthetic and every synthesized type carries different micro- and macroscopic benefits for process use. Plasma is also categorized by pressure in response to the method of ionization and the structure of the electrical field. For instance, in very low pressure environments plasma may always be considered nonthermal. The following is a list of conventional plasmas with descriptions grouped by pressure.

Low Field Pressure ($0 \text{ atm} < P_{\text{plasma}} < 1 \text{ atm}$)

Capacitive coupled plasma (CCP) and inductive coupled plasma (ICP) (Fig. 40.3a–d) are produced by high frequency RF electric fields where positive ion collisions are the dominant factor leading to electron dissociation. The bombarding ions are directly affected by the magnitude of frequency, typically at the MHz level, capable of causing an electron or Townsend avalanche cascading the electrons into a plasma state. CCP is generally used in material processing to enhance surface properties like that of integrated circuitry via etching or film deposition. A substrate is present upon one of the two interacting electrodes that are aided by a positive sheath material maintaining excess negative charges and directing them appropriately. ICP utilizes a coiled electrode (Fig. 40.3c,d) placed outside of the reactive zone in-

still an electromagnetic field that negates the direct current (DC) requirement necessary to reach efficient power in CCP. For analytical methods such as spectrometry, ICP provides a reliable detection limit over a wide range of sample elements. The RF power source can also be directed into the plasma gap itself as opposed to through the electrodes for both ICP and CCP.

Cascaded Arc

High-density, low-temperature cascaded arc is plasma in a relatively homogeneous thermal equilibrium. This creates an exception to the hot-thermal plasma classification since the gas, ions, and electrons are all thermally equal ($\approx 1 \text{ eV}$) at ambient conditions. The field is stabilized by cascaded plates with a floating voltage potential and is typically structured cylindrically. Operated under a DC supply, the power requirement is in the lower kW range (1–10 kW). This form of plasma and device is used in material deposition and surface treatment as well.

Electron Cyclotron Resonance (ECR) and Helicon Discharge

Electron cyclotron resonance (Fig. 40.3a) and helicon discharge (Fig. 40.3b) are produced by an axial varying DC magnetic field sustained by electromagnetic coils. The coils surround a cylindrical chamber in which microwaves are injected through a dielectric window propagating a rotating polarized wave. This generates the source plasma where it can be directed into the processing chamber. Electron cyclotron resonance (ECR) is operated with a strong magnetic field versus helicon discharge, which is much weaker by comparison. Helicon discharge uses an RF-driven antenna coupled with the weaker magnetic field to create a resonant helicon wave at the plasma source where it is believed that the particle-wave interaction is the cause of the wave energy transfer into the plasma. Conventional areas of interest for these plasma devices include semiconductor manufacturing, electric propulsion devices, or in advanced medical treatment.

Glow Discharge

Glow discharge is produced by a low frequency electrical field induced by DC or RF in the open area between interacting electrodes. Once adequate voltage is met, ionization occurs releasing a vibrant light based on the ionized gas. The system is usually enclosed in a non-conducting transparent tube. Known for its usage in fluorescent lamps and neon lights as well as plasma-screen television devices, glow discharge plasma also has applications in analytical chemistry via spectroscopy and mass spectrometry and in material surface treatment via a method known as sputtering.

Fig. 40.2 Synthetic and universal plasma on energy (logarithmic temperature voltage equivalent) versus density plot. λ_{De} = Debye length – the distance scale over which charge densities can exist spontaneously or more simply, how far the electrostatic effects travel. As an example, low-voltage and undriven plasmas are generally a few Debye lengths wide (*middle portion* of figure) (after [40.1])

High Field Pressure ($P_{\text{plasma}} > 1 \text{ atm}$) Plasma Torch and Thermal Plasmatron

Plasmatron is a high-powered DC thermal plasma generated by electric resistive heating of a turbulent flow of gas molecules. The plasmatron provides highly controllable electrical heating, but requires resilient electrodes to withstand corrosion from the strong arcs and extreme heat. A relatively large amount of energy is required to harness a homogeneous field in thermal equilibrium due in part to the elastic collisions of the propagating energized electrons. Utilizing an annular configuration, the input gas is injected tangentially to produce a vortex that extends the plasma arc field inside of the ionization zone. Water is used as a heat sink to cool and control electrode temperature preventing thermal damage to the

components. The high power requirement pitfall limits widespread use of the thermal plasmatron in industry, but the plasma torch finds a niche in plasma cutting, pollution control and hydrocarbon reformation.

Corona Discharge

This form of nonthermal plasma is generated through finely pointed electrode tips at a voltage high enough to initiate a conductive field, but not so high to cause an electrical arc discharge to the grounded path. Although the corona charge can be positive or negative, the positive corona is undesirable due to the extremely high energy requirement to excite positive ions. This is not the case for a negative corona, in which electrons are much lighter and more easily ionized in a non-

Fig. 40.3a–d
Example sources
of low-pressure,
high-density
plasma in basic
configurations
(after [40.1])

thermal low-pressure setting. The Townsend avalanche causes the highly energized and separated electrons to move radially in all directions creating a plasma cloud. As the electrons move further and further away from the voltage point, they lose energy and eventually are no longer able to force ionization as they begin to approach the grounded electrode. The field, or cloud of electrons, maintains ionization for as long as a voltage is supplied. Corona discharge is a method for ozone production, volatile organics (VOCs) removal, air clean-up, and water sanitization as well as for analytical techniques.

Dielectric Barrier Discharge (DBD)

An insulating dielectric barrier is used to separate, including the space gap, the field producing electrodes that uses low-RF or microwave frequency from a high voltage alternating current (AC) (1–10 kV)

power source. The material used for the dielectric barrier ranges from polymers to glass or ceramics, all nonconductive in nature. Planar or axial configurations may be utilized depending on flow applications and can be seen in Fig. 40.4. DBD is another form of nonthermal plasma that can be generated at ambient pressure and low temperature that is not in total particle equilibrium. Microdischarges occur at the dielectric surfaces and propagate like a glow discharge while maintaining homogeneity, but within a more pressurized environment. Originally designed for ozone generation, DBDs find use in catalysis enhancement, surface modification of materials, emissions control, excimer lamps, and silent-discharge CO₂ lasers.

Gliding arc

Gliding arcs are arc discharges that initiate from the point of shortest distance between parallel, but diverg-

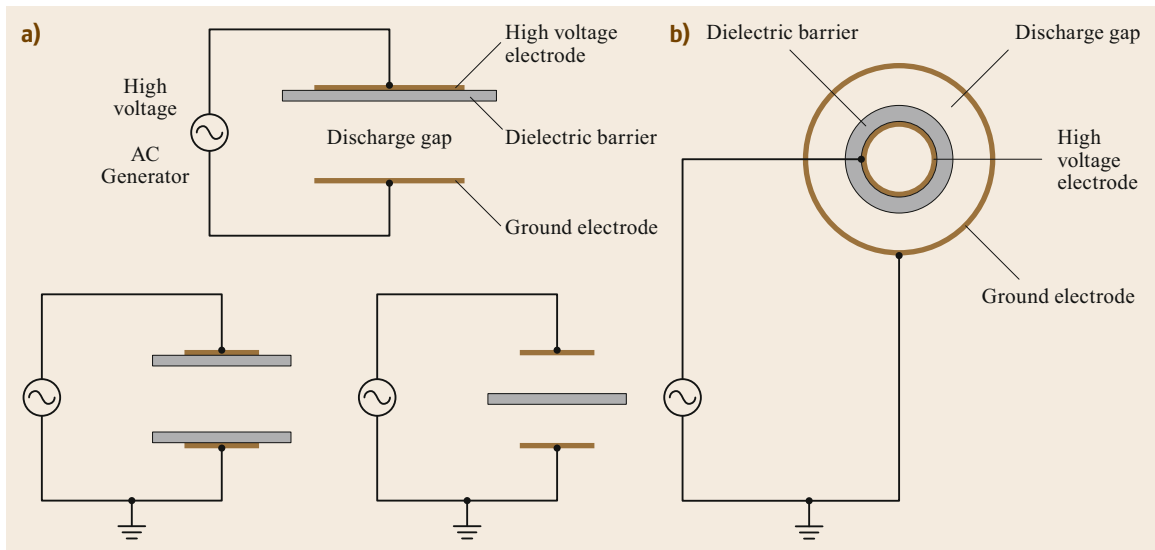

Fig. 40.4a,b Configurations of different DBD plasma devices (apparatus similar to other plasma devices minus the dielectric barrier) (after [40.4])

ing electrodes. The arcs travel along the length of the electrodes until complete breakdown of the arc occurs near the endpoints of the divergent electrodes [40.5]. As the gliding arc dissipates, the encompassing turbulent gas maintains a glow discharge plasma state. This continuous cycle is determined by the system parameters, which include characteristics of the electrical power source (AC or DC), range of current and voltage capacity, gas type, gas velocity, electrode geometry, and field pressure. Associated with a high level of current (≈ 50 A/arc discharge), this thermal plasma

reaches extreme temperatures ($T > 10\,000$ K) energizing all the chemically active species (CAS) present in the medium. The power requirement varies from 1–10 kW based on the parameter conditions. Gliding arc can be considered a hybrid form of thermal and nonthermal plasma reaching only temporary equilibrium with traits similar to the plasmatron and glow discharge. Some of the many applications of gliding arc plasma include metallurgy, chemical reformation, reformation of flue gas, dissociation of CO_2 , and decontamination.

40.2 Partial Oxidation Reformation Using Cold Plasma

40.2.1 Methane Reformation

Industrial practices often vary in regards to reformation techniques as the end goal is unique to each process. Hydrocarbon reformation can be utilized as a supplement to larger-scale processes by making use of utility streams and side products that would otherwise be a detriment to overall system efficiency. For instance, when a surplus amount of steam is generated after primary and secondary cooling, it can be in the engineer's interest to make use of it. If a steady supply of natural gas is also available, then steam methane reforming (SMR) could be a source of additional revenue for a wide range of production applications, the most common and basic of these being the synthesis of hydrogen or methanol. Below are the ideal reactions that accompany the SMR process:

- Steam methane reformation (SMR)

- Water gas shift (WGS)

- Methanol synthesis

Being diverse in its usage and easily storable, methanol typically equates into a positive revenue

source. It is possible to deploy SMR as a primary process, but would require large-capacity equipment and a high rate of production to compensate for the high cost of generating steam given SMR's low conversion efficiency. The SMR process is well documented and currently used at the commercial level, but is only one method of methane reformation and the focus of this chapter is on partial oxidation reformation techniques.

Reformation with the goal of hydrogen production has seen real promise for small-scale and on-hand applications like fuel cell technology or enhancement of internal combustion engines (ICEs). The advantages of hydrogen include fast flame speed and high octane (which enables high-pressure operation), allowing either high compression ratios or strong turbocharging with associated downsizing. The use of hydrogen-rich gas addition to spark-ignited (SI) engines allows for highly diluted operation. It is possible to extend the dilute-operation burn limits where nitrogen oxides are reduced to near nonexistent levels, eliminating the need for NO_x after-treatment (thus removal of the three-way catalyst). Dilution also allows for improved efficiency, from either reduced pumping losses at light load or lower in-cylinder temperature, thus reducing heat transfer to the cylinder walls. Running with hot hydrogen-rich gas further improves the flame speed as well as extends the dilution limit. Faster flame speed is another contributor to increased engine efficiency by enabling a more isochoric combustion zone.

Hydrogen is unfortunately a difficult molecule to store for extended periods of time. Aside from a high mass heating value, 120 kJ/g compared to methane (50 kJ/g), methanol (20 kJ/g), and gasoline (42.8 kJ/g), hydrogen is characterized by a low volumetric heating value due to its low density (2.016 g/mol): 11 kJ/l versus 16 MJ/l for methanol at standard temperature and pressure [40.2]. Volatility, flammability, and small molecule size all add to the storage difficulties of hydrogen. Some presented solutions to these issues are cryogenic and high-pressure containment, which have some validity but are not ideal due to further increase in efficiency losses and explosion hazards that are deemed high risk for mobile applications. Methanol has been used on occasion as a storage medium for utilities like fuel cells that are typically designed to operate on a source of hydrogen.

The integral step of methane reformation is the production of synthesis gas or syngas, a mixture of hydrogen and carbon monoxide. Often, realities of operation interfere, producing a syngas with adulterants such as carbon dioxide, methane, water, oxygen and nitrogen. Generally, these side constituents are unfavorable and limit overall efficiency in downstream processing requiring minimization when possible throughout oper-

ation. The methane POX reaction and other macroreactions of concern that are associated with methane POX (which include the SMR reactions above) are listed below. The following reactions can be considered competitive as well as reversible in nature:

- Methane partial oxidation

- Combustion reactions

Other Possible Side Reactions

- Thermal decomposition

- Dry methane reformation

- CO reduction (undesired)

- Boudouard reaction (undesired)

- Methanation (undesired)

Partial oxidation is an exothermic reaction capable of producing an ideal syngas product of a 2 : 1 ratio of hydrogen to carbon monoxide. The reaction is able to reach temperatures in excess of 1300 °C that need to be levied and maintained through use of a catalyst in order to avoid nitrogen-based reactions. Nitrogen oxides (NO_x) are considered an emission that have, by orders of magnitude, a much greater environmental impact than unburned hydrocarbons and carbon oxides. Not only does NO_x cause the formation of ground-level ozone, but it also has negative effects upon the human respiratory system. The rate of formation of NO_x increases exponentially as temperatures rise in a lean and oxygen-rich flame zone during partial or total oxidation with air. Nitrogen, if not removed before reformation, must remain inert throughout the process. This factor is taken into consideration along with reactant conversion and hydrogen yield, all of which are influenced by thermal conditions.

Thermal Equilibrium

Not including plasma interaction, the factors that affect syngas production are reactor size, space velocity, flow dynamics, catalyst type, reactor and catalyst geometry, feed material and feed ratio, system pressure, and thermal equilibrium. Exothermic processes are controlled not only for safety reasons, but also for system efficiency and minimization of side products. Thermal equilibrium helps justify why the SMR reaction is inefficient and energy intensive while also explaining POX efficiency and NO_x formation.

The tubular reactor is commonly employed in industry and most often utilized for homogeneous gas-phase reactions. It is assumed that the reactants are consumed over the length of the reactor while experiencing some concentration variance both radially and in the direction of flow. This forces the rate of reaction to adjust accordingly as reactants are consumed and products are formed that become intermediate reactants themselves. In a POX reactor, the plug flow apparatus is selected to maximize production rate. The reactor can be used with, or without, a form of packed catalyst; when under a turbulent flow regime, equilibrium is maintained in a quasisteady state of operation creating a relatively stable, predictable thermal profile. As the process approaches completion under this configuration, different zones of the reactor experience a rise and fall in temperature due to the multitude of occurring reactions. This effect is more apparent in a shorter amount of reactor length using a packed-bed catalyst design and even more so if the reactor diameter is reduced. The thermal profile and reactions that take place are directly proportional to the ratio of fuel and oxidizer. More specifically, a carbon-to-oxygen atomic ratio of

1 correlates to stoichiometric POX while a ratio of 0.25 gives way to stoichiometric and complete combustion. Oxygen, within these stoichiometric bounds, is depleted quickly after injection due to its fast reaction rate and will not be present in the product stream. Oxygen can only be present postreactor if the system is not functioning properly or if lean operation is being conducted. Any ratio < 0.25 is considered lean (or fuel deficient) combustion and a ratio > 1.0 inactivates the reaction by extending the gas mixture past its flammability and reactive limits.

In order to lower reaction temperature, eliminate NO_x formation, and increase methane conversion, a catalyst is typically present inside the reactor. Currently, catalytic reformation is commonplace in the industry and as so, it is the most economically well-developed technique for hydrogen production. Typical POX catalysts include Pt, Rh, Ni, Co, Ir, Pd, or Ru metals that are supported on metal oxides, which include Al_2O_3 , CeO_2 , MgO , and TiO_2 in different proportions, mixtures, and geometric configurations [40.3,6]. Though difficult to fully model theoretically, the experimental reaction pathways using catalysis are consistent and repeatable. Initially, exothermic reactions of POX and combustion are activated together to provide heat to the reactor. This spike in temperature allows the intermediate products of H_2O , CO , and CO_2 to then immediately react via the SMR and WGS reactions with unconverted hydrocarbon as well as the hydrogen product. Due to the continuous nature of the plug flow reactor and high gas space velocity, the residence time of the reactive species is short (< 1.0 s). The short residence time in relation to the competing exothermic and endothermic reactions forces the process to reach completion that is not necessarily preferential to the best possible results.

Thermal equilibrium tends to develop in localized spots of the POX reactor and is contributed mostly from gas flow convection, downstream or upstream radiation, catalytic reaction, and heat conduction of the reactor and catalyst wall [40.7]. Even through well-controlled operation, the active species are always in a constant state of reactive flux. The bed temperatures along the length of the reactor help justify these claims, which have been seen through experimentation and are well documented in literature.

Maximization of hydrogen yield and selectivity can be achieved through manipulation of reactor temperature. Figure 40.5 shows this relationship and provides an example of thermal equilibrium influencing the product composition [40.7]. It is easy to see the asymptotic increase in conversion and the perfect selectivity that is achieved as temperatures rises in the reactor.

The syngas yield of purely two hydrogen molecules to each CO molecule from a 1.0 ratio of C/O would the-

Fig. 40.5 Experimental POX using Rh-coated foam monolith catalyst. CH₄ conversion with H₂ and CO selectivity versus temperature (after [40.7])

oretically be perfect for downstream applications like methanol production, but combustion is unavoidable during POX making this idealization next to impossible. It should be noted, that some CO₂ is necessary for methanol production as well, and though mostly viewed as a negative aspect to the process, combustion can be controlled to assist in reformation. As more oxygen is introduced to the feed, hydrogen yield tends to increase until a peak is reached (C/O ratio ≈ 0.85) where further addition of oxygen begins to lower hydrogen yield. Peak ratio is unique to each process with high dependency on reactor structure and plasma or catalysis assistance. The stability of feed ratio also contributes greatly to thermal equilibrium and, from a mechanical standpoint, reactor temperature provides a quick indication of syngas quality and possible system deficiencies. If the reaction is controlled solely by thermal activation then product selectivity is predictable, but will limit maximum product potential. When plasma becomes a dominant presence in the system, thermal equilibrium is overcome and the achievement of an even greater efficiency is then possible [40.8].

Chemical Kinetics

The reformation process can be summarized by the enthalpy changes exhibited throughout the system. Each reaction either imparts or removes heat in an effort to approach completion. The POX reaction itself has relatively slow kinetics and cannot initiate without the assistance of energy from an external source or an internal source such as combustion. Overall, the process of POX is still exothermic even with the multitude of associated competitive endothermic reactions. In the event

that the total net enthalpy change to the system is approximately zero ($\Delta H_r^\circ \approx 0$ kJ/mol), the process can then be considered autothermal. In order to compensate, some form of direct injection is required using water, CO₂, a process recycle stream, or simply the exhaust from an internal combustion engine:

- Partial oxidation

- Steam reformation

- Combustion

- Autothermal reformation (ATR)

The above global reactions give a straightforward overview and are the initial basis for modeling any reformation process. Reaction kinetics can then be utilized to help more thoroughly map the intrinsic system properties for determination of syngas product composition and yield. Temperature, pressure, and phase all play a role in the mechanism determining the pathway for reactions to follow. The homogenous gas phase reactions of POX do not inherently promote the formation of a high-quality syngas; this problem is partly resolved with the insertion of a durable and appropriate supported catalyst placed within the reactive zone [40.6]. The heterogeneous catalytic environment enhances the normal molecular pathway via active sites on the catalyst that reduce the energy barrier required for stoichiometric POX and lower the amount of combustion heat necessary for reaction stability. In a prior study, the CPOX of methane on a rhodium-coated catalyst has been indirectly modeled based on combustion, steam reformation, water gas shift, and dry methane reformation (DMR) kinetics. These equations, which are listed below, follow the Arrhenius model and have been

determined using empirical methods [40.9, 10].

$$R_{\text{Combustion}} = 2.119 \times 10^{10} \exp\left(\frac{-80}{RT}\right) p_{\text{CH}_4}^{0.2} p_{\text{O}_2}^{1.3}$$

$$R_{\text{SMR}} = 1.0 \times 10^{-9} T^5 \exp\left(\frac{-47.3}{RT}\right) \times \left(p_{\text{CH}_4} p_{\text{H}_2\text{O}} - K_{\text{eq,SMR}}^{-1} p_{\text{H}_2}^3 p_{\text{CO}}\right)$$

$$R_{\text{DMR}} = 7.0 \times 10^{-7} T^4 \exp\left(\frac{-32}{RT}\right) \times \left(p_{\text{CH}_4} p_{\text{CO}_2} - K_{\text{eq,DMR}}^{-1} p_{\text{H}_2}^2 p_{\text{CO}}^2\right)$$

For the WGS reaction ($r = \text{steam/CO ratio}$)

$$R_{\text{WGS}} = k \left(p_{\text{CO}} p_{\text{H}_2\text{O}} - K_{\text{eq}}^{-1} p_{\text{CO}_2} p_{\text{H}_2} \right)$$

$$k_{\text{HTSR}} = 1.78 \times 10^{22} (1 + 0.0097r - 1.1364r^2) T^{-8} \times \exp\left(\frac{-70}{RT}\right)$$

$$k_{\text{LTSR}} = 1.74 \times 10^{17} (1 + 0.154r + 0.008r^2) T^{-8.5} \times \exp\left(\frac{-35}{RT}\right)$$

Overall thermodynamic equilibrium constant (K_{eq})

$$K_{\text{eq}} = \exp\left(\frac{\Delta S^\circ}{R} - \frac{\Delta H^\circ}{RT}\right) (P_{\text{atm}})^{\sum_{j=1}^N \nu_j'' - \nu_j'}$$

The equilibrium constant (K_{eq}) takes into account the reversibility of each of the process reactions. This must be addressed due to the variability of conditions during operation. As an example, the WGS reaction approaches completion at two different temperature ranges. The high-temperature shift (HTSR) and low-temperature shift (LTSR) are performed in the ranges of 300–500 and 200–300 °C respectively. Lower temperatures support better CO conversion, but the kinetics favor an increased reaction rate at higher temperatures. The WGS reaction is always present, shifting the product composition towards thermodynamic equilibrium between CO, CO₂, H₂, and water. The subsequent production of hydrogen-rich syngas with minimal CO content, in particular to polymer electrolyte membrane (PEM) fuel cell application, is also based on WGS kinetics [40.11]. Industrial-scale applications looking to maximize hydrogen production tend to operate both HTSR and LTSR in separate reactors in series downstream of the reformation reactor. The use of both shift reactors as ancillary units downstream from the reformer allows for near-total conversion of CO into CO₂ and provides additional hydrogen from steam with

further intent to isolate the product hydrogen. This happens through the most economical form of separation possible and can be accomplished using one of the several following techniques: pressure-swing adsorption (PSA) to separate hydrogen, PSA to separate the CO₂ followed by condensation of the remainder of water, and membrane or sieve separation of the hydrogen [40.12]. With regards to the overall POX process, WGS is unavoidable and can be seen as neither beneficial nor detrimental to downstream application. This is especially true when engine combustion or electrical generation directly follows syngas production, as CO is also a suitable, burnable energy source.

40.2.2 Plasma Catalysis

Low-input energy capable of producing highly active species has become the focal point of potential for development of more efficient plasma reactors. In plasma catalysis, there exist a number of different configurations that rely upon location of the plasma field and catalyst zone. If the placement of the catalyst zone is prior to or much further downstream of the plasma field, then the process is a two-stage system (Fig. 40.7). Hot thermal plasma imparts extreme amounts of heat energy that cannot be used in conjunction with catalysis due to the structural limitations of catalytic material. The coating and the substrate are unable to withstand the high temperatures of the plasma field resulting in immediate thermal degradation as well as sintering of the coating material. In the immediate area surrounding the thermal plasma field, the cost of processing equipment and piping material would also rise in an effort to resist the high temperatures using higher durability equipment. This leads to applications in which thermal plasma has very limited appeal because of the inefficiency from the high energy demand and the inability to integrate into established chemical processes. For thermal plasma to have a role in catalysis, ample distance between the catalyst and plasma field is required, eliminating most of the potential synergy of the combined systems.

When the catalyst zone is located inside the plasma field or in close proximity postplasma generation, the process is known as a single-stage system (Fig. 40.6). In a single-stage plasma catalysis system, the effects of plasma and catalysis that contribute to the process become dependent on each other. This differs greatly from conventional catalysis due to the introduction of highly active species and the creation of a voltage potential and current flow by result of plasma discharge across the catalytic surface. The active species alter the status of the gas-phase reactions and associated reaction kinetics, which no longer ensues from the ground state. Elec-

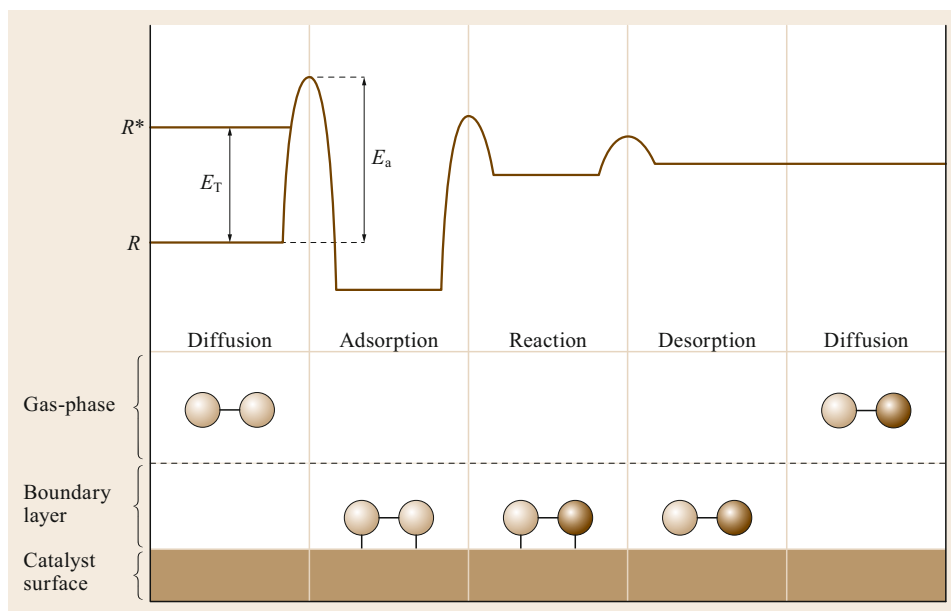

Fig. 40.6 Illustration of vibrationally excited species from a plasma-induced state accelerating a catalytic reaction. R represents the gas-phase molecule at ground state (uncharged) and R^* stands for the reactant in a vibrational state (charged). E_a is the activation barrier of chemisorption for R and E_T is the threshold energy for the formation of R^* through a plasma-induced electron-impact reaction (after [40.3]). The thermal energy required to initiate the catalytic process is now much less than the standard catalytic reaction and even further so than the reaction without catalyst

Fig. 40.7a,b Schematic drawing of rotating arc reactor used in a prior study conducted by Dae Hoon Lee et al. Side view (a) and overhead view (b) (after [40.13])

trical field enhancement depends on curvature, contact angle, and the dielectric constant of the packing pellets. Higher electric field leads to higher electron density promoting the electron-impact reactions responsible for hydrocarbon reforming. The decomposition of hydrocarbons is attributed to ionization and electron-impact dissociation of the excited molecules. Simply through

vibrational excitation it has been noted that activation energy is reduced in gas-phase reactions.

Physical adsorption and chemisorption are the methods where gas-phase molecules or ionized particles attach to the surface of the catalyst (Fig. 40.8). Physical adsorption is slightly exothermic and is mainly attributed to the weak Van der Waals attractive forces

Fig. 40.8 Reaction effects flowing through a catalytic monolith, which include transport processes and a microscopic view at the nanoscale level (after [40.11], reproduced with permission of The Royal Society of Chemistry)

between the interactive surfaces. As the temperature profile surrounding the catalyst rises, the adsorption of particles steadily declines until critical temperatures are obtained in which physical adsorption no longer occurs. At this point, physical adsorption gives way to the sole influence of chemisorption. In the rate-influencing step of chemisorption, valence forces create highly reactive instances via bond stretching of the exposed and absorbed chemical species on the surface of the catalyst. Chemisorption produces heat comparable to the exotherm of the chemical reactions being performed. Atom and metastable compound formation along with electron multiplication cascade into the catalyst bed manipulating the normal conditions in which the catalyst performs. These effects are apparent and usually happen under very short electrical contact times. The heightened interaction between the surface and adsorbate then create new bonds, forming molecules that are specific to the catalyst and operating conditions.

40.2.3 Reactor Apparatus

In a lab setting, a reactor that imparts all of the above-listed chemical and physical effects has been constructed. The proprietary unit, known simply as PRISM and shown in Fig. 40.9, has demonstrated successfully the ability to reform methane gas into syngas at high efficiency and near perfect conversion using very little energy input. The process incorporates a three-step approach coinciding with intermediate stages that contribute to the final composition of the produced syngas.

At ambient or elevated temperatures, a stream of dry air or pure oxygen is introduced to a stream of natural gas and is well mixed prior to exposure of the plasma-

generating field within the plasma head. The plasma head is a precision-designed, stainless steel structure consisting of a tapered rod that acts as the anode, which is housed inside a cylindrical wall of like material (the cathode). The point of largest diameter along the length of the anode rod is where the plasma field initiates and can also be considered the choke point of the flowing element. The axial design makes use of the annular gap to hold steady the electrical field. This closely resembles that of a dielectric barrier discharge (DBD) apparatus, but without direct internal insulation while incorporating more of a coronal discharge approach to the plasma type utilized. In place of a fine-tipped point that is typically seen in a coronal design, the annular region is used to grant a larger volume coverage that increases the duration of electrical exposure to the gas molecules ensuring sufficient ionization. The plasma chamber of the PRISM mimics the flow patterns of the schematic shown in Fig. 40.9 for the rotating arc reactor, but differs in dimensionality and in orientation. The radial injection points allow for a toroidal arc that further increases residence time within the plasma head apparatus. As concentrated charges dissipate from the added rotational turbulence, both metal erosion and degradation upon the electrodes are reduced, extending their overall lifetime. An observation of the anode after long-term operation reveals minor impressions of spiral-type markings across its metal surface indicating the tangential path taken by the flowing gases.

The annular chamber provides uniform exposure to the incoming gas assisted by the well-mixed effect of the turbulent flow regime promoting molecular interactions and ion collisions, while the toroidal flow lengthens the space and time of the overall exposure.

These factors all contribute to the formation of the highly energized cold plasma state necessary for the reformation stage of the process.

An external power source is placed above the reactor providing voltage directly to the electrodes that are held inside a barrier of ceramic/quartz in order to maintain the uniform three-dimensional electric field throughout the annular gap. The power supply operates at high voltage (≈ 3 kV) and very low current expending no more than 100 W of combined processing power at maximum feed flow rate. Voltage to the plasma head is variable based on the fluid properties, which are primarily defined by gas density and velocity. The PRISM system operates with a 12+ kV compact transformer that allows for additional reserve voltage when fluid properties drastically change, and will adjust automatically without manual input control to sustain the plasma arc field.

Thermal expansion follows quickly after the gas stream is ionized by the plasma field. From there, the flow path continues by entering the main portion of the reactor that houses the proprietary catalyst crafted specifically for promoting the POX reaction. Catalyst composition is a mostly nickel-based coating prepared upon an alumina substrate. These monolithic, cylindrically sculpted blocks of catalyst remain stationary in a tightly packed fashion; these extend to the inner reactor wall.

In this chamber, the core of the partial oxidation reaction takes place. This is monitored through temperature readouts using multiple thermocouples drilled to the center of each catalyst. The external body of the reactor is 22" in length and roughly 8.5" in diameter. The inner wall of the reactor is lined by a nonconductive refractory material of high alpha alumina roughly 1" in thickness. This refractory participates as an insulator, but more importantly ensures containment of the electrical properties that were imparted to the incoming ionized gas stream. Figure 40.9 is an example schematic of an older generation model of the PRISM reactor.

Zonal Reactions

As listed in the section of methane modeling reactions that occur throughout the process (Sect. 40.2.1), each zone of the reactor and catalyst bed itself experience a fluctuation in primary reactions when favorable conditions arise during each reaction. This, however, can be manipulated through a well-controlled system. Initially, the plasma zone operates as an ignition source for the controlled combustion heating to the catalyst bed. When optimal bed temperature is achieved, the plasma field then takes responsibility for molecular breakdown by ionization and electron dissociation of the exposed compounds. Oxygen ionization into its atomic state and

Fig. 40.9 PRISM reactor body and internals

the formation of ozone molecules are the first reactions to occur. Not only is ozone formed, but decomposition is also apparent in the complementing stream of hydrocarbons. These feed streams are well mixed and in a preferential syngas yielding ratio prior to introduction into the plasma zone. Hydrogen atoms released from C–H bond breakage and excited electrons that are initially released contribute to the reactions downstream as well as to the final syngas product. The remaining intermediate hydrocarbon compounds also react more readily in their hydrogen-depleted configurations. This first step helps drive the reaction rate of POX up to a level sufficient for effective overall system operation.

In the subsequent portion of the reactor, the diameter is increased to allow expansion of the gases granting longer exposure to the high surface area of the catalyst. Even distribution from turbulent flow of the particles onto the active sites of the catalyst is observed through stability of the temperature profile. Given a consistent feed composition at a specific ratio during steady-state operation, the specific zonal temperatures fluctuate at a ΔT near $\pm 1.0^\circ\text{C}$. This suggests all the participating reactions are held constant along the length of the reactor in their corresponding zones. As stated prior, oxygen atoms are the first particles to be consumed

and do not appear downstream of the reactor. If the oxygen atoms are not reduced with the carbon source into CO, then the atoms along with some CO will be fully oxidized into CO₂ before leaving the catalyst zone. The POX reaction not only produces the syngas mixture, but also releases sufficient enough heat to stabilize the reactor and perpetuate the overall reactionary process. Due to the fuel-rich environment and high process temperature, the unconverted methane tends to react with the steam side product via the SMR reaction also enhancing the syngas ratio [40.14]. The final stage falls to the WGS reaction and the reverse WGS reaction, which augment the CO₂ component forming either more hydrogen or more CO. The WGS reaction is not optimized in this configuration and purely participates as an indirectly controlled and closely monitored side reaction. Should the syngas ratio require more CO than hydrogen or vice versa, then a downstream WGS reactor can be implemented at a low additional capital cost to the system. The combination of reactions resulting in a net exothermic process leaves the product stream hot (> 600 °C) requiring heat exchange, if desired, to cool the syngas as well as condense any residual water.

Thermal Profile

With the operation of the plasma head being under a cold plasma configuration, there is not a significant enough generation of heat to give cause for thermal

readings of this zone. Temperature measurement for a predictable profile is thus only conducted in the main body of the reactor housing the fixed bed catalyst, which is monitored via eight equally spaced thermocouples. The thermocouples are placed in predrilled holes of appropriate dimensions and sealed tightly at the protruding ends that are connected to the wiring relay. The temperature of the catalyst bed is directly linked to the exo- or endothermicity of the reactions, and also to the conditions of the catalyst, plasma head activity, system pressure, and gas flow rate. As a comparative example that provides an accurate visual of catalyst temperature distribution, this noninduced flow in a laminar to transitional regime produces the temperature profile shown in Fig. 40.10.

The effect of modifying the flowrate through the catalyst suggests that at higher flows, the reaction encompasses a larger volume and initiates further downstream within the catalyst itself. The PRISM differs only slightly in flow path due to its transitional-to-turbulent regime reducing the radial variability of key parameters.

The thermal profile shown in Fig. 40.11 represents the consistency in occurring POX reactions down the length of the catalyst. In actual operation where flow rate and ratio are unaltered set points, the bed temperature and product composition do not deviate by more than the error present in the sensors-measurement equipment. The overall temperature drop within the

Fig. 40.10 Example POX catalyst temperature profile in laminar setting at differing flowrates. The catalyst coating is rhodium and the hydrocarbon is *iso*-octane (after [40.11], reproduced with permission of The Royal Society of Chemistry)

Fig. 40.11 Experimental operation of a PRISM reactor displaying average temperature readings for each catalyst zone over increasing rates of flow. The operational ratio was adjusted only to the automatic feedback control for the temperature rise in the system. The initial set point of the C/O atomic ratio was 0.55, which increased to 0.57 at the completion of the experiment

catalyst bed between thermocouples 2 and 6 is no more than 60°C translating to good thermal stability throughout reactor operation. The rise and fall of zonal temperatures correspond directly to each other and are dependent on the prior zone's temperature, and even more so the active zone temperature (thermocouple 2). At each discrete flow set point, an accurate representation of the PRISM's temperature profile can be observed if no manipulation of flow rate had been done. It should be noted that the PRISM under this experimental

scheme was operated closer to a combustion-oriented ratio at 0.55 of C/O species. As expressed previously in Sect. 40.2.1, *Thermal Equilibrium*, it was stated that peak hydrogen yield is achieved at ≈ 0.85 C/O ratio. While this holds true, results were more than adequate citing consistent results of over 99% methane conversion and a ≈ 1.8 H₂/CO product ratio. It stands to show that improvements can still be made on this already highly effective process, but are not necessary for viability of the technology in the field.

40.3 Cold-Plasma-Assisted Experimentation

40.3.1 Steady State Operation

Many experiments have been conducted at a facility in Brooksville, FL through research as well as trial and error. The PRISM system in a standalone configuration is ready for early-stage commercialization for stable, continuous production of usable clean syngas. Another experimental-phase application has been performed for syngas-hydrogen enhanced combustion in spark-ignited (SI) engines. The benefits of hydrogen fuel addition during combustion are well known to the scientific community, and the difficulties of its implementation have been discussed. A skid that consists of a General Motors 8.11 overhead valve/eight-cylinder

V configuration (OHV/V8) natural gas, turbocharged engine and a 100 kWe corresponding alternator have been integrated with a single PRISM unit for successful continuous slipstream engine operation.

The PRISM is a relatively simple system requiring a fuel valve, air valve, power source, and control system along with some corresponding instrumentation. In continuous operation, the system is stable under a well-controlled apparatus of a quick response ratio feedback loop based on system temperature. Attached are mass flow controllers that dictate the feed input based on ratio control and oxidizer flow rate. Adjustments can be allocated to either set point resulting in an automatic change in fuel flow. The feedback control loop

is responsive to changes in catalyst bed temperature, but focused on the main zone of operation, which is also the highest temperature zone of the process. This keeps reactor conditions favorable for higher hydrogen production and safe during long term operation. The control mapping has been optimized through many phases of testing on the PRISM unit. Manual control input is unnecessary when consistent homogeneous fuels are being used as the system will respond accordingly. This follows suit for the power supply, which operates within its voltage limits to always provide the electrically induced plasma field within the plasma head. The simplicity of the system and stability of the reactor make it possible for the need of only one operator overseeing the process. As syngas is being produced, it is then guided through heat exchange removing the formed water and lowering gas temperature to ambient levels. After a final water knockout point, the syngas is led to a low-tolerance oxygen sensor confirming the absence of oxygen before compression and then to storage of the syngas product. Excess syngas is sent to flare during experimentation.

When added to the 8.11 engine skid, the PRISM functionality remains the same; filtered air is either actively fed to the reactor or naturally pulled through the reactor via the engine requirement. The controls in place respond accordingly to either arrangement. In this case, the gen-set engine is brought to steady operation first, followed by the PRISM reactor, which is fully introduced to the engine fuel inlet. The natural gas valve is then slowly closed until the engine is no longer being fed with fuel other than freshly produced syngas. From this point, system operation will continue until shutdown. It must be noted that there is a drop in engine power return when fully supplied with only syngas, which is mainly due to the excess dilution of nitrogen from air being processed twice during the same system loop. Syngas can also be introduced hot or cold, eliminating the need for heat exchange if deemed unrequired. The main focus of this system is to eliminate NO_x production and the need for exhaust gas after-treatment. Using a five-gas analyzer, NO_x levels have been routinely recorded at less than 10 ppm prior to after-treatment while using slipstream syngas operation.

4.0.3.2 Transients: Startup/Shutdown

The startup sequence for operation of the PRISM begins with simply turning on the power supply and opening system flow. The plasma field is on at all times and initiates the process acting as a spark to ignite a very lean mixture of air to fuel. These gases are well mixed before introduction to the plasma head chamber. As temperatures rise, the fuel mapping for the controls ap-

proaches a fuel-to-air ratio that is richer in operation. Above 900°C the methane will flood the system and be too rich for any oxidation, thus cooling the catalyst bed and stabilizing the reactor conditions. At this point, the temperature of the system reaches its peak moment $\approx 1000^\circ\text{C}$ and will no longer approach this temperature range again under steady operation. The system is now self-sustained and very stable. Any adjustments to the fuel mapping at this point will only induce minor changes in temperature. If flow is increased, then the main reaction moves toward the next catalyst zone followed by the controls. Given added backpressure, a gas chromatograph (GC) analysis can be processed at any point during this time. In order to shut the system down, simply turn off the power supply and close the fuel valve. A slight air peak may cause a minor combustion instance with any remaining fuel in the system, but quickly subsides as shown by the drop in measured temperature. The reactor retains heat well and may require roughly 3 h to return to ambient levels.

In engine operation, many more transient situations must be considered. Startup ensues in the same manner, with normal engine startup first followed by PRISM startup. Once the temperature change in zone 1 approaches zero, syngas is being produced and can now give way to reduced fuel consumption on the engine's main line. Discontinuities from the piston's compression strokes do not affect the stability of the reactor even when air is being pulled through. This setup requires minimal manipulation to operate steadily, but additional instrumentation would be necessary in a real-life application using a motor vehicle where stops are frequent. A few ideas are in place to alleviate these potential transient issues. The most logical approach would be to implement the lowest possible flow through the reactor during engine idle. The system, though it retains heat well, would fluctuate more than desired since the unit is designed for continuous flow and not for on-off applications. If added to current motor vehicles, the benefit of the hydrogen-rich syngas can be used in a cursory manner; this makes the PRISM advantageous in highway situations. To shut the system down, fully open the engine fuel valve while shutting off the reactor fuel valve and power to the unit. After this, total shutdown is as simple as turning the ignition key.

4.0.3.3 Conversion and Efficiency

In order to achieve high conversion and efficiency, optimization on a working system is vital. True optimization requires experimentation, analysis of experiments, and adjustment thereafter from theory. This is a repeatable, stepwise process that demonstrates the versatility of the technology and potential for performance im-

Fig. 40.12 GC results of PRISM operation with pure oxygen

provement. For instance, nonthermal plasma on its own does not provide enough energy or the environment to achieve any significant selectivity of hydrogen and carbon monoxide production. On the other hand, thermal plasma is capable of converting methane into hydrogen unassisted, but the high amount of energy required for thermal plasma generation coupled with the low methane conversion and low hydrogen selectivity is not an economically feasible path to any commercial application. There exists a point, between nonthermal and thermal plasma, which instills the necessary amount of energy required to fully convert the feed stream when coupled with other processes. Plasma does not simply exist in one form; it is affected by intensive properties just as any other phase of matter would by a change in its density or viscosity. The difference with plasma is the constant fluctuation of every property over short time intervals. Methane conversion into hydrogen using only a pure methane feed and nonthermal plasma is close to 6.0%, while thermal plasma with pure methane is near a 12.0% conversion. In an environment supportive of POX using air and methane, thermal and nonthermal plasma systems are capable of achieving a 99.0% conversion of starting material.

Conversion weighed against the energy input to the system is at its peak when nonthermal plasma is used in conjunction with catalysis. The active field of the system provides an ideal environment for the chemical species to react. Deviation from stoichiometry of

POX by decreasing the C/O ratio enhances the selectivity and yield of hydrogen (peaked curve) approximately around $C/O \approx 0.85$ and $T \approx 800^\circ\text{C}$. Efficiency is also increased at higher temperatures. The leaner partial oxidation ratios suggest that a little combustion initially assists in producing greater amounts of hydrogen through the side reactions (mainly steam reformation) immediately downstream in the reactor.

A number of reactions occur simultaneously along the length of the reactor while carrying the electrical properties of the plasma field throughout the process. The participating reactions are combustion, partial oxidation, steam methane reforming, and water gas shift. All of these reactions are reversible in nature, making it difficult to surmise and predict the product outcome from so many variables. The goal is to influence the outcome to the end user's needs, and this can be accomplished through manipulation of the necessary parameters. With a feedback control loop based on internal catalyst temperature and reactant ratio, stable reactor conditions are maintainable and adjustable. Through experimentation and analysis of these parameters at varied set points, a database is established for specific product yield. A production database also allows for early problem detection and error analysis.

Product Measurement

The product stream is analyzed via a small slipstream of gas into a high-precision SRI 1068C gas chromato-

Table 40.1 Volume/mole percentage display of GC results for air and oxygen

PRISM syngas product – GC analysis (% by volume)		
Compound	With air	With oxygen
H ₂	30.7%	58.5%
CO	15.9%	32.2%
CO ₂	3.3%	2.9%

Total	100.0%	100.0%

graph (GC) attached with Haysep D and Molesieve 13X columns. The GC uses a thermal conductivity detector (TCD) with the attachments to accurately measure the molecular content of the syngas that the unit is receiving. An algorithm has been implemented to the GC interface based on calibration gas at various compositions pertaining to the compounds of interest being synthesized. Based on the GC configuration, every compound known to be present in the gas product is accounted for and returned to the user in a percent volume composition. Refer to Table 40.1 and Fig. 40.12 for actual experimental GC results. The GC is maintained frequently and recalibrated on a three-month cycle. Third-party analysis of a process-derived fuel (PDF) from municipal solid waste (MSW) reformed into syngas from producer gas has also been performed resulting in high levels of hydrogen yield and a large

40.4 Analysis and Discussion

40.4.1 Process Challenges

The areas of concern that were encountered during design and operation of the PRISM process are system controls, modeling, catalyst durability, safety precautions, variable feedstock, and overall scale-up. The feedback control loop is responsive to changes in zonal reactor temperature where the fuel-to-air ratio set point adjusts accordingly to balance reaction heat, firstly preventing catalyst damage and secondly for safety in eliminating any potential runaway reaction. Though stable, the system must always be monitored. Plasma-assisted POX with catalysis provides a wide range of variables that are difficult to model at the atomic level. This limits the depth of process understanding to broader generalizations using separate macrolevel modeling techniques and theories that are well established. The catalyst is susceptible to thermal deactivation, coking, carbon deposition, chemical poisoning (typically sulfur), and deactivation after heavy usage over long periods of time.

Table 40.2 GC-MS results of producer gas composition directly after PRISM system reformation

Component	Mole percent	Weight percent
Oxygen and argon	1.995	2.787
Nitrogen	53.749	65.723
Methane	10.668	7.471
Hydrogen	17.789	1.565
Carbon monoxide	11.273	13.783
Carbon dioxide	4.488	8.622

percentage of tar reduction in the gas stream. Results from this experiment are shown in Table 40.2.

The transient issue is minor and ideas are in place to remedy these negatives, such as timing control to maximize the benefits of hydrogen supplementation.

40.4.2 Design Improvements

Startup requires short-term ignition in the form of a modified fuel-to-air ratio. This is viewed more as an unavoidable hindrance that has a greater affect on an operation with a high-frequency modulation between transient and steady-state operation. It is safe to assume that syngas is in full production from cold startup after approximately one minute; this dead time is lessened if system operation was recently shutdown due to the substantial thermal mass of the system. If possible, a more durable catalyst that has greater resistance to sulfur poisoning and thermal decomposition would be ideal for future experimentation and commercialization. This would loosen the restrictions that decrease the lifespan of the catalyst bed.

The system's flow capacity is high for the small footprint of the apparatus itself providing over 150 scfm of high-quality syngas per unit. Dimensions of each PRISM unit are 15" × 18" × 50", approximately. The limitation thus far is the capacity of the mass flow controllers, which reach maximum allowable flow rate before the reaction is extended beyond the catalyst bed. A safe assumption is that the PRISM is able to produce upwards of 200 scfm of syngas. This coincides with nitrogen displacement that reduces product output and system efficiency. Using pure oxygen from gas cylinders is not a viable avenue for long-term system operation, negating the low cost benefits of the process. Pressure swing adsorption (PSA) or vacuum pressure swing adsorption are both viable methods of producing > 95% oxygen content from air in a continuous manner at low operating costs. The physical footprint of the systems tend to be large, but even a small separation of oxygen from nitrogen would provide dramatic improvements in production efficiency and power recovery.

40.4.3 Higher Hydrocarbon Reformation

Longevity tests showing system durability are conducted regularly and for months at a time. Under stable operation, process efficiency does not diminish over time and, in fact, results tend to improve slightly. Under a previous control schema, a fluctuation in syngas product yields and conversion is observed in the range of ±2% of the average data acquired over time. For ex-

ample, average hydrogen percent by volume of syngas was 30% with low-end results being 28% and high-end results being 32% by volume. Some variance could also be attributed to the inconsistent composition of the natural gas pipeline. This range of syngas composition is observed for all components of the product stream during short-term operation as well as month-long continuous experimentation. Data have been logged and thoroughly examined to show stable production of high volume and quality syngas. Reformation efficiency versus stoichiometrically perfect conversion is high in the 80% range for air operation and in the 90% range for oxygen operation. Methane conversion efficiency has been recorded to > 99% at higher process flows while generally in the ≈ 98% range otherwise.

It has been deemed plausible to reform all chains and types of hydrocarbons using the PRISM reactor. Given a vapor phase of feeds such as heptane or aromatics like benzene in stoichiometric proportions with oxygen for POX, a product that consists of mostly hydrogen and carbon monoxide can be achieved. The plasma field imparts enough energy and the heated catalyst bed allows for activation of the POX reaction that could result in near-perfect conversion comparable to the use of methane. Higher hydrocarbon reformation results in a ratio of H₂ to CO much closer to 1.0 than 2.0, which would inhibit downstream processing, but again could be alleviated by a PSA unit to increase hydrogen content. The reformation of waste has also been successfully observed at the facility.

40.5 Synergistic Benefits of Plasma

40.5.1 Chemical Processes

In gasification, a portion of potential product is lost through tar buildup, which consists of higher carbon chained molecules that are condensable, but only at high temperatures up to 400 °C. Not only is it a loss in production, if not properly removed before downstream processing, the tars will obstruct process flow and cause eventual shutdown. These concerns can be dealt with by a plasma-induced field in a catalytic environment supportive of partial oxidation of the hydrocarbons into syngas (Fig. 40.13).

The production of hydrogen is possible through many processes, as it is such an abundant element. The various methods of obtaining hydrogen are energy intensive and also typically involve the destruction of another compound that could hold value on its own. In processes that create excess side hydrocarbons or hydrogen-containing compounds, there is little to no

value in them unless further processing is done. This is true for a side product such as dirty glycerol, which is difficult to handle and costly to remove as well. The PRISM is able to make these side products useful for additional heating to primary processes or for a valuable side product such as methanol. Because of its low operating expense, the PRISM can be utilized in any process looking to maximize its hydrogen potential. PEM and solid oxide fuel cells that run directly on hydrogen are another potential beneficiary of this technology.

40.5.2 Commercial Implementation

This process has the flexibility to create numerous market-worthy products, allowing the user to choose their path of profitability. Syngas, once synthesized, can be taken down any processing path that would use the H₂ and CO molecules as building blocks for the product. Olefins are the raw material for most plastics

Fig. 40.13 Operation and view of the ionized plasma field exposed to the air (pre-catalysis)

and can be produced in a high-pressure, temperature-controlled environment when provided with the proper catalyst. Methanol, ammonia, and diesel fuel are just some of the many other products that can be made from feedstock derived of syngas.

Decreasing emissions from motor vehicles and increasing engine efficiency is a necessary step toward improving air quality and decreasing greenhouse gases. Internal combustion engines for transportation constitute as one of the largest consumers of imported oil and are also a major source of ozone-eliminating gases such as NO_x . A variety of potential improvements are presently being investigated: lean-burn engines, engines designed with increased compression ratios, improved catalyst formulations, use of close-coupled catalysts,

new types of exhaust treatment, electric and fuel-cell powered vehicles, and alternative fuels.

One outlet for plasma reforming technology, which also presents a solution to the negatives of internal combustion in transportation, is for onboard vehicular implementation. In a fully integrated system, the generation of hydrogen as syngas into an ICE allows for lower combustion temperatures, better flame speed and propagation, increased sparkplug life, and decreased NO_x emissions during engine operation. Onboard production of hydrogen may be attractive for reduction of cold-start emissions and minimizing engine cranking during cold start. This is beneficial for catalyst regeneration and posttreatment as well. The robust, compact design of the PRISM unit can be used with a variety of fuels to provide a rapid response without the necessity of reformed gas storage. Complete integration of the vehicle operating system with the PRISM reactor would call for an intuitive approach to achieve a seamless, well-controlled operation. This would factor in startup, shutdown, ratio control, valve timing, and additional temperature sensors, but would otherwise not require further manipulation of either new or old standard vehicle engine designs.

Upon total oxidation or combustion of fuel with or without syngas, large quantities of water and CO_2 are produced in the exhaust. The hydrogen-rich gas may be useful during cold start, both minimizing the cranking, as well as potentially decreasing the hydrocarbon emissions due to cold-start ignition. In an exhaust gas recycle (EGR) process the dry reforming reaction plays a major role in altering the stoichiometry of the system. The main goal of EGR is to lower peak combustion temperature in the piston chamber. This provides a smoother cycle of operation reducing NO_x and ensuring maximum conversion while boosting thermal-to-mechanical efficiency.

40.6 Conclusion

Very few configurations exist, outside highly specialized areas of use, which allow thermal plasma to be implemented in a profit-worthy system. A low energy, nonthermal plasma creates a better source for utilization of resources, providing efficient production of high quality syngas. Nonthermal plasma also requires assistance from catalysis in the form of a tailored reaction as opposed to simple decomposition. If unassisted, gaseous carbon and hydrogen atoms in a heated environment will preferentially recombine into methane instead of separating into hydrogen and carbon monoxide molecules. Plasma-assisted catalytic

POX has great potential to address many environmental concerns while maintaining profitability for the end user. In its present design, PRISM is a viable tool for implementation into small- to middle-scale syngas production plants. Expending roughly 100 W of energy in a robust system configuration built for extended operation, nonthermal single-stage plasma catalysis has proven to be a viable technology for reforming. Full integration of the PRISM reactor into future commercial endeavors is possible with only minor adjustments to the current benchmark operation.

Acknowledgments. This chapter was written with the assistance of Dr. Leslie Bromberg from MIT and Michael Carpenter of RTI International. Leslie has over 40 years of plasma and reformation experience most of which was spent in conducting research, educating students, and writing a vast number of published documents for the field of plasma science and plasma engineering. Michael has degrees in both physics and chemistry with a focus on nanoscience at NCSU. He has participated first-hand in key developments of the PRISM system and successful downstream processing of our fresh syngas product. His insight has been invaluable towards the growth of our technology. We would like to thank Leslie and Michael for their time and contributions to our research and to this book chapter. A kind thank you to all previous studies on reformation and plasma technology, especially to the authors and

contributors whose works were incorporated and cited as an influence to the completion of this chapter. I'd like to thank Shiva Wilson and Nat Mundy of Freedom Energy Tech, LLC and Mr. Larry Bell for their tireless efforts and dedication to the company as well as lending their wisdom and expertise to the technology and the opportunity. Freedom Energy Tech, LLC has the exclusive license on the PRISM Plasma technology. I would also like to acknowledge Chet Staron and Mike Wirthman of TopLine Automotive Engineering, Inc. Finally, I would like to acknowledge the Chemical and Biomedical Engineering Department of the University of South Florida for the thorough education provided to me and every student involved with the department. The credit goes to the well-established curriculum and one-of-a-kind faculty devoted to the wellbeing of each individual and to the engineering society as a whole.

Hydrocarbon

41. Hydrocarbon Processing by Plasma

Robert J. Wandell, Bruce R. Locke

Nonthermal plasma processes have been successfully utilized commercially in air pollution control, ozone generation, polymerization processes, and microelectronics processing. The addition of a liquid phase that contacts the plasma has given rise to a wide range of other potential applications in materials synthesis, biomedicine, and chemical synthesis. Applications in the petroleum and energy fields utilizing organic chemistry plasma processes have been investigated as well, for example, in hydrogen generation, gas reforming, and partial oxidation. Partial oxidation of hydrocarbons is a longstanding challenge in organic chemistry, and recent work with plasma and plasma contacting liquids have demonstrated the formation of alcohols and other oxygenated species from a range of hydrocarbons. This review focuses on the functionalization of hydrocarbons with radical species produced by nonthermal plasma discharges primarily in oxygen and argon gases with liquid water. Since the types of chemical reactions that can be induced by plasma depend strongly on the composition of the gases utilized, the reactor configuration, and the plasma properties, we address two major ways of functionalizing hydrocarbons with plasma; 1) utilization of oxygen radicals from molecular oxygen and 2) utilization of hydroxyl radicals from liquid water. Both methods supply oxidants that lead to similar reaction product distributions and such plasma processes have the potential to produce value-added products efficiently and with reduced environmental impact.

The functionalization of saturated hydrocarbons is a fundamental problem in industrial organic chemistry because there are very limited ways to induce selective reactions into the relatively strong and localized C–H and C–C bonds of these molecules [41.1, 2]. Hydrogen abstraction of alkanes at high temperature, mostly for combustion, has been studied [41.3–11]. However, various catalysts must be employed, and the harsh conditions often lead to over oxidation of the

initially formed alcohols. Enzymes exist and synthetic inorganic catalysts have been developed that selectively oxidize alkanes, typically with hydrogen peroxide addition, but these catalytic methods can be impractical due to the high cost, limited availability of the catalysts, and the relatively slow reaction rates [41.12–14]. Conventional high temperature thermal cracking can generate valuable products; however, the energy costs are significant and the process leads to the generation

of unsaturated hydrocarbons which present additional challenges. Therefore, there is a significant need for new methods that can be used to capitalize on valuable hydrocarbon natural resources to make useful chemical products efficiently and with low environmental impact [41.1, 2, 15]. The use of plasma discharge to induce these reactions has the potential to provide such

an alternative; however, significant challenges must be overcome to facilitate this application. The goal of this review is to provide the current status of plasma processes focusing primarily on hydrocarbon partial oxidation, and to consider this application within the context of other applications of chemical synthesis by plasma processes.

41.1 Historical Aspects

Chemical reactions induced by electrical discharge, including sparks and arcs, have long been of interest since the early observations in the Netherlands on the formation of oily condensed products from ethylene in spark discharges at the end of the 18th century [41.16–19]. Development of commercial ozonizers by Siemens led to an increased interest in chemical synthesis (including ozone and nitrogen oxides) at the end of the 19th century. During the early to middle 20th century, studies on chemical synthesis by electric discharge included ammonia synthesis [41.20–22], acetylene production from methane and hydrogen [41.23], formation of nitrogen oxides [41.24–33], synthesis of other organics (e.g., cyanhydric acid) [41.34–43] and work on nitric acid reactions with water vapor [41.44, 45]. A landmark study of amino acid formation by elec-

tric discharge under atmospheric conditions simulating the earth before the origin of life led to extensive work on electrical discharge-induced chemical synthesis and chemical evolution [41.46–48]. Reviews of the wide range of other organic compounds synthesized by plasma have been published [41.16–18, 49] with more recent work focusing on hydrogen formation and methane conversion due to increased interest in processing of natural gas and the hydrogen fuel cycle [41.50–56].

This review will focus on work dealing with hydrocarbon processing with nonthermal plasma with particular emphasis on the role of water and hydroxyl radicals to induce functionalization into organic molecules and to form high value added products rather than complete oxidation or polymerization.

41.2 Properties of Plasma – Thermal versus Nonthermal

Plasma is an ionized gas containing both positive and negative ions, as well as free electrons. The overall volume of the plasma is electrically neutral because charge is not lost to the surroundings [41.57]. Many types of plasmas exist in nature and technology. They are primarily distinguished by the density of ions and electrons and the energy of those species. Thermal plasmas have very high energies as well as densities, and in such plasma the energy of the free electrons is of the same order of magnitude as the ions and molecules (temperatures > 10 000 K). In nonthermal, or cold plasma, the free electrons have much higher energies than the ions and molecules; here the temperature of the background gas can be close to ambient while the electron temperatures range from 10 000–100 000 K (1–10 eV) [41.58].

A key factor in utilizing a plasma process to perform chemical synthesis is to suppress reactions that destroy the desired products through degradation reactions with ions, radicals, and other species formed in the plasma. Some thermal plasma processes can utilize high quenching rates (i. e., steep spatial or temporal

gradients of plasma conditions) to partially suppress these back reactions [41.49]. In contrast, nonthermal plasma offers the potential to perform useful chemistry by utilizing primarily the higher energy electrons to initiate reactions through electron collisions with the background gases to produce radicals, ions, and excited species which can react with the targets, and because of the low ambient background gas temperature less energy is utilized in thermal processes and less heat is lost.

One of the most common and effective ways of making nonthermal or cold plasma for technological applications is to use electrical discharges by AC (alternating current), DC (direct current), or pulsed electric fields [41.60]. Microwave and radiofrequency plasmas are also used. A large number of reactor configurations utilizing various electrode arrangements and plasma contacting schemes have been investigated for a variety of applications [41.61]. Figure 41.1 shows an example of the commonly studied gliding arc plasma discharge [41.55, 59].

41.3 Commercial Viability of Plasma Processes

The major commercial successes of chemical synthesis with plasma are in ozone generation, plasma polymerization, and the fabrication of semiconductor devices [41.19, 62, 63]. It is noteworthy that the application of plasma processing in semiconductor manufacturing has contributed to the success of the \$ 300 B worldwide market in computer technology [41.19]. It can also be noted, that pilot- and commercial-scale plasma processes have been successful in air pollution control [41.64–70] and some pilot-scale systems for water pollution control have been developed [41.71].

The commercial success of ozone generation with oxygen plasma discharge is due to the key factor of reaction selectivity. To generate ozone with a plasma discharge, only one chemical feed to the system is necessary, molecular oxygen. Not only can oxygen be easily separated from air, but this single feedstock limits the chemical reactions that are possible to ones that only contain oxygen species [41.72–75]. In turn, this significantly narrows the number of possible stable products which can be generated, the most dominant

being ozone, making the process commercially viable. Ozone generation by plasma discharge does not require catalyst due to the relatively simple chemistry, and only compressed oxygen is needed as a chemical feed with no separation or purification of the products generated required. It can be noted that in practical applications the tradeoff between using pure oxygen and air requires consideration of the cost of the oxygen relative to the formation of by-products from air and lower ozone generation efficiency. More complicated systems of chemical reactions occur in plasma polymerization and plasma processing in microelectronics where process control by variation of feed gas composition and other plasma properties can be used to facilitate the desired reactions and both of these applications feature plasma interactions with substrate surfaces. It is possible that a deep understanding of the underlying chemistry, physics, and engineering principles involved in initiating chemical reactions with electrical discharges will lead to the development of new plasma chemical synthesis applications to petroleum-based technologies.

41.4 Challenges in Performing Selective Organic Reactions with Plasma

The reactions of organic compounds in plasma discharges have been investigated for a wide range of applications and conditions including plasma discharge in pure organic liquids, oxidation of dilute organic compounds in liquid water for pollution control [41.76–81], and the more commonly studied and commercialized case of plasma polymerization [41.63]. However, there

are important differences between the functionalization of hydrocarbons to produce small intermediate products by plasma and the intensively studied case of plasma polymerization. It is because of these differences that polymerization with plasma has become commercially viable, while selective functionalization with plasma has not. In plasma polymerization, the desired goal is to

form a surface polymer coating using gas phase plasma which contains the precursor molecules. In such cases, a large conversion is required to form the coating. In order to produce large conversions, high plasma energy is required which leads to complete dissociation of the precursor compounds into small organic fragments. The resulting recombination reactions are not significantly selective due to the large distribution of compounds generated and the large number of possible chemical reactions which can occur [41.63]. While this does not pose a problem for surface coating, a significant challenge in chemical synthesis of smaller nonpolymeric compounds with plasma discharge is the requirement for higher selectivity. Although selectivity may come at the cost of lower conversion, this cost can often be compensated in synthetic chemistry by component recirculation as well as series or parallel reactor designs [41.82].

A second major issue relates to the location where the reactions occur. In plasma polymerization there is still debate on whether the main polymerization reac-

tions occur in the gas phase or on the substrate surface. While both cases are predicted to lead to the *irregular structure* of the polymer, it has been shown that the reactor pressure and plasma pulsing can influence the location of these reactions [41.63]. In gas–liquid plasma systems the physical location of the plasma chemical synthesis will depend, in part, on the volatility of the precursor molecule. Under conditions of low volatility, the plasma radicals may directly impinge on the liquid surface initiating reactions at the interface or even generating some radicals in the liquid phase. For high volatility cases, the organic liquid is fully vaporized and can react directly in the gas phase. Different product distributions are expected in these different conditions. A third issue relates to modification of reactor/reaction conditions including pulse generation by the power supply. For example, shorter plasma pulses (of order μs) (or with superimposed pressure pulses) have been shown to control chain propagation in plasma polymerization, but again at the cost of yield [41.63].

41.5 Strategies to Induce Selectivity

As previously stated, a major hurdle in the development of viable bulk phase chemical synthesis with plasma discharge which greatly complicates commercialization is that overall production is limited by degradation of the desired product by electron or radical attack before it can be collected. This issue is a fundamental problem in that many synthetic processes are dominated by endothermic reactions where electron impact dissociation of the parent compound is rapidly followed by a series of radical chain reactions leading to the product, which itself is susceptible to additional attack by radical species [41.83]. Thus, one must control or stop the plasma-induced radical reactions in order to promote reaction selectivity.

Typical strategies to suppress plasma degradation reactions are to impose strong spatial and temporal gradients between the plasma and the surroundings so as to limit the degradation reactions and/or to rapidly quench undesired radical species [41.83–86]. Partial selectivity can be achieved by the addition of gas and/or liquid phase radical quenchers which prevent undesired reactions and potentially enhance desired ones. While it is desirable to introduce completely inert quenching media it is difficult to find any such compounds that do not to some degree participate in the plasma reactions. Additional selectivity can also be achieved by:

1. Decreasing residence time of all species by adjusting reactor geometry and flow rates

2. Imposing large spatial or temporal gradients on the plasma
3. Adjusting characteristics of the applied electric field
4. Imposing large cooling gradients in the system.

Another strategy is to sequester the desired product in an environment that protects it or removes it from the plasma [41.87, 88]. This concept is analogous to the chemical engineering processes that utilize simultaneous reaction and separation [41.82, 88–91]. The addition of a liquid phase in which the desired product is highly soluble was a significant advancement in chemical synthesis with plasma, and well studied in the synthesis of hydrazine from ammonia where it was shown that the introduction of a liquid ethylene glycol solution can significantly increase the energy yield for hydrazine [41.92]. In that study, the liquid phase was sprayed in to the gas phase discharge and acts only as an absorbent which sequesters and protects the hydrazine molecule after it has been formed in the gas phase.

Water can also be used as an absorbent in plasma systems. It has been shown that formaldehyde, methanol, and hydrogen peroxide can be synthesized from methane–water vapor mixtures [41.93]. This situation provides a unique advantage in that the liquid water acts not only as an absorbent but also as a source of reactive species (hydroxyl radicals, $\bullet\text{OH}$). Significant work has been conducted to investigate various reactor designs which increase the gas–liquid interfacial area to

take advantage of this duality, particularly in the generation of hydrogen peroxide from liquid water [41.87, 94, 95]. The large solubility of hydrogen peroxide in liquid water is one of the primary reasons the energy yield for hydrogen peroxide is high in liquid water/gas plasma systems [41.87]. The thermodynamics of such phase equilibrium are extensively covered in the literature [41.96]. However, it should be noted that the nature

of the gas–liquid equilibrium and component solubility becomes significantly more complicated in systems with more complex chemistry such as those where hydrocarbons are present. Nonetheless, some selectivity has been demonstrated in a gas phase microwave plasma with *n*-hexane vapor in flowing argon through changes in the plasma input power, feed flow rates, and location of the feed [41.97].

41.6 Radical Chemistry in Various Plasma Discharges

Because of difficulties in analyzing the diverse distributions of reactive species formed when a large number of complex reactants such as hydrocarbons are subjected to plasma, studies have been made in situations with limited chemical complexity, where some degree of selectivity can be achieved and analysis simplified. These studies are essential towards understanding the fundamental factors involved in generating reactive species with plasma discharges before more complicated situations can be understood. As already mentioned, of these simplified cases, electrical discharges with pure oxygen gas are among the simplest.

When pure oxygen is subject to a plasma discharge the dissociation of diatomic oxygen occurs through direct electron impact as shown in reaction (41.1).

The O resulting from reaction (41.1) may be of the form ^3P , ^1D , and ^1S . In the case of ozone generation the plasma parameters can be adjusted to favor the recombination of O to form O_3 through reaction (41.2), where M is a third collision partner [41.74].

Alternatively, the plasma and reactor parameters, particularly pressure, can be adjusted to favor the generation of $\text{O}(^3\text{P})$. This highly reactive species can then be utilized to oxidize other components in the plasma system [41.98].

Other studies utilizing liquid or vaporized water and noble gases have established that the major reactive species formed when electrical discharges contact liquid water are hydroxyl radicals ($^{\bullet}\text{OH}$) and hydrogen peroxide (H_2O_2) [41.76, 87, 99–104]. Other species, including molecular hydrogen (H_2), molecular oxygen (O_2), and reducing compounds such as O_2^- and $^{\bullet}\text{H}$, can also be formed [41.102, 105, 106]. When liquid water contacts a plasma channel a portion of the liquid is vaporized into the gas phase where it then undergoes reaction. Many reactions with water can occur in the gas

phase including electron dissociation reactions (41.3) and (41.4) [41.107, 108].

Generally, the hydroxyl radical density in gas–liquid plasmas is sufficient to produce hydrogen peroxide by hydroxyl radical recombination through reaction (41.5), and H recombination forms H_2 by reaction (41.6).

Limitations on hydrogen peroxide formation generally come from reactions that either degrade it by radical attack (reaction (41.7)) or limit the hydroxyl radical density through recombination to make water (reactions (41.8) and (41.9)). Therefore, strategies to increase the formation of hydrogen peroxide require means to suppress reactions (41.7)–(41.9). At high temperature, thermal degradation of hydrogen peroxide can also occur.

It is for the above reasons that the energy yield for hydrogen peroxide is significantly higher for cases with liquid water rather than for vaporized water alone [41.87]. In gas phase systems, the hydrogen peroxide produced can quickly undergo further degradation by the plasma. However, when liquid water is present, the liquid phase acts as an absorbent to collect and protect the chemical species generated in the plasma phase. Liquid water also provides a continuous source of water molecules transferring into the plasma by evaporation. In these cases, the plasma is pulsed and of low energy so as to not completely evaporate the liquid phase and this leads to quite large energy yields for H_2O_2 [41.109].

41.7 Pure Organic Compounds in Direct Contact with Plasma Discharge

When organic molecules such as hydrocarbons are directly subject to plasma discharge the chemistry can become significantly more complicated due to the likelihood of breaking carbon–carbon and carbon–hydrogen bonds. Generally, in alkanes, the C–C bonds are much weaker than the C–H bonds. For example, the C–C bond dissociation energy in *n*-hexane is 338.9 kJ/mol, while the C–H bond energy is 410.03 kJ/mol. Thus, when vaporized hydrocarbons are directly subject to a plasma discharge one would expect the C–C bond to break more easily than the C–H bond resulting in fragmentation of the molecule [41.110].

Plasma generated directly in an organic liquid phase has been demonstrated to form diamond coatings [41.111] and other carbonized materials such as nanofibers [41.112]. Gas phase plasma (spark discharge: 3–12 W) generated with argon over heavy oils (*n*-C₁₀ to *n*-C₂₅ hydrocarbons) has been shown to lead to significant chain breakage forming one to four carbon-containing compounds with ethylene and hydrogen being the predominant species [41.113, 114]. Liquid *n*-hexadecane was studied as a model compound for hydrocarbon oil and was cracked into C₆ to C₁₅ hydrocarbons using a dielectric barrier discharge with a methane carrier over the liquid hydrocarbon [41.115]. In another example, crude oil was treated with a dielec-

tric barrier discharge for various carrier gases (H₂, CO₂, CH₄) where rheological analysis showed a decrease in viscosity of the crude oil treated by plasma, and nuclear magnetic resonance (NMR) analysis showed that the plasma treatment primarily led to water extraction from the naturally occurring emulsified water in the crude [41.116]. Further, an 80 W microwave plasma with water vapor over an aromatic heavy oil liquid (viscosity: 2–8 cSt, density: 1100 kg/m³, distillation interval: 280–500 °C) demonstrated a series of reaction products including long-chain aromatics, linear and shorter aromatic rings, and also, syngas, CO₂, and small alkanes and alkenes. Trace amounts of other carbonaceous products were also reported [41.117]. Clearly at high enough plasma power and exposure time, a wide range of hydrocarbons, even heavy oils, can be cracked to relatively small compounds. On the subject of smaller gaseous hydrocarbons, extensive literature also exists on methane conversion in dry gas plasma reactors into higher hydrocarbons [41.118–120]. Key issues that will make these types of applications useful for chemical synthesis of valuable products are controlling or stopping plasma-induced radical reactions and promotion of reaction selectivity, which, as previously discussed, is an extremely difficult task when fragmentation and polymerization are predominant reactions in the system.

41.8 Functionalization of Hydrocarbons with Plasma-Generated Radical Species

In order to avoid the fragmentation and polymerization seen when pure organic compounds are subject directly to plasma discharge studies have been performed with organic molecules mixed with other easily ionized compounds such as oxygen or water. The strategy here is to not ionize, dissociate, or otherwise activate the organic molecule directly with the free electrons in the plasma. Instead, reactive chemical species are produced from the other major components in the mixture, which are then able to attack the organic molecules present in the system.

One of the simplest of these plasma systems is the oxidation of methane with reactive species formed in oxygen or carbon dioxide plasma discharges. Gas to liquid conversion of methane to methanol has been demonstrated in these systems [41.121–127]. Research efforts have also been devoted towards methane to methanol and/or formaldehyde conversion with water vapor and or liquid water films [41.93, 125, 128–130]. As with the formation of hydrogen peroxide [41.131–

133] and hydrazine [41.134–138], the formation of methanol may be optimized under conditions where degradation reactions with radicals are minimized and over oxidation to CO and CO₂ is suppressed [41.130]. The reaction kinetics of methane oxidation have been extensively studied [41.139–141] and include the main reactions (41.10)–(41.14) [41.141].

In plasma discharge with humid gas, *Okazaki* [41.129] suggests that the direct conversion of methane to methanol, reaction (41.15), proceeds by the direct reaction of methyl radicals, CH₃·, with hydroxyl radicals

produced from water.

Using a 500 Hz pulsed discharge reactor at approximately 400 °C with a relatively low pressure of 10–40 Torr and 2–6 W power, they found a methanol yield of approximately 0.8% with energy yields of up to 10 g/kWh (8.68×10^{-8} mol/J) for glow-like discharge. However, with a high-voltage spark-like discharge with lower power (5 mW) they claim approximately 100 times better efficiency at 1 kg/kWh (8.68×10^{-6} mol/J). In addition to methanol, formaldehyde and formic acid were also formed. While the yield was relatively small, the energy efficiency is extremely high and would be economically competitive.

Larger hydrocarbons can also be successfully oxygenated by oxygen radicals produced from oxygen plasmas to form predominantly alcohols and ketones [41.18, 98, 142–160]. However, functionalization

of organic compounds with hydroxyl radicals formed from water plasma systems has been less studied. Oxidation with water plasma discharges has mostly been limited to water pollution control and biomedical applications such as sterilization where the goals are larger degrees of mineralization [41.94, 161]. Recent reviews on the chemistry and physics of plasma discharges in contact with liquid water discuss hydroxyl radical reactions with various organic compounds including those of interest in biology such as cell membrane components [41.61, 94, 162, 163]. It can also be noted that plasma oxidation in water has significant similarities with supercritical water oxidation for both chemical destruction and hydrogen formation [41.164–174]. In addition, the functionalization, or partial oxidation, of hydrocarbons such as *n*-hexane, cyclohexane, and cyclohexene with radicals produced from water by plasma discharges has been demonstrated, with results similar to that of oxygen plasmas [41.109, 175].

41.9 Functionalization of Liquid Hydrocarbons with Oxygen Plasma

Because of the ease of generating $\text{O}(^3\text{P})$ radicals with oxygen plasma discharges, significant work has been conducted to utilize the high reactivity of this species to oxygenate various types of hydrocarbons. A schematic of an apparatus frequently employed to perform such experiments is shown in Fig. 41.2 [41.142]. In this system, $\text{O}(^3\text{P})$ produced by the gas phase oxygen plasma impinge directly on the surface of the liquid hydrocarbon under investigation, which is well mixed and cooled to a temperature close to its freezing point. The cooling prevents vaporization of the hydrocarbon into the gas phase plasma (8–40 W) which would create the potential for fragmentation and polymerization. Here the goal is to control the plasma conditions so that radical chain reactions that would normally form a polymer film are not favored. Thus, the relative amount of alkyl radical must be low compared to the plasma formed $\text{O}(^3\text{P})$ so that fragmentation and polymerization can be suppressed in favor of oxygenation. It is for this reason that cooling of the liquid hydrocarbon is an essential aspect of this system.

Utilizing the system shown in Fig. 41.2, functionalization has been demonstrated for a variety of short- and long-chain normal alkanes (*n*-hexane – 1.02×10^{-8} mol/J, *n*-heptane, *n*-octane, *n*-dodecane – 1.11×10^{-8} mol/J, and *n*-tridecane – 7.48×10^{-8} mol/J) as well as branched alkanes such as 4-methyl-heptane (9.77×10^{-8} mol/J) and squalane (2,6,10,15,19,23-hexamethyltetracosane) (4.87×10^{-8} mol/J) [41.98, 158].

In the experiments with normal alkanes, the predominant products generated were secondary alcohols and ketones. One of the most interesting results of these experiments is that functionalization of the primary carbons of these molecules did not occur. An explanation for this lies in the fact that previous research has suggested simple hydrogen extraction is the dominant mechanism in the reaction of saturated hydrocarbons with $\text{O}(^3\text{P})$ and this results in the generation of an alkyl and a hydroxyl radical as shown in reaction (41.16) [41.158].

With this information, the preferential attack on the secondary and tertiary carbons in these experiments can be accounted for by the different energies of the various C–H bonds found in saturated hydrocarbons as illustrated in Fig. 41.3. This hypothesis is supported by results with 4-methyl-heptane where the major product was found to be 4-methyl-4-heptanol (52.6%), the result of hydrogen abstraction of the single tertiary carbon in the molecule as shown in the reaction in Fig. 41.4 [41.98].

These experiments also demonstrated that the pressure of the system, the temperature of the liquid hydrocarbon, and the total reaction time significantly impact overall conversion of the hydrocarbons. In the case of temperature, maximum conversion of the hydrocarbon

Fig. 41.2 Low-pressure oxygen plasma system (reprinted (adapted) with permission from [41.142], Copyright (2002) American Chemical Society)

Fig. 41.3 Various bond dissociation energies for a *n*-hexane molecule

was found at temperatures closest to the pure component freezing point of the liquid hydrocarbon. Once the freezing point was reached and solidification of the pure liquid hydrocarbon commenced, conversion sharply decreased because the reactivity of active oxygen species and solid particles is negligible. Pressure

was found to significantly impact the density of $O(^3P)$ atoms. An optimum pressure was found to maximize the $O(^3P)$ population, which resulted in the highest conversions [41.158]. Higher conversions were also achieved with longer total reaction times. However, it was also shown that the reaction time has an additional effect on the selectivity of the reaction products [41.98]. This is apparent in the case of squalane, where increasing the reaction time increased the ratio of ketones to alcohols generated. An explanation for this can be found in the fact that the reactions to produce the ketone products are a result of interaction between $O(^3P)$ and the previously generated alcohols, an example of which can be found in Fig. 41.5.

In addition to these alkanes, functionalization of various liquid olefins using the system described in Fig. 41.2 has also been investigated [41.98, 159]. The

Fig. 41.4 Oxidation of 4-methyl-heptane to an alcohol by attack with $O(^3P)$

Fig. 41.5 Oxidation of 4-methyl-heptanol to a ketone by attack with $O(^3P)$

Fig. 41.6 Oxidation of *n*-propyl-cyclohexane to 1-propylcyclohexanol

Fig. 41.7 Oxidation of propylbenzene to *o*-*n*-propylphenol

trends of overall conversion with the temperature of the liquid hydrocarbon and reactor pressure are the same as those seen for alkanes. However, in the case of reaction time versus product distribution, significantly higher conversions were found at much shorter reaction times with olefins than with alkanes. This is a result of the higher reactivity and faster rate of reaction between the $O(^3P)$ atoms and the hydrogen bound to the unsaturated carbons. Because of the change in chemistry, intermediate epoxide products are generated before the alcohols or ketones are formed. When the results for 1-dodecene are examined the epoxide and aldehyde products dominate for short reaction times. However, when the reactions are allowed to proceed, these compounds further oxidize into alcohol and ketone products, which dominate the product distribution for long reaction times [41.98]. From a commercial viability standpoint, comparison of the product distributions found for *n*-dodecane and 1-dodecene are significant, wherein if reactions are allowed to proceed for long periods with these differing starting materials the same products can be generated because oxidation beyond the ketone does not appear to be favored. This suggests that under certain conditions the same product distributions can be achieved for a mixture of an alkane and alkene of the same carbon number, a result which could prove important due to the difficulty of separating such chemically similar components from a mixture.

When various branched cyclic hydrocarbons were investigated it was found that the predominant products resulted from $O(^3P)$ reactions with the branched carbon in the ring, Fig. 41.6 [41.142]. In contrast, when branched aromatics were examined, the dominant products were a result of alcohol addition to an unbranched carbon in the conjugated ring [41.160], Fig. 41.7. With this information, combined with data from the oxidation of other more complex branched hydrocarbon species, as well as mixtures, it is possible to rank the reactivity of $O(^3P)$ with the various types of hydrocarbons

in the following manner: olefins are the most reactive, followed by branched alkanes, then normal alkanes, aromatics, and finally naphthenes [41.143].

Other work conducted with a different type of oxygen plasma reactor system (i.e., dielectric barrier discharge, DBD) illustrates the reactivity trends of various hydrocarbons with $O(^3P)$ in an alternate manner [41.145]. In this work, oxygen saturated with various hydrocarbons (*n*-hexane, cyclohexane, cyclohexene, and cumene) flowed through a dielectric barrier discharge reactor. The following trend in energy yield (moles of functionalized products generated/mean discharge energy) for conversion of these species was found: cyclohexene (3.64×10^{-7} mol/J) > cumene (2.77×10^{-7} mol/J) > cyclohexane (1.99×10^{-7} mol/J) > *n*-hexane (1.09×10^{-7} mol/J). When the major products for each hydrocarbon are compared with these energy yields, shown in Table 41.1, similar trends for the reactivity of $O(^3P)$ with various types of hydrocarbons can be seen for the DBD reactor system as was found with the system shown in Fig. 41.2.

The high energy yield for cyclohexene with the DBD system can be attributed to unsaturated hydrocarbons having the highest reactivity with $O(^3P)$, in that the dominant product was a result of oxidation of the double bond in the ring structure. The major product from cumene was dimethylphenylcarbinol, a result of oxidation of the tertiary carbon of the branch off the aromatic ring, Fig. 41.8. Therefore, the high energy yield for cumene can be attributed to the high reactivity of $O(^3P)$ with the tertiary carbon of branched alkanes. Following suit, the oxidation of cyclohexane was less energy efficient due to it being an unbranched naphthene, which

Table 41.1 Product distribution and energy yields for oxidation of hydrocarbons in DBD with oxygen. G is the energy consumption for the conversion of the starting hydrogen. Note: G is the inverse of energy yield (after [41.145])

Compound	G (kWh kg ⁻¹)	Products	Proportion (wt %)

contains only the less reactive, secondary carbons. It is interesting to note that the product distribution was significantly narrowed in the case of cyclohexane when compared to the other hydrocarbons investigated in this study. With cyclohexane, the distribution was narrowed to only two major products. This displays a unique quality of unbranched cyclic hydrocarbons, where all the carbons of the molecule are chemically indistinguishable and attack on any one of them would result in the same product.

On the basis of the results from the previously discussed work, one would expect the energy yield for *n*-hexane to be equal or greater than cyclohexane. However, the energy yield for the functionalization of *n*-hexane was almost half of what was found for cyclohexane when both molecules were studied in the same DBD reactor system. A possible explanation for this difference is oxidation of the primary carbon of the *n*-hexane molecule did not occur in the low-pressure oxygen system described in Fig. 41.2, which is likely due to its higher bond dissociation energy. However, in the experiments performed with the DBD reactor, hexanal was one of the predominant products. While it is

still unclear why oxidation of the primary carbon occurred in one system and not the other, the higher bond dissociation energy of the primary carbon is a likely explanation for the lower energy yield.

While the reactivity trend in the DBD system is mostly in line with that of the low-pressure oxygen system, it should be noted that the energy yields for total conversion with the DBD reactor are approximately an order of magnitude higher. One major difference between the two systems that could be attributed to this is the fact that the hydrocarbon was vaporized into the oxygen gas feed in the DBD reactor in low concentration (≈ 10 ppm), while a liquid hydrocarbon was used in the low-pressure oxygen system. The difference in discharge power and operating pressure are other possible explanations. Lower discharge power has been shown to result in higher energy yields in other plasma systems [41.176]. Discharge power for the DBD system was 10.6 W, whereas the discharge power for the low-pressure oxygen plasma system was 29 W. Additionally, an interesting advancement in the DBD reactor system discussed above should be noted, where it was shown that the energy yield for cyclohexane and *n*-hexane could be significantly increased (1.99×10^{-7} mol/J $\rightarrow 4.03 \times 10^{-7}$ mol/J for cyclohexane and 1.09×10^{-7} mol/J $\rightarrow 1.51 \times 10^{-7}$ mol/J for *n*-hexane) with the addition of a condensed phase of the liquid hydrocarbon [41.150]. As previously discussed, this liquid phase acts as an absorbent to collect the generated products, protecting them from the gas phase discharge.

Table 41.2 Properties of LCGO before and after treatment with oxygen plasma (after [41.143])

Property	Original	Original treated −40 °C, 120 min	Simulated	Simulated treated −90 °C, 60 min
Alkanes (vol.%)	62.1	73.9	61.4	73.9
Aromatics (vol.%)	34.8	26.1	34.1	26.1
Olefins (vol.%)	3.1	0.0	4.5	0.0
Carbonyl index (%) ^a	0.0	6.0	0.0	2.4
Alcohols and epoxide index (%) ^a	0.0	4.4	0.0	6.5

^a Calculated from NMR spectra

In order to demonstrate the potential commercial application of these oxygen–hydrocarbon plasma systems, actual and simulated mixtures of LCGO (light cycle gas oil) were prepared and treated with the low-pressure oxygen plasma reactor system. An assay of the mixtures both pre- and post-treatment can be found in Table 41.2 [41.143]. This table shows that the olefins in the mixtures were completely converted in both plasma-

treated samples, a result which is attributed to their high reactivity. In contrast, while there were no alcohols or carbonyl (ketone) compounds in the untreated mixtures, treatment with plasma demonstrated significant oxygenation of both samples. It should also be noted that the percent volume of alkanes increased in the samples after treatment while that of the aromatics decreased.

41.10 Functionalization of Liquid Hydrocarbons with Water Plasmas

While significant work has been performed to investigate the use of oxygen plasmas for the functionalization of hydrocarbons, the use of radicals produced from water has been limited primarily to pollution control where the objective is more complete oxidation [41.76]. Only a limited number of studies have explored the high reactivity of the radicals produced when water is introduced into a plasma discharge (reactions (41.3) and (41.4)) in order to functionalize the organic molecules to produce partially oxidized products. Of these studies, one subjects vaporized water molecules to a low-pressure plasma discharge to generate reactive species and utilized a system almost identical to that shown in Fig. 41.2 [41.175], while a second system utilized a plasma discharge in direct contact with liquid water to generate the reactive radical species [41.109]. In addition to work already cited previously on methane conversion in humid gases, other work involved the functionalization of methane with a pulsed corona discharge using oxygen gas, water vapor and discharge over a liquid film of water [41.141].

In the study utilizing low-pressure water vapor, it was shown with emission spectroscopy that the relative abundance of active species in the plasma was significantly affected by the flow rate of the water vapor, Fig. 41.9 [41.175]. It was shown that some reaction selectivity can be achieved by exploiting this relationship through the fact that $\cdot\text{H}$ radicals would hydrogenate an olefin while O and $\cdot\text{OH}$ would lead to oxidation. To explore this, cyclohexene was utilized to

test if the reaction conditions with various water vapor flow rates favor either oxidation or hydrogenation. It was found that at low water vapor flow rates hydrogenation dominates, thus cyclohexane was found to be the predominant product generated (50.94%), a result

Fig. 41.9 Relative abundance of active species in water vapor plasma. Reprinted with permission from [41.175]. Copyright (2002) American Chemical Society

which coincides with the high abundance of $\cdot\text{H}$ radicals found under these conditions. In contrast, at higher water vapor flow rates oxidation dominated, shifting the product distribution towards ketone and alcohol products. At a discharge power of 100 W, the energy yield for the conversion of cyclohexene with this system was found to be 1.89×10^{-9} mol/J when hydrogenation dominated and 1.62×10^{-9} mol/J when oxidation dominated [41.175].

In a study utilizing plasma directly impinging on a liquid water surface, the functionalization of *n*-hexane and cyclohexane was investigated [41.109]. Here, the hydrocarbons were vaporized at low concentration (approximately 10 ppm) into the gas phase. This low concentration was essential to avoid fragmentation and polymerization of the hydrocarbon. In this system, the liquid water acted not only as a source of radical species but also as a sink to collect the functionalized products. The product distributions in this study are similar to those found for the oxygen plasmas previously discussed [41.150]. For the case of *n*-hexane, the major product identified were 3-hexanol (26%), 2-hexanol (21%), 3-hexanone (17%), 2-hexanone (17%), 1-hexanol (11%), and hexanal (8%). For cyclohexane the major products found were cyclohexanone (47%), cyclohexene (20%), cyclohexanol (19%), hexanal (11%), and 2-cyclohexenone (2%).

When the distribution of products generated from the oxidation of *n*-hexane in this system is examined, the radical species appear to preferentially attack

the C-2 and C-3 carbons of the *n*-hexane molecule. This is indicated by the lower ratios of 1-hexanol and hexanal in comparison to the ketones and secondary alcohols, and these results are consistent with those in the previous study with oxygen plasmas. When the distribution of the products generated from the oxidation of cyclohexane is examined, the product distribution is significantly narrowed when compared to the oxidation of *n*-hexane, as evident from the large portion of cyclohexanone, 47%, found relative to the other products. The fact that there is no distinction between carbons in the cyclohexane molecule again leads to the increase in selectivity. Detailed reaction pathways for this system using both density functional theory and experiments have also been reported [41.177].

The energy yield for products generated from *n*-hexane in this study was found to be 8.6×10^{-9} and 9.0×10^{-9} mol/J for the products of cyclohexane. These values are approximately an order of magnitude lower than those found for the conversion of *n*-hexane and cyclohexane by oxygen plasma in the DBD system previously discussed [41.150]. However, it should be noted that this does not represent the total energy yield for all generated products, because hydrogen peroxide was also produced with an energy yield of 0.54 mol/kWh (1.5×10^{-7} mol/J). Therefore, it may be possible to significantly increase the energy yield for the oxygenated products in this system by capitalizing on the unutilized hydroxyl radicals which generate the hydrogen peroxide.

41.11 Conclusions and Future Trends

The main factors which limit the commercial viability of functionalizing hydrocarbons with plasma discharge are percent conversion, energy yield, and product distribution. It has been demonstrated that for a given experimental apparatus, yield and selectivity for a particular compound can be optimized by varying parameters such as pressure, discharge power, and reaction time. However, the structure of the starting material itself also plays a large role in these factors as well as the resulting distribution of products. One of the major complicating factors in assessing the viability of these processes is that there are many different plasma reactor configurations as well as resulting plasma properties which can be employed to study these processes. This makes drawing general conclusions for various systems difficult to formulate.

In order to develop a more complete understanding of which factors dominate these plasma systems, more data is needed for various experimental condi-

tions in a single reactor system. Studies which include variation in the oxygen–water vapor content to determine differences in oxidation while utilizing various radicals are needed. In addition, because there are numerous reactor configurations available to study plasma processes it is necessary to report more detailed information on the various plasma properties of these systems such as electron density, gas temperature, and electron energy to allow for more relevant comparison.

Nonetheless, these systems show particular promise in improving the quality of mixtures of fuel oil or gas by oxygenation. A one-step plasma oxidation process may provide similar results as the current commercially practiced oxygenation method where oxygenate compounds are separately added to these fuels in order to improve performance and reduce exhaust emissions. Because olefins have been shown to be the most reactive chemical species in these plasma processes, mixtures

with high concentrations of these molecules would be particularly suited to this method.

Acknowledgments. This work was partially supported by the National Science Foundation grant CBET

1236225 and Florida State University. We would also like to thank Prof. Igor Alabugin and Mr. Stefan Bresch for collaboration on studies dealing with electrical discharges and hexane and Prof. Sam Hsu for discussion and encouragement to prepare this chapter.

Important Conversion Factors in Petroleum Technology

Table 1 Oil volume and mass

To convert Into				
	Tonnes (metric)	Kiloliters	Barrels	US gallons	Tonnes/yr ^b
Tonnes (metric)	1	1/SG ^a	6.2898/SG ^a	264.17/SG ^a	–
Kiloliters	1 SG ^a	1	6.2898	264.17	–
Petroleum barrels	0.159 SG ^a	0.159	1	42	–
US gallons	0.0038 SG ^a	0.0038	0.0238	1	–
Barrels/day ^b	–	–	–	–	58.03 SG ^a

^a SG = specific gravity of the oil @ 15.55 °C

^b For converting between mass and volume, some sources use an assume or average density. That can be misleading and is not best practice

Table 2 Flow/consumption ratios

To convert Into	Multiply by
Standard cubic feet per barrel (scf/bbl)	Normal cubic meters per cubic meter (Nm ³ /m ³)	0.178

Table 3 Geothermal gradients

To convert Into	Multiply by
°C/100 m	°F/100 ft	0.549

Table 4 Density

To convert Into	Use the formula
API gravity	Specific gravity @ 60 °F (sp.gr.)	API gravity = (141.5/sp.gr.) – 131.5
Specific gravity @ 60 °F (sp.gr.)	API gravity	sp.gr. = 141.5/(API gravity + 131.5)

Table 5 Volume

To convert Into	Multiply by
Standard cubic feet (scf) of gas @ 60 °F and 14.73 psi	Standard cubic meters (Sm ³) @ 15 °C and 101.325 kPa	0.0283058
Standard cubic meters (Scm) of gas @ 15 °C and 1.0325 kPa	Normal cubic meters (Nm ³) @ 0 °C and 101.325 kPa	1.0549000

In considering industrial gases, especially when negotiating contracts, it is crucial to know the difference between *standard* and *normal*.

Table 6 Temperature

To convert Into			
	°C	°F	K	R
	Use the Formula			
Celsius (°C)	–	Multiply by 1.8, then add 32	Add 273.15	Convert to °F, then add 459.67
Fahrenheit (°F)	Subtract 32, then divide by 1.8	–	Convert to °C, add 273.15	Add 459.67
Kelvin (K)	Subtract 273.15	Subtract 273.15, then convert to °F	–	Add 273.15, then convert to °F, then add 459.67
Rankine (R)	Subtract 459.67, then convert to °C	Subtract 459.67	Subtract 459.67, then convert to °C, then add 273.15	–

Table 7 Temperature difference

To convert Into	Multiply by

Table 9 Masses and energy

- 1 metric tonne = 2204.62 lb = 1.1023 short tons = 1000 kg
- 1 kilolitre = 1 cubic meter = 6.2898 barrels
- 1 kilocalorie (kcal) = 4.187 kJ = 3.968 Btu
- 1 kilojoule (kJ) = 0.239 kcal = 0.948 Btu
- 1 British thermal unit (Btu) = 0.252 kcal = 1.055 kJ
- 1 kilowatt-hour (kWh) = 860 kcal = 3600 kJ = 3412 Btu

Table 10 Energy equivalencies^a

One tonne of oil equivalent equals approximately:	
Heat units	10 × 10 ⁶ kcal 42 GJ 40 × 10 ⁶ Btu
Solid fuels	1.5 tonnes of hard coal 3 tonnes of lignite
Electricity	12 MWh

10⁶ tonnes of oil or oil equivalent produces about 4400 GWh of electricity in a modern power station.

Glossary of Defining Terms

A

Absorbent

A material (solid or liquid) able to take in and hold (absorb) a gas or liquid. Examples include alkanolamine solutions, which absorb H₂S and CO₂ from sour gas, and absorbent clays, which pick up oil by incorporating the oil into their structure

Absorption tower

A column or tower in which absorption of selected components from mixtures occurs

Acid gas

Natural gas or a gas mixture containing high concentrations of hydrogen sulfide (H₂S) and/or carbon dioxide (CO₂). Acid gas is a more general term than ► *sour gas*, which contains H₂S but does not always contain CO₂

Acid number

► *total acid number (TAN)*

Adsorbent

A material like activated charcoal, alumina, or silica gel that is used in an adsorption process. Impurities selectively attach to its surface

Adsorption

A process of removing selected components from a stream by adherence to an adsorbent

Alcohol

A chemical compound composed of an alkyl group and an –OH group. Examples include methanol (CH₃OH) and ethanol (CH₃CH₂OH). In the oil industry, ethanol is used as gasoline additive and isopropanol as a solvent

Aldehyde

A chemical compound in which one carbon atom is bound to both =O and –H. Examples include formaldehyde, H(C=O)H, and acetaldehyde, CH₃(C=O)H. Formaldehyde is a building block in the synthesis of many other compounds of specialized and industrial significance. Acetaldehyde is mainly used as a chemical precursor, for example to make acetic acid, resin, pyridine derivatives, etc.

Alkanes

► *Hydrocarbons, paraffins*

Alkenes

► *Hydrocarbons, olefins*

Alkylate

The main product from an alkylation process unit. Alkylate is a high-octane gasoline blending component with many desirable properties, such as zero sulfur, olefins and benzene

Alkylation

A refining process in which isobutane reacts with C₃ to C₅ olefins to produce alkylate – a mixture of C₆ to

C₉ isoparaffins. The process is catalyzed by strong acids such as sulfuric acid or hydrofluoric acid.

American Petroleum Institute (API)

The largest trade association for the oil and gas industry in the United States. API publications include technical standards and online products designed to help users improve the efficiency and cost-effectiveness of operations, to comply with legislative and regulatory requirements, to safeguard health, to improve safety, and to protect the environment

Amine treating (amine washing)

Used in petroleum refineries, natural gas processing plants and other industrial facilities to remove acidic components, such as hydrogen sulfide and carbon dioxide, from gas streams by treatment with an alkanolamine

Aniline point

The lowest temperature at which aniline is soluble in a specified amount of oil. The aniline point is proportional to aromatics content; a low value indicates high aromatics. The aniline point is a specification for certain refining processes

Anticline

A type of fold with an arch-like shape resembling an inverted bowl, with the oldest beds at its core. Some of the world's largest oil fields, including many of those in the Middle East and the East Texas oil field, reside within anticlines

Antiknock index (AKI)

► *Octane number*

API gravity

Used for expressing density of crude oil. API gravity is defined as $^{\circ}\text{API} = 141.5 / (\text{specific gravity at } 60^{\circ}\text{F}) - 131.5$

Aquifer

A subsurface rock formation (stratum), such as permeable rock, sand, or gravel, which holds water. An aquifer often underlies a petroleum reservoir

Archie's law

Named after Gus Archie, this empirical equation relates the electrical conductivity of sedimentary rock to its porosity and brine saturation. It is used to relate borehole electrical conductivity measurements to hydrocarbon concentration of the material

Aromatics or aromatic hydrocarbons

► *Hydrocarbons, aromatic*

Asphalt

(1) A dark brown or black cement-like material precipitated from atmospheric residue with aliphatic solvents, usually propane. (2) Often used as a synonym for bitumen. (3) Also used as a feed for coking to increase the yields of more valuable products

Asphaltene structures

Archipelago and continental (pericondensed) structures. Surrogate molecules used to model asphaltenes are commonly classified based on their resemblance to archipelagos and continents

Asphaltenes

Polar fraction of petroleum that is insoluble in light alkanes, e.g., pentane or heptane, but soluble in aromatic solvents. Asphaltenes do not dissolve in crude oil but exist as a colloidal suspension

Asphaltic crudes (Naphthenic crude)

► *Crude oil, asphaltic*

ASTM

ASTM International, formerly known as the American Society for Testing and Materials, develops and publishes consensus standards for materials, products and processes.

Atmospheric distillation

► *Distillation, atmospheric pressure*

Atmospheric equivalent boiling point (AEBP)

Calculated based on observed boiling points at a reduced pressure, the atmospheric equivalent boiling point (AEBP) is relevant to compounds for which the atmospheric boiling point cannot be measured because they decompose before they boil

Autothermal reforming (ATR)

An alternative to traditional steam methane reforming (► *SMR*). ATR does not require external heat. It processes mixtures containing hydrocarbon gases (primarily methane), steam, and oxygen. In a combustion zone, partial oxidation generates syngas and heat. The syngas flows to a catalyst zone, where reforming reactions occur, producing mainly hydrogen. The product can also be syngas with a specific composition

Aviation gasoline (Avgas)

A high-octane blend of hydrocarbons and additives, which meets ASTM Specification D910 or Military Specification MIL-G-5572. Used primarily in airplanes with piston-driven propellers. Often contains tetraethyl lead (TEL)

B**Barrel (bbl)**

In petroleum, a unit of volume equal to 42 US gallons, 33.6 Imperial gallons, or 158.9873 liters

Barrels per calendar day (BPCD)

The average daily amount of oil produced, transported or processed in a petroleum facility during one calendar day. BPCD is less than BPSD, because BPCD includes downtime for maintenance

Barrels per stream day (BPSD)

The maximum daily amount of oil produced, transported or processed in a petroleum facility when the facility is running under normal operating conditions, with referal to the feedstock quality, process operating conditions, and product objectives

Base oil

A blend of one or more basestocks

Base stock (Basestock)

Products produced from the lube refinery without any additives in the oil. Group I: with saturates < 90%, sulfur > 0.03%, and viscosity index 80–120. Obtained from solvent processing (solvent refining). Group II: with saturates > 90%, sulfur < 0.03%, and viscosity index 80–120. Obtained from hydroprocessing. Group III: with saturates > 90%, sulfur < 0.03%, and viscosity index > 120. Obtained from severe hydroprocessing, isodewaxing or gas-to-liquid processes. Group IV: made from polyalpha olefins (PAO). Group V: Basestocks not included in Groups I–IV, such as synthetic lubricant oils

Basins (sedimentary basins)

Large-scale region of the earth where long-term subsidence has created a depression. Provides space for infilling by sediments and oils

Batch processing

A noncontinuous process in which material is loaded into a vessel and given time to react. When the reaction is complete, the vessel is opened and products are removed. Examples include delayed coking, digestion, batch polymerization, and the roasting of ores

Batch reactor

A typical batch reactor consists of a large, sturdy canister or vessel with its own heating and cooling mechanisms. Sometimes includes a rotating agitator inside the vessel to facilitate mixing

Benfield process

A process for removing acid gases (CO₂ and H₂S) from natural gas or manufactured hydrogen. The acid gases are adsorbed into molten potassium carbonate then recovered in concentrated form during thermal regeneration of the carbonate

Biodiesel

A fuel comprised of monoalkyl esters. Derived from the long-chain fatty acids found in vegetable oils or animal fats

Biogenic

Material derived from biological sources, such as bacteria, algae, and vegetables

Biomarkers (petroleum biomarkers)

Organic compounds contained in rocks and petroleum whose carbon skeletons remain after paleotransformation stages and can be linked to known biological precursors

Biomass

Biological organic matter

Biomass to liquid (BTL)

A process to produce liquid biofuels from biomass, which may include the Fischer-Tropsch process, pyrolysis or catalytic depolymerization

Biopolymer

High molecular weight polymers, such as

carbohydrates, proteins, lipids, and lignin, in living organisms

Bitumen

A naturally occurring thick, sticky form of hydrocarbon found in pits or associated with oil sand. It will not flow unless heated or diluted with lighter hydrocarbons. It is also the British term for asphalt or extra heavy crude oil

Blending terminal

A facility used for intermediate storage of refinery products and for blending them with additives. Gasoline additives might include oxygenates such as ethanol and detergents to mitigate intake valve deposits. Additives for diesel might include cetane improvers and antioxidants. Oil trucks (lorries) are loaded at blending terminals, from which they transport the products to retail filling stations

Blending unit

A facility in a refinery where streams are mechanically blended to make finished products. In the case of US gasoline, the main product is RBOB reformulated blendstock before gasoline blending

Blowout

Uncontrolled escape of oil or gas from a well

BHCI (Bureau of Mines Correlation Index)

A method of petroleum classification.
 $BHCI = 48,640/TB + 473.7G - 456.8$, where TB is mean average boiling point in K and G is specific gravity at 60 °F. Also called CI. CI for straight-chain paraffins is 0 and for benzene it is 100. 0–15 indicates a predominance of paraffinic hydrocarbons; 15–50 indicates a predominance either of naphthenes or of mixtures of paraffins, naphthenes, and aromatics. > 50 indicates the predominance of aromatic character. For a petroleum fraction, CI correlates with many characteristics, such as crackability, steam cracking feed quality, and aromaticity

Borehole logging

► *Well log*

Bottoms

The product coming out of the bottom of a distillation column

Brent crude oil

An important group of crude oils produced in North Sea, which is used as a reference crude for international crude trading

Bright stock

A heavy lube basestock derived from vacuum resid after dewaxing

British Thermal Unit (BTU)

The quantity of heat required to raise the temperature of 1 pound of water by 1 °F

Bromine number

The grams of bromine absorbed in 100 g of oil. Correlates to the percentage of double bonds in the oil sample

BTX

A mixture of benzene (C_6H_6), toluene ($C_6H_5CH_3$),

and xylenes ($C_6H_4(CH_3)_2$). Commonly used as a solvent or feedstock to chemical plants

Bunker oil (Bunker fuel)

Fuel oil used in engines aboard ships. Bunker A corresponds to No. 2 fuel oil, Bunker B corresponds to No. 4 or No. 5 fuel oil, and Bunker C corresponds to No. 6 fuel oil

Butanes: A mixture of two isomers

normal butane and isobutane. Normal butane was used as a RVP booster during cold weather prior to the use of ethanol. It is isomerized to isobutane. Isobutane is an important (key) feed for alkylation
 (► *Hydrocarbons*)

Butene (butylene)

A colorless alkene with the formula C_4H_8 generated in refineries or olefin plants by cracking
 (► *Hydrocarbons, olefins*)

Butyl rubber

A synthetic rubber. Specifically, it is a copolymer consisting of about 98% isobutylene with about 2% isoprene. Butyl rubber and halogenated rubber are used for the impervious inner liner of tubeless tires

C

Calcining (calcination)

Decomposition of a solid with heat below the melting or fusing point. Causes loss of moisture and the decomposition of carbonates and other compounds

Cap rock (seal rock)

Impermeable rock that serves as a cap to stop petroleum migration. A key component of a petroleum and/or natural gas reservoir

Carbene

The pentane or heptane insoluble fraction that is insoluble in benzene or toluene but soluble in carbon dioxide or pyridine

Carboid

The pentane or heptane insoluble fraction that is insoluble in benzene or toluene but also insoluble in carbon dioxide or pyridine

Carbon Preference Index (CPI)

The ratio obtained by dividing the sum of the odd carbon-numbered n -alkanes to the sum of the even carbon-numbered n -alkanes between C_{25} and C_{34}

$$CPI = 1/2 [(C_{25} + C_{27} + C_{29} + C_{31} + C_{33}) / (C_{24} + C_{26} + C_{28} + C_{30} + C_{32})] + [(C_{25} + C_{27} + C_{29} + C_{31} + C_{33}) / (C_{26} + C_{28} + C_{30} + C_{32} + C_{34})]$$
 It can also be used to estimate thermal maturity of organic matter

Carbon rejection

Upgrading processes in which coke and other hydrogen-deficient products are formed. Examples include FCC and coking. Carbon rejection is accompanied by the formation of light products. The heavy products contain less hydrogen than the feed, while the light products contain more hydrogen than the feed. Often, molecular hydrogen is one of the products

Carrier rock

Permeable rock that allows oil and gas to migrate from source to reservoir

Catagenesis

A process that consolidates sediment containing dead organic material, water, minerals, and numerous living organisms, providing conditions that convert biopolymers to geopolymers (kerogen)

Catalyst

A substance that increases the rate of a chemical reaction without itself undergoing any permanent change

Catalyst acidity

For heterogeneous catalysts, acidity refers to the number and strength of acid sites per unit of weight or volume. Includes both Lewis and Brønsted sites; generally, the Hammett function is used instead of pH to indicate strength. Relative acidity is determined by adsorption of ammonia or other volatile bases with known acidity. For homogeneous systems, acidity can refer either to the strength of the acid itself or to the concentration of acid in the system

Catalyst activity

Relative rate at which a catalyzed reaction proceeds

Catalyst coke

Carbonaceous material that deposits on catalysts

Catalyst deactivation

Loss of catalyst activity due to routine fouling, attrition, or agglomeration (► *Catalyst poisoning*)

Catalyst fouling

Plugging of catalyst beds with particulates or gums. Sometimes used as a synonym for deactivation due to coking (► *Catalyst deactivation*)

Catalyst impregnation

A method for adding active metals to a solid catalyst support

Catalyst poisoning

Partial or total deactivation of a catalyst caused by exposure to a range of chemical compounds

Catalyst regeneration

Restoration of catalyst activity. Heterogeneous refining catalysts for FCC, hydroprocessing, and catalytic reforming are regenerated by controlled combustion, which removes accumulated coke, sulfur, nitrogen, and other volatile or flammable materials

Catalyst rejuvenation

Further restoration of catalyst activity via chemical treatment of a regenerated catalyst. Used (for example) to redispense active metals on catalysts in which agglomeration has occurred

Catalyst selectivity

Percentage of desired product from a catalyzed reaction

Catalytic cracking

The conversion of high-boiling feedstocks into lower-boiling products over a catalyst. Occurs in fixed beds or fluid beds, in the absence of excess hydrogen (as in FCC) or in the presence of external hydrogen (as in hydrocracking)

Catalytic dewaxing

Catalytic process for converting normal paraffins to isoparaffins, usually with a heterogeneous catalyst in a fixed-bed reactor

Catalytic hydrocracking

(► *Hydrocracking*)

Catalytic hydrotreating

(► *Hydrotreating*)

Catalytic reforming

A catalytic refining process in which C6 to C12 naphthenes and paraffins are converted into aromatics while producing hydrogen. The liquid product (► *reformate*) serves as high-octane gasoline blendstock or as a feedstock to aromatics production units. Hydrogen purities range from 80–90 vol%. This hydrogen goes primarily to hydroprocessing units. The three main catalytic reforming processes are semiregen, cyclic, and CCR. In *semiregen* units, the catalyst occupies fixed-bed reactors and slowly deactivates. When liquid yields and hydrogen purity become unacceptably low, due to increased formation of C1–C5 hydrocarbons, operators shut the unit down and regenerate the catalyst. Typical semiregen cycles last six to 12 months. *Cyclic* reformers include four to six reactors. The reactors deactivate sequentially. Every week or so, a reactor goes down for regeneration as a regenerated reactor returns to service. With this strategy, a unit can run for years without a total shutdown. The most profitable option is CCR – *continuous catalyst regeneration* – in which the catalyst moves through several reactors before circulating through an online regeneration section and back to the lead reactor. CCR liquid yields are greater, because they operate continuously, and at lower pressure, which favors dehydrogenation. For semiregen units, catalysts usually contain both platinum (Pt) and rhenium (Rh), where the Rh improves stability. For CCR units, Rh is not needed, but promoters such as tin (Sn) are added to improve selectivity. To provide acidity, chloride is injected into the unit at prescribed rates. Chloride promotes important reactions, but too much chloride can lead to excessive cracking

Caustic Wash

The process of treating a product with a caustic soda solution to remove minor but especially undesired impurities

Cetane index

Used as an alternative for cetane number. Based on density and distillation range.

$$CI = -420.34 + 0.016 G^2 + 0.192 G \log M + 65.01(\log M)^2 - 0.0001809 M^2$$

where G = API gravity at 60 °F and M = D86 temperature at 50% volume, in °F

Cetane number (CN)

A measure of the tendency of a diesel fuel to knock and undergo ignition delay. It is measured in a standard diesel engine according to ASTM D613. Originally, the CN of a test fuel was compared to

standard mixtures that knocked with the same intensity as the test fuel. The original standards were prepared by mixing *n*-hexadecane (CN = 100) with *a*-methyl-naphthalene (CN = 0). In 1962, *a*-methyl-naphthalene was replaced with 2,2,4,4,6,8,8-heptamethyl-nonane, which has a CN of 15

Characterization factor (UOP K or Watson K, K_w)

A method of petroleum classification.

$K_w = (TB)1/3/G$, where *TB* is mean average boiling point in K and *G* is specific gravity at 60 °F. K_w ranges from 10.5 for highly naphthenic crude to 12.9 for highly paraffinic crudes

Chemical injection

A tertiary recovery or enhanced oil recovery method. It involves injecting water-soluble polymers, surfactants or alkaline solutions into rock to flood the formation and drive oil to production wells for recovery

Claus process

Converts hydrogen sulfide into sulfur in a two-step process. (1) The thermal step entails combustion of a mixture containing H₂S and air in which the H₂S: oxygen molar ratio is 2 : 1. The products are SO₂, water, and unreacted H₂S. (2) The catalytic step entails the reaction of SO₂ from step 1 with unreacted H₂S to form elemental sulfur. Named after Carl Friedrich Claus

Cloud point

Temperature at which a haze appears in a sample due to the formation of wax crystals. Determines the plugging tendency of a fuel as it flows through small orifices. Particularly important for jet fuel and diesel at cold operating temperatures

Coal

A combustible black rock. A solid fossil fuel comprised of 65–95% carbon and different amounts of hydrogen, sulfur, oxygen, nitrogen, and ash. It is a sedimentary rock formed from peat that is buried under rocks

Coal bed methane

Natural gas extracted from natural coal beds. Contains fewer C₂+ hydrocarbons than natural gas from conventional reservoirs

Coke (petroleum coke)

Carbonaceous product generated in refineries by coking processes

Coke, anode grade

Calcined petroleum coke, low in sulfur and metals. Primarily used to produce electrodes for steel and aluminum (► *Coke, needle*)

Coke, catalyst

Undesired carbonaceous material that deposits on catalysts

Coke, fuel grade

Calcined sponge coke or shot coke from a delayed coker, with lower quality than anode-grade coke due to excessive ash or trace metals. Suitable as a replacement for coal in fired boilers in power plants. Can be a feedstock for gasification with partial

oxidation. In power plants, some form of sulfur capture is required to meet current North American emission standards

Coke, green

Uncalcined raw coke from a delayed coker

Coke, needle

Premium highly crystalline petroleum coke used in the manufacturing of graphite electrodes of low thermal expansion for arc furnaces in the steel, aluminum and titanium industries (► *Coke, anode grade*)

Coke, shot

Lowest quality coke from a delayed coker. Typically, shot coke is comprised of small round pellets ranging 1.5–4 or 5 mm in diameter, which are loosely bound together in structures roughly the size and shape of ostrich eggs. Shot coke can disrupt coke drum operations by causing blowbacks during the cutting of coke from drums, plugging of the bottom nozzle of a coke drum, and fouling of coke handling equipment

Coke, sponge

Sponge-like coke from a delayed coker with a relatively uniform consistency

Coking

A thermal process for continuous conversion of reduced crude, straight-run residua or cracked residua into hydrocarbon gases, H₂S, NH₃, naphtha, gas oils and petroleum coke. The most common processes are ► *delayed coking* (batch), ► *fluid coking* and ► *Flexicoking* (continuous)

Coking, delayed

A semicontinuous (semi-batch) process by which residue and other heavy fractions, such as FCC decant oil or coal tar, are thermally decomposed to produce coke and cracked products. The feed is heated to ca. 500 °C and sent to large coking (soaking) drums. Usually, four or more drums are used so that operation can be staggered. Drums are switched every 18–24 h. Hot oil is added until a drum is full. Cracking begins immediately, generating coke and hot cracked vapor. The oil stays in the drum for several hours (hence the term delayed) until coking is complete. Vapors rise to the top, from whence they are sent to a fractionator for separation and recovery. Coker gases and liquids contain sulfur and olefins. The liquids must be stabilized by hydrotreating or hydrocracking. The coke can be used either as a fuel or in other applications such as the manufacturing of anodes for steel or aluminum production

Coking, Flexi-

A combination of continuous fluid coking and oxidative steam reforming, which can upgrade virtually any pumpable feed including residual, pitch or total crude. Approximately 95 wt% conversion of feed can be achieved. Products include coke and a full range of gas and liquid products. Some of the coke is heated and circulated back to the reactor to supply process heat. Excess coke goes to a gasifier, where it reacts with air and steam to produce Flexigas. After treatment to remove particulates and hydrogen sulfide,

the Flexigas is ready for use as fuel in refinery boilers and furnaces and/or for steam and power generation

Coking, fluid

A continuous thermal cracking process for converting residua to more valuable products, such as gases, a full range of liquids, and coke. The coke is burned or gasified and returned to the main reactor to provide some of the heat required for cracking

Combined feed ratio (CFR)

In a process where unconverted feed is recycled, the combined feed ratio = $(FF + RO)/FF$, where FF = fresh feed rate and RO = recycle oil rate

Compression ratio

The ratio of the volumes in an internal combustion engine when the piston is at the bottom of the stroke and the top of the stroke

Condensate

Liquids produced during the processing of natural gas. Also referred to as gas condensate, and (historically) natural gasoline. Includes pentanes and heavier hydrocarbons

Conradson carbon residue (CCR)

Also known as Concarbon. A quantitative measurement of carbonaceous residue remaining after evaporation and pyrolysis of oil from a sample under controlled conditions. An indication of the coke-formation tendency of the oil being tested

Conversion

In refining, conversion means boiling point reduction. That is: transforming material that boils above a product cutpoint into material that boils below that cutpoint. Most conversion is accomplished by breaking C–C bonds. Depending on the feedstock, up to 15% conversion of material that boils above 700 °F (370 °C) can be achieved by other reactions: saturating aromatics and removing heteroatoms

Correlation index (CI)

► *BMC1*

Crack spread

Expressed as $X : Y : Z$ where X = price of X barrels of crude, Y = price of Y barrels of gasoline, and Z = price of Z barrels of distillate fuel oil (diesel, etc.). By convention, $X = Y + Z$. Corresponds roughly with refinery profitability

Cracked gas

The gas from thermal crackers, steam crackers, catalytic crackers and cokers. Depending on the process and reaction conditions cracked gas is often rich in hydrogen and olefins

Cracking

Breaking down large molecules into smaller molecules by heat. Thermal cracking includes steam cracking and coking. Catalytic cracking includes FCC and hydrocracking

Crude assay (crude oil assay)

A collection of the results of physical tests, which determine key properties (boiling point, density, viscosity, heteroatom contents, acid number, etc.) of a crude oil and its fractions. Important for determining the value and processability of crude oil

Crude oil

Liquid form of petroleum. A mixture of naturally occurring hydrocarbons in (or produced from) underground ► *reservoirs*. It is formed from the bodies of dead microorganisms, which accumulated millions of years ago in sediments at the bottoms of ancient seas and lakes. Deep underground, the sediments were subjected to heat and pressure, which converted them into sedimentary rock via diagenesis. During diagenesis, the organic matter was transformed into fossil hydrocarbons. Depending on local conditions, including time, diagenesis produces natural gas, petroleum, heavy oil, bitumen, or coal. Crude oil in reservoirs is associated with dissolved hydrocarbon gases, water, salt, dirt, dissolved light natural gas, CO_2 , H_2S , and trace metals such as Fe, Ni, V, As, and Hg. When brought to the surface, dissolved gases desorb and are collected and processed in associated facilities. Widely construed, the term crude oil also includes other fossil hydrocarbons: bitumen recovered from tar pits by conventional mining, bitumen recovered from tar sands (oil sands), and liquids produced from the kerogen in oil shale. Liquids from natural gas processing plants are often included, especially when they are back-blended with crude oil prior to transportation. Crude oil is refined into a wide array of fuels and other products

Crude oil, asphaltic

also called naphthenic crudes, containing higher concentrations of naphthenes and aromatics than paraffinic crudes

Crude oil, conventional

Oil extracted from the ground by conventional drilling methods. Includes oil produced with primary, secondary, and tertiary recoveries

Crude oil, paraffinic

Paraffinic (waxy) crude oils contain relatively high concentrations of long-chain n -paraffins. In comparison, naphthenic crudes contain relatively low concentrations of paraffins. Waxy crudes cause problems due to their high viscosity and tendency to leave deposits in equipment

Crude oil, synthetic

Crude oil produced from coal, bitumen or shale oil; in this context, shale oil comes from retorted oil shale. To make so-called synthetic bitumen (synbit), bitumen is upgraded by a coker, visbreaker, or hydroprocessing unit. To make so-called diluted bitumen (dilbit), the bitumen is diluted with cutter stock. The quality of synbit is much higher than the quality of dilbit

Crude oil, unconventional

Unconventional crude oils include oil and natural gas condensates that are not recovered by conventional means, such as primary to tertiary recoveries. These include oil sand bitumen and syncrude, extra heavy crude oil, and shale oil

Cut

The portion or fraction of a crude oil boiling within

certain temperature limits. Also called ► *distillate* in distillation

Cut point

The temperature limit of a cut or fraction, usually (but not always) specified on a true boiling point basis

Cyclic steam stimulation (CSS)

A thermal recovery method for heavy oils, also known as the Huff and Puff method, consisting of three stages: steam injection, soaking, and production

D

Deasphalted oil (DAO)

The extract or residual oil from which asphalt and resins have been removed by an extractive precipitation process called deasphalting

Deasphalting

A refinery process for removing asphalt from reduced crude or vacuum residua (residual oil) by light alkanes (propane, pentane, heptane, etc.)

Deep catalytic cracking (DCC)

A modified catalytic conversion technology that uses heavy hydrocarbon feedstocks, such as VGO, VR or VGO, blended with DAO to produce light olefins (ethylene, propylene and butylenes), LPG, gasoline, middle distillates, etc

Delayed coking

► *Coking, delayed*

Desalting

Removal of salts and other material, such as particulates, from crude oil. Usually the first step in crude oil refining. The process entails: (1) adding and dispersing water, (2) forming an emulsion to expedite the dissolution of salts in the water, and (3) separating the emulsion into oil and water phases by electrostatic and/or chemical methods

Desulfurization

Removal of organic sulfur compounds by scrubbing, mercaptan oxidation, or catalytic hydrotreating via hydrodesulfurization (HDS)

Dewaxing

A lubricant plant process to remove wax (higher-boiling normal paraffins) from oil after extraction of aromatics. Solvent dewaxing often employs methylethyl ketone (MEK) mixed with toluene or propane

Dewaxed oil (DWO)

The oil remaining after dewaxing processes for lubricant oil production

Diagenesis

Formation of sedimentary rocks from sediments or from different sedimentary rocks at high temperature and pressure. Diagenesis occurs at depths reaching several kilometers. When the sediments contain enough organic matter, kerogen forms. Over time, the kerogen starts evolving into liquid petroleum, various ranks of coal, and gases (mostly methane)

Dibenzothiophenes

A class of sulfur-containing aromatic compounds. They are difficult to remove, especially when they

have alkyl groups adjacent to the sulfur atom or when they include fused aromatic rings (► *Hydrocarbons, heteroatom-containing*)

Diesel

Fuel used in compression-ignition (diesel) engines. Most diesel (petro diesel) is produced in petroleum refineries from distillation of crude oil and by conversion processes such as hydrocracking. Other sources include biomass, biogas or natural gas. Diesel is produced from synthesis gas with the Fischer-Tropsch process. No. 1 diesel is lighter than No. 2 diesel (close to kerosene) and with high cetane number and volatility, it is better suited for cold temperatures. No. 2 diesel is less volatile than No. 1 (containing heavy gas oil), enabling it to carry heavy loads for long distances at sustained speed. No. 4 diesel fuel is used for low- and medium-speed diesel engines and conforms to ASTM Specification D 975

Dilbit (diluted bitumen)

Bitumen diluted with cutter stock to facilitate transportation. In refineries, dilbit is processed as if it were a conventional heavy crude oil

Distillate

An overhead or side-draw distillation fraction from a distillation column after cooling

Distillate fuel oil

A collective term referring to heating oils for which the distillation endpoint is less than about 400 °C (750 °F). No. 1, No. 2, and No. 4 fuel oils are similar to No. 1, No. 2, and No. 4. diesel respectively, but with different (fewer) additives. Used primarily for space heating and electric power generation

Distillation

Process of selective evaporation and condensation to separate substances from a liquid mixture. Primary means of separation in oil refineries

Distillation, atmospheric

Distillation at atmospheric pressure up to 700 °F or 370 °C. In petroleum refining, atmospheric distillation separates crude oil into fractions, which are subsequently transformed into finished products. Typical fractions include C1–C4 gases, naphtha, middle distillates, atmospheric gas oil, and atmospheric residue

Distillation, vacuum

Distillation of crude oil under vacuum or reduced pressure, such as 40 mmHg (50 mbar), up to 700 °F or 370 °C. Recovers components that thermally decomposed before they vaporize under atmospheric pressure

Donor solvent process

A hydrogenation process, such as donor-solvent coal liquefaction, in which a hydrogen-rich liquid solvent such as tetralin replaces gaseous molecular hydrogen. Much of the hydrogenated coal liquefies; the coal liquids are easier to transport and process than solid coal. Due to the modest pressure of the coal section, construction and processing costs are relatively low.

The dehydrogenated solvent is removed by distillation, rehydrogenated, and recycled

Downhole fluid analysis (DFA)

Technique to characterize reservoirs and the distribution of reservoir-fluid properties using optical spectroscopy

Downstream

Business sector in the oil industry for refining crude oils and purifying natural gas. Includes the marketing and distribution of refined products

Drilling engineering

A branch of petroleum engineering for designing and implementing procedures to drill wells safely and economically

Dry gas

Natural gas or refinery gas that does not contain significant amounts of C₂+ components

E

Ebulated bed (e-bed) hydrocracking

► *Hydrocracking*

Ebulated bed (e-bed) reactor

Key part of an ebulated bed unit

Engine oils

Lubricant oils for internal combustion engines

Enhanced oil recovery (EOR)

► *Tertiary recovery*

Entrainment

Entrainment is the carryover of liquid by the vapor phase or of gas by the liquid phase. Liquid may be in the form of a spray, foam or mist

Epimers

Stereoisomers with different configurations of atoms around one of several asymmetric carbon atoms (chiral centers). Important isomeric molecule for maturity assessment through petroleum biomarkers

EST (ENI Slurry Technology)

A slurry-phase hydrocracking process licensed by ENI

Exploration (discovery)

Searching for oil and gas deposits under the Earth's surface. A branch of the petroleum upstream business

Extract

For solvent refining in general, the extract is the stream rich in impurities. In solvent extraction for preparing lube basestocks, the extract is rich in aromatics and other undesirable components. In wax deoiling, the extract is rich in oil (► *Raffinate*)

Extraction

In general, extraction is the process of separating a mixture into a fraction soluble in a solvent and an insoluble residue. In solvent refining for lube oil production, the aromatic portion of an oil is separated from the paraffinic and naphthenic portions. This improves the viscosity index, oxidation resistance, and color of the basestock. It also reduces carbon and sludge formation. Solvents used include furfural, phenol or *N*-methylpyrrolidone (NMP)

Extra heavy crude oil

Crude oil with °API gravity less than 10 (specific gravity > 1.0). The heaviest of *heavy crude oils*

F

Facies

Characteristics of a rock expressed by its morphology, composition, and fossil content. *Fasces* is a Latin term for the bundles of sticks carried by lictors in Ancient Rome

Fatty acid methyl ester (FAME)

Primary constituent of biodiesel, resulting from the transesterification of fats with methanol

Fault

Natural fracture in stratum caused by plate tectonics. Serves as a conduit for petroleum migration or as a reservoir in the presence of cap rock

Fold (geological)

A permanent deformation caused when flat sedimentary strata are bent or curved by geological forces

Fischer-Tropsch process

A series of chemical reactions to convert a mixture of carbon monoxide and hydrogen into liquid hydrocarbons. The key process in the production of synthetic lubricants or fuels in gas-to-liquid (GTL) technology

Flash point

The lowest temperature at which vapor of a volatile material will ignite

Flexicoking

► *Coking, Flexi-*

Flue gas

The exhaust gas from a furnace, boiler, reactor, etc.

Fluid catalytic cracking (FCC)

Catalytic cracking in a fluidized bed reactor. The cracking reaction occurs on high-acidity zeolite catalysts, which have the consistency of sifted flour. Reaction products include gases, predominantly C₃+, which are highly olefinic; high-octane FCC gasoline; highly aromatic cycle oils; and coke. The coke goes to a regenerator, where it is burned in air (or oxygen-enriched air) to produce CO₂, H₂O, and heat. Hot catalyst is mixed with fresh feed and returned to the reactor. FCC produces a significant portion of the world's gasoline

Fluid coking (fluidized bed coking)

► *Coking, fluid*

Fluidized bed reactor

A reactor in which the catalyst bed is fluidized by upflowing gas. Used in fluid catalytic cracking and fluid coking

Foots oil

The oil washed out of slack wax

Formation (geological)

Stratified sedimentary bed. The fundamental unit of petrostratigraphy in geology

Formulated oil

A blend of base oils with special additives

Fouling

The deposition and accumulation of unwanted materials such as scale, algae, suspended solids and insoluble salts on the internal or external surfaces of processing equipment including boilers and heat exchangers

Fracking

► *Hydraulic fracturing*

Fractional distillation

Primary means of separating crude oils at refineries into fractions with different boiling ranges

Fracture

A natural or man-made crack in reservoir rock

Frasch Process

Method to extract sulfur from underground deposits, where superheated water is pumped into the formation to melt the sulfur. Compressed air is used to froth the sulfur and bring it to the surface

Froth treatment

A process of eliminating the aqueous and solid contaminants from bitumen froth to produce a clean bitumen product

Fuel ethanol

Ethanol intended for fuel use, as in reformulated gasoline. Fuel ethanol in the United States must contain less than 1 wt% water and be denatured with > 2 vol% C5+ paraffins or conventional gasoline

Fuel oils (heating oils)

A range of oils used for heating or for locomotion in ships and locomotives. No. 1 fuel oil is a volatile distillate oil with a boiling range similar to that of kerosene, but a higher pour point and an end point that is adjusted to suit vaporizing pot-type burners. No. 2 fuel oil is a distillate home heating oil, similar to No. 1. It may contain hydrotreated cracked stock. The chain length of the hydrocarbons ranges from 10 to 20. No. 3 fuel oil is for burners requiring low-viscosity heating oil, merged with No. 2 in specifications. No. 4 fuel oil is usually a light residual oil used in a furnace that can atomize the oil and is not equipped with preheater. The chain length of the hydrocarbons ranges from 12 to 70. No. 5 fuel oil has higher viscosities than No. 4. In use, it requires preheating to 170–220 °F for atomizing and handling. Also known as Bunker B oil. The chain length of the hydrocarbons ranges from 12 to 70. No. 6 fuel oil is a high-viscosity residual oil that requires preheating to 220–260 °F for storage, handling and atomizing. Also specified by navies as Bunker C oil for ships. The chain length of the hydrocarbons ranges from 20 to 70. *Residual fuel oils* are the heaviest, including No. 5 and No. 6 fuel oils

G**Gas hydrate**

Solid ice-like form of water cage that contains gas

molecules inside its cavity. In nature, the gas is mostly methane

Gas injection (for oil recovery)

Gas injection is used both in secondary recovery for artificial lift of the oil, and in tertiary recovery. In the latter, carbon dioxide or nitrogen is introduced through an injection well to sweep the formation for remaining oil

Gas oils

Distillation fractions boiling between heavy naphtha and kerosene and atmospheric residue. They are obtained from atmospheric distillation as atmospheric gas oils (AGOs), vacuum distillation as vacuum gas oil (VGOs) and coker as coker gas oils (KGOs). Also known as middle distillates. After subsequent processing, gas oils become suitable for blending into finished fuel oil and transportation fuel

Gas oils, heavy coker (HKGO)

Heavy gas oil fraction from coker with boiling points > 650 °F (340 °C), which contains very high concentrations of polycyclic aromatic compounds and other contaminants, such as metals. If used as a hydrotreating or hydrocracking feed, it is crucial to control endpoint, CCR, and metals to avoid shortening catalyst cycle life.

Gas oils, heavy straight run (HGO or HAGO)

Liquid petroleum distillates from atmospheric distillation heavier than kerosene with boiling points between 600 °F and 800 °F (315–420 °C) in the diesel range

Gas oils, light coker (LKGO)

Highly olefinic middle distillates produced by coking units, with boiling points that range from about 400 °F to 650 °F (200–340 °C). Highly reactive with air. Hydroprocessing transforms light coker gas oils into diesel blendstocks or heavy naphtha

Gas oils, light straight run (LGO or LAGO)

Liquid petroleum distillates from atmospheric distillation heavier than naphtha with boiling points between 400 °F and 600 °F (200–315 °C) in the kerosene and jet fuel range. Also called middle distillates

Gas oils, vacuum (VGO)

Overhead and side-streams from a vacuum distillation unit. Include light vacuum gas oil (LVGO) and heavy vacuum gas oil (HVGO). A typical VGO boiling range is 650–1050 °F (340–560 °C). They are feedstocks for catalytic cracking or hydrocracking

Gasohol

A mixture of gasoline and ethyl alcohol used as fuel in internal combustion engines

Gasoline

A mixture of C5–C12 hydrocarbons used as fuel in spark-ignition internal combustion engines. A high-octane naphtha blend with additives to meet official specifications for octane number, RVP, and other properties as described by ASTM D4814, EN 228, JIS K2202, China V, etc.

Gasoline, blending

Mechanical mixing of motor gasoline blending

components from refinery process units with additives, including oxygenates when required. Final blends must meet official specifications for octane number, RVP, sulfur, and other properties

Gasoline, blending components

Refinery streams containing C5-C12 hydrocarbons with suitable properties for blending into gasoline. Typically, the streams include straight-run naphtha, reformate, FCC gasoline, alkylate, isomerate, polymer gasoline, and others. Oxygenates and other additives are included as required or needed

Gas-to-liquids (GTL)

A process for converting natural gas into liquid hydrocarbons

Gravity drainage

The movement of oil in a reservoir due to gravity

Grease

A semisolid lubricant usually prepared by emulsifying a lubricant basestock with soap. Greases are highly viscous when first applied, but they undergo sheer thinning (their viscosities fall) during operation. Because they are semisolid, greases stay in place where liquid lubricants will not. Bearings are typically lubricated with grease instead of with less-viscous oil. Some greases act as sealants or waterproofing agents

Green coke

Unprocessed raw coke from a delayed coker (► *Coke*)

H

Heating oil

No. 2 to No. 4 fuel oils (► *Fuel oil*)

Heavy coker gas oil (HKGO)

► *Gas oils, heavy coker*

Heavy crude oil

Crude oil with °API gravity ranging from 10 to 20

Heavy gas oil (HGO)

Petroleum distillates with an approximate boiling range from 500 to 750 °F (260–400 °C)

H-Oil

An ebullated-bed hydrocracking process licensed by Axens

Houdry process

A process invented by Eugène Houdry, a French chemist. Revolutionized thermal cracking with the use of a moving bed of catalyst integrated with oxidative regeneration. Produced less gas, higher liquid yields, and gasoline with higher octane

Huff and Puff

► *Cyclic steam stimulation*

Hydraulic fracturing (fracking)

Injecting fluid (about 90% water, 9.5% proppant, and chemical additives) under controlled pressure intermittently over a short period (three to five days) to create fractures in a targeted rock formation. The fracture permits oil or natural gas to flow to the wellbore. The proppants are small grains of sand, ceramic, aluminum oxide or other particulates to keep the fracture open

Hydrocarbons

Molecules that contain carbon and hydrogen. The term is loosely used in the oil industry to include all compounds containing carbon and hydrogen, including those that also contain heteroatoms. Hydrocarbons are classified into the following groups: saturates (paraffins and cycloparaffins), olefins, aromatics (monoring and polyring) and heteroatom-containing

Hydrocarbons, acetylene

Acetylenes have a formula of C₂H₂ with a carbon-carbon triple bond. They are not found in petroleum or natural gas due their high reactivity, but can be manufactured from the hydrolysis of calcium carbide, and the partial oxidation of methane, coke, or coal. Acetylene has mainly been used in oxyacetylene welding and as a feedstock for a variety of plastics and acrylic acid derivatives

Hydrocarbons, aromatics

Aromatics are hydrogen-deficient ring compounds with the general formula C_nH_{2n} + z, where z = -6 for benzenes, -8 for indans, -10 for indenenes, -12 for naphthalenes, etc. The rings are stabilized with resonance energy, making them difficult to open with cracking processes. Aromatics are dense and have higher boiling points than other hydrocarbons with the same number of carbon atoms. Important examples include benzene (C₆H₆), toluene (C₇H₈), and four isomers of C₈H₁₀: *o*-xylene, *m*-xylene, *p*-xylene, and ethylbenzene

Hydrocarbons, diolefins

Diolefins have two carbon-to-carbon double bonds, which are usually conjugated. Butadiene is an important monomer for making petrochemicals. In refining, due to their high reactivity, diolefins cause storage and processing problems as well as gum formation in gasoline engines. Coking units produce significant butadienes and pentadienes, which can polymerize at the top of hydroprocessing reactors, producing gums that increase pressure drop and can shut a unit down

Hydrocarbons, heteroatom-containing

Strict definitions of hydrocarbons exclude compounds that contain heteroatoms. However, they are included with hydrocarbons in much of the literature because their hydrocarbon backbones are the main interest. The most common heteroatom compounds contain sulfur, nitrogen, and oxygen. They are *bad actors*, i. e., they cause equipment problems and poison catalysts. The sulfur compounds include mostly thiols, sulfides, thiophenes, benzothiophenes, dibenzothiophenes, etc. The nitrogen compounds include pyrroles, pyridines, carbazoles, etc. The oxygen compounds include acids, phenols, furans, etc. Trace metal compounds include nickel and vanadyl porphyrins, the removal of which is the subject of intensive research

Hydrocarbons, naphthenes (cycloparaffins or cycloalkanes)

Naphthenes have the general formula C_nH_{2n+z} where

$z = -((\text{number of rings}) \times 2 - 2)$. They contain a fully saturated ring comprised of five or six carbons. Cyclopentane and cyclohexane are the simplest naphthenes. Commercially, naphthenes can be prepared by saturating aromatics with hydrogen. Cyclohexane (C_6H_{12}) is an important solvent and petrochemical

Hydrocarbons, naphthoaromatics (hydroaromatics)

Naphthoaromatics contain at least one aromatic ring fused to at least one naphthene ring. One example is tetralin ($C_{10}H_{12}$). Alkyl naphthoaromatics are highly isomeric. The isomers tend to have similar chemical and physical properties and are very difficult to separate from each other

Hydrocarbons, olefins

Olefins (alkenes) have the general formula C_nH_{2n} and contain one carbon-to-carbon double bond. Olefins are rare in nature, but they are produced in large quantities by thermal cracking and steam cracking. Examples include ethylene (ethane), propylene (propene), 1-butene, 2-butene (butylenes), and isobutylene (2-methylpropylene). Far more reactive than paraffins, olefins have a tendency to polymerize. They serve as building blocks of polyethylene, polypropylene, and hundreds of other important polymers

Hydrocarbons, paraffins

Paraffins (alkanes) have the general formula $C_nH_{(2n+2)}$. They can be divided into normal paraffins, where chains of carbon atoms are straight (linear) and isoparaffins, containing at least one branch. The lightest paraffins are methane (CH_4), ethane (C_2H_6) and propane (C_3H_8). There are two stable isomers of butane (C_4H_{10}), three stable isomers of pentane (C_5H_{12}), five for hexane (C_6H_{14}), 75 for decane ($C_{10}H_{22}$), and many, many thousands for $C_{34}H_{70}$. Light paraffins are highly flammable. Large normal paraffins are waxy. Large isoparaffins are excellent lube basestocks

Hydrocarbons, polynaphthenes (polycycloparaffins)

Polynaphthenes contain more than one fully saturated five- or six-membered ring, where at least two of the rings are fused. At high temperatures, polynaphthenes readily lose hydrogen to form naphthoaromatics and/or polyaromatics. Examples include cis- and transdecalin ($C_{10}H_{18}$). Polynaphthene structures can be three-dimensional, as diamondoid hydrocarbons

Hydrocarbons, polynuclear aromatic (PNA or PAH)

Polynuclear aromatics (PNA) are also known as polynuclear aromatic hydrocarbons (PAH). They contain more than one aromatic ring, and at least two of the rings are fused. They are more hydrogen deficient than benzene. Important examples include naphthalene ($C_{10}H_8$), anthracene ($C_{14}H_{10}$), chrysene ($C_{18}H_{12}$), pyrene ($C_{16}H_{10}$), perylene ($C_{20}H_{12}$), coronene ($C_{24}H_{12}$), and ovalene ($C_{32}H_{14}$). Large polyaromatics are difficult to crack and readily form coke. Many of them are carcinogenic or mutagenic

Hydrocracking

A group of upgrading processes that convert heavy oils into light products in the presence of high-pressure hydrogen. Hydrocracker (HC) products are low in sulfur and nitrogen. HC light naphtha can be blended into gasoline. HC heavy naphtha is an excellent feedstock for catalytic reforming. With certain feeds, HC middle distillates can meet sales specifications for jet and diesel fuels. HC unconverted oil (UCO, also called hydrowax) is a superb FCC feed. In some locales, UCO serves as a feedstock for olefin production plants. For lubricant basestock production, hydrocracking replaces the aromatic extraction step by saturating aromatics to naphthenes and converting the naphthenes into isoparaffins (► *Isodewaxing*)

Hydrocracking, ebullated-bed (e-bed)

Ebullated-bed (e-bed) hydrocracking employs bifunctional catalysts. E-bed processes can achieve significant conversion of vacuum residue. A mixture of catalysts, hydrogen, and resid-containing oil is pumped upwards through a reactor into a reaction zone at high temperature and pressure. The mixture expands as hydrocracking reactions generate light molecules. At the top of the reactor, the catalyst is separated from the product gases and liquids, which pass through a series of separators. Hydrogen is scrubbed to remove H_2S and recycled. Reaction products go through a stripper to a fractionator. The catalyst is returned to the reactor with a recirculation pump at a rate that maintains equilibrium flow inside the reactor

Hydrocracking, fixed-bed catalytic

Fixed-bed catalytic hydrocracking produces C_3+ hydrocarbons from vacuum gas oil and other distillates with similar boiling points. The catalysts are bifunctional, providing both acid-derived cracking activity and metal-derived hydrogenation activity. Hydrocracking catalysts are protected by hydrotreating upstream

Hydrocracking, slurry-phase (thermal)

Slurry-phase hydrocracking is thermal, employing small-diameter additives, which might or might not be catalytic. In combination with a fixed-bed second stage, slurry-phase processes can achieve 95 wt% conversion of vacuum residue, FCC slurry oil, and coal

Hydrodemetalation (HDM)

Removal of trace metals, such as Fe, Ni, V, As, Hg, and Si, in a hydroprocessing unit. HDM is accompanied by HDS, HDN, and saturation reactions

Hydrodenitrogenation (HDN)

Conversion of organic nitrogen compounds into hydrocarbons and ammonia in a hydroprocessing unit. HDN is accompanied by HDO, HDS, and saturation reactions

Hydrodeoxygenation (HDO)

Conversion of organic oxygen compounds into hydrocarbons and water in a hydroprocessing unit.

HDO is accompanied by HDN, HDS, and saturation reactions

Hydrodesulfurization (HDS)

Conversion of organic sulfur compounds into hydrocarbons and hydrogen sulfide in a hydroprocessing unit. HDS is accompanied by HDN, HDO, and saturation reactions

Hydrofinishing

A high-pressure hydrotreating process to improve the color and oxidation stability of lubricant oils

Hydrogen

The lightest chemical element. Molecular hydrogen is H₂. In petroleum processing, H₂ streams might contain different amounts of CO, CO₂, N₂, Cl₂, CH₄, H₂S, and higher hydrocarbons. On-purpose hydrogen is manufactured by steam-hydrocarbon reforming, colloquially called ► *steam-methane reforming* (SMR). Coproduced hydrogen comes from catalytic reformers, olefin manufacturing plants (steam crackers), and electrolytic chlorine-production plants. H₂ is consumed in large quantities in hydroprocessing units

Hydrogen purification

Processes for recovering and purifying hydrogen. Pressure-swing adsorption (PSA) units produce hydrogen with 99.99% purity. In hydrotreaters and hydrocrackers, membrane units can recover > 90% of the hydrogen in high-pressure offgas streams, achieving purities > 95%. Benfield units remove CO₂ and H₂S with potassium carbonate. Amine units remove CO₂ and H₂S with diethanolamine (DEA), methyldiethanolamine (MDEA), or similar compounds. Lean-oil adsorption units remove C₃+ hydrocarbons. Turboexpanders can separate H₂ and methane from other hydrocarbons, and cryogenic units can separate H₂ from everything

Hydroisomerization

Isomerization under hydrogen, also known as isodewaxing in lubricant base oil manufacturing

Hydroprocessing

A general term for refining processes in which hydrogen is consumed. Includes catalytic hydrotreating (to remove sulfur, nitrogen, oxygen, and trace contaminants), catalytic hydrocracking (to convert heavy hydrocarbons into lighter hydrocarbons), catalytic saturation of aromatics (to produce cyclohexane from benzene), and noncatalytic thermal hydrocracking (to convert vacuum residue)

Hydrotreating

A refining process for removing contaminants from petroleum fractions in the presence of catalysts and excess hydrogen. Required pressures depend of feedstock properties. Naphtha hydrotreaters may operate at 300 psig (about 20 barg) while residue hydrotreaters require 2000–3000 psig (about 140–200 barg). Most hydrotreaters employ fixed-bed reactors. Hydrotreating reactions include saturation of olefins and aromatics, HDS, HDN, HDO, and HDM

Isobutylene (C₄H₈)

2-methylpropene, also known as isobutylene. An important feedstock for polyisobutylene, butyl rubbers, ethers (e.g., methyl-*t*-butylether) and antioxidants (e.g., butylated hydroxytoluene).

► *Hydrocarbons*

Isocracking

A fixed-bed hydrocracking process licensed by Chevron Lummus Global (CLG)

In situ

In the original place, as within a reservoir or inside a reactor

Inhibitor

A substance that prevents chemical reactions from happening

Isodewaxing

A fixed-bed hydrocracking process licensed by Chevron Lummus Global (CLG). Specifically designed to catalytically isomerize *n*-paraffins with minimal cracking, thereby reducing the wax content and pour point of lube basestocks and serve as a replacement for solvent dewaxing

Isomerate

High octane product from an isomerization unit. Excellent for blending into gasoline

Isomerization

Refinery processes for isomerizing linear paraffins. C₅/C₆ isomerization converts low octane *n*-pentane and *n*-hexane into high octane *i*-C₅ and *i*-C₆ compounds, which are excellent blendstocks for gasoline. C₄ isomerization converts normal butane into isobutane, which is a necessary feedstock for alkylation units

Isomers

Chemical compounds with the same formula but different structures

Jet and turbine fuels

Middle distillate fuels with boiling ranges of 350 to 550 °F (175–285 °C). Must meet specifications for Jet A, Jet A-1, JP-5, JP-8 and JP-50, and others. Prepared from hydrotreated straight-run kerosene and hydrocracking. Naphtha-based jet fuel (Avjet) is mainly for military usage. *Jet A and Jet A-1 (Commercial)* have been used in the US since the 1950s. Jet A-1 is used in the rest of the world. The freezing point of Jet A is –40 °C, while the freezing point of Jet A-1 is –47 °C. Both Jet A and Jet A-1 have a flash point higher than 38 °C (100 °F) with an autoignition temperature of 210 °C (410 °F). Kerosene-type jet fuel has a carbon number distribution between 8 and 16, similar to JP-8. *Jet B (Commercial)* is a fuel comprising about 70% naphtha-range material and 30% kerosene-range material. It is used for its enhanced cold-weather performance. Its lighter composition makes it more

dangerous to handle. Hence, it's rarely used except in very cold climates. Naphtha-type jet fuel has a carbon number distribution between 5 and 15, similar to JP-4. *JP-4 (Military)* is a turbine or propeller fuel, and a wide-cut fuel (kerosene-gasoline blend) for broader availability. *JP-6 (Military)* is a turbine or propeller fuel and a higher cut than JP-4 with fewer impurities. *JP-7 (Military)* is a turbine fuel and a high-flashpoint specialty kerosene used in advanced supersonic aircraft. *JP-8 (Military)* turbine fuel is kerosene modeled on the Jet A-1 fuels used in civilian aircraft

K

Kerogen

A mixture of complex organic compounds and minerals found in sedimentary rocks. Geologically, kerogen is a precursor to petroleum and natural gas. When heated above 510 °C (950 °F), kerogen decomposes into a full range of hydrocarbon gases and liquids, leaving behind trapped oil/gas, undecomposed geopolymers and minerals. *Type I kerogen (sapropelic)* has a H : C ratio > 1.25 and an O : C ratio < 0.15. It has a great tendency to produce liquid hydrocarbons. *Type II (planktonic) kerogen* has a H : C ratio < 1.25 and an O : C ratio 0.03–0.18. It tends to produce a mix of gas and oil. *Type III (Humic) kerogen* has a H : C ratio < 1 and an O : C ratio 0.03–0.3. It tends to produce coal and gas. *Type IV (residue) kerogen* has a H : C ratio < 0.5. It has no potential to produce hydrocarbons

Kerosene

A fuel with a boiling range between about 150 °C and 275 °C. Historically, due to its use as an illuminant, it was called lamp oil. At present, kerosene is widely used to fuel turbine engines, primarily those that power jet aircraft. It is also a fuel for domestic heaters or furnaces (▶ *Fuel oil* and ▶ *Jet fuel*)

Kerosene-type jet fuel

▶ *Jet fuel*, *Jet A* and *Jet B*

L

LC fining

An ebullated-bed hydrocracking process licensed by CB&I and Chevron Lumms Global (CLG). It is a hydrocracking process capable of desulfurizing, demetallizing and upgrading a wide spectrum of heavy feedstocks. It allows the processing of heavy feedstocks, including atmospheric resids, vacuum resids and bitumen

LC MAX

A CLG process that combines LC-fining and solvent ▶ *deasphalting* (SDA) in an integrated hydroprocessing configuration. Vacuum residue conversions ranging from 80 up to 90% can be attained, even when processing very difficult high-sediment feeds

Lean oil

An absorbing liquid (oil) entering the absorption tower

LHSV

An acronym for liquid hourly space velocity. LHSV is the ratio of the hourly volume of oil processed to the volume of catalyst

Light coker gas Oil (LKGO)

▶ *Gas oil*, *light coker*

Light cycle oils (LCO)

Highly aromatic light middle distillate produced by FCC units, with boiling points that range from about 200 to 400 °C (400–750 °F). Hydrotreaters saturate much of the aromatics and reduce the amounts of sulfur and nitrogen. A typical cetane number for LCO is < 25, and the sulfur content can exceed 0.5 wt%. With severe hydrotreating, LCO can be made suitable for blending into diesel. In hydrocrackers, LCO is converted into naphtha. LCO is commonly used as a *cutter stock* to decrease the viscosity of heavy fuel oils

Light ends

The lowest boiling (lightest) fractions of crude oil. Note: light ends of oil are not referred to as gases

Light gas oils

Liquid petroleum distillates heavier than naphtha, with boiling ranges similar to kerosene

Liquefied natural gas (LNG)

Natural gas, mainly methane, which has been liquefied under pressure and supercooling. The removal of carbon dioxide is critical for dry-ice formation during transportation

Liquefied petroleum gases (LPG)

Liquefied hydrocarbon gases, mainly propane and butanes. Usually sold as fuels

Liquefied refinery gases (LRG)

Hydrocarbon gas liquids produced in refineries, liquefied with pressurization and/or refrigeration. LRG might include ethane, propane, butanes, and refinery olefins (ethylene, propylene, butylene, and isobutylene)

Lithology

The physical characteristics of rocks

Lube assay

Similar to a crude assay. Specifically for crude oils or distillates intended for production of lube basestocks. Includes atmospheric distillation, vacuum distillation, aromatics content, naphthene content, wax content, viscosity, and sulfur content

Lubricant (lube)

A substance that reduces friction between surfaces in contact, which ultimately reduces the heat generated when surfaces move against each other. The finished product is a blend of basestocks with special additives. *Lubricant base oil* is a blend of one or more
▶ *basestocks*

M

Magnaforming

A semiregenerative catalytic reforming process developed by Engelhard and Atlantic Richfield (now a part of BP). Its characteristic feature is a split flow of recycled hydrogen, with about half going to the first

two reactors, which operate at mild conditions, and the other half going to the third reactor, where conditions are more severe (i. e., temperatures are higher). Initially, it employed a monometallic-supported platinum catalyst. More recently, most units contain Pt-Re catalysts for enhanced stability (► *Catalytic reforming*)

Maltenes

Solvent-soluble fraction from deasphalting

MEK

Methyl ethyl ketone, a commonly used solvent in lubricant dewaxing units

Mercaptan

► *Thiols*

Merox

A mercaptan oxidation process developed by UOP for the removal of odorous mercaptans from LPG, propane, butane, naphthas, kerosene, and jet fuel. Mercaptans are converted to liquid disulfides, which can be processed with hydrotreating

Metagenesis

A process that occurs when sedimentary rocks are exposed to the influence of magma and hydrothermal effects (metamorphism). At this physicochemical paleotransformation stage, the only remaining carbon-containing molecules are methane and a carbon residue

Metalloporphyrins

Organometallic compounds in which metals such as nickel and vanadium are bound by chelation within a tetrapyrrolic structure

Methanol (CH₃OH)

The simplest alcohol. An important source of petrochemicals. An intermediate to synthetic gasoline from the Fischer–Tropsch process

Methanol-to-gasoline (MTG)

A process that converts methanol to gasoline via the initial formation of dimethyl ether (DME) by dehydration, followed by DME dehydration over a zeolite catalyst, ZSM-5

Methanol-to-olefin (MTO)

A process that converts methanol to olefins via the initial formation of dimethyl ether (DME) followed by dehydration over an acidic zeolite catalyst, such as H-SAPO-34, to yield ethylene and propylene

MIBK

Methyl isobutyl ketone, a commonly used solvent in wax deoiling units

Microcrystalline wax

Wax derived from vacuum resids, which contains mostly cycloparaffins with *n*-alkyl and isoalkyl sidechains

Middle distillates

Fractions boiling between about 200 and 400 °C (400–700 °F). Middle distillates include kerosene, jet fuel, diesel, and fuel oils

Midstream

Business sector in the oil industry that involves bulk transportation, storage, and distribution of crude oil,

LNG, natural gas, and refined petroleum products. In some companies, midstream includes trading, marketing, and/or retail sales

Motor gasoline (Mogas)

► *Gasoline*

Motor octane number (MON)

► *Octane number*

MTBE (methyl tertiary butyl ether, (CH₃)₃COCH₃)

An oxygenate initially used in reformulated gasoline. Banned in the United States after it leaked into groundwater from some filling station storage tanks. Still used in Europe, where filling station storage tanks are properly maintained

N**Naphtha**

The lowest-boiling liquid fractions from petroleum distillation

Naphtha, heavy (HN)

Heavy naphtha boils between 90 and 200 °C. Constituents have carbon numbers ranging from 6 to 12. The octane rating is usually too low for direct blending into gasoline. Therefore, after sulfur removal, HN is generally conveyed to a catalytic reforming unit, which converts it into high-octane reformate (► *Catalytic reforming*). Small amounts of hydrotreated HN are used as solvents

Naphtha, light (LN)

Light naphtha boils between 30 and 90 °C. Constituents have carbon numbers ranging from 5 to 6. The octane rating of straight-run LN is often suitable for blending into gasoline, usually after treating to remove sulfur compounds (► *Merox*). Treated LN can be used as a solvent

Naphtha, petrochemical (PCN)

Full-range low-sulfur naphtha that is converted into olefins in steam-cracking plants. Paraffinic naphthas are preferred

Naphthenes

► *Hydrocarbons, naphthenes*

Naphthenic crudes (asphaltic crudes)

Contain more naphthenes than paraffinic crudes. Good for producing certain lubricant basestocks

Natural gas

A mixture of naturally occurring hydrocarbon gases, primarily methane. Used for fuel and to make petrochemicals. Merchant natural gas must contain less than 2 vol% CO₂ and less than 4 ppmv hydrogen sulfide

Natural gas liquids (NGL)

Components of natural gas other than methane, including ethane, propane, butane, isobutane and pentanes. Separated from methane by absorption, condensation or other methods in a field facility or in a gas processing plant

Natural gasoline

A mixture of hydrocarbons, mostly pentanes and heavier, which are extracted from natural gas. To be

transported in common-carrier pipelines, it must meet specifications on vapor pressure, endpoint, and composition set by the Gas Processors Association or similar organizations

Needle coke

▶ *Coke, needle*

Normal paraffin

▶ *Hydrocarbons, paraffins*

O

Octane number

A measure of the burning quality of gasoline (petrol) in a spark-ignition internal combustion engine. A higher octane number (ON) means a fuel is less susceptible to knocking (premature ignition). Specifically, ON is the percentage by volume of isooctane in a combustible mixture containing isooctane (ON = 100) and normal heptane (ON=0) for which the knocking characteristics match those of the fuel being tested. The octane number tested in a standard engine at 900 rpm to compare with highway driving conditions is the *Motor octane number (MON)*. The *Research octane number (RON)* is tested in a standard engine at 600 rpm to compare with low-speed or city driving conditions. The *Posted octane number (PON)* is defined as $(RON + MON)/2$ and is posted on pumps in gasoline filling stations in North America, where it is also referred to as the antiknock index (AKI)

Oil sand (tar sand)

Loose sand or partially consolidated sandstone containing mixtures of sand, clay, water, and bitumen

Oil shale

Organic-rich fine-grained sedimentary rock containing kerogen from which liquid hydrocarbons can be recovered

Olefins

▶ *Hydrocarbons, olefins*

Organization of Petroleum Exporting Countries (OPEC)

An intergovernmental organization, founded in 1960, whose stated objective is to *coordinate and unify the petroleum policies of member countries*. Founding members include Iran, Iraq, Kuwait, Saudi Arabia, and Venezuela. Other members now include Algeria, Angola, Ecuador, Libya, Nigeria, Qatar, and the United Arab Emirates. Former members are Gabon and Indonesia. It is not true that Alberta, a Province of Canada, is a member of OPEC

Outcrop

A visible exposure of bedrock or ancient superficial deposits on the surface of the Earth

Overburden rock

Rock that overlies the source rock, seal rock, and reservoir rock of a petroleum system. The weight of the overburden affects the pressure and temperature in a reservoir

P

PAH

▶ *Polynuclear aromatic hydrocarbon*

Paraffinic (waxy) crudes

▶ *Crude oil, paraffinic*

Paraffins

▶ *Hydrocarbons, paraffins*

Partial oxidation (POX)

Process for converting coke, coal, or resid into a mixture of CO and H₂ (synthesis gas) in the presence of substoichiometric oxygen and steam

Petrol

A term commonly used in some countries as a synonym for gasoline

Petrolatum

Petroleum jelly derived from dewaxing heavy lube basestocks. Its color is translucent white, amber or yellowish. It has no odor or taste. It can be used in medicines, ointments and cosmetics, as well as in polishes and greases

Petroleum

Generally includes liquid crude oils and condensates. Sometimes includes natural gas and synthetic petroleum. Synthetic petroleum, also known as synthetic crude or syncrude, is liquid obtained from the processing of oil shale, oil sands, and biomass (▶ *Crude oil*). Physical properties of petroleum include boiling point, density, viscosity, heteroatom contents, etc., measured by crude assay tests

Petroleum classification

Petroleum (crude oil) is broadly classified as paraffinic, asphaltic or mixed crudes by Watson Characterization Factor for paraffinic or Correlation Index for aromaticity (▶ *Crude oil*)

Petroleum coke

▶ *Coke, petroleum*

Petroleum components (chemical composition)

Petroleum is mainly composed of hydrocarbons, which may include heteroatoms of sulfur, nitrogen, oxygen and metals. Hydrocarbons include saturates, such as paraffins and naphthenes, and aromatics

Petroleum engineering

A field of engineering related to the production of crude oil and natural gas, including drilling engineering, reservoir engineering, production engineering, etc.

Petroleum gas

Hydrocarbons that are gases at ambient temperature and pressure. Includes natural methane and ethane along with C₂–C₄ olefins from refining processes. May include small amounts of propane and butanes

Petroleum system (hydrocarbon system)

The petroleum system is a unifying concept that encompasses all of the disparate elements and processes of petroleum geology, including the essential physical elements: source rock, in which oil and gas were formed; reservoir rock, in which oil and

gas accumulate; impermeable seal rock (cap rock), which prevents oil and gas from escaping the reservoir; and overburden rock (► *Overburden*). It also includes the processes that form traps and enable petroleum formation, migration, and accumulation. Finally, it includes mechanisms for the movement of petroleum from reservoirs and other sources into shows, seeps, or accumulations

PIONA Analysis

► *PONA analysis*

Pipe still

A distillation apparatus composed of a series of pipes used to fractionate petroleum. Synonym for atmospheric distillation unit

Plastics

Materials made of organic compounds, typically polymers of high mass. Plastics are malleable and can be molded into solids

Play or petroleum play

A group of oil fields or prospects in a geographic region that are controlled by the same set of geological circumstances. Usually refers to an area with conditions favorable for hydrocarbon accumulation, including a specific source, reservoir, and trap type

PNA

► *Polynuclear aromatic hydrocarbon*

Polyalphaolefin (PAO)

Star-shaped polymer (oligomer) with a central carbon atom connected to four arms (alkyl groups). Derived from alpha olefins and used as high-viscosity index lube basestock

Polyester

Polymer with units linked by ester groups. Mainly used as a resin for making synthetic textile fibers

Polymer gasoline

Gasoline product from polymerization of light olefins

Polymerization

A chemical reaction in which two or more small molecules combine to form larger molecules that contain repeating structural units of the original molecules. In oil refining, catalytic polymerization (Catpoly) converts propylene (and sometimes isobutylenes) into high-octane C6–C12 isoparaffins suitable for gasoline blending. The most common catalyst is solid phosphoric acid (SPA). In the petrochemical industry, polymerization is the key process for producing high polymers, such as polyethylenes and polypropylenes

Polynuclear aromatic hydrocarbon (PAH or PNA)

Molecules that include at least two fused aromatic rings (► *Hydrocarbons*)

Polyolefins

High polymers derived from olefins, such as polyethylenes, polypropylenes, ethylene/propylene copolymers, polyisobutylenes, etc.

Polyol Esters

Esters made from polyols (pentaerithritol, trimethylol propane or neopentyl glycol) with acid. Due to their high viscosity indexes (VIs), they are excellent Group V lube basestocks

PONA or PIONA analysis

Distributions of paraffins, isoparaffins, olefins, naphthenes, and aromatics

Pour point

The lowest temperature at which an oil loses fluidity. Determined as 3 °C above the temperature at which a sample no longer moves when inverted. Important parameter for pipeline transportation and diesel fuel

Powerforming

A semiregenerative catalytic reforming process developed by Esso (now ExxonMobil) (► *Catalytic reforming*)

Pressure swing adsorption (PSA)

An adsorbant-based process in which a gas is purified by differential pressure. In refining, PSA is used for hydrogen purification. Applications include removal of CO and CO₂ from ► *SMR* product gas, and purification of refinery offgas streams. PSA employs adsorbents, usually activated carbon, silica gel, alumina, and zeolite molecular sieves. The process steps are as follows: 1. At high pressure, *dirty* gas containing hydrogen, CO, CO₂, N₂, Ar, light hydrocarbons, and sometimes H₂S, passes over a clean bed of adsorbents. The adsorbents remove most of the nonhydrogen components. The hydrogen continues on to a subsequent reactor. 2. In the first low-pressure step, the reactor is depressured under concurrent flow, i. e., the gases continue to flow in the original direction. 3. During the second low-pressure step, clean hydrogen flows across the loaded adsorbent in the opposite direction, sweeping the contaminants into a tail gas stream. When the bed is clean, the reactor is repressured with dirty gas. PSA can achieve 80–90% hydrogen recovery while producing hydrogen with 99.99 vol% purity

Primary migration

The expulsion of newly generated hydrocarbons from a source rock and movement into carrier rock

Primary recovery

Oil recovery by natural underground pressure, usually supplied by associated natural gas and evolution of dissolved gas (gas drive), or driven by hydrostatic pressure, liquid expansion and expansion of reservoir water (water drive)

Process control

A system of valves, instruments, controllers, and computer programs that are used to operate an industrial process unit. *Advanced process control (APC)* describes a broad range of techniques that enhance process control. Applications can reside within a DCS computer or supervisory computer. *Advanced regulatory control (ARC)* describes techniques including feed-forward, override, adaptive gain, switching logic, and inferentials. It is a catch-all term for customized DCS-resident techniques that do not fall into any other category. ARCs are typically implemented in the DCS computer. *Inferential control* calculates a stream property from process measurements. Inferentials are developed and verified

with laboratory measurements. They are used to replace online analyzers when suitable analyzers do not exist or are deemed to be too expensive to install and maintain. *Model predictive control (MPC)*, also called *multivariable predictive control (MVPC)*, manipulates several MVs simultaneously to achieve multiple objects. It is based on a matrix of important independent variables (MVs and DVs), a matrix of controlled variables, and a third matrix that captures dynamic relationships between the other two. Proper matrix identification, for example with manual or automated step tests, is the key to success. An MPC controller executes on a predetermined schedule, typically every minute; some controllers in the glass industry execute far more frequently

Process control, distributed control system (DCS)

A system in which control elements (controllers) are located in many places throughout a system. In modern facilities, operators in a central control room can operate important control elements from a single location. Computerized DCS systems include the ability to host computer programs, including ARC and APC applications

Process control, proportional–integral–derivative (PID)

A common type of feedback controller, which continuously calculates the difference between a measurement and a setpoint. The controller calculates how to minimize the error based on P, I, and/or D algorithms. It then adjusts the relevant MV accordingly

Process control, time to steady state (TSS)

The time it takes for a CV to reach a steady value after an MV is changed

Process control, variables

The *Controlled variable (CV)* is the process target achieved by adjusting manipulated variables. The *Disturbance variable (DV)* is an independent variable, such as ambient temperature, which cannot be manipulated. The *Manipulated variable (MV)* is an independent variable that can be used to manage process performance. The change in the value of a CV divided by a unit change in an MV is called *Gain*

Production

A branch of upstream petroleum business that recovers gas or oil from reservoirs

Production engineering

A branch of petroleum engineering that includes a combination of manufacturing technology, engineering practices, and management principles related to oil and gas production. A production engineer is engaged in reviewing seismic and other data, designing and executing drilling plans, selecting drilling technology (mud weight, bits, piping, centralizers, motors, etc.) and well completion technology, and the handling of produced oil and gas at the well head

Propane (C₃H₈)

A three-carbon alkane used as a chillant in sulfuric

acid-catalyzed alkylation, a solvent in deasphalting, or a diluent in catalytic polymerization of propylene

► *Hydrocarbons*

Propylene (C₃H₆)

► *Hydrocarbons*

Prospect

An individual exploration target. A specific trap that has been identified and mapped but has not yet been drilled

Pseudocomponents

Hypothetical components used to model petroleum during the design and optimization of equipment and processes. The properties of pseudocomponents are averages of the properties of many individual compounds with similar boiling ranges. Traditional pseudocomponents do not include molecular information, such as hydrocarbon types or concentrations of heteroelements. This makes them ill-suited for kinetic reaction models, in which conversion, HDS, HDN, and saturation are important parameters

PVT measurements

The pressure, volume and temperature of a material, usually a gas

Pyrolysis

Thermochemical decomposition of organic material at elevated temperatures in the absence of oxygen

Q

Quantitative structure-activity relationship (QSAR)

Correlation or classification that quantitatively relates the response (activity, adsorptivity, etc.) of a group of chemicals to changes in certain common physicochemical characteristics (descriptors) of the constituent species, usually by modeling

Quench

A relatively cool stream (liquid or gas), which is mixed with hot reactants to control reaction temperatures

R

Raffinate

In general, the raffinate in a solvent extraction process is the stream from which undesired components have been removed. In lube basestock preparation, the raffinate is the dearomatized oil. In extractive wax deoiling, the raffinate is the oil-free wax

Raffinate hydroconversion

Hydroconversion of raffinate from solvent extraction processes to produce lubricant basestock with a high viscosity index and low volatility

Reboiler

A heater or heat exchanger at the bottom of an atmospheric distillation tower, which vaporizes a portion of the liquid and introduce it several trays above the bottom to assure some of light components not carried out with the bottom product

Recycle cut point (RCP)

In hydrocracking, the recycle cutpoint (RCP) is the final boiling point of the heaviest product of conversion. If it were possible for a fractionator to give square-cut distillation with no overlap, the RCP would be the initial boiling point of unconverted oil (UCO). In many units, the hydrocracker UCO is recycled. The analogous term for once-through units, in which there is no recycling, is *conversion cutpoint*. RCP has been applied to delayed coking units in which heavy liquids are recycled to improve separation in the fractionator

Refinery

An installation that manufactures finished petroleum products from crude oil, unfinished oils, natural gas liquids, other hydrocarbon streams, and oxygenates. Refinery operations include: planning and scheduling, crude blending, preprocessing in desalting units, separation with distillation or extraction, treating (including chemical treatment, mercaptan oxidation, and hydrotreating) conversion (breaking C–C bonds) with thermal and catalytic cracking, catalytic reforming (dehydrogenation of naphthenes and formation of ring compounds; no C–C bond breaking), alkylation and polymerization (making high-octane C6 to C12 molecules from C3 to C5 molecules), catalytic isomerization, lubricant manufacturing, sulfur removal and recovery, hydrogen production, product blending, and environmental protection

Refinery, hydroskimming

A refinery with atmospheric distillation, hydrotreating and reforming units designed to produce desulfurized fuels, petrochemical naphtha, and high-octane gasoline. In many modern hydroskimming refineries, the atmospheric residue goes to an asphalt plant

Refinery, integrated

A refinery integrated with a petrochemical manufacturing plant

Refinery, topping (simple)

A simple refinery that consists of tankage, an atmospheric distillation unit, recovery units for gas and light hydrocarbons and necessary utility systems (steam, power and water treatment plant). Due to tight restrictions on product quality, very few of these are left in developed countries

Refinery yield

The amount of finished product from a refinery divided by the sum of feedstocks (crude oil and other imported unfinished oils), expressed either as volume percent or weight percent. The calculation generally excludes produced sulfur, natural gas liquids, oxygenates and other imported blending components

Reflux

That portion of the condensed top stream from an atmospheric distillation tower that is returned to the tower to provide cooling. Reintroduction of the condensed liquid reduces the amount of heavy components that otherwise would be carried out with

the top product. Reflux is an essential manipulated variable (MV) for controlling tower temperature

Reflux ratio

The ratio of the portion of condensed liquid returning to the distillation tower to the portion collected as top product

Reformate

Liquid product from a catalytic reformer. Reformate is highly aromatic, and has a high octane number and a low vapor pressure (RVP). It can be blended into gasoline or converted into solvents and chemical precursors in an aromatics plant

Reforming, catalytic

A catalytic process for dehydrogenating naphthenes into aromatics. Also converts acyclic paraffins to alkyl cyclopentanes and alkyl cyclohexanes, which then undergo dehydrogenation. The products are high-quality hydrogen and reformate (► *Reformate* and ► *Catalytic reforming*)

Reforming, thermal

A process to convert low-octane naphtha to high-octane gasoline

Reformulated gasoline

Low-emissions gasoline that meets regulations promulgated by the US Environmental Protection Agency (EPA) under Section 211(k) of the Clean Air Act. Specifications include upper limits on RVP, olefins, sulfur, air toxics such as benzene, and lower limits on oxygen. A gasoline can be designated as reformulated if it meets or exceeds EPA emissions and benzene content standards in engine tests, even though it may not meet all composition requirements (e.g., oxygen content). This category includes Oxygenated Fuels Program Reformulated Gasoline (OPRG). Reformulated gasoline excludes Reformulated Blendstock for Oxygenate Blending (RBOB) and Gasoline Treated as Blendstock (GTAB)

Refractive Index

The ratio of the velocity of light of a specific wavelength in air to the velocity in a test sample. Used to estimate polynuclear aromatic (PNA) content

Regenerator

► *Catalyst, regeneration*

Reid vapor pressure (RVP)

Common measure of the volatility of gasoline determined at 100 °F (≈ 38 °C) of vapor pressure of the liquid by ASTM D-323

Research octane number (RON)

► *Octane number*

Reserve

Oil and gas accumulations that have been drilled and can be produced economically

Reservoir (petroleum)

Subsurface pool of oil or gas contained in porous or fractured rock formation, broadly divided into conventional and unconventional reservoirs. In *conventional reservoirs* buoyant forces keep hydrocarbons in place below a sealing caprock. The term *unconventional reservoir* is used for any reservoir that requires special recovery operations.

These include tight shale, tight sands, oil shales, coalbed methane, heavy oil, oil sands, and gas-hydrate deposits

Reservoir engineering

A branch of petroleum engineering concerned with characterizing and defining oil and gas reservoirs. Reservoir engineers work closely with production engineers as they develop drilling and production plans. It also deals with drainage problems or other challenges arising during development and production

Resid

A term commonly used in the oil industry as a synonym for *residue* or *residuum*. Specifically refers to the residue at the bottom of a distillation after all light fractions distill off

Resid FCC (RFCC)

A version of ► *FCC* designed to process resid. Includes provisions to deal with both the high metals content of resid and its high propensity to form coke. Typically, most metals are removed in an upstream resid hydrotreater. Remaining metals are accommodated with metal-resistant catalysts. When burned in the regenerator, the excess coke on the FCC catalysts produces more than enough heat to run the unit. The excess heat can be removed with catalyst coolers (steam coils) in the regenerator. Another solution is to burn off part of the coke in a primary regenerator and the rest of the coke in a secondary regenerator

Resid hydrocracking (RHC)

Hydrocracking processes that convert resids (► *Hydrocracking, e-bed* and ► *Hydrocracking, slurry-phase*)

Resid upgrading

Processes for upgrading resids, either thermally, catalytically, or with extraction (► *Coking* ► *Hydrocracking, e-bed* ► *Hydrocracking, slurry-phase* and ► *deasphalting*). The choice of technologies depends upon both the quality of the resid stream and the desired quality of the naphtha, diesel, and VGO products. Products from coking and solvent extraction require hydroprocessing to remove sulfur, nitrogen, metals, Conradson carbon residue (CCR), and any remaining asphaltene

Residual oil supercritical extraction (ROSE)

A process for extracting oil from atmospheric and vacuum resids with supercritical propane, butane or pentane, leaving behind resins and asphaltenes

Residuum

► *Resid*

Resin

Polar fraction of petroleum isolated by solvent fractionation, containing relatively high-molecular-weight, polar, polycyclic, aromatic ring compounds

RFCC

Resid FCC or reduced crude cracking (► *FCC*)

Rheniforming

A semiregenerative reforming process developed by Chevron, which employs bimetallic platinum-rhenium

catalysts. The rhenium improves catalyst stability (► *Catalytic reforming*)

Rich oil

The absorbing liquid (oil) containing selectively absorbed components

Rock-Eval pyrolysis

An analytical method used in petroleum exploration to measure the quantity, quality, and thermal maturity of organic matter in rock samples

S

Scrubber

An apparatus to remove particulates and/or gases from process streams, including industrial exhaust streams. Examples include amine scrubbers, which remove H₂S and CO₂, and flue-gas scrubbers, some of which remove SO_x and NO_x

Secondary migration

After primary migration, further movement of the hydrocarbons in carrier rock into reservoir rock in a hydrocarbon trap or other area of accumulation (reservoir)

Secondary recovery

When the natural pressure of a reservoir is low and not sufficient for oil recovery, surface or submerged pumps are used. Alternatively, it is possible to increase reservoir pressure by water injection (water flood) and gas injection (gas flood). Chemicals are often applied to free up oils

Selective catalytic reduction (SCR)

A catalytic process for removing nitrogen oxides from flue gas. The nitrogen oxides are reacted with ammonia to produce N₂ and water

Selectivity

The amount (percentage) of a desired product in the total product

Shale gas

Natural gas trapped within shale formations and recovered by unconventional means, such as hydraulic fracturing

Shale oil

Oil trapped within shale formations and recovered by unconventional means, such as hydraulic fracturing. Also refers to oil produced by thermally cracking the kerogen in oil shale

Shell Claus Offgas Treatment (SCOT)

The sulfur compounds in Claus tail gas are converted to H₂S by hydrotreating over a Co-Mo catalyst. The gas is cooled and contacted with di-isopropanolamine (DIPA) to recover the H₂S. The sulfur-rich DIPA is sent to a stripper, where H₂S is removed and sent back to the Claus plant. The lean DIPA is recycled to the absorber

Slack wax

Raw wax containing oil. A byproduct of solvent dewaxing during lubricant oil manufacturing

Slurry Reactor

Slurry reactors process mixtures of solids, mixtures, and gases, where the solids are so finely divided that

they behave as part of the liquid. Bubble-point gas is introduced at the bottom of the reactor and reacts with the slurry as the mixture moves toward the top (► *Hydrocracking, slurry-phase*)

Smoke point

A test (ASTM D1322) performed to determine the smoke-forming tendency of jet fuels and kerosene. It is the maximum flame height at which a test fuel will burn without smoking in a standard smoke point lamp and a circular wick made of woven cotton. Smoke points are highest for paraffins and lowest for aromatics

Solubility

The amount of a compound or liquid that can be dissolved in a specific amount of solvent

Sour crude

Crude oil containing > 0.5 wt% total sulfur

Sour gas

Natural gas and any other gas containing more than 5.7 mg of H₂S per cubic meter (equivalent to 4 ppmv in methane)

Source rock

Rocks containing kerogens that could generate hydrocarbons

SO_x

The sum of SO₂ and SO₃

Sponge oil

The liquid used in an absorption tower to soak up the constituents to be extracted

Stabilizer

A fractionator used to stabilize products by removing volatile or reactive lighter components. A prominent example is removal of butane from gasoline range streams

Steam-assisted gravity drainage (SAGD)

An enhanced oil recovery technology for producing heavy crude oil and bitumen. A pair of horizontal wells is drilled into the oil reservoir. Steam is pumped through the top well, where it mobilizes oil with heat. The oil flows down to the bottom well, a few meters below, where it is collected and brought to the surface

Steam cracking

A process for converting saturated gaseous or liquid hydrocarbons – such as ethane, LPG, naphtha, and hydrocracker UCO – into olefins. The feed is diluted with steam and heated to ≈ 1050 °C in Cr-Ni reactor tubes, where the hydrocarbons crack into smaller compounds, primarily olefins; at such high temperatures, olefins are more stable than paraffins. Reaction time is measured in milliseconds. The cracked products exit at around 850 °C and are rapidly quenched to 300 °C to improve yields and avoid coke formation. Steam cracking is the principal industrial means of producing ethylene, propylene, and other olefins, which are converted into polyolefins (polyethylenes, polypropylenes, etc.)

Steam-hydrocarbon reforming

(► *Steam-methane reforming, SMR*).

Steam-hydrocarbon reforming is a more accurate term

than SMR, because some feeds contain up to 20% nonmethane hydrocarbons

Steam-methane reforming (SMR)

The most common method for producing high-quality hydrogen from methane. The reaction between steam and methane (1 : 1 mole ratio) occurs at 1500 °F (815 °C) over a nickel catalyst. The main reaction products are hydrogen and carbon monoxide (3 : 1 ratio). In a downstream high-temperature shift reactor, CO reacts with water via the water-gas reaction to form CO₂ and more hydrogen. In modern units, CO and CO₂ are removed from the product with a PSA unit, which makes hydrogen with a purity > 99.9%. It is common now to send refinery offgas streams to SMR units; in addition to methane, these offgas streams contain hydrogen and C2–C3 gases

Still gas (refinery gas)

A general term for gases produced in refineries by strippers or distillation units. Depending on composition, still gas is used as a refinery fuel, a source of recoverable hydrogen, or a petrochemical feedstock

Straight-run

A fraction taken directly from the atmospheric distillation unit and not from a conversion process

Strategic petroleum reserve

Petroleum stocks maintained by the US government for use during periods of major supply interruption

Stratum

A layer or a series of layers of rock in the ground

Surfactant

A chemical that reduces interfacial resistance for the mixing of oil and water. In oil production, surfactants change the wettability of reservoir rock

Sweet crude

Crude oil containing < 0.5 wt% total sulfur

Sweet gas

Natural gas with a low sulfur content (< 4 ppm by volume under standard temperature and pressure)

Sweetening

A process for improving odor and color in petroleum products by oxidizing or removing sulfur-containing compounds

Syncrude (synthetic crude oil)

Crude oil produced from coal, bitumen or shale oil; in this context, shale oil comes from retorted oil shale. To make so-called synthetic bitumen (synbit), bitumen is upgraded by a coker, visbreaker, or hydroprocessing unit

Syngas (synthetic gas)

A mixture of CO and hydrogen produced by steam-methane reforming, partial oxidation, or Fischer–Tropsch synthesis

Synthetic gasoline (note: not syngas)

Gasoline produced from biomass, coal and heavy oil fractions with Fischer–Tropsch or methanol-to-gasoline (MTG) processes

Synthetic lube basestock (synlube)

Basestock synthesized from polyalphaolefins. Used to make lubricants of very high quality, with high

viscosity index (VI), low pour point, low volatility, and high thermal and oxidation stability

T

Tail ends

The highest boiling components of a mixture

Tank farm

A collection of tanks at a given location for storing crude oil and products

Tanker and barge

Tankers transport crude oil and products over oceans and seas. The largest supertankers can carry more than three million barrels of crude. Barges transport smaller quantities on rivers or lakes

Tar sand

► *Oil sand*

Tertiary recovery (enhanced oil recovery)

Tertiary recovery or enhanced oil recovery (EOR) is designed to reduce viscosity of the crude oil in low-permeability carbonate reservoirs that respond poorly to conventional secondary recovery. Three primary techniques for EOR are gas injection, chemical injection, and thermal recovery

Tetraethyl lead (TEL)

A nearly extinct gasoline additive used to enhance the octane number of gasoline. It is used in avgas and in some countries with loose environmental regulations

Thermal cracking

Breaking C–C bonds with thermal energy (heat). Modern thermal cracking processes include visbreaking, delayed coking, fluid coking, and one particular brand of slurry-phase hydrocracking. Compared to catalytic cracking, thermal cracking makes far more undesirable light ends (methane, ethane) and olefinic naphtha. The advantage of noncatalytic thermal hydrocracking is the ability to achieve up to 95 wt% conversion of vacuum resid

Thermal recovery

Thermal recovery introduces heat into a reservoir with steam, hot water, or hot gas. This increases pressure and reduces the viscosity of oil in the reservoir, allowing it to make its way to a production well. In situ combustion, supported by pumping air into an injection well, is another thermal recovery method

Thermofor catalytic cracking (TCC)

An obsolete catalytic cracking process, which contained a moving bed to which regenerated catalysts were added and from which spent catalysts were removed. Catalysts were transported by baskets on elevators

Thermoplastic

Synthetic resin that becomes plastic on heating and hardens on cooling

Thiols (mercaptans)

Organosulfur compounds containing an –SH group. Many have strong odor. Some mercaptans, especially *t*-butyl mercaptan, are used as odorants in natural gas for leak detection

Toe-to-heel air injection (THAI)

An in situ combustion method for producing heavy oil, also known as *fireflooding*. Air is introduced through a vertical injection well. Oil is produced from a horizontal well having its *toe* in close proximity to the air-injection well. Combustion supported by air injection generates a flame front, which pushes oil through the horizontal well to its *heel*, where a production well conveys the oil to the surface

Toluene (C₆H₅CH₃)

An aromatic hydrocarbon, used as a solvent or petrochemical feedstock (► *Hydrocarbons*)

Topped crude

The bottoms of atmospheric distillation of crude oil after the removal of gas oil and lighter fractions

Topping

Removal of light fractions from crude oil by distillation (► *Refinery*, *topping*)

Total acid number (TAN)

The acidity of a crude oil determined by titration with potassium hydroxide. Results are expressed as milligrams of KOH required to neutralize the acids in a gram of oil

Total boiling point (TBP) curve

A distillation curve in which accumulated yield is plotted against boiling point. Determined from atmospheric and vacuum distillation, where vacuum distillation boiling points are converted to atmospheric equivalent boiling points (AEBP)

Trap

Impermeable rock that enables the accumulation of petroleum. Typical petroleum traps include anticline traps, faults and salt-domes (► *Petroleum system*)

Trickle bed reactor

A fixed-bed reactor containing a packed bed of catalyst, in which reacting fluids flow concurrently downwards. Typically used in catalytic hydrogenation, hydrotreating, and hydrocracking processes

True boiling point (TBP) curve

A distillation curve in which accumulated yield is plotted versus boiling point, determined from atmospheric and vacuum distillation with vacuum distillation boiling points converted to atmospheric equivalent boiling points (AEBP)

U

Ultraforming

A cyclic semiregenerative reforming process developed by Standard Oil of Indiana (Amoco, now a part of BP) in 1954

Ultralow sulfur diesel (ULSD)

Diesel fuel with sulfur content < 10 ppmw in North America, Europe and many other countries. As of January 1 2017, ULSD in populous regions of China must contain < 10 ppmw sulfur

Unicracking

A collection of hydrocracking processes designed and licensed by UOP

Uniflex

A slurry-phase hydrocracking process licensed by UOP that achieves higher than 90 wt% conversion of vacuum residue and other low-quality feeds. Achieves > 60 vol% diesel yield. Uniflex VGO can go to a conventional refinery unit, such as FCC or a hydrocracker

Upstream

Business sector in the oil industry. Includes discovery (exploration) and recovery (production) of crude oils and natural gases. Commonly known as exploration and production (E&P)

Urea dewaxing

Using urea to dissolve waxy paraffins for producing low-pour-point oils

V**Vacuum distillation**

► *Distillation, vacuum*

Vacuum gas oil (VGO)

► *Gas oil, vacuum*

Vacuum residue or vacuum resid (VR)

Resid from a vacuum distillation unit; typically everything that boils above about 1050 °F (≈ 565 °C) (AEBP). Contains the highest boiling and nonboiling components in crude oil

Van Krevelen diagram

Plots the hydrogen-to-carbon ratio as a function of the oxygen-to-carbon ratio. Used to assess kerogens and petroleum

Vapor lock

A condition under atmospheric conditions of high temperature that causes excessive gasoline vaporize in fuel lines, disabling the fuel pump and shutting down the engine

Veba Combi-Cracking (VCC)

A two-stage hydrocracking process developed by Veba (now BP) and licensed by KBR. Vacuum residue, FCC slurry oil, coal tar, and coal are converted into finished gasoline, finished diesel, and high-quality unconverted oil. Total conversion of 1050 °F-plus (565 °C-plus) can exceed 95 wt%. Slurry-phase hydrocracking occurs in the first stage. The slurry is a mixture of oil, hydrogen, and a finely divided additive. Thermal cracking generates light products and intermediate microcoke, which deposits on the additive and undergoes hydrogenation. First stage products then go to the second stage, which is a conventional fixed-bed hydrocracking unit. The hydrogen pressure for both stages is 200 bar. Temperature in the first stage is about 465 °C. Second-stage temperatures are lower
 (► *Hydrocracking, slurry-phase*)

Visbreaking

A mild thermal cracking process, which operates at 470–490 °C (880–920 °F) and at 3.4–13.8 bar (50–200 psi), and reduces the viscosity of fuel oil to acceptable levels. Conversion is not the prime

purpose. The residence time is low to avoid coke formation. The cracking reaction is quenched before completion to minimize overcracking

Visbreaking, coiled cracking

Occurs in furnace tubes (coils). The quench is provided by heat exchange with feed or a stream of cold oil. Compared with soaker visbreaking, it has higher outlet temperatures (885–930 °F or 473–500 °C) and shorter reaction time (1–3 min)

Visbreaking, soaker cracking

Occurs not in the furnace, but in a soaker drum after the furnace. Oil is held in the drum for a predetermined time prior to quenching to allow cracking to occur. Compared with coiled visbreaking, it has lower outlet temperatures (800–830 °F or 427–433 °C) and longer reaction time

Viscosity

Resistance of a fluid to shear and/or tensile stress. The dynamic viscosity is the resistance of a fluid against shearing flows, where adjacent layers move with different speeds, parallel to each other. Kinematic viscosity is the ratio of the absolute viscosity of a liquid to its specific gravity at the temperature at which the viscosity is measured

Viscosity index (VI)

A measure of kinematic viscosity as a function of temperature. Higher VI lubricant oils are superior, because for them the relative change in viscosity with temperature is lower

W**Water flooding**

The injection of water into a reservoir to displace oil for secondary recovery

Water gas shift (WGS) reaction

Reaction of carbon monoxide (CO) with steam to produce carbon dioxide and hydrogen. The second reaction step in a steam-methane (steam-hydrocarbon) reformer

Watson (or UOP) characterization factor (K_w)

► *Characterization factor*

Wax (petroleum wax)

A solid or semisolid material consisting of a mixture of hydrocarbons obtained or derived from petroleum fractions, or through a Fischer–Tropsch-type process, in which straight-chained paraffins with high carbon numbers predominate

Wax deoiling

A process for making food-grade wax from low-sulfur slack wax, which is a byproduct of solvent dewaxing during lube basestock preparation. Oil is extracted from the slack wax with solvents such as MIBK (methylisobutyl ketone). The wax is crystallized in a chiller and recovered by rotary drum filtration

Weathered crude oil

Crude oil that has lost an appreciable quantity of more volatile components during transportation, handling and storage

Weight hourly space velocity (WHSV)

Weight of feed flow per hour divided by catalyst weight. Units: 1/hr

Well completion

In petroleum production, the process of making a well ready for oil recovery or fluid injection. Wells are completed by casing the well bore with steel pipe and cementing the casing into place

Well log

A record of chemical and physical measurements along the depth of a well bore. Well logs can be updated in real time with signals transmitted via wire to the surface. An *Acoustic well log (Aonic)* is a record of the speed of sound as it travels through rock, and is useful in determining porosity. *Electric resistivity well logging* records the resistivity of the rock. The downbore measurement of various physical properties, such as porosity, resistivity, mineral contents, etc., versus depth is also often described as electric resistivity well logging. Well logs augment other geological information and hence are important in defining a reservoir. Oil-filled sand has higher resistivity than water-filled sand. A *Gravity well log* (or radioactivity well log) is a record of the absorption of gamma radiation through the rock, used to determine the rock density. A *Magnetic well log* is a record of the mineral content of rock formations, especially ferromagnetic minerals

Well stimulation

Performed on oil or gas wells to increase the flow of hydrocarbons for higher production

Wellhead

Equipment at the surface of an oil or gas well that provides the structural and pressure-containing interface for the drilling and production equipment

West Texas Intermediate (WTI)

An important group of crude oils produced in Texas

and southern Louisiana, which is used as a reference crude for domestic trading

Wet gas

Natural gas containing C₄+ and natural gasoline that has not been removed

White oil

Kerosene or treated kerosene used for pharmaceutical purposes or in the food industry

wppm

Parts per million by weight

X**Xylene (C₆H₄(CH₃)₂)**

An important aromatic molecule (► *Hydrocarbons*), used as a solvent or petrochemical feedstock

Y**Yen–Mullins model (modified Yen model)**

Describes the predominant molecular and colloidal structure of asphaltenes in crude oil, whether the asphaltene molecules form nanoaggregates or clusters. The model provides a foundation for the development of the first asphaltene equation of state for predicting asphaltene gradients in oil reservoirs

Z**Zeolites, synthetic**

Microporous, crystalline aluminosilicates used as commercial adsorbents and molecular sieves, and as catalyst components in petroleum refining

ZSM-5

Important shape-selective aluminosilicate patented by Mobil in 1975. Used in numerous heterogeneous catalytic processes, including FCC, catalytic dewaxing, and the conversion of methanol to gasoline

About the Authors

Hendratta N. Ali

Fort Hays State University
Dept. Geosciences
Hays, USA
h_ali@fhsu.edu

Chapter B.9

Hendratta Ali obtained her PhD in Geology from Oklahoma State University-Stillwater in 2010. Prior to this, she obtained a Diplôme D'études Approfondie (DEA), MSc in Soil Science, and a BSc in Earth Sciences, from the University of Yaoundé I, Cameroon. She teaches Geosciences and coordinates the Petroleum Geology Program at Fort Hays State University, Kansas, USA.

Mubarak M. Al-Mujaibel

Kuwait Institute for Scientific Research (KISR)
Environment & Life Sciences Research Center
Safat, Kuwait
mmojbel@kisir.edu.kw

Chapter C.32

Mubarak Al-Mujaibel is a Research Technician with over 15 years of experience in various petroleum downstream processes, including pilot unit commissioning for hydro-cracking and distillation. He graduated from the Technical Studies College of Kuwait, Chemical Engineering Department and before joining the Kuwait Institute for Scientific Research, where he is still affiliated to this day.

Adel Al-Mutairi

Kuwait Institute for Scientific Research
Petroleum Research Center
Safat, Kuwait
amutairi@kisir.edu.kw

Chapter C.21

Adel Al-Mutairi received his BSc from Clarkson University in 2001. He works as a Chemical Engineer, focused on heavy oil (AR and VR) pre-treatment and hydroprocessing using pilot plants at the Petroleum Research Centre (PRC), Kuwait Institute for Scientific Research (KISR).

Sultan M. Al-Salem

Kuwait Institute for Scientific Research (KISR)
Environment & Life Sciences Research Center
Safat, Kuwait
ssalem@kisir.edu.kw

Chapter C.32

Sultan Al-Salem is a Chemical Engineer with degrees from Kuwait University and a PhD from University College London. His work experience at a number of institutions has linked him with a strand of projects in the crude oil refining and petrochemicals area, air pollutants monitoring, dispersion, and chemical mass balance modeling. He is currently an Associate Research Scientist at the Environment and Life Sciences Research Center of KISR.

Jan T. Andersson

University of Münster
Inst. of Inorganic and Analytical Chemistry
Münster, Germany
anderss@uni-muenster.de

Chapter A.5

Jan Andersson obtained his PhD from the University of Lund, Sweden, and moved to Germany after 2 years of postdoctoral research in USA. He obtained his Habilitation degree in Analytical Chemistry from the University of Ulm and was appointed Professor at the University of Muenster in 1991. His research interests center on separation techniques of supercomplex mixtures like petroleum.

A. Ballard Andrews

Schlumberger-Doll Research
Sensor Physics
Cambridge, USA
bandrews@slb.com

Chapter A.6

A. Ballard Andrews received his PhD in Condensed Matter Physics from the University of Texas at Austin, where he investigated the electronic structure of magnetic thin films. His postdoctoral research at Los Alamos National Laboratory concentrated on heavy fermions. He worked at Brookhaven National Laboratory in computation and scientific visualization. He now works on laser applications in spectroscopy and asphaltene science.

Brent E. Beasley

Brent E. Beasley and Associates, LLC
Consulting, Contracting and Engineering
Laguna Woods, USA
brentbeasley@brentbeasleyllc.com

Chapter D.33

Brent Beasley worked in various capacities for ExxonMobil over a 34-year career, including a decade in conventional lube research, pilot plant operations, manufacturing plant troubleshooting, and technical licensing support. Brent is President and CEO of Brent. E. Beasley and Associates, LLC, a consulting contracting and engineering company.

F. Emmett Bingham

Haldor Topsoe, Inc.
Orange, USA

Chapter C.23

Emmett Bingham is the Manager of Hydroprocessing Technology for Haldor Topsoe Inc. He has more than 40 years of experience. He has worked for Topsoe for 10 years, Unocal for 20 years, and Dow Chemicals for 10 years.

Gary Brodeur

Intel Corp.
Logic Technology Development
Hillsboro, USA
gary.brodeur@intel.com

Chapter D.38

Gary Brodeur received his PhD from Florida State University in 2013. He worked at the National Renewable Energy Laboratory in Golden, CO, within the National Bioenergy Center division. He now works as a Senior Process Development Engineer at Intel Corporation in Hillsboro, OR.

Leslie Bromberg

Massachusetts Institute of Technology
Plasma Science and Fusion Center and
Sloan Automotive Laboratory
Cambridge, USA
brom@psfc.mit.edu

Chapter D.40

Dr Bromberg received his BS and PhD from the Massachusetts Institute of Technology. He worked at MIT in plasma physics, first on fusion and recently on industrial applications of plasmas and microwave based sensors. He has over 70 issued patents and started three companies in the automotive market.

Michael Carpenter

RTI International
Energy Technology
Research Triangle Park, USA
mcarpenter@rti.org

Chapter D.40

Michael Carpenter received degrees in physics and chemical engineering in 2011 from North Carolina State University. His work at RTI International focuses on catalysis relevant to the natural gas industry such as GTL and ammonia synthesis. He also has interest and experience in modeling physical systems and chemical synthesis.

Shengnan Chen

University of Calgary
Dept. Chemical and Petroleum
Engineering
Calgary, Canada
snchen@ucalgary.ca

Chapter B.14

Shengnan Chen is an Assistant Professor in the Department of Chemical and Petroleum Engineering at the University of Calgary. Her major interests include the development of unconventional reservoirs, reservoir simulation, and production optimization. Chen holds BSc and MSc degrees in Petroleum Engineering from China University of Petroleum and a PhD degree in Petroleum Systems Engineering from the University of Regina, Canada.

Dennis Cima

Aspen Technology, Inc.
Houston, USA

Chapter C.26

Cortis K. Cooper

Chevron Energy Technology Company
San Ramon, USA
cortiscooper@alum.mit.edu

Chapter B.15

Dr Cooper is a Chevron Fellow, one of 27 scientists and engineers recognized by Chevron for their contributions. His primary job is providing wind, wave, and current criteria for Chevron's worldwide operations. He received a PhD from the University of Maine in 1987, has published 44 papers, co-authored 8 books, served on 7 National Academy of Sciences committees and Boards, and advisory panels to Federal agencies.

M. Andrew Crews

Chicago Bridge and Iron
Houston, USA
andyc6362@yahoo.com

Chapter C.24

M. Andrew Crews received his degree in Chemical Engineering from the University of Arkansas in 1991. He has held various management positions at Chicago Bridge and Iron over the last 25 years. His most recent assignment was as the Vice President of Operations for CB&I India and he is currently assigned as the Regional Vice President of Engineering for the Americas.

Sudhin Datta

ExxonMobil Chemical Co.
Global Chemical Research
Baytown, USA
sudhin.datta@exxonmobil.com

Chapter D.37

Sudhin Datta received his PhD in Chemistry from Harvard University in 1978. He has been at ExxonMobil Chemical Company developing new polyolefin polymers and their blends for the last 35 years. He has authored 118 US patents and 13 review chapters on polyolefins. Sudhin Datta is the recipient of the 2015 Charles Goodyear Medal of the Rubber Division of the American Chemical Society.

Geoffrey E. Dolbear

Katy, USA
geoffd41@gmail.com

Chapter C.22

Geoff Dolbear is a Physical Chemist with a BSc from UC Berkeley and a PhD from Stanford. After 24 years in industrial research, he became an independent consultant in 1989, retiring in 2014. His publications and patents describe catalysts and processes, with particular strengths in hydrocracking, heavy oil, and coal. He is a Fellow of the American Chemical Society.

Antonios Doufas

ExxonMobil Chemical Co.
Global Polymer Technology
Baytown, USA
antonios.k.doufas@exxonmobil.com

Chapter D.37

Antonios K. Doufas received his PhD in Chemical Engineering at the University of Illinois at Urbana-Champaign in 2000. He worked at the corporate R&D laboratories of the Dow Chemical Company and later in polypropylene product development at Sunoco Chemicals and Braskem Americas. He is currently a Technical Leader in Global Polymers Technology at the ExxonMobil Chemical Company with interests in structure properties, rheology, and flow-induced crystallization.

Rudraksha Dutta Majumdar

University of Toronto Scarborough
Dept. Physical and Environmental
Sciences
Toronto, Canada
r.duttamajumdar@utoronto.ca

Chapter A.6

Rudraksha Dutta Majumdar received his PhD from the University of Lethbridge, Canada, in 2015, working on asphaltene structure elucidation using NMR spectroscopy. His current position as a Postdoctoral Research Associate at the University of Toronto Scarborough is focused on developing novel comprehensive multi-phase NMR and *in vivo* NMR spectroscopic techniques for materials and organisms of environmental relevance.

David Fiscus

ExxonMobil Chemical Co.
Global Research Product Development
Baytown, USA
david.m.fiscus@exxonmobil.com

Chapter D.37

David M. Fiscus received his PhD from the Ohio State University in 1985. He has run technical programs in research, manufacturing, and customer support positions mainly related to polyethylene resins and products. He currently works for ExxonMobil Chemical Company in Global Product Research supporting the development of new metallocene catalyzed polyethylene resins.

Go Fujisawa

Schlumberger Gould Research
Cambridge, UK
gufujisawa@slb.com

Chapter A.7

Go Fujisawa received his Master's degree in Applied Physics from Osaka University. Since he joined Schlumberger in 1999, he has worked on various projects related to spectroscopic downhole fluid analysis for oil field wellbore applications as Engineer, Scientist, and Project Manager in engineering and research organization.

Graham Ganssle

Sandstone Oil&Gas
New Orleans, USA
graham@ganssle.com

Chapter B.12

Graham Ganssle received his PhD from the University of New Orleans. He is the Owner and Principal Geoscientist of Sandstone Oil & Gas, a petroleum exploration company operating in the North America, South America, and Africa. His research interests are in the fields of acoustic imaging and digital signal processing, specializing in optimization methods for seismic data migration.

Adam A. Gentile

Freedom Energy Tech, LLC
Clermont, USA
agentile@mail.usf.edu

Chapter D.40

Adam A. Gentile has served as Lead Research Analyst of the Prism cold plasma catalytic partial oxidation technology for use with various hydrocarbon feed stocks producing high quality synthesis gas for the purpose of synthetic fuel production using Fischer–Tropsch processes. He currently works as a Scientist and Analyst in a GLP compliant bioanalytical laboratory on the development and validation of immunoassays for clinical and non-clinical drug studies.

Pierre–Yves le Goff

Axens SA
Rueil–Malmaison, France
pierre-yves.le-goff@axens.net

Chapter C.18

Pierre le Goff holds a PhD from the Ecole de Chimie de Mulhouse and an MBA from Sorbonne University. He started his career in the field of inorganic chemistry. He joined Axens in 2000 and was involved in reforming and hydrotreating activities. Since 2013 he has been in charge of the R&D program covering reforming, isomerization, and aromatics.

Martin R. Gonzalez

BP
Refining Technology and Engineering
Naperville, USA
martin.gonzalez@bp.com

Chapter C.31

Martin R. Gonzalez received his PhD in Chemical Engineering from the University of Wisconsin, with research in heterogeneous catalysis. In his 20-year career with Amoco and BP, he has held positions in R&D, process design, and refinery operations, including commissioning and start-up of hydrotreaters for BP's North American heavy-oil project. He is currently Discipline Leader for Hydroprocessing and Reforming technologies.

Lamia Goual

University of Wyoming
Dept. Petroleum Engineering
Laramie, USA
lgoual@uwyo.edu

Chapter A.6

Lamia Goual received her PhD in Petroleum Engineering from Imperial College, UK, in 2003. She worked at the University of Alberta and the Enhanced Oil Recovery Institute. She is currently an Associate Professor of Petroleum Engineering at the University of Wyoming. Her research interests include interfacial phenomena with applications to energy and environment. She holds an NSF CAREER award on remediation of oil-contaminated aquifers.

Nick Hallale

AspenTech
Warrington, UK
hallalen@gmail.com

Chapter C.25

Nick Hallale holds BSc and PhD degrees in Chemical Engineering from the University of Cape Town. He has experience across the academic, consulting, and industrial sectors.

Thomas Hantschel

Schlumberger Aachen Technology Center
Aachen, Germany
thantschel@slb.com

Chapter B.11

Thomas Hantschel is the Manager of the Schlumberger Technology Center for Exploration Geology, in Aachen, Germany. He is a physicist with a focus on basin modeling simulations related to heat flow, pore pressure and stress evolution, and multiphase fluid-flow. He has worked as a peer reviewer for more than 100 exploration projects and applications worldwide related to petroleum systems modeling and geomechanics.

**Yalin Hao**

Chevron Lubricants
Chevron Base Oils
Richmond, USA
yalinhao@chevron.com

Chapter D.34

Yalin Hao joined Chevron as a Research Engineer after receiving her PhD from University of California, Davis in 2008. Her work focused on process/catalyst studies for base oil and fuel hydroprocessing. Since she joined Chevron Base Oils in 2012, she has been responsible for providing technical support for Chevron's Group II Base Oil Slate and other key marketing activities.

Paul Hazendonk

University of Lethbridge
Dept. Chemistry and Biochemistry
Lethbridge, Alberta, Canada
paul.hazendonk@uleth.ca

Chapter A.6

Paul Hazendonk is an Associate Professor at the University of Lethbridge. He obtained his MSc at the University of Manitoba and received his PhD from McMaster University. An expert in NMR spectroscopy, Paul specializes in solid-state NMR, developing experimental techniques particularly suited to complex organic-inorganic mixtures and fluorine containing systems. His current projects include the investigation of nano-structural motifs in fossil fuel materials.

Donald G. Hill

University of Southern California
Walnut Creek, USA
dgh@hillpetro.com

Chapter B.13

Donald G. Hill is a Consulting Petrophysicist and Adjunct Professor of Petrophysics at the University of Southern California. He holds a PhD in Geology and Exploration Geophysics. Over 40 years he has been in developing and conducting innovative projects in petroleum, mining, and geothermal exploration and production worldwide.

Suzzy C. Ho

Exxon Mobil Research & Engineering Co.
Corporate Strategic Research Department
Annandale, USA
suzzy.c.ho@exxonmobil.com

Chapter D.35

Suzzy Ho is a Senior Research Associate at ExxonMobil's Corporate Strategic Research. She received her PhD in Organic Chemistry from the California Institute of Technology in 1986. After a postdoctoral position at Princeton University, she joined ExxonMobil and has worked primarily in the area of lubricant base stocks ranging from research to product, processes, and new market development.

**Teh C. Ho**

Bridgewater, USA
tehcho@yahoo.com

Chapter C.27

Teh C. Ho received a BSc degree from Tunghai University, Taiwan, and a PhD in Chemical Engineering from the University of Delaware. He is an independent consultant, having retired from ExxonMobil's Corporate Strategic Research Labs. in 2013. He received Wilhelm and Evans Awards of the American Institute of Chemical Engineers and is a member of the National Academy of Engineering.

Allegra Hosford Scheirer

Stanford University
Dept. Geological Sciences
Stanford, USA
allegras@stanford.edu

Chapter B.11

Allegra Hosford Scheirer is a Research Geophysicist at Stanford University specializing in basin and petroleum system modeling. Allegra's obtained her PhD degree from the MIT-Woods Hole Oceanographic Institution Joint Program in Oceanography. Prior to joining Stanford, Allegra was a member of the Geophysical Unit of Menlo Park and the Energy Resources Program at the US Geological Survey, where she constructed three-dimensional geologic models for use in the resource assessment process.

Chang Samuel Hsu

Chapters 1, A.3, A.4, C.16, C.17, D.38

For biographical profile, please see the section "About the Editors".

Manhoi Hur

Iowa State University
Genetics, Development and Cell Biology
Ames, USA
mhhur@iastate.edu

Chapter A.4

Manhoi Hur received his BS from PaiChai University, Korea, in 2002. At the Korea Basic Science Institute he improved the performance of FT-ICR mass spectrometers. Since 2008, his research focuses on the development of novel statistical models and software for petroinformatics. His work at the Iowa State University also includes bioinformatics and big-data integrative analysis of multi-omics data.

**Maurice D. Jett**

Chapter C.28

BP Refining
Refining Technology & Engineering
Houston, USA
mdjett1@gmail.com

Maurice Jett received his PhD in Chemical Engineering from Rice University in 1991. He spent more than 19 years at Aspen Technology executing reactor modeling and real-time optimization projects for a wide range of refinery and petrochemical processes. He is currently employed by BP, building and deploying high fidelity operator training simulators.

**Sriganesh Karur**

Chapter C.28

Katy, USA
srikarur@gmail.com

Sriganesh Karur received his DSc in Chemical Engineering from Washington University in Saint Louis. He worked with Aspen Technology Inc. as Optimization Engineer for 10 years before joining Shell Global Solutions (US) Inc., where at present he heads the Process Engineering and Supply Chain Applications group.

Sunghwan Kim

Chapter A.4

Kyungpook National University
Dept. Chemistry
Buk-Gu Daegu, Korea
sunghwank@knu.ac.kr

Sunghwan Kim received his PhD from the Ohio State University in 2003. He has worked at the National High Magnetic Field Laboratory at Florida State University and at the Korea Basic Science Institute. He is an Associate Professor at Kyungpook National University. His research focusses on understanding the chemical composition of crude oil at the molecular level.

William Kostka

Chapter C.18

Axens North America
Houston, USA
bkostka@axensna.com

Bill Kostka received his PhD from Purdue University in 1981. He worked at Mobil Research and Development Corporation in Paulsboro, NJ and ExxonMobil Research and Engineering Company in Fairfax, VA. After retirement from ExxonMobil, he came to Axens North America in Houston, TX as a Technical Advisor for reforming and isomerization.

**Stephen K. Lee**

Chapter D.34

Lee Associates
Oakland, USA
stephen.lee9@comcast.net

Stephen Lee has a BS and an MS in Chemical Engineering. He worked 36 years at Chevron Corporation in process engineering, project engineering, refinery planning and operations, capital projects, and new technology development. Stephen is an expert in the manufacture of premium lube base oils using hydroprocessing technology. He has extensive experience in technical consultation and process design of base oil plants.

**Guan-Dao Lei**

Chapter D.34

Chevron Energy Technology Company
Downstream Technology and Service
Richmond, USA
guandao.lei@chevron.com

Guan-Dao Lei received his PhD from the University of Houston. He worked at Honeywell International, in Illinois, US and Süd-Chemie Inc. in Kentucky, US. He now works on hydroprocessing catalyst and process development at the Chevron Energy Technology Company in California, US.

Zaiting Li

Chapter D.36

Research Institute of Petroleum Processing
Beijing, China
leitsaiting@sina.cn

Zaiting Li studied Chemical Engineering at Tsinghua University and Petroleum Processing at China University of Petroleum. She worked at the Research Institute of Petroleum Processing, SINOPEC. She is the inventor of the deep catalytic cracking (DCC) technology for the production of low-carbon olefins from heavy oil.

Bruce R. Locke

Florida State University
Dept. Chemical and Biomedical
Engineering
Tallahassee, USA
blocke@fsu.edu

Chapter D.41

Bruce Locke earned his degrees in Chemical Engineering from Vanderbilt University, University of Houston, and North Carolina State University. He serves on the Faculty of Chemical and Biomedical Engineering as a Distinguished University Research Professor at Florida State University. His research interests include plasma reaction engineering for chemical synthesis and environmental pollution control.

Shuji Luo

Exxon Mobil Research & Engineering Co.
Corporate Strategic Research Department
Annandale, USA
shuji.luo@exxonmobil.com

Chapter D.35

Shuji Luo received her PhD in Organometallic Chemistry from the University of Chicago in 2007. Since 2009, she has worked in the Corporate Strategic Research Laboratory of ExxonMobil Research and Engineering company in Clinton, NJ, conducting research related to performance fluids and polymers. She currently holds the position of Research Associate.

Xiaoliang Ma

Kuwait Institute for Scientific Research
(KISR)
Petroleum Research Center
Safat, Kuwait
maxiaoliang@kisir.edu.kw

Chapter C.32

Xiaoliang Ma received his PhD from Kyushu University in 1995. He has worked at the China Coal Research Institute, the National Institute for Resources and Environment in Japan, Pennsylvania State University, and the Kuwait Institute for Scientific Research. He works on petroleum refinery processes and fuel science, focusing on hydrotreating, adsorption, and separation in clean fuel production.

Ekaterina V. Maksimova

University of South Florida
College of Marine Science
St. Petersburg, USA
maksimova@mail.usf.edu

Chapter B.15

Dr Maksimova is an NSF Postdoctoral Fellow affiliated with the University of South Florida and Florida State University (FSU). Her interests are in fundamental physical processes that govern ocean dynamics. She is a recipient of several prestigious awards, including the Gold Medal for Academic Excellence from Moscow State University, an O'Brien Graduate Fellowship from FSU, and an Ocean Sciences Postdoctoral Fellowship from NSF.

Abdulazeem M. J. Marafi

Kuwait Institute for Scientific Research
Petroleum Research Center
Safat, Kuwait
amarafi@kisir.edu.kw

Chapter C.21

Abdulazeem M.J. Marafi received his PhD from the University of Oklahoma in 1996. He works as a Senior Research Scientist, focused on petroleum refining (heavy oil hydroprocessing) and kinetics at the Petroleum Research Center (PRC), Kuwait Institute for Scientific Research (KISR).

Blaine McIntyre

Calgary, Canada

Chapter C.28

Milo D. Meixell

Aspen Technology, Inc.
Professional Service
Houston, USA
milo.meixell@aspentech.com

Chapter C.29

Milo D. Meixell, Jr. is a chemical engineer. He worked with Exxon Chemical Company in the area of agricultural chemicals and with Dynamic Matrix Control Corporation, before joining Aspen Technology, Inc. in 1996. His area of expertise is real time and plant-wide optimization using large-scale, high-fidelity models, reactor modeling, kinetics, simultaneous, matrix-based modeling, and optimization.

Isao Mochida

Kyushu Environmental Evaluation
Association
Fukuoka, Japan
mochida@keea.or.jp

Chapter C.21

Isao Mochida received his PhD from the University of Tokyo in 1968. He was Professor at Kyushu University for 22 years and has been Professor Emeritus since 2004. He is now a consultant to Kyushu Environmental Evaluation Association and works in applied chemistry on petroleum refining, **coal conversion** and carbon materials for environmental protection.

Ian Moore

Jacobs Consultancy
Power and Energy
Stockport, UK
ian.moore@jacobs.com

Chapter C.25

Ian Moore has over 30 years' experience in engineering services, modeling, optimization, and capital project development for the refining and petrochemicals industries. He has led hydrogen management studies in North America, Europe, and Asia. He is an expert in the application of pinch analysis in energy-intensive industries, and executes energy improvement, power generation, carbon management, and GHG reduction studies worldwide.

Daniel Morton

Haldor Topsoe Inc.
Refinery and Chemicals
Houston, USA
dim@topsoe.com

Chapter C.23

Daniel Morton received his degree in Mechanical Engineering from Auburn University. He worked in various industries, including paper-mills, steel fabrication, and building maintenance and construction. In 2009 he joined Topsoe and has since been involved in the design and sale of much of the proprietary hardware in the company's refinery and chemical business.

Dale R. Mudt

Suncor Energy Products Partnership
Sarnia Refinery
Sarnia, Canada
dmudt@suncor.com

Chapter C.28

Dale R. Mudt is the Process Automation Manger at the Suncor Energy Products Refinery. For the last 30 years he has implemented and maintained DMC controllers and closed-loop real-time optimizers, and managed the Process Automation group at the Sarnia Refinery. Dale was a key contributor to the development of the online version of Sun Oil Company's hydrocracker model, which is now marketed worldwide as AspenHydrocracker.

Oliver C. Mullins

Schlumberger–Doll Research
Cambridge, USA
mullins1@slb.com

Chapters A.6, A.7

Dr Oliver C. Mullins, Science Advisor at Schlumberger, is the primary originator of downhole fluid analysis (DFA) in well logging. Dr Mullins also leads an active research group leading to the Yen–Mullins model of asphaltenes and the Flory–Huggins–Zuo EoS. His current interests include utilizing DFA technology and new asphaltene science for reservoir evaluation and clarifying reservoir fluid geodynamic processes.

Douglas E. Nelson

Haldor Topsoe, Inc.
Orange, USA

Chapter C.23

Douglas E. Nelson is the Engineering Manager for Haldor Topsoe Inc. He has worked for more than 38 years in refinery hydroprocessing for Unocal, Fluor, and now at Haldor Topsoe. Doug has a BSc in Chemical Engineering from Oregon State University.

Joo-II Park

Kuwait Institute for Scientific Research
Petroleum Research Center
Safat, Kuwait
jpark@kisir.edu.kw

Chapter C.21

Joo-II Park received his PhD from Kyushu University in 2012. He worked at Kyushu University as an Associate Professor from 2012–2015. Since 2015 he has been researching heavy oil upgrading, focused on the advanced characterization and catalysis of heavy oil at the Petroleum Research Center (PRC), Kuwait Institute for Scientific Research (KISR).

**Clifford C. Pedersen**

Chapter C.28

Pedersen Enterprises Inc.
Sarnia, Canada
cliffpedersen@sympatico.ca

Clifford (Cliff) C. Pedersen is regarded as one of the pioneers of computer process control in the oil refining industry. His career in the oil refining industry has spanned technical and management leadership positions with NWR, Suncor Energy, Shell Canada, and Imperial Oil in plant automation and information technology. He is currently President of Pedersen Enterprises Inc., an independent consulting agency specializing in advanced process control, real-time optimization and systems interoperability.

Kenneth E. Peters

Chapter B.11

Schlumberger
Mill Valley, USA
Stanford University
Geological Sciences
Stanford, USA
kpeters2@slb.com

Ken Peters is Science Advisor for Schlumberger, where he uses geochemistry and basin modeling to study petroleum systems and teach or consult with external clients. He has 37 years of experience with Chevron, Mobil, ExxonMobil, USGS, and Schlumberger and teaches geochemistry and basin modeling throughout the industry and at various universities, including UC Berkeley and Stanford. Ken has a PhD in Geochemistry from UCLA.

Andrew E. Pomerantz

Chapter A.6

Schlumberger–Doll Research
Cambridge, USA
apomerantz@slb.com

Andrew E. Pomerantz received a PhD in Chemistry from Stanford University in 2005. His research focuses on developing and applying novel techniques to characterize the structure of kerogen and asphaltenes, including methods in mass-spectroscopy, and IR-spectroscopy. That information is used to understand fundamental processes in petroleum such as asphaltene compositional grading and hydrocarbon transport in shales.

Subramanian Ramakrishnan

Chapter D.38

Florida A&M University/Florida State
University
Dept. Chemical and Biomedical
Engineering
Tallahassee, USA
sramakrishnan@fsu.edu

Subramanian Ramakrishnan received his PhD from the University of Illinois at Urbana Champaign in 2001. After a postdoctoral appointment at Princeton and then at the University of Illinois, he joined FAMU-FSU College of Engineering in 2005, where he currently works on biofuels production and processing of complex fluids. In 2016 he was a Visiting Professor at Harvard University.

Henrik Rasmussen

Chapter D.39

Haldor Topsoe Inc.
Houston, USA
hwr@topsoe.com

Henrik Rasmussen graduated from the University of Copenhagen in 1989 with a degree in Chemical Engineering before relocating to the US in 1991. He has worked at Haldor Topsoe for over 25 years, holding numerous technical and management positions for all Topsoe's business units. Mr Rasmussen is currently Vice President of Catalyst and Technology and responsible for catalyst and license technology business for USA, Canada, and the Caribbean.

Paul R. Robinson

Chapters 1, .2, C.16, C.17, C.20, C.22, C.25, C.26, C.28

For biographical profile, please see the section "About the Editors".

John M. Rosenbaum

Chapter D.34

Chevron Lubricants
Chevron Base Oils
Santa Cruz, USA
energyengineerjohn@gmail.com

John Rosenbaum has a PhD in Materials Science and Mineral Engineering from UC Berkeley and retired in 2015 after 34 years working for various Chevron Companies in minerals processing, petroleum hydroprocessing, catalyst development, and lubricant base oil product technology.

Joseph Ross

Axens North America
Princeton, USA
jross@axensna.com

Chapter C.18

Joseph Ross is a graduate from Princeton University with a degree in chemical engineering. He has over 30 years of commercial experience in the field of transportation fuels including engineering design, R&D, and process licensing. He is a Technology and Marketing Manager for Axens North America specializing in fluid solid systems, heavy oil upgrading, FCC, and catalytic reforming.

Yosadara Ruiz-Morales

Mexican Petroleum Institute
Mexico City, Mexico
yruiz@imp.mx

Chapter A.6

Yosadara Ruiz-Morales received her PhD in Theoretical Chemistry from the University of Calgary in 1998. Since 1999, she has been working at the Mexican Petroleum Institute. She is a pioneer in the application of electronic structure calculations to elucidate the asphaltenes' aromatic core and inventor of the Y-rule for asphaltene stability. In her current research on oil rheology, she investigates asphaltene interfacial activity using particle dynamics.

Marco A. Satyro (deceased)

Chapter A.8

Oliver Schenk

Schlumberger Aachen Technology Center
Aachen, Germany
oschenk@slb.com

Chapter B.11

Oliver Schenk is a Geologist and received his PhD from RWTH Aachen University (2006), focusing on the influence of fluids on recrystallization and the deformation behavior of rocks. Since 2006 he has been working for Schlumberger, specialized on multi-dimensional applications of basin and petroleum system modeling (BPSM). Since 2007, he has been Research Affiliate at Stanford University, lecturing and mentoring graduate students in BPSM.

John M. Shaw

University of Alberta
Dept. Chemical and Materials Engineering
Edmonton, Canada
jmshaw@ualberta.ca

Chapter A.8

John M. Shaw obtained his PhD from the University of British Columbia in 1985 and was a Professor at the University of Toronto, before joining the University of Alberta, in 2001, where he holds a Natural Sciences and Engineering Research Council of Canada Industrial Research Chair in Petroleum Thermodynamics. His research focuses on experimental methods development, and thermophysical property measurement and prediction of hydrocarbon resources.

B. Gregory Shumake

CB & I
Engineered Products
Tyler, USA
gshumake@cbi.com

Chapter C.24

Greg Shumake is the Director of Engineering for the Engineered Products business group within CB&I. He has over 20 years of experience in the hydrogen and synthesis gas industry. He has a BS in Chemical Engineering from the University of Arkansas. He has published several articles on various aspects of hydrogen plants.

James G. Speight

CD&W Inc.
Laramie, USA
jamesp8@aol.com

Chapter C.19

Dr James G. Speight has degrees in Chemistry, Geological Sciences, and Petroleum Engineering and is the author of more than 60 books in petroleum science, petroleum engineering, and environmental sciences. He has more than 45 years of experience in the petroleum industry and has taught at various universities worldwide. Among other honors, he received the Scientists without Borders Medal of Honor (Russian Academy of Sciences) and the Einstein Medal.

**Dennis Vauk**

Chapter C.25

Phillips 66
Refining Business Improvement
Houston, USA
dennis.a.vauk@p66.com

Dennis Vauk received a Chemical Engineering degree from the University of Idaho. He worked as Senior International Expert for Air Liquide, where he conducted hydrogen optimization studies for refineries worldwide. He is currently Hydroprocessing Technology Director for Phillips 66. He started his career doing research, process design, and technical services for hydrotreaters and hydrocrackers at Unocal.

Clifford C. Walters

Chapter B.10

ExxonMobil Research & Engineering Co.
Corporate Strategic Research
Annandale, USA
clifford.c.walters@exxonmobil.com

Clifford C. Walters received his PhD in Geochemistry from the University of Maryland in 1982. Since then, he has been a Research Geochemist with Gulf, Sun, Mobil, and ExxonMobil with efforts focused on petroleum biomarkers, models of generation and reservoir transformations, and geomicrobiology.

Robert J. Wandell

Chapter D.41

Florida State University
Dept. Chemical and Biomedical
Engineering
Tallahassee, USA
rjw05c@my.fsu.edu

Robert J. Wandell studied Chemical Engineering at Florida State University. His research interests include the study and development of electrical discharge plasma reactors for synthesis of useful chemical species, as well as transfer of university technologies into commercial markets.

Xieqing Wang

Chapter D.36

Research Institute of Petroleum Processing
Beijing, China
wangxieqing.ripp@sinopec.com

Xieqing Wang received his PhD in Chemical Engineering from Merseburg University of Applied Sciences in 1961. His work at SINOPEC's Research Institute of Petroleum Processing concentrates on petroleum refining, with a special focus on catalytic cracking.

Keith Wisecarver

Chapter C.30

University of Tulsa
Dept. Chemical Engineering
Tulsa, USA
keith-wisecarver@utulsa.edu

Keith Wisecarver is Professor of Chemical Engineering at the University of Tulsa. He received his PhD from the Ohio State University in 1987 and has been on the faculty at Tulsa since that time. He has been doing research in the field of delayed coking since 1999, as co-PI of the Tulsa University Delayed Coking Joint Industry Project.

Margaret M. Wu

Chapter D.35

Exxon Mobil Research & Engineering Co.
Corporate Strategic Research Department
Annandale, USA
margaret.m.wu@exxonmobil.com

Margaret Wu received her PhD from the University of Rochester at Rochester in 1976. She worked at ExxonMobil Research & Engineering Co. for 32 years, conducting research related to synthetic lubricant products and processes and was the author or co-author of numerous patents and publications. Since her retirement in 2009, she holds the position of Emeritus Senior Scientific Advisor for the same organization.

Björn Wygrala

Chapter B.11

Schlumberger Aachen Technology Center
Aachen, Germany
bwygrala@slb.com

Björn Wygrala received his PhD in Petroleum Geology from the University of Cologne in 1989. He has worked for Uranerz in Australia, for Integrated Exploration Systems (IES) in Germany, and for Schlumberger in Germany. He currently works on global business development for software and services related to exploration risk and resource assessments.

Chaogang Xie

Chapter D.36

Research Institute of Petroleum Processing
Beijing, China
xiecg.ripp@sinopec.com

Chaogang Xie received his MSc from Tianjin University in 1987. He works at the SINOPEC Research Institute of Petroleum Processing. His research centers around catalytic cracking processes, focusing on the production of light olefins.

**Harvey W. Yarranton**

Chapter A.8

University of Calgary
Dept. Chemical and Petroleum
Engineering
Calgary, Canada
hyarrant@ucalgary.ca

Harvey Yarranton is a Professor of Chemical and Petroleum Engineering and the NSERC Industrial Research Chair in Heavy Oil Properties and Processing. He received his PhD degree from the University of Alberta in 1997. His research interests are the phase behavior and properties of heavy oils and the fundamentals water-in-oil emulsions, with application to heavy oil and oil sands processes.

Richard N. Zare

Chapter A.6

Stanford University
Dept. Chemistry
Stanford, USA
rnz@stanford.edu; zare@stanford.edu

Richard (Dick) Zare is the Marguerite Blake Wilbur Professor in Natural Science at the Department of Chemistry of Stanford University. He works in the area of physical and analytical chemistry with an emphasis on the development of new methods and new instrumentation.

Genquan Zhu

Chapter D.36

Research Institute of Petroleum
Processing
Beijing, China
zhugq.ripp@sinopec.com

Genquan Zhu received his PhD from China University of Petroleum in 2001. He works at the SINOPEC Research Institute of Petroleum Processing. His research centers around catalytic cracking processes, focusing on the production of light olefins.

 total
 – acid number (TAN) 20, 153, 183,
 186, 199, 722, 917, 1059
 – depth (TD) 441
 – dissolved solids (TDS) 487
 – isomerization process (TIP) 59,
 571
 – organic carbon (TOC) 365, 385
 tower
 – flash zone 967
 – fractionation 967

– overhead pressure 969
 – pressure survey 970
 – wash section 967
 TPR model 504
 trace contaminant 720
 transformation 322
 – ratio (TR) 387, 397
 transient flow 502
 transient heat flow 394
 trap 343
 – anticline 26
 – salt dome 27, 332
 – stratigraphic 348
 – structural 347
 treatment 916
 – catalyst 636
 trimethylolpropane (TMP) 1055
 truck tape recorder (TTR) 448
 true
 – boiling point (TBP) 67, 718, 870
 – conversion 722
 – vertical depth (TVD) 263
 tube metal temperature (TMT) 897
 turbine 557
 – oil stability test (TOST) 1059
 two-dimensional heteroatom single
 quantum coherence (HSQC) 228
 two-phase reservoir
 – IPR 503
 two-stage dewaxing 1002
 two-stroke engine 555

U

ultra-deep hydrodenitrogenation for
 hydrocracking 857
 ultra-deep hydrodesulfurization of
 diesel 856
 ultrahigh molecular weight
 polyethylene (UHMWPE) 1089
 ultra-low-sulfur diesel (ULSD) 38,
 729, 836, 916, 1134
 – production 916
 ultra-stable (US) 61
 unconformity 341
 unconverted oil (UCO) 6, 713, 757,
 1019
 uninvasion zone 470
 unit of measure (UOM) 722
 UOP
 – fluid-bed catalytic cracking 640
 – Mercox process 662
 – Selectox process 661

upflow 706
 upgrading process 151
 upstream 14, 151–153, 167
 USY 696
 utility 931

V

vacuum
 – distillation 546, 965
 – distillation unit (VDU) 541, 568,
 717, 865, 951, 958, 960
 – gas oil (VGO) 22, 167, 548, 568,
 622, 713, 841, 865, 936, 1019,
 1072, 1127, 1130
 – pipestill (VPS) 958, 960
 – residue (VR) 21, 36, 546, 679,
 684, 706, 717
 – residue upgrading 716
 – residuum 904
 – -ultraviolet laser light (VUV) 164
 validity condition for asymptotic
 lumped kinetics 858
 van der Waals
 – condition 297
 – equation of state (EoS) 222, 252
 van Krevelen diagram 192, 368
 vanadium 681, 700, 704
 vapor pressure osmometry (VPO)
 163, 226
 vapor-lift tray (VLT) 780
 – distributor performance 781
 vapor-liquid equilibrium (VLE)
 538
 vertical seismic profiling (VSP)
 448
 very low-density polyethylene
 (VLDPE) 1089
 vibrational spectroscopy 153
 vibroseis 421
 vinyl acetate monomer (VAM) 87
 vinyl chloride monomer (VCM) 87
 Vis/NIR spectroscopy 252
 – hydrocarbon reservoir fluid 254
 visbreaking 50, 903, 912
 viscosity 1016, 1044
 – blend index (VBI) 308
 – dynamic 959
 – grade (VG) 1048, 1053
 – heavy oil 307
 – kinematic 959
 – modifier (VM) 1017

viscosity index (VI) 70, 329, 959,
1016, 1044
– droop 1031
– loss 1038
visible ultraviolet (UV) spectroscopy
683
vitrinite reflectance 397
volatile organic compound (VOC)
65, 90, 130, 563, 665, 1146
volatile products 910
volatility 1017, 1045
volatilizing roasting 653
vortex separation system (VSS)
1071

W

Wankel engine 556
wash
– acceptance 998
– efficiency 998
– oil 967
waste heat recovery (WHR) 801
waste product 322
wastewater 100, 806
– treatment 79
water gas reaction (WG) 1123
water gas shift (WGS) 789, 1123,
1135, 1147
– reaction 789, 1124
water phase behavior 280
water-based mud (WBM) 253
wax 1125
– crystal 982
– hydrocracking 1033
weight hourly space velocity
(WHSV) 722, 1073
weighted average bed temperature
(WABT) 724, 784
weighted average reactor temperature
(WART) 829, 873
well
– bore 501
– completion 28
– failure blowout 27
– log 436, 445, 466
– log analysis 435
– site 465
– stimulation 512
West Texas intermediate (WTI) 30,
922
wet
– flue-gas desulfurization 657
– gas 655
– -gas scrubbing (WGS) 135
– sulfuric acid 663
wetting 347
whole-oil
– gas chromatograms 372
wide angle x-ray scattering (WAXS)
279
wireline formation tester 491

wireline log 439
World Petroleum Council (WPC)
1068
Wyllie's time-average equation 452

X

x-ray fluorescence spectrometry
(XRF) 637, 639
x-ray powder diffraction (XRD)
639
xylose 1128

Y

yankee whaling 9
Yen–Mullins 371
– model 252, 262, 681

Z

zeolite 61, 685, 695
– catalyst 633
– catalyzed alkylation 579
Zeolite Socony Mobil-5 (ZSM-5)
1033, 1064, 1128
Zero-Zero-Zero campaigns 86
Ziegler–Natta catalyst 1090
zig-zag mechanism 727
zinc/calcium-aluminate 1076
zonal reaction 1154
