Springer

**Springer Handbook
of Petroleum
Technology**

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Foreword

This *Springer Handbook of Petroleum Technology* could not have appeared at a more appropriate time. Petroleum and its close cousin, natural gas, continue to provide most of the energy we consume, and will undoubtedly do so for many decades to come. Oil and gas also serve as basic materials for manufacturing construction materials, fertilizers, and a panoply of chemicals.

We are now beginning to see a technology-driven transformation of global economics. Since the 1970s, the oil-rich countries of OPEC (Organization of the Petroleum Exporting Countries) have exerted disproportionate economic and political power by manipulating the availability of petroleum. But the balance of power is shifting.

Consider the United States (Fig. 1):

- In 2014, thanks to a creative combination of directional drilling and hydraulic fracturing, the US was the world's leading oil producer, pumping out an average of 12.3 million barrels per day [1].
- In 2007, the US imported 59% of its oil, but in 2014, US oil imports were down to 35% of consumption. Imports of natural gas had also dropped by 65% [2].
- The price of crude (West Texas Intermediate) reached \$146 per barrel in June 2008, fell to \$104 per barrel in May 2014, then crashed to below \$30 per barrel on January 12, 2016 before recent recovery [3].
- US CO₂ emissions have decreased, thanks to an ongoing shift in electricity production from coal to natural gas, solar, and wind. Another factor is higher efficiency automobiles, which are reducing gasoline consumption.

The net effect is that, compared to a couple of years ago, about \$320 billion per year stays in the US economy instead of enriching someone else. Lower prices for oil and gas are decreasing revenues from production and increasing margins for refining and petrochemicals. Upstream investments are being delayed or cancelled. Meanwhile, fuel-intensive industries, such as air transportation, are thriving [4]. Lower prices appear to be fueling renewed growth in non-OECD countries. (OECD is the Organization for Economic Cooperation and Development, which represents 14 of the world's richest countries in natural resources.) According to the US Energy Information Administration, in 2014 OECD consumed less than half the oil used in the world [5].

Other factors may influence the supply/demand picture. The recent US accord with Iran increased supply

when supply was already excessive. This further suppressed prices. Impact on prices also came from amending the 1975 Energy Policy Conservation Act and the 1979 Export Administration Act, which ban crude oil exports from the United States. Undoubtedly, light, sweet US crude will pour into the global oil pool, decreasing income in other producing countries, both by suppressing prices even more and by lowering how much the other producing countries can sell. The change will reverberate politically, perhaps in Russia, which has been using gas supply as a tool of diplomacy. It would raise strategic questions. Does America really want to drain itself first? Does it want to impoverish religiously restive North African countries, for which oil and gas are essentially the only source of external income? The US dollar is strengthening [6]. How would an even stronger dollar affect the US balance of trade with, for example, China?

Also consider the environment and worker safety. As Barry Commoner and others have said: There is no free lunch [7]. Despite tremendous profits, and well-publicized (and undoubtedly sincere) campaigns to improve work safety and protect the environment, catastrophic accidents continue to occur. Most are preventable, and most are due to poor training or lack of maintenance. As a colleague says, lessons have been learned, but not everyone has learned them, and many of those who have learned them have since forgot them or choose to ignore them. Major accidents include:

- On 23 March 2005, an explosion in an isomerization process unit at the BP Texas City refinery killed 15 people and injured 180 others. The official report [8] cited inadequate training and worker fatigue as root causes. BP declared profits of 3.68 billion for the fourth quarter of 2005 and \$5.62 billion for the first quarter of 2006 [9].
- On 20 April 2010, on the *Deepwater Horizon* drilling rig, a blowout killed 11 people and gushed 560 to 585 thousand tons of crude oil into the Gulf of Mexico. According to the official report [10], the blowout was preventable, and several poor decisions were made for economic reasons. Perhaps the most important were a lack of training, a lack of

Geoffrey E. Dolbear, PhD

Lifetime Achievement Award,
American Chemical Society Energy
and Fuels Division

Fig. 1 Source: Energy Information Administration, <http://www.eia.gov>, retrieved 14 July 2015

technical supervision, and the use of only six centralizers instead of the recommended 21, apparently to save ten hours (page 97 of the report).

- The infrastructure for transporting *frack oil* from North Dakota was known to be limited and in poor condition, making problems inevitable. On 5 July 2013, a 74-car freight train carrying crude oil from the Bakken shale formation derailed and overturned in Lac-Mégantic, Quebec. The consequent fire and explosion killed 47 people and destroyed most of the town. The root cause was a known problem in a locomotive engine [11].

All of which brings me back to this *Springer Handbook*. It's a one-stop information shop. When I want to know something about any aspect of oil and gas, and related topics, I will look first in this book. If I can't find what I need in one of the 41 chapters written by more than 80 experts from ten countries, I will surely find a relevant reference among the book's roughly 2000 citations.

Here are some specific examples:

- I've heard that a lack of centralizers might have been largely responsible for the *Deepwater Horizon*

disaster. This book describes centralizers and explains why they are important. If I want to know how BP knew there was so much oil so deep under the sea in the Mississippi Canyon, I will consult the chapters on petroleum engineering and reservoir modeling.

- The Energy Independence and Security Act of 2007 exempts contaminated fluids associated with fracking from certain clean water regulations. If I want to know more about fracking, I will consult the chapters on advances in oil production technology. If I want to know how the exemptions might affect my drinking water, I will refer to the chapter on Safety and the Environment.
- I'm considered by some to be an expert in petroleum in the chemistry and catalysis of petroleum processing, obtaining chemicals from coal, and alternative energy. This book will update my knowledge of these topics, too.

I just wish something like this had been available when I entered the industry in the late 1960s.

I am proud to have contributed to this work and its predecessor, *Practical Advances in Petroleum Processing*, and I was honored to be invited to write a foreword

for this work, which promises to serve as a superb reference not just for students and industry professionals, but for people from many walks of life.

Preface

The *Springer Handbook of Petroleum Technology* provides a comprehensive overview of the petroleum industry, and acts as a single reference touching on every important subject: the formation of oil and gas, characterization of petroleum and bitumen, exploration, production, upgrading, emerging technologies, and economics. It also covers special topics, such as catalytic production of lube base stocks and petrochemicals, optimization of hydrogen networks, process modeling, model-predictive control, online optimization, plasma applications, and renewable fuel/chemical processes. And lest we forget: safety, reliability, and pollution control.

The Times They Are a-Changin' is the title of a 1964 album by Bob Dylan, who won the 2016 Nobel Prize for literature [1]. For petroleum, it is far more apropos now than it was a decade ago, when we quoted the signature song in the preface to *Practical Advances in Petroleum Processing* [2].

1965–2005

We noted in our prior book, *Practical Advances in Petroleum Processing*, that in 1964, a wall divided Berlin. The Moon was free of footprints. In America, we said, *Fill 'er up with ethyl*, referring to the tetraethyl lead octane-number additive, as a team of uniformed fueling-station attendants hurried to check the oil level and wash the windows of our gasoline-thirsty Fords and Chevrolets. In the world of petroleum, natural gas, and petrochemicals, major changes began in 1962 with *Silent Spring*, the classic book by Rachel Carson on the global dangers of DDT (dichlorodiphenyl-trichloroethane), and with the efforts of Linus Pauling and other renowned scientists to publicize the dangers of radioactive fallout. The resulting public outrage led to the establishment of the Environmental Protection Agency (EPA) in the United States and the concurrent founding of similar agencies around the globe. In 1972, the EPA issued a general ban on DDT and strengthened the Federal Water Pollution Control Act, thereafter known as the Clean Water Act. In 1973, EPA began its stepwise program to remove tetraethyl lead from gasoline. More than anything else during this time, laws to protect the environment led to new research and development in the petroleum industry.

Crude oil prices leaped from US\$3 per barrel to nearly US\$12 per barrel during the Yom Kippur War in 1973–74, then leaped again during the Islamic Rev-

olution in Iran in 1978–79. Prices topped out at nearly \$40 per barrel – equivalent to more than \$100 per barrel in 2016 currency. The high prices motivated significant drops in worldwide oil consumption and opened automobile markets in Europe and the United States to fuel-efficient imports. Idle, non-OPEC oil and gas wells were reopened, and non-OPEC oil companies intensified efforts to find new reserves. World oil consumption dropped from 63.9 million barrels per day in 1979 to 57.6 million barrels per day in 1983 [3] due to significant conservation, especially in the United States and Europe, the world's major energy consumers. The drive to conserve created a market for rigorous models and advanced process control in refineries and petrochemical plants; advances which greatly improved energy efficiency and formed the foundation for online optimization.

A series of large-scale disasters intensified pressure to improve safety and protect the environment in the petroleum and petrochemical industries. Oil spilled from the *Amoco Cadiz*, the *Exxon Valdez* fouled coastlines and killed wildlife. Preventable refinery explosions at BP Texas City and Tosco Avon were deadly. The tragic release of MIC (methyl isocyanate) from a plant in Bhopal, India killed more than 3700 people and injured more than 550 000 others.

European Union directives and the US Clean Air Act Amendments (CAA) of 1990 again changed the industry. Both regulations required a phase-in of low-sulfur diesel with < 500 ppm sulfur, followed by ultralow-sulfur diesel (ULSD). (By 2017 in the EU, the UK, the United States, the most populous regions of China, and much of the rest of the world, ULSD must contain < 10 ppmw sulfur.) For gasoline, the CAA required the inclusion of oxygenates such as ethanol or methyl-*t*-butyl ether (MTBE), which is synthesized from methanol and isobutylene. Billions of dollars were spent building MTBE and methanol plants. Eventually, MTBE was banned in the United States, only to be replaced by a highly questionable ethanol mandate.

Meanwhile, the world economy boomed, especially in Asia, and the demand for fossil fuels increased accordingly.

2005–2015

When *Practical Advances in Petroleum Processing* was published in 2006, construction was underway in New York City on the new World Trade Center transportation

hub. Allied forces were bogged down in Afghanistan and Iraq. The US embargo of Cuba was still going strong. The US had just frozen the assets of individuals associated with Iran's nuclear program. Energy consumption and oil prices were approaching all-time highs. And Pluto was still a planet.

In *Practical Advances in Petroleum Processing*, we predicted that several ongoing trends would continue:

1. The industry would continue to consolidate.
2. Advances in automation would continue to improve efficiency and safety.
3. Consumption would continue increase in China and India, driving prices upward.
4. Environmental regulations would continue to tighten.
5. The world would continue to rely more heavily on heavier and heavier oil.

With one significant caveat, the first four predictions have come to pass. Consolidation continues, and automation is indeed improving efficiency and safety in our homes and factories [4]. Energy use in Asia is climbing, but – here is the caveat – oil prices have fallen precipitously. Prices dropped for the same reason that our fifth prediction was wrong: innovative technology.

In 2005, we tacitly assumed that United States oil reserves would continue to fall, and that the country would continue to import most of its oil and gas. We assumed that improvements in technology for hydrocarbon production and processing would be incremental, not revolutionary. We weren't quite as wrong as the person who wrote in 1899 that *Everything than can be invented has been invented* [5], but we were certainly surprised. (Contrary to popular lore, Charles H. Duell did NOT make that statement. The quote has been traced to a piece in *Punch or the London Charival*, entitled *The Coming Century*.)

By 2008, due to a creative meld of horizontal drilling and hydraulic fracturing, US producers tapped vast but previously unrecoverable reserves of oil and gas. Due to that technology, colloquially dubbed *fracking*, the United States is now the world's leading oil and gas producer. Instead of being heavy and sour, the new oil is light and sweet. Refineries thrive on frack oil, for which processing costs are reduced.

Eventually, overproduction of frack oil led to a glut, and prices for Brent crude fell from US\$110 per barrel in September 2013 [6] to less than US\$40 in December 2015. Prices for Brent clawed their way back to \$52 in October 2016 [7], but they were still less than half of their recent peak. Natural gas is now a glut in the United States; imports from Canada have dropped precipitously. In the US, exports of liquefied natural

gas (LNG) have begun, putting further downward pressure on energy prices. Thanks to cheap gas, for the first time in decades foreign companies are constructing huge petrochemical plants in the United States. The US Energy Information Administration predicts that the world's largest economy will be energy independent by 2025. As a colleague said, referring to these industry changes, *Oil is upside down*.

For the transportation and processing sectors, frack oil is a good- and bad-news story. Pipelines are the safest, most efficient way to move petroleum liquids long distances, but while pipeline construction is delayed, oil is being shipped by rail with sometimes-questionable rolling stock; the derailment of a poorly maintained frack-oil train led to an explosion in Lac-Mégantic Quebec on 6 July 2013 [8], killing 47 people.

More and more biomass-derived oil is being co-processed with conventional petroleum. Advances in other areas – characterization methods, reservoir modeling, process modeling, lubricants, petrochemicals, and safety systems – are enhancing the way the industry works.

Environmental regulations suffered a significant reversal when the US Energy Independence and Security Act of 2007 (EISA) exempted contaminated fluids associated with fracking from the Clean Air Act and certain Clean Water Act regulations. Arguably, the Energy Policy Act of 2005, in combination with EISA, delivered another setback by prompting the blending of vast amounts of corn ethanol into gasoline. Since Donald Trump became President of the US in 2017, there have been additional rollbacks of environmental regulations. Time will tell how significant and permanent the regulations will be.

Purpose of this Book

The issues above are complex, with significant worldwide impact, politically, economically, and technically. Our ultimate purpose is to provide a tool with which technically sound science-based opinions are developed. We hope that informed opinions will serve as the basis for sound decisions on energy policy.

Target Audience

Our target audience includes students, engineers, and scientists, including those who are experts in one area but want to learn about other fields.

Organization

The book is divided into four parts, except for the first two chapters: the introduction and the chapter on safety

and the environment, which are of general interest. Part 1 includes chapters on specific topics, including petroleum characterization. Part 2 covers the formation of fossil hydrocarbons, and the science and engineering of finding and recovering oil and gas. Part 3 focuses on upgrading technologies, with chapters on coking, fluid catalytic cracking (FCC), hydroprocessing, hydrogen production, catalytic reforming, and refinery-wide optimization. Part 4 provides enlightening information on lubricants, polymers, and novel and emerging technologies.

Contributors

We are pleased to have contributions from several sources, including integrated oil companies, catalyst suppliers, licensors, consultants, and academic researchers. Our 82 contributors hail from ten different countries on 3 continents.

Putting this book together has been a rewarding challenge. We trust that you, our readers, will find it useful and valuable.

Acknowledgements

We wish to thank our editors from Springer – Dr. Kenneth Howell and especially Dr. Judith Hinterberg – for their guidance and limitless patience. We also want to thank our many contributors for their time and effort. Obviously, without them, this book would be a lot shorter.

Most of all, we wish to thank our devoted, magnificent wives, Grace Miao-Miao Chen and Carrie Robinson, for putting up with our absences – mental if not physical – during so many nights and lost weekends throughout the past two years.

About the Editors

Chang Samuel Hsu 許強 had over 32 years' experience at ExxonMobil and BP before joining Florida State University in 2010 to establish the Future Fuels Institute. He also established the Refinery of the Future Lab at BP. Currently, he is an Adjunct Professor at the Department of Chemical and Biomedical Engineering at Florida A&M University/Florida State University, and also at the State Key Laboratory of Heavy Oil Processing of the College of Chemical Engineering at the China University of Petroleum in Beijing as *111 Plan* Professor sponsored by the Ministry of Education of People's Republic of China. He is also a visiting scholar at Guangzhou Institute of Geochemistry, Chinese Academy of Sciences. In 2012, he founded Petro Bio Oil Consulting, LLC.

Dr. Hsu was the first researcher to introduce ultrahigh resolution Fourier-transform ion cyclotron resonance mass spectrometry (FT-ICR MS) for in-depth molecular characterization of petroleum fractions, which has become common practice for analyzing resids/asphaltenes and other heavy oil fractions. He introduced a diophantine algorithm to eliminate the limitation encountered by the polynomial approach for calculating isotopic distribution, which has been used for very large molecules, such as high polymers and proteins. He was one of the pioneers of tandem mass spectrometry (MS/MS) at Exxon, which provides an additional dimension for the determination of the molecular structure of components in complex mixtures.

Dr. Hsu's research interests cover petroleum (both upstream and downstream), coal, shale and biomass oils. His current focuses are novel characterization of petroleum biomarkers for exploration and exploitation, and heavy hydrocarbon characterization for hydroprocessing, catalytic cracking, coking and fuels/lubes analysis. He also has extensive experience in environmental damage assessment and remediation for large scale oil spills. Dr. Hsu has published three books, 13 patents, ten book chapters and over 240 other publications and presentations prior to this handbook. He is a member of the American Chemical Society and American Society for Mass Spectrometry.

In 2016, **Paul R. Robinson** is a recognized expert on petroleum processing. During his 39 years in commercial energy, he visited more than 140 sites in 34 countries on 5 continents. At nearly half of these sites, he participated in project work or provided operations support. He started his career at the Oak Ridge National Laboratory, where his research focused on splitting water with thermochemical cycles. He then spent more than 30 years in various roles with Unocal, Aspen Technology Inc., Chevron, Shell, and KBR. At Unocal, he developed hydrotreating catalysts, studied conversion of syngas to alcohols, and became a Regional Manager for the technology licensing group. Along the way, he received three creativity awards and a patent achievement award. As a senior engineer at Chevron and Shell, he provided process monitoring, operations support, and troubleshooting for commercial hydroprocessing units. At AspenTech, he became Best Practice Leader for online optimization of hydrocracking units. In this role, he co-developed Aspen Hydrocracker, which was based on a model developed by Sun Oil Company and implemented online. At KBR, he was the Chief Technology Advisor for VCC technology, which converts vacuum residue and coal into clean diesel and gasoline.

In 2016, Dr. Robinson founded the Katy Institute for Sustainable Energy, a nonprofit organization devoted to stimulating science-based dialog on energy. KISE teaches courses and provides consultation on petroleum, hydroprocessing, climate change, and related topics.

Dr. Robinson earned BS (Honors) and MA degrees at the University of Missouri, Columbia. At the University of California, San Diego, he spent a year at the Scripps Institution of Oceanography before receiving a PhD in Chemistry. He has authored or co-authored more than 105 publications and presentations, including two books and 15 book chapters. He holds 11 patents, primarily on catalyst and process technology. He is Public Policy Chair for the Energy and Fuels Division of the American Chemical Society. He is most proud of his wonderful family and black belt in TaeKwonDo.

Glossary of Defining Terms	1185
About the Authors	1208
Subject Index	1220

List of Abbreviations

1-D	one-dimensional
2-D	two-dimensional
3-D	three-dimensional
4,6-DMDBT	4,6-dimethyldibenzothiophene
4-D	four-dimensional
4-MDBT	4-methyldibenzothiophene
5-D	five-dimensional

A

A/D	analog to digital
AARD	average absolute relative deviation
ABE	acetone-butanol-ethanol
ABS	acrylonitrile–butadiene–styrene terpolymer
ACDA	aminocyclopentene dithiocarboxylic acid
ACM	Aspen Custom Modeler
ADU	atmospheric distillation unit
AEBP	atmospheric equivalent boiling point
AED	atomic emission detector
AFR	air/fuel ratio
AGO	atmospheric gas oil
AGR	acid gas removal
AH-GO	Arabian heavy gas oil
AKI	anti-knock index
AL-GO	Arabian light gas oil
ALKY	alkylation
ALT	array laterolog tool
AM-GO	Arabian medium gas oil
AMD	acid mine drainage
AMW	average molecular weight
APC	advanced process control
APCI	atmospheric pressure chemical ionization
APCI MS	atmospheric pressure chemical ionization mass spectrometry
APGC	atmospheric pressure gas chromatography
API	American Petroleum Institute
APLI	atmospheric pressure laser ionization
APPI	atmospheric pressure photo ionization
APR	aqueous phase reforming
AR	atmospheric residue
ARC	advanced regulatory control
ARD	acid rock drainage
ARDS	atmospheric residue hydrodesulfurization
ART	asphalt residual treating
AS	acrylonitrile styrene
ASA	amorphous silica alumina
ASAT	aromatics saturation
ASO	acid-soluble oil
AST	array sonic log
ASTM	American Society for Testing and Materials
ATF	automatic transmission fluid
ATR	autothermal reforming

AVO	amplitude variations with offset
AVR	Athabasca vacuum residue

B

B-acid	Brønsted acid
BACT	best available control technology
BCF	bulked continuous filament
BDC	bottom dead center
BHC	borehole compensated
BHGM	borehole gravity meter
BHT	bottom-hole temperature
BHTV	borehole televiewer
BIIR	brominated butyl rubbers
BKB	brown coal briquettes
BO	butylene oxide
boe	barrel of oil equivalent
BPD	barrels per day
BPSM	basin and petroleum system modeling
BR	butadiene rubber
BSI	British Standards Institution
BSR	Beavon sulfur removal
BSW	basic sediment and water
BTL	biomass-to-liquid
BTU	British thermal unit
BTX	benzene, toluene, and xylene
BWR	boiling-water reactor

C

C–C	carbon–carbon
CAD	collisional activated dissociation
CAE	computer-aided engineering
CAL	caliper
CAP	combustion air preheat unit
CAST	circumferential acoustic scanning tool
CAT	catalyst average temperature
Cat-Ox	catalytic oxidation
cat/oil	catalyst/oil
CBA	cold-bed adsorption
CBM	coal bed methane
CCC	critical clustering concentration
CCD	carbonate compensation depth
CCR	Conradson carbon residue
CCS	carbon capture and storage
CDR	cold dilution ratio
CDU	crude oil distillation unit
CDW	catalytic dewaxing
CEOS	cubic equation of state
CFC	chlorofluorocarbon
CFD	computational fluid dynamics
CFR	combined feed ratio
CHNS	carbon–hydrogen–nitrogen–sulfur contents
CHOPS	cold heavy oil production with sand

CHPS	cold high-pressure separator	ECR	electron cyclotron resonance
CI	chemical ionization	EDP	emergency depressuring
CIIR	chlorinated butyl rubbers	EF	expanded fluid
CMI	compact microimager	EFI	electronic fuel injection
CMP	common midpoint	EG	ethylene glycol
CNAC	critical nanoaggregate concentration	EI	electron-impact ionization
CNL	compensated neutron logs	ELSD	evaporative low-angle light scattering detector
CNT	carbon nanotube	EMI	electrical microimaging
COC	Cleveland open-cup method	ENB	5-ethylidene-2-norbornene
COD	crude oil distillation	EO	ethylene oxide
COS	carbonyl sulfide	EoS	equation of state
COT	coil outlet temperature	EPDM	ethylene-propylene-diene terpolymer
CPI	carbon preference index	EPM	ethylene-propylene monomer
CPOX	catalytic partial oxidation	EPR	ethylene-propylene rubber
CPP	catalytic pyrolysis process	ES	electrical survey
CR	controlled rheology	ESI	electrospray ionization
CRU	catalytic reforming unit	ESP	electrical submersible pump
CSM	chloro sulfonated rubber	ESR	electron spin resonance
CSO	clarified slurry oil	ETBE	ethyl tertiary butyl ether
CSS	cyclic steam stimulation	EVA	ethylene vinyl acetate
CSTR	continuous stirred tank reactor	E&P	exploration and production
CTO	catalyst-to-oil		

D

DAFVA	dialkyl fumarate-vinyl acetate
DAO	deasphalted oil
DAWNT	dilute acid with NMMO treatment
DBD	dielectric barrier discharge
DBE	double-bond equivalent
DBT	dibenzothiophene
DCC	deep catalytic cracking
DCS	distributed control system
DCU	delayed coking unit
DDL	direct digital logging
DDT	dichlorodiphenyltrichloroethane
DEA	diethanolamine
DFA	downhole fluid analysis
DFT	density functional theory
DGA	diglycolamine
Dilbit	diluted bitumen
DIPA	di-isopropanolamine
DLA	diffusion limited aggregation
DMDBT	dimethyldibenzothiophene
DMDS	dimethyl disulfide
DME	dimethyl ether
DMR	dry methane reformation
DMT	dimethyl terephthalate
dP	pressure drop
DST	drill stem test
DWA	dewaxing aids
DWO	dewaxed oil

E

e-bed	ebullated bed
E-SBR	emulsion SBR
EAF	electric arc furnace
ECBM	enhanced coal-bed methane

F

F-theory	friction theory
F/E	feed/effluent exchanger
FAME	fatty acid methyl ester
FAR	fused aromatic ring
FCC	fluid catalytic cracking
FCE	flares carbon emission
FD	field desorption
FE	formation evaluation
FEA	finite element analysis
FF	feed-forward
FFR	filter feed rate
FHZ	Flory-Huggins-Zuo
FI	field ionization
FIC	flow-induced crystallization
FID	flame ionization detector
FLNG	floating liquid natural gas
FMI	formation micro-imager
FPS	floating production system
FPSO	floating production, storage and offloading
FPU	feed preparation unit
FSO	floating storage and offloading system
FT	Fischer-Tropsch
FT-ICR	Fourier-transform ion cyclotron resonance
FT-ICR MS	Fourier-transform ion cyclotron resonance mass spectrometry

G

GBS	gravity-based structure
GC	gas chromatography
GC×GC	comprehensive two-dimensional gas chromatography

GC-AED	gas chromatography-atomic emission detection	HTSC	high-temperature shift converter
GC-FID	gas chromatography-flame ionization detection	HTU	hydrotreating unit
GC-ICP-MS	gas chromatography-inductively coupled plasma-mass spectrometry	Hue-GRZ	Hue-gamma ray zone
GC-MS	gas chromatography mass spectrometry	HVGO	heavy vacuum gas oil
GC-MS-MS	gas chromatography-tandem mass spectrometry	HWEP	hot-water extraction process
GC-TOF	gas chromatography-time of flight		
GCD	gas chromatographic distillation	I	
GCU	gas concentration unit	I/O	isobutane-to-olefin
GHG	greenhouse gas	IBP	initial boiling point
GNT	gamma ray neutron tool	ICE	internal combustion engine
GOD	gas oil desulfurization	ICP-MS	inductively coupled plasma-mass spectrometry
GOHT	gas oil hydrotreater	IEA	International Energy Agency
GOR	gas-to-oil ratio	IFA	in situ fluid analyzer
GPC	gel permeation chromatography	IFO	intermediate fuel oil
GPR	general purpose rubber	IIR	isobutylene-isoprene rubber
GR	gamma ray	IMEP	instantaneous mean effective cylinder pressure
GTL	gas-to-liquid	IP	invasion percolation
		IPCC	Intergovernmental Panel on Climate Change
H		iPP	isotactic polypropylene
H/C	hydrogen-to-carbon	IPR	inflow performance relationship
H2OR	hydrogen-to-oil ratio	IR	infrared
HAP	hazardous air pollutant	IRR	internal rate of return
HC	hydrocracking	ISBL	inside-battery limits
HCA	hierarchical clustering analysis	ISIP	instantaneous shut-in pressure
HCC	Houdry cracking unit	ISO	International Organization for Standardization
HCFC	hydrochlorofluorocarbon	ISOM	isomerization
HCGO	heavy coker gas oil	K	
HCO	heavy cycle oil	KD	kerosene desulfurization
HCU	hydrocracking unit	KEC	Kuwait export crude
HDA	hydrodearomatization	KHT	kero hydrotreater
HDEO	heavy duty engine oil	KPS	permeability, porosity, saturation
HDM	hydrodemetalation		
HDN	hydrodenitrogenation	L	
HDO	hydrodeoxygenation	L ² MS	laser desorption, laser ionization mass spectrometry
HDPE	high-density polyethylene	L-acid	Lewis acid
HDS	hydrodesulfurization	LAB	linear alkyl benzene
HDT	hydrotreating	LAO	linear alpha-olefin
HECO	heterophasic copolymer	LC	liquid chromatography
HF	hydrofluoric acid	LCA	lube crude approval
HFA	hydrofluoric acid alkylation	LCB	long-chain branching
HHPS	hot high-pressure separator	LCGO	light coker gas oil
HI	hydrogen index	LCO	light cycle oil
HLPS	hot low-pressure separator	LDI	laser desorption ionization
HMS	high melt strength	LDI MS	laser desorption ionization mass spectrometry
HN	heavy naphtha	LDPE	low-density polyethylene
HOT	heavy oil treating	LDU	lube deasphalting unit
HPS	high pressure separator	LEC	ligand-exchange chromatography
HRTEM	high-resolution transmission electron microscopy	LFC	lower far crude
HSE	health, safety, environment	LFER	linear free energy relationship
HSQC	two-dimensional heteroatom single quantum coherence		
HSR	heavy straight run		
HTE	high-throughput experimentation		

LGO	light gas oil	MOR	middle-of-run
LGR	local grid refinement	MPC	model-predictive control
LHHW	Langmuir–Hinshelwood/Hougen–Watson	MPSG	mercaptopyryl silica gel
LHSV	liquid hourly space velocity	MRIL	magnetic resonance imaging log
LHV	lower heating value	MRM	multiple-reaction monitoring
LIAD	laser induced acoustic desorption	MRS	microresistivity scanner
LIAD-MS	laser induced acoustic desorption-mass spectrometry	MRT	maximum recording thermometer
LID	lithodensity identification	MRV	mini-rotary viscosity
LIFDI	liquid injection field desorption/ionization	MS	mass spectrometry
LL	laterolog	MSDS	material safety data sheet
LLDPE	linear low-density polyethylene	MSFL	microspherically focused log
LLV	liquid–liquid–vapor	MSSV	microscale sealed vessel pyrolysis
LN	light naphtha	MTBE	methyl <i>tert</i> -butyl ether
LNG	liquefied natural gas	MTG	methanol-to-gasoline
LOR	lean oil recovery	MTO	methanol-to-olefin
LPG	liquefied petroleum gas	Mtoe	million tonnes of oil equivalent
LPS	low-pressure separator	MUGC	makeup gas compressor
LSD	low-sulfur diesel	MV	manipulated variable
LSFO	low-sulfur fuel oil	MVGO	middle vacuum gas oil
LSV	liquid space velocity	MW	molecular weight
LTSC	low-temperature shift converter	MWD	molecular weight distribution
LVGO	light vacuum gas oil	MZCR	multizone circulating reactor
LWD	logging while drilling		
LWR	light-water reactor		

M

MABP	mean average boiling point
MALDI	matrix-assisted laser desorption/ionization
MCH	methylcyclohexane
MCHA	methylcyclo-hexylamine
MCHE	methylcyclohexene
MCHT	methylcyclohexanethiol
MCO	medium cycle oil
MCPBA	<i>m</i> -chloroperbenzoic acid
MCR	micro-carbon residue
MDEA	methyl diethanolamine
MDO	marine diesel oil
MDT	modular formation dynamic tester
MEA	monoethanolamine
MEK	methyl ethyl ketone
MFR	melt flow rate
MGO	marine gas oil
MIBK	methyl isobutyl ketone
MIC	methyl isocyanate
MID	metric matrix identification
MIR	mid-infrared spectroscopy
MLDW™	Mobil Lube Dewaxing
MLL	microlaterolog
MMSCFD	million standard cubic feet per day
MMT	methylcyclopentadienyl manganese tricarbonyl
MODU	mobile offshore drilling unit
MOF	metal–organic framework
MON	motor octane number

N

N slip	nitrogen slip
NA	nanoaggregate
NBR	natural butyl rubber
NCD	nitrogen chemiluminescence detector
NEO	net effective overburden
NHT	naphtha hydrotreater
NIM	nuclear instrument module
NIR	near-infrared
NKD	naphtha, kerosene and distillate fuel oil
NLL	neutron lifetime logs
NMAZ	NiMo/alumina-zeolite
NMI	nuclear magnetic imager
NMMO	<i>N</i> -methyl morpholine <i>N</i> -oxide
NMO	normal moveout
NMP	<i>N</i> -methylpyrrolidone
NMR	nuclear magnetic resonance
NO	nitric oxide
NOx	nitrogen oxides
NPD	nitrogen phosphorus detector
NPG	neopentylglycol
NR	natural rubber
NRTL	nonrandom two liquid
NSO	nitrogen, sulfur and oxygen

O

OBM	oil-based mud
OCC	olefins catalytic cracking
OCR	on-stream catalyst replacement
OCT	olefins conversion technology
OD	optical density
OECD	Organization for Economic Cooperation and Development

OGC	oil–gas contact
OHV	overhead valve
OP	opening position
OPEC	Organization of the Petroleum Exporting Countries
OPEX	operating cost
OSP	oil-soluble PAG
OWC	oil-water contact

P

PA	proton affinity
PAA	polyalkyl acrylate
PAG	polyalkyleneglycol
PAH	polycyclic aromatic hydrocarbon
PAMA	polyalkyl meth acrylate
PAN	peroxyacetyl nitrate
PAO	polyalphaolefin
PASH	polycyclic aromatic sulfur heterocycle
PBN	peroxybenzoyl nitrate
PBR	polybutadiene
PCA	principal component analysis
PCB	polychlorinated biphenyl
PCC	propylene catalytic cracking
PCR	principal component regression
PD	photodetector
PDF	process-derived fuel
PDH	paraffin dehydrogenation process
PDI	polydispersity index
PE	polyethylene
PEF	photo-electric factor
PEL	permissible exposure limit
PEM	polymer electrolyte membrane
PET	polyethylene terephthalate
PFR	plug flow reactor
PHWR	pressurized heavy-water reactor
PI	photoionization
PIB	polyisobutylene
PID	proportional-integral-derivative
PINA	normal paraffinic, branched paraffinic (iso-paraffins), naphthenic, and aromatic
PKN	Perkins–Kern–Nordgren
PM	particulate matter
PO	propylene oxide
PONA	paraffins, olefins, naphthenes, and aromatics
POX	partial oxidation
PP	polypropylene
PPE	personal protection equipment
PPM	proton precession magnetometer
PRT	power-recovery turbine
PS	polystyrene
PSA	pressure swing adsorption
PTA	purified terephthalic acid
PVC	polyvinyl chloride
PVT	pressure, volume, temperature
PWR	pressurized water reactor
PX	paraxylene

Q

QMS	quadrupole mass analyzer or spectrometer
QSRR	quantitative structure–reactivity relationship
QSSA	quasi-steady state approximation
QTOF MS	quadrupole time-of-flight mass spectrometer

R

RBOB	reformulated gasoline before oxygenate blending
RCC	reduced crude conversion
RDD	radiological dispersion device
REAC	reactor effluent air cooler
REL	recommended exposure limits
REMPI	resonance enhanced multiphoton ionization
RFCC	residue fluid catalytic cracking
RGC	recycle gas compressor
RHC	raffinate hydroconversion
RHG	Raymer–Hunt–Gardner
RI	refractive index
RIT	reactor inlet temperature
RLA	reaction limited aggregation
RON	research octane number
ROP	rate of penetration
ROT	riser outlet temperature
RPVOT	rotating pressure vessel oxidation test
RTO	real-time optimizer
RVP	Reid vapor pressure
RWO	refinery-wide optimization

S

S slip	sulfur slip
S-PAC	sulfur-containing polycyclic aromatic compound
SAA	sulfuric acid alkylation
SAFT	statistical associating fluid theory
SAGD	steam-assisted gravity drainage
SALDI	surface-assisted laser desorption ionization
SANS	small angle neutron scattering
SAOS	small angle oscillatory shear
SAPO	silica-alumina phosphate
SAPS	sulfated ash, phosphorus, and sulfur
SAR	Si–Al ratio
SARA	saturates, aromatics, resins, and asphaltenes
SAXS	small angle x-ray scattering
SBL	structure-based lumping
SBR	styrene–butadiene rubber
SC	shielding cone
SCAL	special core analysis laboratory
SCD	sulfur chemiluminescence detector

SCFOGIP	standard (temperature and pressure) original gas in place
SCR	selective catalytic reduction
SCWR	supercritical-water reactor
SDA	solvent deasphalting
SFC	supercritical fluid chromatography
SFE	supercritical fluid extraction
SimDist	simulated distillation
SLS	sodium lauryl sulfate
SM	styrene monomer
SMR	steam methane reforming
SNO	solvent neutral oil
SOL	structure-oriented lumping
SOR	start-of-run
SOx	sulfur oxides
SPA	solid phosphoric acid
SPD	slurry-phase distillate
SPI	single photon ionization
SPR	strategic petroleum reserve
SR	straight run
SR LGO	straight-run light gas oil
SRGO	straight run gas oil
SRU	sulfur recovery unit
SSC	scraped surface chiller
SSE	scraped surface exchanger
SSOT	single-stage once-thru hydrocracker
SSREC	single-stage with recycle hydrocracker
STG+	syngas-to-gasoline plus
STL	syngas-to-liquids
STOOIP	stock tank original oil in place
STP	standard temperature and pressure
SUS	Saybolt universal seconds
SWC	side wall core
SWS	sour-water stripper
syncrude	synthetic crude

T

TAME	<i>t</i> -amyl methyl ether
TAN	total acid number
TBP	true boiling point
TCC	Thermoform catalytic cracking
TCD	thermal conductivity detector
TD	total depth
TDC	top dead center
TDS	total dissolved solids
TEL	tetraethyl lead
TGTU	tail-gas treating unit
TI	temperature indicator
TIP	total isomerization process
TLC	thin-layer chromatography
TLP	tension-leg platform
TLV	threshold limit values
TMP	trimethylolpropane
TMT	tube metal temperature
TOC	total organic carbon
TOF	time-of-flight
TOF MS	time-of-flight mass spectrometry
TOST	turbine oil stability test

tpa	tons per annum
TPE	thermoplastic elastomer
TPO	thermoplastic olefin
TR	transformation ratio
TRFD	time-resolved fluorescence depolarization
TSP	thermospray
TSS	third-stage separator
TTR	truck tape recorder
TVD	true vertical depth
TWIM	thin-wall injection molding

U

UCO	unconverted oil
UHMWPE	ultrahigh molecular weight polyethylene
ULSD	ultra-low-sulfur diesel
US	ultra-stable

V

VAM	vinyl acetate monomer
VBI	viscosity blend index
VDU	vacuum distillation unit
VG	viscosity grade
VGO	vacuum gas oil
VI	viscosity index
VLDPE	very low-density polyethylene
VLE	vapor-liquid equilibrium
VLT	vapor-lift tray
VM	viscosity modifier
VOC	volatile organic compound
VPO	vapor pressure osmometry
VPS	vacuum pipestill
VR	vacuum residue
VSP	vertical seismic profiling
VSS	vortex separation system
VUV	vacuum-ultraviolet laser light

W

WABT	weighted average bed temperature
WART	weighted average reactor temperature
WAXS	wide angle x-ray scattering
WBM	water-based mud
WGS	water gas shift
WHR	waste heat recovery
WHSV	weight hourly space velocity
WPC	World Petroleum Council
WTI	West Texas intermediate

X

XRD	x-ray powder diffraction
XRF	x-ray fluorescence spectrometry

Z

ZSM-5	Zeolite Socony Mobil-5

1. Introduction to Petroleum Technology

Paul R. Robinson, Chang Samuel Hsu

When people consider petroleum, they first think of energy. Petroleum and other fossil fuels now provide more than 86% of the energy consumed by mankind. In addition, fossil resources, especially petroleum and natural gas, serve as the organic source of tens of thousands of consumer products, which enrich our daily lives.

To understand petroleum and the petroleum industry, one must be familiar with the technology used to find and recover crude oil and natural gas and transform them into useful products. These technologies can also be applied to gases and liquids from coal, shale, and renewable biomass. Research and development aimed at improving or modifying existing technologies and developing new ones usually require physical testing and chemical characterization.

Three-dimensional imaging exhibits geological formations most likely to contain oil and gas. Rigorous basin modeling optimizes exploration and production. Modern production technology includes enhancements in horizontal drilling and offshore platform design. The application of hydraulic fracturing to previously unrecoverable oil and gas from tight reservoirs has transformed the United States into the world's leading producer of oil and gas.

Midstream technology includes trading, shipping, and transportation, along with processing prior to transportation. Midstream processing includes froth treatment for upgrading bitumen from steam-assisted gravity drainage (SAGD) into synthetic crude oil (syncrude). Sophisticated planning models enable global energy companies to quickly decide logistics: which oils to buy, how to allocate them between numerous processing plants, and whether to resell them.

Crude oil goes to refineries, which use distillation, treating, conversion, extraction and blending processes to produce fuels, hydrogen, lubricants, waxes, coke products, asphalt, and sulfur. Some refinery streams are sent to petrochemical plants.

Ever-improving mathematical models enhance all aspects of petroleum technology. Model-predictive control (MPC) stabilizes operations and reduces product-quality giveaway, increasing profitability at relatively low cost. The simple return on investment for an MPC project can be 3–4 months. Process engineers rely on rigorous equipment and piping models to optimize designs, not just in the oil and chemical businesses, but in all process industries. With such models, energy consumption in processing plants has been reduced by up to 70% since the 1980s. Rigorous reaction models, based on molecular characterization, serve as the foundation for real-time online economic optimization, in some cases for entire refineries. Economic optimization uses an objective function to find the most profitable balance between equipment constraints, feed quality, product yields, product properties, and utilities costs.

One cannot over-emphasize the importance of safety and protection of the environment. Failure to understand technology fundamentals and process details is the root cause of many infamous industrial catastrophes. Lack of understanding of technology fundamentals occurs at all levels, from the control board to the board room. Corporate executives who insist that safety is Number One must invest in safety-enhancing infrastructure. They must ensure that operators are well-trained and equipment is well-maintained.

Petroleum will remain significant for decades to come. Hopefully, ever-advancing technology will continue to supply energy and raw materials while protecting workers and the environment.

When people consider petroleum, they first think of energy. Energy is the ability of a system to do work. Forms of energy include heat, light, magnetic, mechanical, chemical, nuclear, and gravitational. Importantly, energy can be transformed from one form into another. For example, burning petroleum converts the energy stored in chemical bonds into heat, light, and mechanical energy.

Figure 1.1 shows that in 2014, fossil resources – coal, petroleum and natural gas – provide more than 86% of the energy people consume in modern societies. As discussed in more detail below, in addition to sup-

plying energy, oil and gas serve as the organic source of tens of thousands of chemicals and consumer products, which enrich our daily lives.

Petroleum plays a crucial role in economics and politics. It has made small countries rich, and the wealth of large countries depends on its cost and availability. Petroleum has played a critical or decisive role in all major wars since the start of the twentieth century.

The petroleum industry is huge and complex. To understand the industry, one must gain familiarity with the underlying science and engineering, which are used to find and recover crude oil and natural gas and transform

Fig. 1.1 World energy consumption by fuel type in 2014. (After [1.1]). The sum for fossil hydrocarbons is 86.3%, 1.4% lower than the 2013 total. Petroleum includes crude oil produced from tight formations with hydraulic fracturing. Gas includes co-produced petroleum gas, condensate, dry gas, and coal-seam gas. Renewable includes wind, solar, geothermal, and biomass (largely ethanol and oil from plants and animal fat). Data for the figure come from the BP Statistical Review of World Energy, 2015

them into useful products. These technologies can also be applied to gases and liquids from coal, shale, and renewable biomass. Research and development aimed at improving or modifying existing petroleum technologies and developing new ones starts with physical testing and chemical characterization.

Three-dimensional imaging exhibits geological formations most likely to contain oil and gas. Rigorous basin modeling optimizes exploration and production. Modern production technology includes enhancements in horizontal drilling and offshore platform design. Recently and significantly, hydraulic fracturing is recovering oil and gas from previously inaccessible reservoirs, transforming the United States into the world's leading producer.

1.1 Petroleum and Its Uses

1.1.1 Primary and Secondary Energy Sources

Petroleum, coal, and natural gas were formed from the remains of ancient organisms. Ultimately, they were created from the solar energy captured by plants, and the heat and pressure of the geological structures in which they were formed. But today, so far as we are concerned, fossil fuels are primary sources of energy.

Midstream technology includes transportation, trading and midstream processing, such as froth treatment for upgrading bitumen recovered by steam-assisted gravity drainage (SAGD) into synthetic crude oil (syn-crude).

Crude oil goes to refineries, which rely on distillation, treating, conversion, and blending to produce fuels, hydrogen, lubricants, solvents, sulfur, waxes, coke products, and asphalt. Refineries and natural gas plants supply raw petrochemicals. Refineries provide light olefins, aromatics (benzene, toluene, and xylenes) and petrochemical naphtha. Natural gas is transformed into light olefins and synthesis gas. From petrochemicals come thousands of vital materials – coatings, polymers, fibers, plastics, cosmetics, pharmaceuticals, and many others.

Ever-improving mathematical models enhance all aspects of petroleum technology. Sophisticated planning survey models enable global energy companies to quickly decide which oils to buy, how to allocate them between numerous processing plants, and whether to resell them.

Model-predictive control (MPC) stabilizes operations and reduces product-quality giveaway, increasing profitability at relatively low cost. The simple return on investment for an MPC project can be 3–4 months. Process engineers rely on rigorous equipment and piping models to optimize designs, not just for oil, gas, and petrochemicals, but for all process industries. With such models, energy consumption in processing plants has decreased by up to 70% since the 1980s. Rigorous reaction models, based on molecular characterization, serve as the foundation for real-time online process and economic optimization, in some cases for entire refineries.

One cannot overemphasize the importance of safety and protecting the environment. The root causes of many infamous industrial catastrophes were the failure of corporate executives, line managers, front-line engineers, and operators to learn and understand technology fundamentals well enough to respond properly to unusual situations.

World energy sources compare different estimates of primary energy reserves from various government agencies [1.2]. It divides resources into three categories:

1. Fossil
2. Nuclear
3. Renewable.

Important sources of nonconventional fossil fuels include bitumen and oil shale. Renewable sources include solar, wind, hydroelectric, ocean waves, biomass, and waste. Biomass also serves as a source of biochemicals. Nuclear and renewable sources are carbon-neutral. They are not net producers of atmospheric CO₂. According to sources [1.2], proven, recoverable fossil sources total 39 ZJ, where 1 ZJ = 10²¹ J [1.3]. The International Atomic Energy Agency estimates that available nuclear power derived from uranium is 2500 ZJ, assuming the use of fast-breeder technology; breeder reactors create more fissile material than they consume. The Intergovernmental Panel on Climate Change (IPCC) estimates that reserves based on uranium are 1000 ZJ. Some estimates of available energy from uranium and fissile thorium are misleadingly low, because they neglect reprocessing and reuse of recovered isotopes. The safety of nuclear power is a huge concern. Nuclear accidents are rare, but when they occur, they are deadly and exceptionally difficult to contain, with planet-wide consequences.

Hydrogen and electricity are not energy sources. The US Energy Information Agency calls them secondary sources. Others prefer to call them energy vectors or energy transfer agents, because their main role is to move primary energy from power plants to consumers.

Now and then, hydrogen automobiles are touted to be pollution free, because hydrogen produces water when it burns. Most commercial hydrogen comes from steam/hydrocarbon reformers, which co-produce CO₂. Stoichiometry dictates that for every ton of produced H₂, 5.5 t of CO₂ are co-produced. The generation of requisite process heat via combustion yields additional CO₂. Natural gas is the primary feed to on-purpose hydrogen plants, in which methane reacts with steam to form CO, which reacts with addition water to form CO₂ and additional H₂ via *water gas shift* reactions. Converting heavier hydrocarbons co-produces even more CO₂.

Electrolytic hydrogen is co-produced in chlorine-manufacturing plants. Most often, the required electricity comes from fossil fuels.

Steam is a short-distance energy transfer agent. Generated from water vaporization in fired boilers or nuclear power plants, it drives turbines to generate electricity or run pumps and gas compressors. SE-TatWork [1.4] describes how Preem refineries near Lysekil and Goteborg, Sweden, deliver waste heat, as hot water, to nearby factories and homes. The corresponding reduction in CO₂ emissions is estimated to be 152 400 t/yr.

Major untapped energy *sources* are conservation and efficiency, for which the cost is far lower than building new facilities.

1.1.2 Oil and Gas as Primary Sources of Energy

Figure 1.2 shows how oil and gas consumption has grown since 1820. Figure 1.2 provides a breakdown of world consumption of energy from wind, biomass, and solar sources since 1965. Geothermal plays a minor role and is not shown. From these graphs, one can make the following observations:

- World consumption of energy has increased more than 500% since the end of World War II. Most of that increase came from coal, oil, and natural gas.
- In 1820, primitive biofuels directly from natural resources – mostly wood, peat, animal fat, and fodder consumed by draught animals – still provided most of our energy. In the graph, primitive and modern biofuels (mainly ethanol) are shown together.
- Near the end of the nineteenth century, coal consumption overtook primitive biofuels.
- In the 1950s, oil and gas overtook coal. Consumption of energy from all sources began to increase exponentially. The rate of increase slowed in the 1970s primarily due to turmoil in the Middle East.
- Energy from renewable sources, especially wind energy, continues to grow rapidly.

Table 1.1 presents a quantitative petroleum product breakdown in the United States for July and December 2014 [1.6]. Sulfur and other contaminants are excluded. Motor gasoline totals do not include ethanol. About 83 wt% (90 vol.%) of the products are fuels – gasoline, kerosene, jet, and fuel oils. Most refinery gases and petroleum coke are also used as fuels. In Europe, yields of motor gasoline and distillate fuel oil would be approximately reversed, and yields of petroleum coke would be lower.

1.1.3 Petroleum as a Source of Nonfuel Products

Petroleum not only provides transportation fuels, but it also supplies building blocks for the thousands of other chemicals and other materials that improve the quality of our daily lives (Tables 1.2 and 1.3).

1.1.4 Advantages of Petroleum

When wisely handled, petroleum can be safe and clean. Conventional crude oils are liquids at ambient temper-

Fig. 1.2 (a) World energy consumption by fuel since 1820 (after [1.5], with kind permission from Gail Tverberg). **(b)** World consumption of renewable energy since 1965. Note that the scale for hydroelectric is 5× the scale for the other sources. Biomass includes both modern biomass, primarily fuel ethanol, and traditional biomass (wood, peat, animal fat, and fodder consumed by draught animals) (after [1.1])

atures; compared to solids and gases, liquids are easier to transport and process. Petroleum is noncompressible, so conventional pumps can push it through pipelines thousands of miles long or into and out of sea-going tankers. Bitumens are solids or goos at ambient temperature, but they can be liquefied by heating or by dilution with lighter oils.

Crude oils can be stored for months with minimal losses in above-ground tanks, or stored indefinitely simply by leaving them under-ground. (*Minimal losses* might include vaporization, leakage, oxidative degradation, and biodegradation. In certain cases, such losses are not so minimal). Fuels distilled from petroleum have high energy densities. 15 gal of gasoline can move a 3300pd automobile across 350 mi of flat road at 65 mi/h. (In metric units, those values are 57 l, 1480 kg, 565 km, and 105 km/h, respectively.)

Belying recent projections, petroleum still is abundant. On April 18, 1977, the US President Jimmy Carter

predicted that if the world consumption of oil kept rising by 5% per year, the world's proven reserves of petroleum would be used up by 1990 [1.7]. Carter then outlined an energy policy that encouraged conservation and stimulated the development of petroleum alternatives. Other countries, notably in Western Europe, already had implemented similar measures. In the years since, new technologies were developed for finding new petroleum deposits and improving production from known fields, including bitumen and oil shale.

While oil and gas are ubiquitous, they are not evenly distributed. In 2014, the top 10 countries held about 83% of world reserves of conventional petroleum and bitumen, led by Venezuela (17.5%), Saudi Arabia (15.7%), and Canada (10.4%). For natural gas, the top 10 countries held about 78% of world reserves, led by Russia (23.8%), Iran (16.4%), Qatar (12.1%), Turkmenistan (8.5%), and the United States (4.7%).

Table 1.1 Industry-average volume-percent yields from petroleum refineries in the United States

US refinery yields ^{a,b} (vol. % of feed)	Summer (Jul 2014)	Winter (Dec 2014)
Liquified petroleum gases (LPG) ^c	5.3	2.4
Motor gasoline ^d	44	46.5
Aviation gasoline	0.1	0.1
Kerosene-type jet fuel	9.7	9.7
Kerosene	0.1	0.2
Distillate fuel oil	29.1	30.7
Residual fuel oil	2.4	2.3
Petrochemical feed (naphtha)	1.3	1.4
Petrochemical feed (other)	0.7	0.5
Special naphthas	0.3	0.2
Lubricants	1	0.9
Waxes	0.1	0
Petroleum coke	5.5	5.3
Asphalt and road oil	2.3	1.7
Still gas ^c	4.2	4
Miscellaneous products	0.6	0.5
Volume gain ^e	6.7	6.4

^a After removal of sulfur, nitrogen, and other contaminants

^b Volumes of solids are expressed in fuel-oil equivalents

^c Still gas is largely methane but can also contain C2–C4 compounds

^d Does not include ethanol

^e The volume gain is due to cracking. Light cracked products have lower densities than crude oil

1.1.5 How Long Will It Last?

Petroleum as an energy source is slowly but surely being replaced, but no other single substance has all the same advantages. As already mentioned, in addition to serving as our major source of energy, oil and gas are the organic sources of thousands of consumer products with exceedingly different properties – from medicines

Table 1.2 Nonfuel petroleum products

Product class	Example	Some uses
Lubricants (including grease and industrial oils)	≫ 800 products	From <i>baby oil</i> to axle grease – all with stringent specifications
Asphalt and waxes	Asphalt Waxes	Paved roads, water-proofed buildings Coated paper packaging, water-proofing, candles
Carbon	Petroleum coke Needle coke Graphite	Fuel and making anodes for metal refining Electric arc anodes for aluminum and high-grade steel Metallurgy, specialty fibers, paints, pencils

^a UCO is highly upgraded unconverted oil from hydrocrackers

to pesticides, from golf club shafts to PVC pipes, from baby oil to asphalt, from adhesives to laxatives.

Deposits of petroleum and other fossil hydrocarbons were formed millions of years ago. They are finite. A commonly asked question is: How long will petroleum last?

It is common to see reports in which projections are made based on a simple ratio of present-day proven reserves by present-day rates consumption, using (for example) data from the US Energy Information Administration (EIA), the International Energy Agency (IEA), and the BP Statistical Review of World Energy (BP) [1.1]. With data from BP, we get the following results:

- Remaining oil, 52 years
- Remaining natural gas, 54 years
- Remaining coal, 110 years.

Fenton et al. [1.8] estimated that 1.3 trillion barrels of oil could be recovered from known reserves of kerogen-rich shale. This is equivalent to 40 more years of oil, bringing the total for oil to 92 years:

- Remaining oil + oil from shale, 92 years.

There are significant problems with using such ratios to predict how long fossil fuels will last. The problems include:

- *Failure to anticipate advances in technology.* While still theoretically finite, proven oil reserves are *increasing* – from 683 billion barrels in 1980 to 1690 billion barrels in 2014.
- *Market drivers.* As will be shown, consumption decreases, often dramatically, when prices rise.
- *Synthetic petroleum.* Synthetic petroleum is being generated from other fossil resources – natural gas, bitumen, and kerogen. Especially in China, coal is

Table 1.3 Chemicals derived from petroleum and uses

Family	Chemical	Used to make ...
Alcohols and derivatives (from natural gas processing)	Methanol	Methyl tertiary butyl ether (MTBE), acetic acid, formaldehyde, synthetic gasoline (MTG process)
	Acetic acid	Vinyl acetate ⇒ plastics, latex paints, cellulose acetate ...
	Cellulose acetate	Yarns, sheet plastic, films, lacquers
	Formaldehyde	Resins, butanediol, inks, nylon
	Ethyl alcohol (from ethylene)	Gasoline, solvents, personal care products, ethyl chloride ...
	Ethyl acetate	Solvent (e.g., nail polish remover)
	Isopropyl alcohol	Solvents, personal care products
Aromatics (from petroleum)	Higher alcohols	Solvents, plasticizers, detergents
	Benzene	Styrene, cumene, cyclohexane, maleic anhydride ...
	Toluene	Polyurethane
Aromatics derivatives	Xylenes	Polyester fibers, resins, plasticizers
	Cyclohexane	Nylon precursors
Olefins (from natural gas and petroleum)	Cumene and phenol	Phenolic resins, epoxy and polycarbonate resins
	Ethylene	Polyethylene, ethylene dichloride, ethylene oxide
	Ethylene dichloride	Polyvinyl chloride (PVC) ⇒ plastics
	Ethylene oxide	Polystyrene, ethylene glycol
	Ethylene glycol	Antifreeze, polyethylene terephthalate (PET) ⇒ plastic bottles
	Propylene	Polypropylene, propylene oxide ⇒ propylene glycol ...
	Propylene glycol	Antifreeze, polyesters, pharmaceuticals, hand sanitizers
	Butenes	Maleic anhydride
	Butadiene	Complex polymers, including synthetic rubbers
	Alpha olefins	Polymers, surfactants, synthetic lubricant oil and additives, fatty acids
Others	Acrylonitrile, acrylic acid	Polymers, including transparent polymers (Plexiglass, Lucite)
	Aldehydes and ketones	Acetic acid, acetone, other solvents
	Ethylbenzene and styrene	Polystyrene
	Isobutane	Methyl methacrylate resins
	Maleic anhydride	Polyesters, resins, plasticizers, dicarboxylic acids, nylon precursors

being converted into liquid fuels, chemicals, and syngas. Renewable plant-derived oils are being co-processed in existing oil refineries.

- *Energy efficiency.* Energy efficiency is improving. Significantly, driven by environmental regulations, the fuel efficiency of vehicles has been rising, slowly but surely, since the 1970s. To meet the regulations, vehicle manufacturers have improved engine design, vehicle body shape, materials, fuels, and lubricants. Rigorous design models have enabled significant energy reduction in many industries. In 10 US states, the energy cost of producing electricity has decreased by more than 70% [1.9].

M. King Hubbert's peak oil method [1.10] is sometimes used to predict how long oil will last. Once highly touted, Hubbert's approach has proven to be misleadingly pessimistic, due to its Malthusian assumptions. Hence, as with simple ratio calculations, Peak oil fails to account for advances in technology, which affect both availability and consumption.

1.1.6 Petroleum Composition

Petroleum is not a uniform substance. It can be present in nature as gas, liquid, or solid under ambient temperature and pressure. The gaseous form of petroleum in nature is also known as natural gas. The solid form of petroleum can be bitumen or tar. The petroleum fractions processed in the refineries are liquids (crude oils) or soluble/diluted viscous liquids or solids, such as syncrudes.

There are hundreds of different crude oils, and each one is a complex mixture of thousands, if not millions, of compounds. Some crude oils (crudes) are listed later in this chapter.

Petroleum is mainly composed of hydrocarbons, compounds of carbon and hydrogen; it also includes compounds containing heteroatoms, primarily sulfur, nitrogen, oxygen, and metals. The major classes of hydrocarbons are paraffins (normal and isoparaffins), cycloparaffins (naphthenes), aromatics (aromatic and naphthenoaromatic hydrocarbons), and heteroatom compounds (nonhydrocarbons). Most heteroatom compounds are harmful to upgrading equipment, processes,

the environment, and even human health, so they are removed during processing.

Petroleum crude oils can be broadly classified as paraffinic, asphaltic, and mixed crude oils. Paraffinic crude oils are composed of aliphatic hydrocarbons (paraffins), wax (long-chain normal paraffin), and high grade oils, but no or little asphaltic (bituminous) com-

ponents. On the other hand, asphaltic crude oils contain no or little paraffins. Some are naphthenic, i.e., they contain predominantly cycloparaffins, which can be feedstocks for making high viscosity lubricating oils. Most crude oils are mixed oils which include all three hydrocarbon types: paraffins, naphthenes, and aromatic hydrocarbons.

1.2 People and Petroleum

People were using petroleum tens of thousands of years ago. This section describes highlights of this long and interesting history, from the stone age to the space age.

1.2.1 Petroleum in Ancient Times

Spears and Baskets

Hafting is the process of attaching the heads spears, arrows, and axes to a shaft. The simplest technique, used in the Stone Age mostly for arrows, was to split the end of the wooden shaft and force the tapered base of the head into the resulting gap. For spears, the base of the head was notched, and leather strips were looped through the notches and wound around the shaft. In both methods, junctions were strengthened with mastic obtained from rendered animal hides or hooves, from tree resin, or from bitumen. According to *Boëda* et al. [1.11] people were hafting with bitumen more than 70 000 years ago near Umm el Tlel, in present-day Syria.

A book by *Jane McIntosh* [1.12] on the ancient Indus Valley describes how baskets were water-proofed with bitumen before 5500 BC in Mehrgarh, an ancient site located in present-day Pakistan between the cities of Quetta, Kalat, and Sibi.

Boats, Towers, and Mummies

Bitumen is described as *mankind's oldest engineering material* [1.13]. It is mentioned by some of the earliest known writing – transactions recorded in Cuneiform script on clay tablets found in the ancient city of Sumer [1.14, 15]. The Sumerian Empire, located in Mesopotamia between the Tigris and Euphrates rivers in present-day Iraq, lasted from about 3500 to 2500 BC. Pitch was used in mortar, for cementing eyes into carvings, building roads, caulking ships, and waterproofing, in general. Sumerian pitch came primarily from oil pits near the river Issus, one of the tributaries of the Euphrates.

Greek and Roman historians describe how Egyptians employed pitch for construction, to grease chariot wheels, and for mummification [1.16]. After they were thoroughly dried, mummies were coated with bituminous plaster and wrapped with bitumen treated cloth.

Molten pitch was poured into empty brain cavities. (One of the first steps in mummification was to remove and discard the brain.) Egypt's primary source of pitch was the Dead Sea, which the Romans called *Palus Asphaltites* (Asphalt Lake).

In Babylon (1900–1600 BC), bitumen was employed during construction of the famous Tower. Persians used bitumen and its fractions for lighting, topical ointments, and flaming projectiles.

By 500 BC, ancient civilizations knew that light petroleum fractions, such as naphtha, could be mixed with asphalt to make the latter easier to handle. The light fractions may have been recovered with alembics or simple batch distillation equipment such as that described by Zosimus of Panopolis, a Greek alchemist who lived at the end of the third century and beginning of the fourth century AD [1.16].

Early Natural Gas

Mark Kurlansky's book on the importance of salt tells a fascinating story about brine wells in the Sichuan region of China [1.17]. In 252 BC, a Qin Dynasty official named Li Bing ordered workers to drill brine wells after he discovered that brine pools on the surface were fed from underground. Occasionally, well diggers became weak or sick, and sometimes explosions killed an entire crew. By 100 AD, people understood that the source of their problems was an invisible, flammable gas, now called natural gas. They piped it into open sheds through leak-proofed bamboo tubes. In the sheds, using the gas as fuel, they boiled away the water, leaving behind crystallized salt. By the end of the second century AD, co-production of gas and brine was controlled by a system of leather valves, which resembled in many respects the valves used in certain modern wells.

By 347 AD, Chinese were drilling for gas with bamboo shafts. They collected bitumen, too, and employed it in unique ways. For example, they warmed it to drive off lighter fractions, leaving behind a thermoplastic material with which scabbards and other items were covered. Statuettes of household deities were cast with this material in Japan, and perhaps also in China.

Coal

Even before civilization took root in China 5000 years ago, people in the region had been using coal for about 1000 years [1.18, 19]. They carved it into ear ornaments, and they created the world's first coal mine. Ancient China's coal use enabled it to develop into a sophisticated economy and society.

Archeological evidence in China indicates surface mining of coal and household usage after approximately 3490 BC [1.20]. Iron artifacts, made between 2700 and 3000 BC, probably were manufactured with heat provided by charcoal.

By the first century AD, Romans were burning coal in hypocausts to heat homes and public baths, in smelters to recover iron from ore, and in forges to shape iron into weapons, ornaments, and other implements.

Greek Fire

Greek fire [1.3] was invented during the reign of Byzantine Emperor Constantine IV (668–685) by Callinicus of Heliopolis, a Jewish refugee from Syria. This formidable weapon was sprayed at enemy ships from siphons. It burst into flame on contact with air and could not be extinguished with water. Greek ships used the weapon to cripple an attacking Arab fleet, breaking the four-year siege of Constantinople (674–678). Experts are still debating the exact composition of Greek fire. Most believe it was comprised of naphtha, liquid petroleum, bitumen, and quicklime.

Early Kerosene

The great Persian scholar, Muhammad al-Razi (865–925 AD), wrote more than 200 books and articles, in which he documented fundamental contributions to medicine, alchemy, music, and philosophy [1.21]. He discovered numerous chemicals and compounds, including kerosene, which he recovered from petroleum. Kerosene has been used for heating ever since.

Early Lamps

Lamps were providing people with artificial illumination before 15 000 BC [1.22]. Lamps found in the Lascaux caves near Dordonis, France, were carved from stone; the Lascaux archaeological site is best known for its Paleolithic cave-wall paintings [1.23]. Ancient lamps found elsewhere were made from hollow stones, sea shells, coconuts, and even egg shells [1.24]. Oil for lamps came from olives and other oil-rich plants. Lard oils from animals were readily available, but they tended to burn with smoky, smelly flames.

Significantly, sea-faring folk discovered that the cleanest-burning animal oils came from whales.

1.2.2 Whaling

Rock carvings found at the Bangudae archaeological site near Ulsan, Korea, show that perhaps as early as 6000 BC, humans hunted whales from boats using harpoons and floats attached to lines [1.25]. Nearby, prehistoric caches of whale bones confirm that the creatures were an important resource for people in the area.

Thousands of years later, near-shore whaling was thriving in the Bay of Biscay near Bayonne, at the southwest corner of present-day France [1.26]. By the fourteenth century, Spanish whalers were venturing far into the north, hunting mainly the North Atlantic Right Whale. English, Dutch, French, and Scandinavian fleets dominated whaling in the eighteenth century. Especially prized was the sperm whale. Spermaceti, a clear, yellowish liquid that burns with a clear, bright flame, was harvested from the head cavity of this creature. Spermaceti sold at a premium, sometimes fetching up to 3 times more than other oils from whales.

In addition to fueling lamps, whale oil furnished lubricants for the machinery of the Industrial Revolution. Baleen from whales provided buggy whips, fishing poles, corset stays, and dress hoops [1.27].

Yankee Whaling

The American whaling industry started late in the eighteenth century. New Bedford, MA, was the hub, supplemented by major ports in Nantucket, MA, and New London, CT. Several important ships were built in Mattapoisett, MA. Yankee whaling flourished from 1783, when the Treaty of Paris ended the American Revolution, until the War of 1812, when the British navy (again) blockaded American ports. From 1814 to the 1870s, except during the American Civil War (1861–1865), Yankee whaling reached its height.

Due to overhunting, whales in the North Atlantic declined. To fill their holds, fleets ventured far and wide, sometimes skirting South America on years-long round trips between New Bedford and the North Pacific, all the way to the Bering Strait. Supplies fluctuated wildly due to world events and the *luck of the fleet*. In lean years, fleets ventured farther into the Arctic and stayed longer in dangerous, freezing waters. Consequently, the number of shipwrecks increased, and the number of whales decreased. By 1860, several species were almost extinct [1.28]. Prices reflected supplies, ranging from less than \$0.40/gal in 1830s to more than \$2.50/gal during and just after the American civil war [1.29]. Significant losses of ships during that war were devastating to whaling – but fortunate for whales. The *CSS Shenandoah*, a fully rigged Confederate ship with auxiliary steam power, captured or sank 38 Union merchant ships, 25 of which were unarmed New Bedford whale-

ships. *John Baldwin* wrote [1.30] that on or about June 23, 1865 – more than two months after Robert E. Lee surrendered his Confederate army to Ulysses S. Grant – the *Shenandoah* fired the last shot of the Civil War across the bow of a whaleship in the Aleutian Islands. In November 1865, to avoid the US Navy and reluctant to face an opponent that might shoot back, Commander James I. Waddell surrendered the *Shenandoah* to the British near Liverpool, England.

1.2.3 Modern Kerosene

More than 900 years after Muhammad al-Razi wrote about recovering kerosene from petroleum, the following occurred:

Gesner and Oakes

In 1846, Canadian geologist Abraham Gesner developed a distillation process to recover kerosene from coal, bitumen, and oil shale. In 1850, his company began installing lighting in Halifax, Nova Scotia, Canada [1.31]. Gesner was granted a patent for his recovery method in 1854. He did not invent kerosene per se.

In 1847, prior to the issue of Gesner's patent, James Oakes built a rock oil refinery in Riddings, Derbyshire, England, to recover oil for lamps [1.32].

Semyenov

In 1848, the *first modern oil* well was drilled by Russian engineer F.N. Semyenov [1.33] on the Aspheron Peninsula north-east of Baku. Eleven years later, a refinery was constructed near the well to convert raw petroleum into several products.

Łukasiewicz

In the 1850s, *Ignacy Łukasiewicz* [1.34] and Robert E. Dietz independently developed practical kerosene lamps [1.35]. Łukasiewicz was a pharmacist in Lvov, Poland. In 1852, he and his assistant, Jan Zeh, experimented with ways to improve the safety of burning seep oil from the Carpathian mountains. From a local peasant, they learned how to boil away the most volatile components. With their own experiments, they devised ways to remove heavy impurities. Working with a local tin smith, they developed a lamp that burned the purified fuel with a clean, steady flame. By 1858–1859, Łukasiewicz/Zeh lamps were replacing other forms of illumination in Austrian railway stations. In 1854, Łukasiewicz moved to Southern Poland, where he collaborated with a partner to develop an oil field near Bobrka. His first wells were dug with picks and shovels and reinforced by wood beams. The deepest was 150 m (480 ft). During subsequent years, he opened several more oil wells, and in 1859, he commissioned a refinery near Jasło.

Dietz

In 1840 in New York, Robert E. Dietz began selling lamps to burn whale oil and camphene. In 1859, he and his brother Michael patented a lamp with a flat-wick burner, one of the first designed specifically for kerosene. Due to their steady performance in windy weather, Dietz lanterns became known as *hurricane lamps*.

Williams

In July or August 1858, James Miller Williams struck oil while drilling a well for drinking water in Oil Springs, Ontario, Canada, near present-day Petrolia [1.36]. The well is often called the first oil well in North America.

The Drake Well

On August 27, 1859, Edwin L. Drake struck oil with a well near Titusville, in northwest Pennsylvania [1.37]. By today's standards, the well was shallow – about 69 ft deep (21 m) – and it produced only 35 bbl/day. The Drake well was not the first to produce oil, but it was the first on record to be drilled through rock with a powered rotary engine, specifically for oil.

The Drake well triggered the Pennsylvania oil rush. Owners of adjacent leases recognized that they and their neighbors were accessing the same large underground pool. The key to success, they believed, was to drill more wells faster than their neighbors. The result is illustrated in Fig. 1.3. Note the short distance between the two wells – the Phillips well and the Woodford well, which were among the most productive of the time. In the middle of the photo are wooden barrels in which the crude was stored and transported. The size of a barrel was not standardized yet, so the barrels shown are of different sizes.

At first, Drake was able to sell his oil for US\$20/bbl. The price of kerosene from the oil was slightly less than the price of lard oil and 50–70% less than the price of whale oil. But kerosene prices soon fell, largely due to overproduction. Another factor was the lack of infrastructure for transportation to population centers on the US East Coast. During the next few years, prices swung wildly, from \$10/bbl in January 1861 to \$0.10/bbl at the end of that year. Similar swings occurred in 1862. By September 1863, prices reached \$7.25/bbl.

After the Drake Well

Figure 1.4 shows important events subsequent to the Drake well. It includes annual average oil prices, both in money of the day and inflation-corrected dollars.

Russian crude became internationally significant when, starting in 1873, the Nobel brothers (Ludwig and Alfred) and then the Rothschild family invested heavily

Fig. 1.3 A Pennsylvania oil field in 1862. The two wells shown are the Phillips well and the Woodford well, among the most productive of the time. Note the small distance between them. In the middle of the photo are wooden barrels in which the crude was stored. The size of a barrel was not standardized yet, so the barrels shown are of different sizes

in developing Russian oil fields. These efforts led to the widespread use of tankers for transportation and to the Baku–Bantum railroad, which opened Western Europe to Russian Oil.

Significant discoveries in other countries include the following:

- Indonesia: Telaga Said well (1885)
- United States, East Texas: Spindletop well (1901)
- Iran (1908)
- Venezuela: Zumaque well (1914)
- Iraq: Kirkuk (1927)
- Bahrain (1932)
- Kuwait (1937)
- Saudi Arabia (1938)
- United States, Alaska: Prudhoe Bay (1967)
- North Sea: Brent field (1976)
- United States: Fracking in the Barnett Shale, Eagle Ford, and Bakken formations (starting in 1999).

1.2.4 Major Oil Companies

Standard Oil Company

In the mid-nineteenth century, John D. Rockefeller brought order to the US oil industry by monopolizing it. In 1865, his first major step was to acquire full ownership of a major refinery in Cleveland, OH, about 105 air miles from Titusville, PA [1.23]. By 1870, Rockefeller controlled several refineries in Cleveland. In that year, he led the formation of the Standard Oil company, which, at its peak, controlled 85–90% of the US oil industry and held significant interests in much of the rest of the world.

Rockefeller is vilified as the ultimate *robber baron*, but he probably saved the US oil industry from itself. His monopoly enabled him to hamper large price swings, largely preventing the boom/bust economics that plagued the industry elsewhere. In other parts of the world, notably Austrian Galicia, unrestrained overproduction, even when prices were very low, irreparably depleted one of the world's largest oil fields and damaged the nearby environment; evidence of that damage lingers even today, more than 100 years later [1.38].

In 1911, due to a ruling by the US Supreme Court, Standard Oil was split into 34 smaller companies. Among these were Standard Oil of New York (Mobil), Standard Oil of New Jersey (Exxon), Standard Oil of Ohio (Sohio), Standard Oil of Indiana (Amoco), Standard Oil of California (Socal), Continental Oil (Conoco), and The Ohio Oil Company (Marathon). Both Continental Oil and the Ohio Oil Company had been independent before. In the late 1990s, BP acquired Sohio and Arco (formerly Atlantic Richfield). In 1999, Exxon and Mobil merged into ExxonMobil. Socal is now Chevron, which grew significantly due to a series of mergers and acquisitions – notably of Gulf (1985), Texaco (2001), and Unocal (2005).

US oil companies that maintained independence from Standard Oil include Union Oil (Unocal), which was founded in California in 1890, and Pure, which was founded in 1895. A notable Pure accomplishment was to circumvent Standard's railroad monopoly by building a pipeline from the oil regions to the US east coast; the Pure advantage lasted only a short time – until Standard led the development of alternative pipelines. In 1901, Gulf and Texaco were spawned by the East Texas

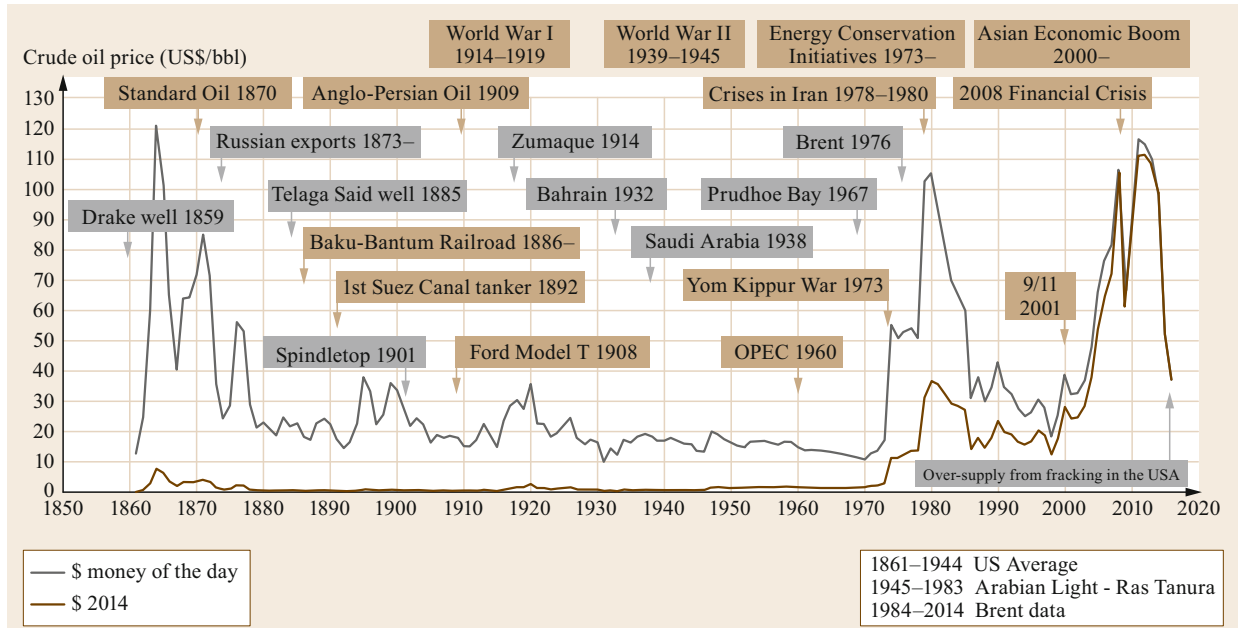

Fig. 1.4 Selected world events and crude oil prices in 1859–2015, prices are annual averages. Items in gray boxes indicate the start dates for major new production. The underlying format comes from the BP Statistical Review of World Energy (after [1.1]). Many events are described in Daniel Yergin’s book (after [1.39, Parts I and II]). Selected events and recent prices come from the US Energy Information Administration (after [1.40, 41])

oil boom. US companies founded after the Standard Oil breakup include Sinclair (1916), Phillips (1917), and Occidental (1920).

Major Multinationals

There are five major multinational oil and gas companies: ExxonMobil, Chevron, Royal Dutch Shell, BP, and Total. The Royal Dutch Petroleum company was formed in 1890 to develop an oil field in Sumatra, following up on discoveries at Telaga Said in 1885. In 1907, Royal Dutch merged with the Shell Transport and Trading Company to form the Royal Dutch Shell group, chartered in both the United Kingdom and the Netherlands. The British Petroleum Company (now BP) began in 1909 as the Anglo-Persian oil company. It grew through a combination of significant oil discoveries – notably the Prudhoe Bay field in Alaska and the Forties field off the coast of Scotland – and through mergers and acquisitions – notably with Sohio, Amoco, Arco, and Castrol. Total began in 1924, when France created the Compagnie Française des Pétroles (CFP). CFP was renamed Total in 1991. In 1999–2000, it merged with the Belgian company PetroFina and the French company Elf Aquitaine.

National Oil Companies

By establishing national oil companies, governments are better able to control the ways in which their re-

sources are exploited. Major national oil companies, some of which are more or less privatized, include the following: Agip Petroli (1926, Italy), ENI (established in 1953 from Agip), Saudi Aramco (1944, Saudi Arabia), KNPC (1960, Kuwait), NIOC (1951, Iran), Petronas (1974, Malaysia), Pertamina (1968, Indonesia), PTT (1978, Thailand), PetroChina (1999, China), Sinopec (2000, China), CNOOC (1999, China), CPC (1946, Taiwan), Ecopetrol (1951, Columbia), Pemex (1938, Mexico), PDVSA (1976, Venezuela), Petrobras (1953, Brazil), and Repsol (1987, Spain). Statoil was founded by the Norwegian government in 1972. In 2007, it was merged with the oil and gas division of Norsk Hydro.

1.2.5 Petroleum for Transportation

Initially, to improve the safety of kerosene, lighter more flammable fractions, such as naphtha, were driven off and burned. The heavier fractions – gas oil or residue – sometimes served as fuel oil and lubricants, but often they were simply incinerated.

In 1885–1886, Karl Benz and separately Gottlieb Daimler and William Maybach built the first automobiles whose internal combustion engines were powered with naphtha fuel [1.42]. Rudolf Diesel is credited for building a high-compression prototype engine in 1897, after Akroyd Stuart built the first working diesel en-

gine in 1892. The essence of Diesel's prototype was a gasoil-burning, 10 ft-long reciprocating iron cylinder with a flywheel at its base. Such engines burn fuels (gasoils) that are difficult to vaporize in a gasoline engine.

A major development was the switch from coal to oil in warships. In the 1890s, Germany openly discussed the merits of powering a new Navy with petroleum [1.43]. In the 1910s, Winston Churchill, who was then Great Britain's First Lord of the Admiralty, pushed the Royal Navy in this direction. With coal, he explained, storage bunkers closest to the boilers were emptied first. As the coal inventory decreased, the distance between the boilers and the supply increased, so it took more time and/or more sailors to bring coal to the boilers. This could handicap a ship in the heat of battle, when the need for both steam power and manpower were highest. Liquid petroleum could be pumped, so inventory did not affect the availability of fuel or fighters – unless of course the supply ran out. Britain's need to fuel its navy far from home led to the formation of the Anglo-Persian oil company, the precursor to British Petroleum.

The advent of the Model T Ford jump-started gasoline demand in 1908. By mass-producing the car, Henry Ford made automobiles affordable. Faced with high employee turnover and absenteeism, he increased wages to stabilize his work force. The benefits were immediate. Productivity surged, and profits doubled in less than two years. Ford later said that increasing wages was the best cost-cutting move he ever made. The higher pay scale expanded the American middle class which in turn expanded the market for automobiles and related consumer products [1.44].

Eventually, diesel engines replaced steam boilers in ships and railroad locomotives. Diesels became the norm for heavy-duty trucks, mining equipment, farm equipment, and stationary motors such as those that produce emergency electricity.

Today, transportation accounts for most of the world demand for petroleum, and 90% of the transportation fuel market is met by oil. Illumination is no longer the main use for kerosene. Most kerosene is refined into jet fuel.

1.2.6 OPEC, Embargos and Conservation

The Organization of Oil Exporting Countries (OPEC) was founded by five countries in 1960. OPEC now includes 13 members: Algeria, Angola, Ecuador, Indonesia, Iran, Iraq, Kuwait, Libya, Nigeria, Qatar, Saudi Arabia, United Arab Emirates, and Venezuela. Usually, OPEC – especially Saudi Arabia, which is the richest in reserves – strives to stabilize oil prices by

acting as a *swing* producer, raising production when prices are high and cutting production when prices are low.

In 1967, during the Six Days War with Israel, several Middle Eastern countries decreased or ceased oil shipments to the United States and the United Kingdom. This action had limited impact due to the lack of solidarity among exporters. The story was different after the Yom Kippur War in 1973–1974, when the Arab members of OPEC, along with Syria and Egypt, proclaimed an embargo against the United States, United Kingdom, Canada, Japan, and the Netherlands. World prices rose from \$3/bbl to \$10/bbl; US prices went up to \$12/bbl. Prices tripled again during 1978–1980 due to two crises in Iran – the Khomeini revolution and the subsequent war between Iran and Iraq.

Importing countries responded to the embargo with energy conservation measures, by stimulating domestic production, and by encouraging the development of alternatives to oil. In the United States, the Strategic Petroleum Reserve (SPR) was created in 1973 to counter sudden, severe supply interruptions. Short-term conservation initiatives included gasoline rationing, decreased speed limits, year-round daylight savings time, and simply turning off lights.

Long-term measures reaped long-term benefits. Factories invested in energy efficiency. People bought smaller vehicles with higher fuel efficiency. The measures worked. Demand dropped, and prices fell steadily, with occasional ups and downs, until 1998.

1.2.7 Recent Ups and Downs

In 1998, prices began to rise again, driven by rapid economic growth in India and China and OPEC's disinclination to increase supply. Except for a brief dip after the 9/11 attacks on the United States in 2001, prices continued to climb. Figure 1.4 illustrates this volatility.

Up

In June 2008, the weekly average spot price for Brent Crude reached \$141/bbl [1.45].

Down

After the failure of major US financial institutions in September 2008, the world economy suffered, oil consumption fell, and so did oil prices. On December 12, 2008, Brent was selling for \$40/bbl.

Up

In the next 6 years, economies and oil prices recovered. Brent sold for \$127/bbl on March 9, 2012, and on September 5, 2014, it sold for \$100/bbl.

Down

Then seemingly overnight, prices plummeted, hitting \$46/bbl in January 2015 and dipping below \$30/bbl in December 2015. Prices remained low through March 2016, bouncing between \$40 and \$50/bbl. There are several reasons for the dramatic drop in prices:

- *Fracking.* The industry has long known of seemingly inaccessible hydrocarbons trapped in shale formations, where the permeability of the reservoir rock is low. Hydraulic fracturing (*fracking*) increases permeability. First applied in 1947 in Grant County, KS [1.46], fracking involves pumping a slurry of water, sand, and chemicals at high pressure into a well. The pressure fractures the surrounding rock, and the sand props open the resulting passages. The chemicals can include acids, which dissolve particulates; silicones, which enhance flow; and surfactants. In the 1980s, George P. Mitchell, the founder of the Mitchell Energy and Development Corp., experimented with different fracking techniques in the depleted Barnett Shale formation in Texas. Shale is not uniform. Formations include cracks, and some sections are more dense than others. By drilling horizontal wells and fracking just beneath the denser sections, Mitchell got phenomenal results. By 1999, the Barnett Shale had been transformed into a major gas field. Since then, this combination of horizontal drilling and hydraulic fracturing has been improved and applied to several other formations, including the Eagle Ford in Texas, the Bakken in North Dakota, and the Marcellus in Ohio and Pennsylvania. By 2015, the United States once again was the world's leading producer of oil and natural gas. Domestic production displaced imports, creating worldwide oversupply.
- *US–Iran accord.* In 2015, an agreement between the United States and Iran diminished a long-standing embargo against Iranian oil. Exports from Iran poured more oil into an already glutted market.
- *Lower consumption in China.* An economic slowdown in China decreased oil demand.
- *OPEC restraint.* At the time we are writing this, OPEC has been refraining from decreasing its own production to prop up prices.

1.3 The Oil Business

Petroleum production and processing is a huge business. In terms of market capitalization, 9 of the world's 30 largest public corporations are oil and gas companies [1.47]. The oil business involves numerous functions within complicated organizations. The industry can be roughly divided into upstream, downstream, midstream, and petrochemical sectors.

1.3.1 Research and Development

Hydrocarbon production and processing employs cutting-edge technology. All of the main science and engineering disciplines are used. Hydrocarbon industries conduct and support fundamental R&D at an exceptionally high level. Internal R&D is augmented with university research, liberally supported by energy companies.

The sciences include geology, geophysics, oceanography, chemistry, geochemistry, microbiology, seismic imaging, satellite imaging, and more.

The engineering includes traditional disciplines, such as mechanical, civil, electrical and chemical; and special fields such as production engineering and reservoir engineering.

Technology used for petroleum can also be applied to, or integrated with, technologies for processing liq-

uids from coal, oil shale, and biomass to generate fuels and chemicals. Due to environmental considerations, the co-processing of biomass fuels with conventional refinery feedstocks is being intensively studied.

1.3.2 Upstream

The upstream sector deals with the discovery and recovery of petroleum resources, including natural gas, condensates, crude oils, and bitumen. The upstream processes may involve wellhead pretreatment to remove carbon dioxide and toxic hydrogen sulfide from natural gas prior to transportation. Natural gas plants also recover/remove noble gases, mainly helium, neon, and argon.

1.3.3 Downstream

In the downstream sector, refining processes can be divided into two main categories: fractionation/separation, which does not change molecules, and upgrading/conversion, which does change molecules. An important related activity is blending crude oils to meet refinery design constraints, and blending streams from individual processes to ensure that refinery products meet rigid specifications and achieve desired performance.

1.3.4 Midstream

Midstream involves all processes or procedures between upstream wellhead pretreatment and downstream desalting, including transportation and trading. One midstream process is the froth treatment of bitumen derived from oil sands. The treated bitumen is used to make *syncrudes*. The removal of carbon dioxide from natural gas prior to shipping LNG (liquefied natural gas) is also a midstream process.

Crude and product trading can be classified as a midstream technology. With advanced information technology, traders can make better decisions in a timely manner.

1.3.5 Petrochemicals

Non-fuel products from petroleum include lubricants, waxes, asphalts, and different grades of coke. Valuable by-products include sulfur, ammonia, and industrial CO₂; lubricants are discussed in several subsequent chapters, and sulfur and its uses are described in Chap. 20. One might think the term *petrochemical* means all chemicals derived from petroleum, but in practice it excludes by-products and includes chemicals made from natural gas.

Primary petrochemicals can be divided into three groups: olefins, aromatics and synthesis gas:

- Olefins include ethylene, propylene, butylenes and butadiene. They are manufactured with steam cracking from light paraffins from natural gas plants. Steam cracker feeds from refineries include naphtha and gas oils from primary distillation and upgraded vacuum gas oil from hydrocrackers. Many refinery fluid catalytic cracking (FCC) units are significant sources of propylene and C4 olefins. Polymer plants convert olefins into polyolefins such as polyethylenes, polypropylenes, and butyl rubbers. They also produce polyesters from oxygenated intermediates such as ethylene oxide. These

intermediates are transformed into various materials, such as Nylon 6 from adipic acid and hexamethylenediamine; acrylics from acrylonitrile; polyesters from ethylene oxide and terephthalic acid; polyvinyl chloride (PVC) from ethylene and chlorine; and so on. The polymers are converted into fibers, consumer plastics, and engineering plastics. Olefins also serve as sources of alcohols, ethylene glycol, and other simple but useful products.

- Aromatics include benzene, toluene and xylenes, which are mainly produced from catalytic reforming and as by-products of steam cracking.
- Synthesis gas is a mixture of carbon monoxide and hydrogen mainly produced from the steam reforming of methane and other light hydrocarbons from natural gas. It also is produced by gasification of coal and biomass. Synthesis gas is the major source of the hydrogen used in refineries and ammonia plants. It also is the major source for methanol and in a few locales for synthetic hydrocarbon fuels.

Methanol is the starting point for acetic acid and formaldehyde, which in turn are converted into adhesives, foams, and solvents. A growing use for methanol is production of mono-methyl esters of long-chain fatty acids, which are used as synthetic diesel.

Fine chemicals, which may be derived from petrochemicals, are pure chemicals manufactured during multistep processes. Important examples include the aforementioned adipic acid and hexamethylethylenediamine, of which 2.5 billion kg/yr and 1 billion kg/yr are consumed annually. Others include β -lactams, which are structural elements of penicillin and other antibiotics, and imidazoles, which are found in modern pesticides.

Pharmaceuticals are synthesized from fine chemicals and may include specialty waxes and solvents. Major pharmaceutical groups are based on pyrimidines, sulfanomides (most are antibiotics), and benzodiazepine (the starting point for Valium).

1.4 Macroeconomics

This chapter is about technology, but the development of technology is driven by economics. In this section, we provide an overview of macroeconomic trends in the energy industry. As we have witnessed, more than half of world's energy consumption comes from oil and gas.

Economic growth overrides all other macroeconomic trends in energy consumption. Figure 1.5 shows how world energy consumption has increased in dif-

ferent regions since 1965. Much of the recent increase comes from the Asia Pacific, China in particular.

Figure 1.6 shows that on a per capita basis, the Chinese consume far less energy than Europeans, North Americans, and Eurasians. In 2011, per capita consumption in the United States was still 4 times greater than that in China and 20 times greater than that in Africa. Per capita consumption has been falling in North America

Fig. 1.5 Total energy consumption by region. AP = Asia Pacific (after [1.1])

Fig. 1.6 Per capita energy consumption by region (after [1.1, 48])

and Europe since September 11, 2001, hitting a temporary low during the economic crisis of 2009. In Eurasia – in essence, the USSR until December 25, 1991 and the Former Soviet Union afterward – per capita consumption fell by 38% between 1989 and 1996, and then slowly increased to the present-day level, which is still 26% below 1989. In the rest of the world, per capita consumption has been increasing. It has increased by 262% in Asia and Oceania and by 148% in Central and South America, but only by 8% in Africa.

Figure 1.7 illustrates regional differences in present-day consumption of energy from different sources. Oil

and gas were important everywhere in 2013. Coal consumption varied considerably: from 4.3% in South and Central America to 52.3% in Asia-Pacific. In the European Union, 11.8% came from nuclear sources and 4.9% came from hydroelectric. In South and Central America, 0.7% came from nuclear and 23.5% came from hydroelectric.

As mentioned above, in recent years, fracking transformed the United States into the world's leading oil producer (Fig. 1.8). In 2015, the consequent increase in global supply dropped crude oil prices by more than 50%.

Fig. 1.7 Regional energy consumption by fuel in 2014 (after [1.1])

It is impossible to predict the future, but we're likely to see the following:

- Higher than world average economic growth is expected in the less developed regions of Asia, especially China and India.
- Production of frack oil and gas will continue, especially in the United States.
- If prices remain low, American oil and gas consumption will go up. Americans are already driving more than in recent years, due to abundant low-cost fuels; EIA expects average gasoline prices to reach the lowest level since 2004 [1.49]. In response to abundant low-cost frack gas, the US and non-US companies are investing in American petrochemical projects. Gas is replacing coal in electric power production plants, which is decreasing America's production of CO₂.
- Unforeseen events – political, financial, or technical – affect supply or demand in unexpected ways. Recent actions by the United States, which is both the world's largest producer and the world's largest consumer of oil, are especially significant. One such event occurred in December 2014, when the United States decided to allow several companies to export

Fig. 1.8 Crude oil production during 2010–2014 by the United States, Saudi Arabia, and Eurasia (mostly Russia) (after [1.1, 2])

American crude oil beginning in August 2015; the ban had been in effect since 1973.

We can continue to generate pretty graphs and use them to extrapolate, but all we know for sure is that the landscape will change.

1.5 Origin of Fossil Hydrocarbons

Back in the eighteenth century, scientists concluded that coals were derived from plant remains (Chap. 10). Mikhailo Lomonosov gets credit for suggesting that petroleum and bitumen were produced underground from coal at high pressure and temperature. In the mid-nineteenth century, T.S. Hunt concluded that the organic matter in certain rocks comes from marine plants or animals.

In 1936, Alfred Treibs linked the chlorophyll in plants to the porphyrins in petroleum [1.50]. Even after millions of years, porphyrins and other biomarkers retain much of their original structures [1.51]. Biomarkers can be found in crude oil, rocks, sediments, and soil extracts. Figure 1.9 shows the resemblance between the core structure of chlorophyll *a* and porphyrins found in petroleum. The distribution of biomarkers can be correlated with the relative amounts of oil and gas in a source

rock, the age of a source rock, the environment in which organic matter was deposited, the maturity of a source rock, etc. Biomarker data are included in reservoir models of prospective oil fields.

Today, it is believed that petroleum is derived from ancient living microorganisms, such as plankton and algae, which escaped full oxidation upon death and accumulated at the bottoms of ancient lakes or seas, along with sand, clay, salts, and other material. Over time, tectonic movement, pressure, and heat transformed the deeply buried deposits into sedimentary rock through diagenesis and catagenesis. The origin of the organic matter, the depositional environment, age of the sedimentary deposit, and alteration (such as biodegradation) determined whether it became coal, kerogen (trapped in shale), bitumen, heavy oil, petroleum, or natural gas [1.52].

Fig. 1.9a–c Example of biomarkers: a comparison of chlorophyll *a* (a) with porphyrins found in petroleum (b,c)

1.6 Natural Gas, Coal, and Kerogen

Here we discuss natural gas, coal, and kerogen due to their impact on petroleum production and consumption. Crude oil reservoirs always contain some natural gas and vice versa, so oil and gas are coproduced. Like petroleum, natural gas and coal are major sources of energy and chemicals.

1.6.1 Natural Gas

Natural gas contains mostly methane (CH_4). It is called wet gas if it contains significant amounts of ethane, propane, butanes, pentanes, and heavier hydrocarbons, which can be separated from methane in natural gas processing plants. Dry gas includes only traces of higher hydrocarbons. Sour gas contains hydrogen sulfide, and acid gas contains carbon dioxide and/or hydrogen sulfide. Sour-gas-processing plants coproduce elemental sulfur, which is used to make sulfuric acid and fertilizers. According to industry reports [1.53], about 45–48% of world sulfur production comes from petroleum and natural gas. Natural gas can contain nitrogen and commercial quantities of inert gases – helium, neon and/or argon. Almost all commercial helium comes from natural gas plants [1.54].

Synthesis gas (syngas) is a mixture of carbon monoxide and hydrogen, usually derived from natural gas via steam-methane reforming (SMR) technology. Syngas can be converted into hydrogen and petrochemicals such as methanol. Worldwide, vast amounts of syngas-derived hydrogen are used to produce ammonia via the Haber–Bosch process.

1.6.2 Coal

Coal is a black or brown combustible rock composed mostly of carbon, hydrocarbons, oxygenates, and ash (metal oxides). Generally, coal is ranked as anthracite, bituminous, sub-bituminous, and lignite. Anthracite contains 86–97% carbon and has a high heating value. Anthracite is relatively rare. Bituminous coal is far more common. It contains 45–86% carbon and is burned to generate electricity. It is also extensively used in the steel and iron industries. Sub-bituminous coal, also called brown coal, contains 35–45% carbon. As shown in Sect. 1.1, coal is consumed on a large scale to produce heat, steam, and electricity.

Over the years, special circumstances have driven the large-scale conversion of coal into liquids, both directly and indirectly. Direct processes convert coal into various combinations of coal tar, oil, water vapor, gases, and char. The coal tar and oil can be refined into high-quality liquid fuels. Slurry-phase hydrocracking tech-

nology achieves very high direct conversion of coal into liquids; this technology was used extensively in Germany between 1934 and 1945 to make up for a lack of petroleum resources. Several coal conversion processes are described in a book by *James G. Speight* [1.55].

Developed in 1925, the Fischer–Tropsch (F–T) process is the main indirect route for converting coal into liquids. The coal is first gasified to make syngas with a balanced mixture of CO and hydrogen. Over F–T catalysts, syngas is converted into a full range of hydrocarbon products, including waxy paraffins, alcohols, naphtha, gas oils, and syncrude. The F–T process was used extensively in Germany before and during World War II.

In South Africa, the Sasol Slurry Phase Distillate Process (SPD) is the core of the gas-to-liquids (GTL) technology developed by Sasol. Synthesis gas for the SPD process can come from coal, natural gas or biomass. The process has been manufacturing chemicals and liquid fuels for more than 60 years.

1.6.3 Kerogen

Kerogen is the solid organic matter in sedimentary rocks. Unlike bitumen, it does not flow even when heated. But at high enough temperatures – e.g., 900 °F (480 °C) – it decomposes into gases, liquids, bitumen, and refractory coke. Huge amounts of kerogen are trapped in oil shale deposits. *Fenton et al.* [1.8] estimated that 1.3 trillion barrels of shale oil could be recovered from the world's oil shale reserves. Table 1.4 presents composition information on Green River oil shale from the western United States. About 91% of

Table 1.4 Typical composition of green river oil shale

Total	100
^a Equivalent to 25 gal oil per ton of rock	

the kerogen is hydrogen and carbon, but only 15% of the sample is kerogen. Shale oil – synthetic crude from thermally treated oil shale – tends to contain high amounts of arsenic and mercury, severe poisons for refinery catalysts and human health. Usually, the arsenic is removed with special high-nickel chemisorption catalysts, which trap the arsenic by forming nickel arsenides. Chemisorption is the most effective technique to remove mercury from oil and gas. The absorbent is comprised of a support (zeolite, activated carbon, metal oxide, or alumina) and one or more reactants (sulfur, metal sulfide, or iodide) [1.56].

1.6.4 Heavy Oil and Bitumen

As is often the case in the petroleum industry, the definitions of heavy oil and bitumen are functional and fuzzy. Heavy oils flow under most ambient conditions. They have densities greater than 1.0, so they sink in water. The viscosities of heavy oils range from about 5000 to 10 000 cP. Bitumens also have densities greater than 1.0, but their viscosities are higher: > 10 000 cP.

Natural bitumen is a tar or a solid, but when heated it softens and flows. Bitumen accounts for much of the world's recoverable oil. Large deposits are found in Venezuela, where in 2015, proven oil reserves totaled 298 billion barrels, mostly bitumen. Oil sands deposits in Alberta, Canada, contain 170 billion barrels. In addition, Alberta holds 1.4 billion barrels of conventional crude oil [1.57]. In oil sands, bitumen is

associated with sand and clay, from which it can be recovered with hot water or steam. In the United States, tar sands are found primarily in Eastern Utah, mostly on public lands. In comparison, reserves of conventional crude oil in the Middle East were 808 billion barrels [1.58].

For oil sand, froth treatment is applied to recover bitumen. In the froth treatment process, aqueous and solid contaminants are removed from the froth, which is diluted by a hydrocarbon solvent to reduce the viscosity and density of the oil phase. The solvent accelerates the settling of the dispersed phase by gravity or centrifugation. The solvent is recovered and recycled. The bitumen is mixed with light crude oil to form diluted bitumen, or *dilbit*, which flows more easily through pipelines to upgraders or refineries. There, the bitumen is converted into syncrude by means of a coker or a visbreaking unit, or in some cases a hydrotreater. A newer froth treatment developed in 1990 uses a paraffinic solvent to form aggregates composed of water droplets, mineral solid particles, and asphaltene precipitates for easy separation by conventional settlers with less energy [1.59]. In petroleum refineries, heavy oil and bitumen are blended with conventional petroleum crude oil and co-processed.

It is important at this point to distinguish between natural bitumen and refined bitumen. Refined bitumens are primarily used for paving and construction. They are special products with rather tight specifications.

1.7 Petroleum (Crude Oil)

There are hundreds of different crude oils with significantly different compositions. Crudes typically are named for their source country, reservoir, and/or some distinguishing physical or chemical property.

Day-to-day refineries base operations on:

1. Feed bulk properties, such as total acid number (TAN), total sulfur, specific gravity, distillation, and sometimes total nitrogen
2. Desired product properties
3. Analysis of waste streams.

Traders rely on crude assays to make buying/selling decisions.

Central laboratories pay attention to molecules. The identification of biomarkers is important for oil exploration. The development of processes and catalysts depends on in-depth knowledge of functional groups.

1.7.1 Bulk Physical Properties

Bulk properties are summarized in crude oil assay reports. Table 1.5 shows an example assay report template. The assays determine selected chemical and physical properties of whole crudes and several distilled fractions. The fractions correspond to boiling ranges for common fuels. Planners and oil traders select crudes by comparing their properties with refinery specifications. Sulfur content and TAN are common constraints, because they relate to corrosion in piping and process equipment. Traders might purchase off-spec crudes for subsequent trading.

Table 1.6 presents selected bulk physical and chemical properties for 21 crude oils. Athabasca is a heavy oil, with a specific gravity > 1.0. In the table, sulfur contents range from 0.14 to 5.3 wt%, and nitrogen contents range from nil to 0.81 wt%. Specific gravities range from 0.798 to 1.014. In sweet crudes

such as Tapis, the sulfur content is low. Sour crudes have more sulfur, which gives them a tart taste; in the old days, prospectors did indeed characterize crude oil by tasting it.

Table 1.7 shows distillation yields for four common crudes. The naphtha content of Brent is twice as high as Ratawi, and its vacuum residue content is 60% lower. Bonny light yields the most middle distillate and the least amount of vacuum residue.

Crude assay fractions are defined primarily by distillation cutpoints. In commercial practice, cutpoints are not uniform or sharp, and product cutpoints can overlap (Fig. 1.10).

A refiner can adjust distillation yields to meet market demands, in part, just by adjusting cutpoints as shown in Table 1.8. Note that naphtha is not gasoline, kerosene is not jet fuel, and gas oil is not diesel unless they meet the tight specifications discussed below.

Table 1.6 Bulk properties of 21 natural crude oils (after [1.61])

Table 1.9 leads to the next section on molecular composition. The table presents normal boiling points for selected pure compounds, illustrating how boiling point reduction can be due to hydrogen-consuming reactions that do not break C–C bonds. Such reactions include saturation of aromatics, hydrodesulfurization (HDS), and hydrodenitrogenation (HDN). The table also illustrates how changes in commercial cutpoints can include or exclude certain molecules. The boiling points of compounds in blends are not the same as their normal boiling points, and the compounds shown in the table comprise only a tiny percentage of the thousands of molecules in petroleum distillates.

In reaction 1, the desulfurization of 2-methylthiophene converts a gas oil contaminant into light naphtha. In reaction 5, the desulfurization of 4,6-dimethyldibenzothiohene, a heavy gas oil contaminant, gives dimethyl cyclohexyl benzene, a light-diesel or heavy-kerosene molecule. Total saturation of phenanthrene (reactions 9–12) yields a molecule that boils at 274 °C (525 °F).

Table 1.9 Boiling point reduction without breaking C–C bonds (after [1.62]). For comparison, Reactions 17 and 18 illustrate the greater extent of boiling point reduction by hydrocracking. For many compounds, normal boiling points cannot be measured experimentally. In such cases, boiling points were estimated with ACD lab correlations. HDS = hydrodesulfurization, ASAT = aromatics saturation, HC = hydrocracking

	Reaction	Formula	MW	Boiling point		Reaction type	Feed → Prod

Total hydrogenation of chrysene transforms a residue molecule into diesel molecules (reactions 13–16). For comparison, Reactions 17 and 18 illustrate boiling point reduction by breaking C–C bonds via hydrocracking. Note that hydrocracking reduces boiling point to a far greater extent than do the other reactions.

Heavy naphtha goes to catalytic reforming, which generates aromatics and gasoline. The benzene content of gasoline is tightly controlled. The typical cutpoint between light naphtha and heavy naphtha is 180 °F (82 °C). This separates benzene and benzene precursors from C₇–C₁₁ compounds, keeping benzene out of gasoline. It also allows refiners to produce C₆ chemicals.

A typical heavy-naphtha/middle-distillate cutpoint is 400 °F (204 °C). This particular cutpoint improves gasoline by excluding naphthalene and tetralin, which have very low octane numbers. To maximize diesel, the cutpoint is lowered, perhaps to 302 °F (150 °C). For kerosene, limiting the upper boiling point to 525 °F (273 °C) excludes saturated 3-ring compounds, the presence of which would make it impossible to meet smoke-point specifications.

Diesel/VGO cutpoints depend on cold-flow properties, which are described in a subsequent section. Cutting at 650 °F (343 °C) keeps fully saturated 4-ring compounds out of diesel.

1.7.2 Molecular Composition

Prior to refining, crude oils contain some amount of dissolved gas, water, inorganic salts, and dirt. After these are removed, most of the remaining compounds are hydrocarbons, organic compounds which contain heteroatoms – sulfur, oxygen and nitrogen, or trace elements (Ni, V, Fe, Cu, As, Hg, etc.) – and inorganics such as H₂S and inorganic sulfur.

The hydrocarbon content may be as high as 97 wt% in paraffinic crude oil and as low as 50 wt% in heavy/asphaltic crude oil and bitumen. Nonhydrocarbons have characteristics of hydrocarbons with one or two heteroatoms. They are concentrated in higher boiling fractions and residua. More than any other element, carbon binds to itself to form straight chains, branched chains, rings, and complex three-dimensional structures. The most complex molecules are biological – proteins, carbohydrates, fats, and nucleic acids. This is significant, because petroleum was formed from the remains of ancient microorganisms – primarily plankton and algae.

In addition to normal- and isoparaffins (alkanes), petroleum contains a large number of mono- and poly-ring hydrocarbons, which may be saturated (naphthenes) or unsaturated (aromatics). Paraffin chains can

Fig. 1.11 Selected examples of hydrocarbon ring compounds

Fig. 1.12 Selected examples of ring compounds containing heteroatoms

be attached to the rings as substituents, as shown in Fig. 1.11. The long alkyl chains tend to be branched. Organic compounds containing sulfur, nitrogen, oxygen, and trace metals are illustrated in Fig. 1.12. Other sulfur compounds are naphthenic mercaptans (thiols), aliphatic sulfides and disulfides. The

R groups in the figures represent short or long alkyl chains.

Petroleum molecules can be lumped into groups, thereby allowing us to create manageable models for physical properties, chemical composition and reaction kinetics.

1.8 Oil and Gas Exploration

We search for oil and gas by looking for places where they might be trapped underground. Petroleum systems include the following:

- Organic-rich source rock in which oil and gas were formed.
- Pathways comprised of permeable rock such as sandstone and limestone, which allow oil and gas to migrate (secondary migration). Often, the movement of oil and gas is promoted by the flow of underground water.
- Porous, permeable reservoir rock to accumulate gas and oil capped by impermeable rock, which prevents fluids from migrating to the surface. Shale and salt domes are also common caps.

1.8.1 Searching for Traps

When petroleum geologists look for oil and gas, they rely heavily on reflection seismology. During seismic exploration, explosives or thumper devices send sound waves through the Earth's surface. Reflected sound waves are measured with hydrophones (in water) and geophones (on land). Different layers within different rock formations reflect sound in different ways. With the help of sophisticated software, geophysicists transform seismic data into detailed 3-D reservoir models that show the structure of subsurface rock formations. Measure-while-drilling (MWD) technology incorporates sound waves generated by drill bits to refine reservoir models as wells are being drilled.

Three common kinds of traps are illustrated in Fig. 1.13:

1. Anticline traps are like inverted bowls. They can be symmetrical or asymmetrical. A steep anticline

might be called a dome. Anticline traps hold much of the world's conventional crude oil.

2. Faults are formed at the boundaries of cracks in the Earth's crust. The four major kinds of faults are thrust, lateral, normal, and reverse. Thrust and lateral

Fig. 1.13a-c Three types of hydrocarbon traps: anticline (a), fault (b), and salt-dome (c). As with oil and gas, the water layers are not pools, but water-saturated porous rock

faults are created by horizontal movement. The San Andreas Fault in California is a well-known example of a lateral fault. To be more specific, the San Andreas is a right-lateral, strike-slip fault. Normal and reverse faults are created by vertical movement and are more likely to create fault traps for petroleum.

3. A salt-dome trap is created when a mass of underground salt is pushed up by underground pressure into a dome. The salt dome breaks through layers of rock and pushes them aside as it rises. The salt is impermeable, and if it abuts porous rock, it can serve as a reservoir cap.

1.9 Drilling and Production (Recovery)

1.9.1 Drilling

Drilling is the primary method for recovering underground oil. Oil sand can be surface mined, and bitumen can be recovered by techniques such as SAGD [1.63].

The rotary drilling technique is commonly used. Key components of a rotary drilling rig are shown in Fig. 1.14. To drill a well, a bit is attached to the end of a drill string, which is built from sections of steel pipe that are 30 ft (9 m) long. The drill string is lengthened as the well gets deeper by attaching additional sections of pipe to the top. Drill collars are thick-walled sections of drill pipe at the bottom of the drill string; collars apply extra weight to the bit. As the bit cuts through rock,

Fig. 1.14 Components of a typical drilling operation (after [1.64]). See also Fig. 13.1

mud is pumped down through the inside of the drill string, out the bit, and up through the annular space between the drill string and the well bore. Despite its dirty name, drilling mud is a specific blend of fluids, solids, and chemicals. It cools the drill bit and brings rock cuttings back to the surface. The cuttings are removed in shakers, and the fluid goes back to the mud pit, from which it is recycled.

The derrick must be tall enough to accommodate a 90 ft-long *triple* comprised of three pipe sections. The derrick, pulleys, and hawser must be robust enough to support the lifting and manipulation of the entire drill string. The kelly is the top joint of a drill string. It has flat sides that fit inside a bushing on the rotary table, which turns the drill string and bit. Note that not all drilling rigs use a kelly system.

In addition to vertical drilling, directional (horizontal) drilling can be used. First applied in 1934, directional technology allows many wells to be drilled from a single site. The technology can be applied all along the formation and is especially beneficial offshore, because it reduces the number of expensive platforms needed to develop large fields. In directional drilling, the section of pipe at the end of the drill string is bent, so that when the pipe is rotated, it moves to one side.

In percussion drilling, a drill bit is repeatedly raised and lowered, impacting rock on the down stroke, making a hole deeper. As with rotary drilling, circulating mud removes cuttings and cools the bit. Percussion drilling was used thousands of years ago in China.

Thanks to recent developments, offshore platforms do not have to be anchored to the ocean floor. Floating and semisubmersible platforms are kept in place with a combination of GPS and turbine-driven engines [1.65].

1.9.2 Blowouts

Blowouts are a common cause of well failures [1.66]. On April 20, 2010, the Macondo blowout, also known as the *Deepwater Horizon* disaster, killed 11 people and caused the largest accidental oil spill into the sea, spewing 210 million gallons into the Gulf of Mexico from April 20, 2010 until July 10, 2010. On land, the Iraqi soldiers intentionally released or burned 240 to 340 mil-

lion gallons during the 1991 Gulf War. The largest oil spill ever recorded was caused by the Lakeview blowout in Kern County, California. Lakeview gushed for 18 months – from March 1910 through September 1911 – spilling 380 million gallons onto the ground.

A *surface blowout* is a sudden loss of containment and uncontrolled flow of oil and gas into the atmosphere. The density of drilling mud is crucial. If the mud density is too low, a well is susceptible to a surface blowout. If the mud density is too high, it can cause an *underground blowout* – the rupture of the reservoir underground – which pushes drilling mud into another formation. Many surface blowouts begin as underground blowouts. Prompt, correct reaction to an underground event can prevent a dangerous and costly surface blowout.

Blowout prevention technology is a combination of procedures, hardware, monitoring, and control systems. The hardware includes *blowout preventers* (BOPs), which are stacks of valves that can be opened or closed to quickly reduce or stop sudden changes in pressure in oil and gas wells. BOPs are also called *preventers* or *preventer stacks*. The valves are stacked to provide redundancy. The sudden changes are called *kicks* and may signal impending loss of well control. BOPs on land wells are installed on the well head. On offshore rigs, they are often installed below the deck of the rig. Subsea BOPs are installed on the sea floor.

The two most common types of BOPs are *ram* and *annular*. Ram-type BOPs are similar in operation to gate valves. Common ram preventers are *pipe rams*, *sealing rams*, and *shear rams*. A BOP stack may include all three. Pipe rams restrict flow through the annular space between the well bore and the pipe but not through the pipe. Sealing rams can stop flow through both the annulus and the piping. Shear rams are used as a last resort. They compress the drill string and casing completely, sealing the well permanently. Rams can be actuated manually or hydraulically. An annular BOP operates like a wedge. It has a donut-like rubber seal, called the *packing*, which is reinforced with steel ribs. When actuated, a piston forces the packing to constrict like a sphincter, sealing the annulus and/or piping.

1.9.3 Well Completion

Wells are completed by casing the well bore with steel pipe and cementing the casing into place. Casing prevents the well from collapsing. The outside diameters of casing pipe range from 4.5 to 16 in (114–406 mm). Cementing is a key step. In a good cement job, the entire space between the casing and the well bore is filled with cement. Centralizers keep the casing from resting against the well bore and blocking the flow of cement to

the well bore below. In a poor cement job, cementing is incomplete or the cement itself is inadequate. Industry acquaintances say that poor cement jobs are the leading cause of post-completion blowouts. In open-hole completion, the last section of the well is uncased. Instead, the installation of a gravel pack stabilizes the casing and allows fluids to enter the well at the bottom. After cementing, perforation guns punch small holes through the casing and cement into the reservoir rock, providing a path for the flow of oil and gas into the well. After perforation, special acid-containing fluids are pumped into the well to increase porosity and stimulate production. Usually, a smaller diameter tube is inserted into the casing above the production zone and packed into place. This provides an additional barrier to hydrocarbon leaks, raises the velocity at which oil flows under a given pressure, and shields the outer casing from corrosive well fluids.

1.9.4 Production (Recovery)

In primary recovery, petroleum gas and/or oil flow out of reservoir due to reservoir pressure alone, propelled by gas and/or water drive. In gas drive, the drive comes from the excessive underground pressure of natural gas, dissolved gas evolving from oil, as well as liquid expansion. In water drive, oil is driven from the reservoir by hydrostatic pressure. Primary production often includes reinjection of recovered gas to maintain reservoir pressure. In the early days of the industry, operators believed that gas flow inhibited oil flow, so excess gas was flared. In addition to destroying valuable hydrocarbons and polluting the air, flaring substantially decreased the recoverability of oil in the reservoir.

Secondary recovery is applied when the natural pressure is low and not sufficient for primary recovery. Many older *stripper* wells require secondary recovery. Stimulation fluids are injected to push oil through the reservoir and disengage it from reservoir sands. Treated water is the most common stimulation fluid in secondary recovery. As mentioned in Sect. 1.6.1, the crude oil in a reservoir accumulates in permeable strata known as reservoir rock. For oil with higher viscosity, which adheres tightly to the rock, simple surfactants are added to the treatment water to free up the oil as tertiary recovery.

Figure 1.15 illustrates the use of an injection well to stimulate production with either secondary or tertiary treatment. Pumps located either above ground or submersed are used to pump the stimulation fluids.

For very viscous crude oil and impermeable carbonate reservoir rock, secondary recovery is not effective. Tertiary recovery, or enhanced oil recovery, is applied to reduce the viscosity of oil. The commonly used meth-

Fig. 1.15 Injection and production wells

ods are polymer-augmented flooding, surfactant flooding, and alkaline flooding. In these methods, chemicals are injected in the injection well and oil is recovered in the production well (Fig. 1.15). The most extensively used polymers in polymer augmented flooding are partially hydrolyzed polyacrylamines and a biopolymer, xanthan gum. Two steps are usually involved in surfactant flooding, or micellar flooding. A surfactant slug is injected into the well first followed by a large slug of water containing high molecular weight polymer, which pushes chemicals between the injection and production wells to improve mobility and sweep efficiency. Alkaline flooding is usually accompanied by surfactant and polymer flooding. Carbon dioxide has also been used in enhanced oil recovery. The injection of CO_2 is an effective way of achieving carbon capture and storage (CCS) for CO_2 sequestration. CO_2 stimulation and CCS are especially compatible with coal-bed methane production. When evaluating CCS for a particular application, CO_2 transportation and storage costs must be considered.

Production of bitumen is accomplished in several ways. It can be dug out with conventional mining techniques or liquefied by the injection of high-pressure steam. In so-called *huff and puff* operations, production is stopped, either naturally or on purpose. Hot steam is injected into the reservoir and left to soak, usually for a few days. During the soak, heat flows from the steam into the oil and surrounding rock, vaporizing hydrocarbons and increasing reservoir pressure. After the soak, the well is reopened and oil production resumes, at first by natural flow and then by artificial lift. Production decreases over time as the temperature and pressure of the reservoir go down. When the flow of oil drops below a certain limit, the process is repeated.

At surface facilities, notably in Venezuela and Canada, recovered bitumen is diluted with lighter

hydrocarbons. The resulting *Dilbit* (diluted bitumen) flows under ambient conditions, so it can be transported conventionally in pipelines and oil tankers.

Kerogen is recovered from oil shale by several methods. From 1985 to 1990, Unocal recovered some 4.6 million barrels of syncrude oil from oil shale in a complex mining and upgrading venture at Parachute Creek, CO [1.67]. The plant yielded roughly 40 gal of oil per ton of rock. In the vertical-shaft retort, crushed kerogen-containing shale was pumped up from the bottom of the retort vessel. Hot recycle gas flowed counter-currently downward, decomposing the rock and releasing hydrocarbons. Condensed shale oil was removed from the retort at the bottom. Part of the hot gas was recycled. The rest of the gas either was used to produce heat and hydrogen, or recovered as a product. The spent shale was removed from the top of the retort, cooled, and stored in pits or returned to the mine. In the reducing environment of the retort, sulfur and nitrogen were converted to H_2S and NH_3 , which were recovered from product gases by conventional means. The plant yielded high-quality syncrude oil suitable for further refining in conventional facilities.

Other oil shale processes involve partial combustion, either underground, at the surface, or in shafts drilled horizontally into kerogen-rich formations. From 1972 to 1991, Occidental Petroleum developed an in situ process, in which explosives were used to create underground chambers of fractured oil shale. The oil shale was ignited with external fuel, and air and steam were injected to support and control combustion. The hot rock fractured and released shale oil, which was pumped to the surface from a separation sump and collecting well. Bitumen derived from oil shale and many tar sands contain small but significant amounts of arsenic, which are severe poisons for catalysts in refineries.

1.9.5 Well Stimulation: Hydraulic Fracturing

For decades, hydraulic fracturing (*fracking*) has been used to restore production from depleted formations. Since 2008, fracking has dramatically increased new production of oil and gas in the United States, particularly in five areas: the Bakken Shale formation in North Dakota, the Eagle Ford shale formation in Texas, the Permian Basin in Texas and New Mexico, the Niobrara formation in Colorado and Wyoming, and the Marcellus Shale formation in Ohio and Pennsylvania. Several other US states have a significant fracking potential [1.68].

Fracking involves the injection of fluid (mainly water containing acids and other chemicals) and a proppant such as sand under controlled pressure inter-

mittently over 3–5 days. This creates fractures in a targeted rock formation permitting oil or natural gas to flow to the wellbore. As presently practiced,

fracking consumes considerable amounts of water, can contaminate ground water, and may cause earthquakes [1.69].

1.10 Transportation and Storage

Crude oils recovered from wells usually contain dissolved gases, salt, water, and even sand/dirt. Natural gas can contain significant amounts of nonhydrocarbon gases, such as CO₂, N₂, and toxic H₂S. Most of the production sites (gas/oil fields) are remote from the gas plants and refineries which convert natural gas and crude oils into useful products. Hence, the gas and oil must be transported by pipelines and tankers in large quantities and for considerable distances, or in barges, railroad tank cars, and trucks in smaller quantities and for shorter distances. Prior to shipment from gas/oil fields, the gas and oil must be treated. Treatments include gas/liquid/solid separation by gravity in a large vessel (*settler*). Gases are drawn off and treated as described in the next paragraph. In the settler itself, it may be necessary to use demulsifying agents to break oil/water emulsions. Solid materials accumulate in the bottom of the settler and must periodically be removed and disposed of as hazardous waste.

Strict specifications for the maximum water and salt contents of crude oils must be met for pipeline transportation. For heavier oils, viscosity, sulfur content, and nitrogen content are also specified. Similarly, CO₂ has to be removed from natural gas for transportation by specifically designed LNG tankers. H₂S in natural gas or petroleum gas is removed by amine scrubbing and converted into sulfur with the Claus process. Compat-

ible crude oils from several wells are usually blended for transportation. However, caution has to be taken for the characteristics of crude oil can change over time, even when the oil comes from the same well; the oil in a reservoir gets heavier over time as the reservoir is continuously depleted.

Trading revolves around transportation, and therefore is a midstream operation. The price negotiation will depend on the availability, market demand, and quality of different crude oils. The price differential from marker crudes, most commonly North Sea Brent and West Texas Intermediate (WTI), can be significant depending on the assessment of the crude oil by a crude assay.

Large quantities of crude oil arrive at marine terminals and refineries through pipelines and are stored in tanks, most of which are cylindrical with a moving roof under low vapor pressure. Partially refined products from other sites, such as atmospheric residue or vacuum gas oil, are stored in similar tanks. Reactive materials may require gas-blanketed tanks. Spherical tanks are used for high pressure substances such as liquefied petroleum gas; some high-pressure tanks are also thermally insulated. Crude oil can also be stored in salt domes underground, such as the US Strategic Petroleum Reserve (SPR) in Louisiana and Texas. Logistic management of tank farms is an integral part of refinery operations.

1.11 Refining

1.11.1 Refinery Configuration Overview

Modern petroleum refineries include several upgrading processes, such as the following:

1. Feedstock selection and blending
2. Separation:
 - Distillation
 - Solvent processes (extraction).
3. Treating:
 - Desalting
 - Hydrotreating
 - Mercaptan oxidation
 - Solvent scrubbing
 - Visbreaking.
4. Conversion:
 - Thermal cracking/steam cracking
 - Thermal hydrocracking
 - Catalytic cracking
 - Catalytic hydrocracking
 - Coking.
5. Catalytic reforming and isomerization
6. Recombination of light intermediates:
 - Alkylation
 - Oligomerization of C3 and C4 olefins.
7. Product treating and blending
8. Protecting the environment:
 - Gas treating
 - Sulfur recovery
 - SO_x and NO_x abatement

- Waste treatment.
- 9. Related operations:
 - Asphalt production
 - Lubricant base oil manufacturing

- Wax production
- Hydrogen production
- Hydrogen recovery and purification
- Production of petrochemicals.

Fig. 1.16 Oil refinery process units: upgrading processes for top-of-the-barrel cuts – VGO and lighter – boiling below about 1050 °F (556 °C). Almost all processes generate offgas (represented by red arrows). Offgases are collected, purified, and separated into components in refinery gas plants. Usually there are two gas plants, one for saturated streams and another for streams containing olefins. HTU = hydrotreating unit, FCC = fluid catalytic cracking unit, Alky = alkylation unit, Isom = isomerization unit, VGO = vacuum gas oil. Not shown: olefin oligomerization to produce gasoline

No refinery refines a single crude. Different grades of crude oils and partially refined feedstocks are stored in an array of tanks prior to blending to meet refinery configuration and constraints. For example, sulfur constraints can be met by blending high sulfur with low sulfur crudes. Blended crudes must be compatible, i. e., it must be possible to mix them thoroughly and without risk of precipitating asphaltenes. LP (linear program) models are commonly used at refineries as tools for making crude purchase (term or spot) decisions, scheduling, planning, etc. The blended crude is sent to a desalter to remove contaminants prior to distillation.

While reading the remainder of this section, it will be useful to refer to Figs. 1.16–1.18. Figure 1.16

presents a simplified schematic diagram for the *light end* distillation units of high-conversion refineries. In this context, the *light end* includes processes which upgrade vacuum gas oil and lighter cuts with boiling points below 1050 °F (556 °C).

Figure 1.17 shows processes for upgrading vacuum residue, or bottom-of-the-barrel processes, which upgrade vacuum residue boiling above 1050 °F (556 °C). The processes in the figures are discussed individually in the remainder of this chapter.

Figure 1.18 gives an overview of product blending:

- Naphtha and gasoline components come from the following units: distillation, isomerization, alkyla-

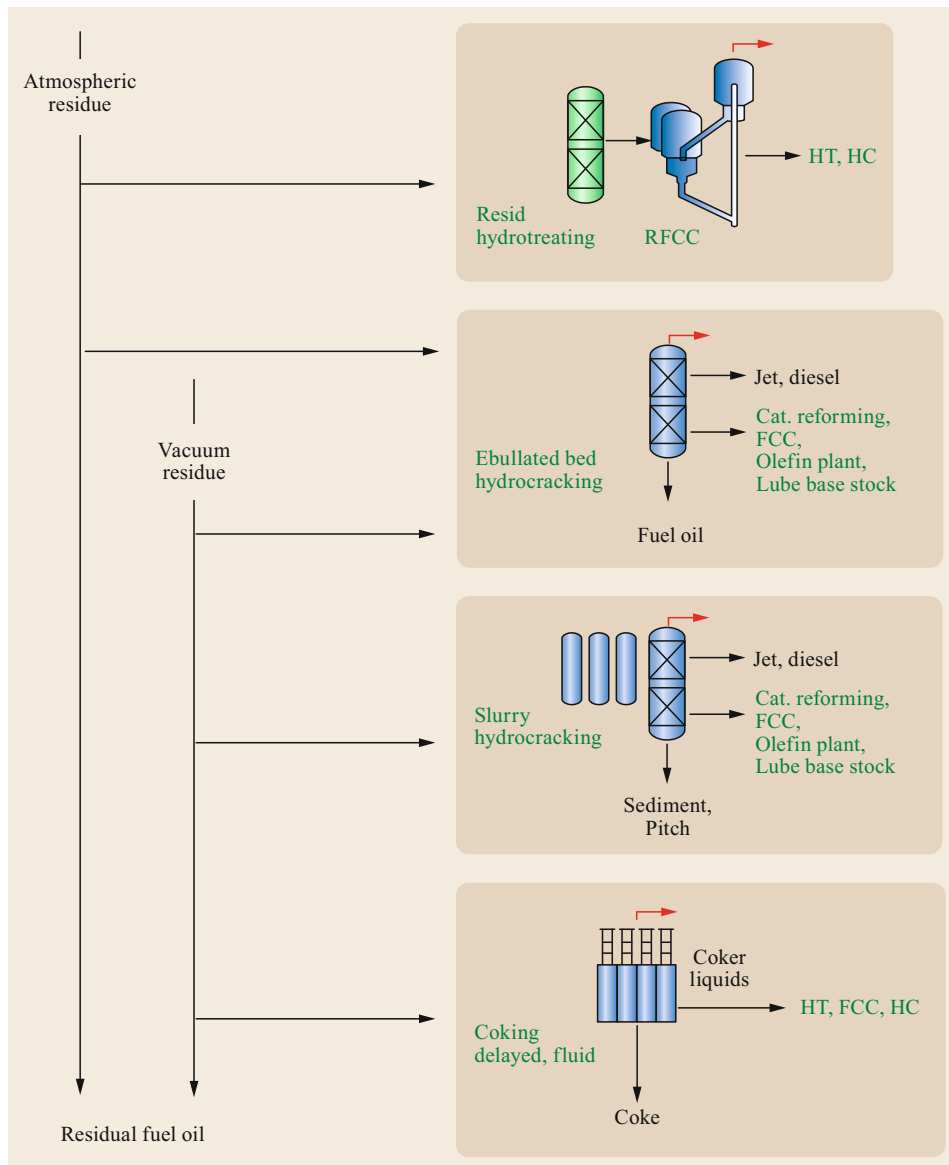

Fig. 1.17 Oil refinery overview: upgrading processes for bottom-of-the-barrel cuts – atmospheric residue, vacuum residue and extraction unit bottoms. The red arrows indicate offgas streams. Individual processes are discussed in the remainder of this chapter

tion, catalytic reforming, C3C4 olefin oligomerization, hydrocracking, catalytic cracking, and coking. Naphthas from different units have similar boiling ranges but may contain different components. Some naphtha molecules might end up in gasoline, some

might be sold as solvent, and others could go to thermal cracking in an olefins plant.

- Kerosene and jet fuel components come from the hydrocracker (HCU) and the kero hydrotreater (KHT).

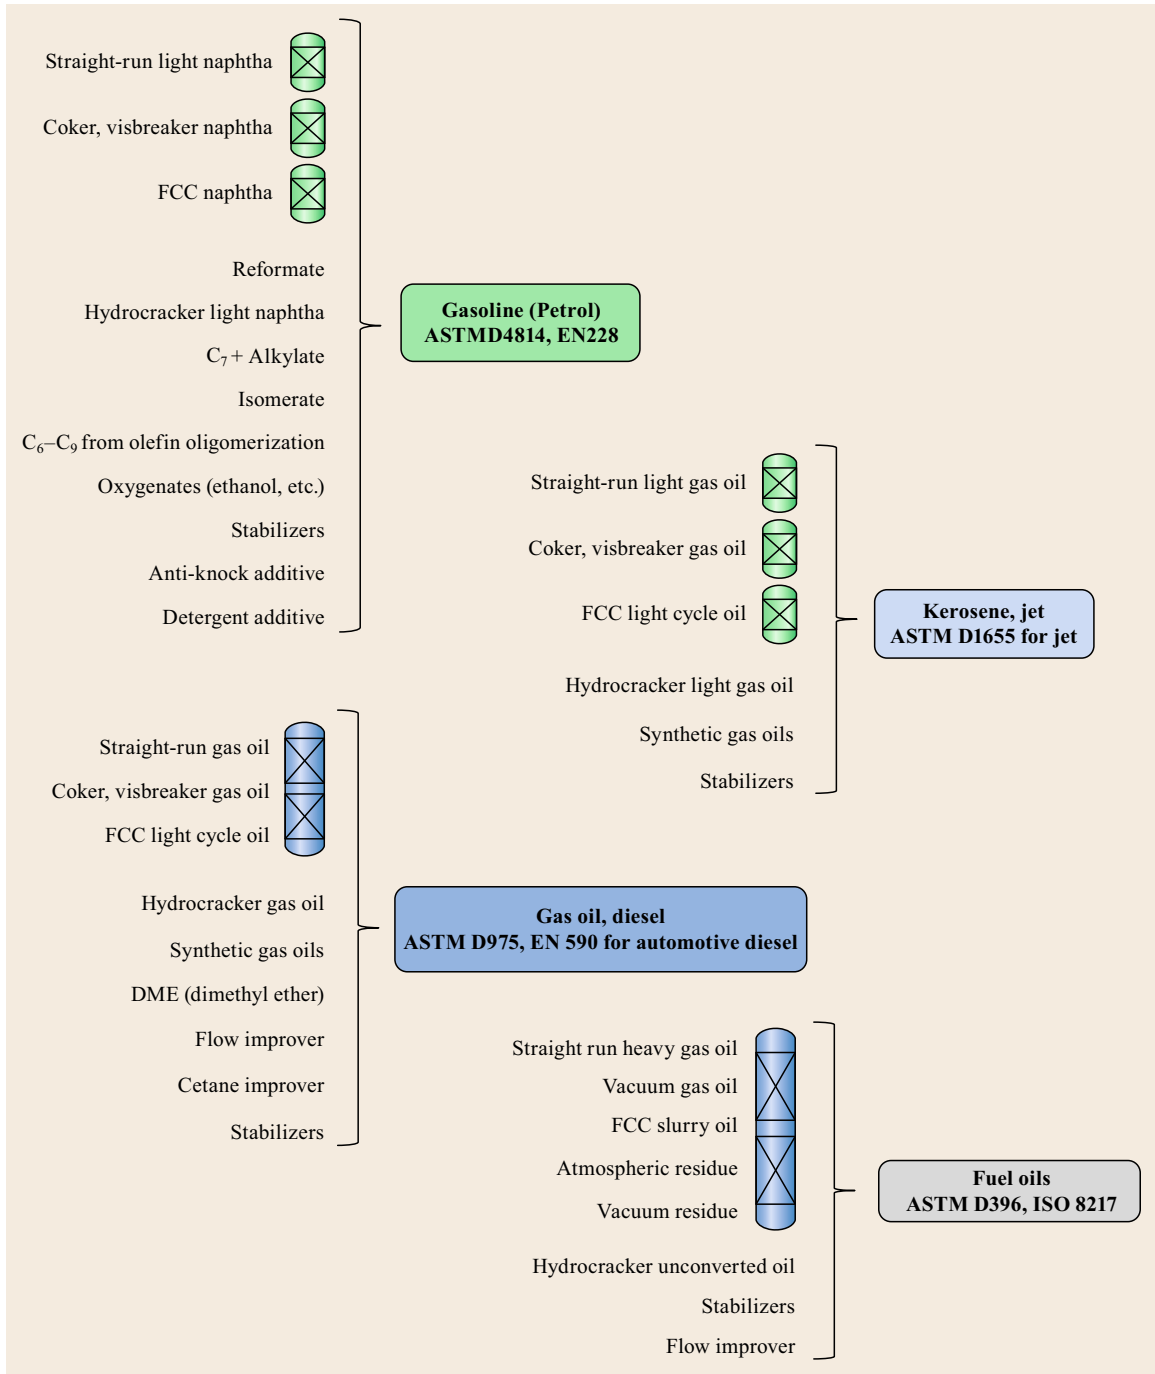

Fig. 1.18 Refinery product blending for gasoline, kerosene, turbine fuel (jet), and fuel oils

- Gas oil and diesel components come from the FCC, the HCU, the gas oil hydrotreater (GOHT), visbreaker, and coker. But in developed countries with tight product specifications, FCC gas oil does not meet specifications for diesel or other finished products. It often is used as *cutter stock* in residual fuel oil, but otherwise it must undergo further refining before it can be sold.
- Almost every unit makes offgas. For the most part, offgas streams are collected into a common system, desulfurized, and used for fuel gas. Propylene and C4 olefins are used in four major ways: to produce high polymers such as polypropylene, to produce epoxides for making polyesters, to react with isobutane in alkylation units, and to undergo oligomerization into C6 to C9 isoparaffins. The product from oligomerization units is commonly called, misleadingly, polymer gasoline.

Finished products are comprised of intermediate streams from different units, along with stabilizers, antioxidants, corrosion inhibitors, and other additives. To be products, the blends must meet specifications developed and published by international organizations such as the American Society for Testing and Materials (ASTM) and the International Organization for Standardization (ISO). ASTM and ISO specifications incorporate information from suppliers, users, government agencies, and equipment manufacturers.

A material in the kerosene boiling range is a jet fuel if it meets ASTM D1655-15 specifications no matter how it is made. Similarly, a material in the naphtha boiling range is gasoline if it meets the specifications of ASTM D4814-14b, no matter how it is made.

1.11.2 The Need for Conversion

To maximize profit, oil companies convert low value fractions into high value products. Throughout the world, 90% of vehicular transportation is powered by

petroleum products. Gasoline still accounts for most petroleum consumption in the United States. In Europe and Asia, diesel demand is relatively higher. Historically, in addition to increasing overall crude oil demand, the automobile increased demand for naphtha from which gasoline is derived.

Table 1.10 shows that in 2014, the United States consumed, on average, 79 wt% of its petroleum as naphtha, kerosene and distillate fuel oil (NKD); major destinations for NKD are gasoline, jet fuel and diesel, respectively. But the NKD contents of crude oil are lower than the demand. In Table 1.10, the NKD gaps range from 17.2 wt% to 45.2 wt% and the naphtha gaps range from 11.9 wt% to 26.2 wt%.

These gaps create a strong economic incentive to convert *other* into NKD. Here is a way to estimate the size of the incentive:

- The crack spread is the difference between the price of a crude oil and the wholesale prices of petroleum products extracted from it. Crack spread calculations are used to estimate refinery profit margins. The crack spread is expressed as $x : y : z$, where x is the price of X barrels of crude oil, y is the price of Y barrels of gasoline, and z is the price of Z barrels of distillate fuel oil (diesel, etc.). By convention $X = Y + Z$. Figure 1.19 shows that the 3 : 2 : 1 crack spread for Brent crude varied between 11 and \$22/bbl during June 2012 and May 2013.
- Assume the United States consumes 18 million barrels per day of oil.
- Assume the NKD gap is 23.9% – the same as for Brent in Table 1.9.
- Assume the crack spread is \$11/bbl.
- On this basis, the US conversion incentive is \$47.3 million per day.

In response to such huge incentives, refiners and licensors have developed an array of processes for converting heavy products into light ones.

Table 1.10 Conversion gaps for four crudes. N+K+D= the sum of naphtha, kerosene, and gas oil. Gaps are the difference between the consumption of a given product and the amount of that product in the crude before conversion

Product cut Becomes:	Naphtha Gasoline	Kerosene Jet	Dist. fuel oil Diesel	Other	NKD ^a	Gaps Naphtha ^b
US consumption (wt%)	42	9	28	21	–	–
Amount in crude (wt%)						
Brent	30.1	9.9	15.1	44.9	23.9	11.9
Bonny Light	27.7	12.5	21.6	38.2	17.2	14.3
Green Canyon	16.9	8.5	14.1	60.5	39.5	25.1
Ratawi	15.8	7.4	10.6	66.2	45.2	26.2

^a NKD gap = consumption of NKD – NKD in crudes

^b Naphtha gap = consumption of naphtha – naphtha in crudes

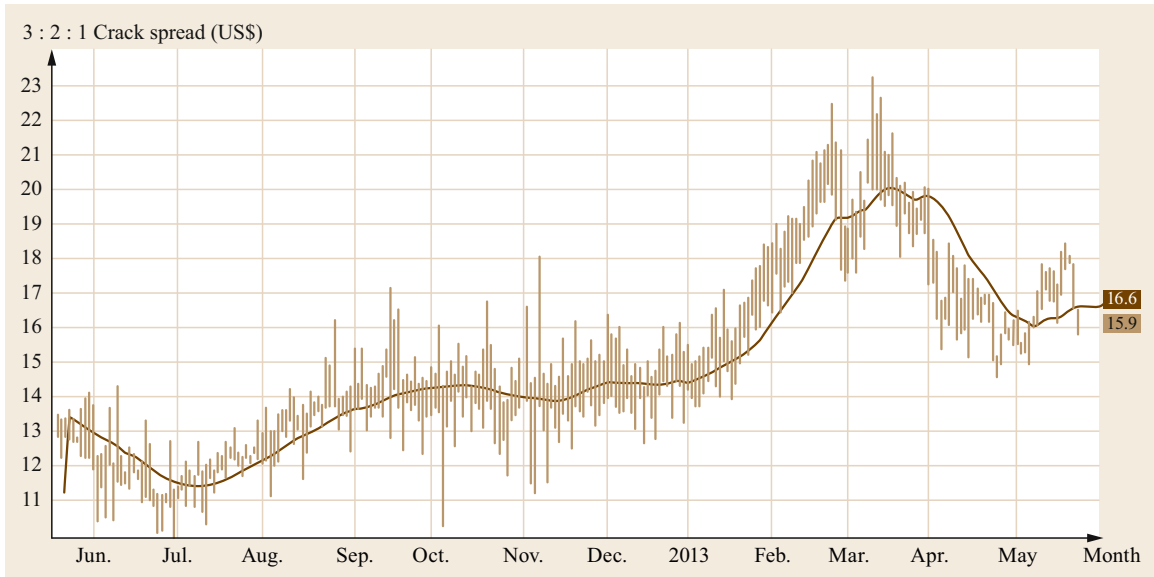

Fig. 1.19 The 3 : 2 : 1 crack spread for Brent crude date between June 2012 and May 2013 (after [1.70])

Table 1.11 Number of refineries and process unit capacities in different regions. VDU = vacuum distillation. Coking = both delayed and fluid coking. Thermal = thermal cracking, primarily visbreaking. Table 1.11 shows average refinery configurations for different regions of the world. Within regions, configurations vary significantly based on crude availability and product demand. Feed rates for individual processes are shown as a percentage of crude distillation rate (CDU). For example, if the CDU throughput is 200 000 bbl/day and the FCC fraction is 50%, the throughput of the FCC is 100 000 bbl/day. The United States and Europe host 45% of the world's refineries and account for 46% of world's crude distillation capacity. The high usage of FCC in North and South America reflects the higher demand for gasoline in those regions.

Table 1.12 shows that four of the world's five largest refineries are Asian, led by 1.24 million bbl/day facility in Jamnagar; the five largest refining companies are ExxonMobil, Shell, Sinopec, BP, and Saudi Arabian Oil.

1.11.3 Petroleum Refining Chemistry

Petroleum-refining processes include the chemical reactions and physical processes listed below:

- Distillation
- Extraction
- Desalting (removing entrained salt by dissolving it in water)
- Hydrogenation and generation of olefins
- Condensation and reversible saturation of aromatics
- Hydrotreating (removing sulfur, nitrogen, and oxygen):
 - Hydrodesulfurization (HDS)
 - Hydrodenitrogenation (HDN)
 - Hydrodeoxygenation (HDO)
 - Hydrodemetalation (HDM).
- Cracking (breaking carbon–carbon bonds):
 - Thermal cracking
 - Catalytic cracking
 - Hydrocracking (catalytic and thermal).
- Steam/hydrocarbon reforming/cracking (making hydrogen, olefins, and aromatics)
- Dehydrogenation, isomerization, reforming (no change in carbon number)
- Alkylation, olefin oligomerization (making carbon–carbon bonds)
- Acid/base reaction processes: amine treating, caustic scrubbing
- Mercaptan oxidation
- Blending, where molecular interactions change key properties.

Distillation

We mention distillation here, primarily because the rejection of heavy feed components from distillates prevents coking in processes designed for light feeds. At the very beginning (just after desalting), temperatures must be limited in atmospheric distillation units to avoid coking; vacuum distillation recovers VGO. VGO conversion units, such as conventional FCC and fixed-bed hydrocracking, choke to death on vacuum residue (VR). In FCC units, VR coking upsets the heat balance. In fixed-bed hydrocrackers, VR shortens catalyst life. Catalytic reforming catalysts deactivate quickly when the feed contains C12+ hydrocarbons.

Desalting. Desalting is a crucial pretreatment process for crude distillation feeds. By removing salts, acid, and inorganic particulates, desalting units preserve the functionality of other refinery units. Desalting entails mixing crude oil with water and treatment chemicals. Salts go into the water which is separated from the oil and purified for re-use.

Generation and Hydrogenation of Olefins

Olefins are produced by thermal cracking in the absence of excess hydrogen by processes such as coking (delayed or fluid), and FCC. Olefins are also produced from naphtha, gas oil, and light gases by thermal cracking in the presence of steam. A general mechanism for hydrocarbon thermal cracking is shown in Fig. 1.27. Hydrogenation of olefins in catalytic hydrotreating and hydrocracking units is rapid, essentially irreversible, and highly exothermic.

Condensation and Reversible Saturation of Aromatics

The saturation of aromatics and polyaromatics (Fig. 1.20) is common to several petroleum-refining processes. It is especially important in catalytic reforming, hydrotreating, hydrocracking, and cyclohexane production. Aromatics saturation is reversible, except when saturated C–C bonds are cracked or when polyaromatics condense to form larger polyaromatics. Carbon–carbon single bonds in polynaphthenes and

Fig. 1.20 Examples of saturation reactions of aromatics and polyaromatics (after [1.71])

naphthoaromatics can be broken irreversibly, but bonds within aromatic rings are more stable and difficult to break.

Figure 1.21 summarizes thermodynamic calculations for the competition between the saturation of naphthalene and the condensation of naphthalene with *o*-xylene to form chrysene. At high pressures and low temperatures, equilibrium favors saturation. At low pressures and high temperatures, equilibrium favors dehydrogenation. At high enough temperatures, equilibrium favors condensation. Fixed-bed catalytic hydrotreating and hydrocracking units operate in the aromatics crossover region between 315 and 425 °C (600–800 °F).

Figure 1.22 shows the so-called zig-zag mechanism for the production of large polyaromatics by adding 2- and 4-carbon species [1.72]. The condensation of large polyaromatics via the Scholl reaction [1.73] can lead eventually to coke formation and deactivation of the catalysts used in FCC, hydrotreating, and hydrocracking.

Figure 1.23 shows a mechanism for the one-at-a-time buildup of rings on a nucleus of coke [1.74]. The mechanism includes the following steps:

- Hydrogen abstraction by radicals
- Alkylation (olefin addition)
- Cyclization
- Dehydrogenation.

Hydrotreating: Sulfur Removal by HDS

Figure 1.24 shows representative hydrodesulfurization (HDS) reactions. For sulfur removal from the first three reactants, the mechanism is straightforward [1.76]. That is, the sulfur-containing molecule interacts with an active site on the catalyst, which removes the sulfur atom and replaces it with two hydrogen atoms. Additional hydrogen converts the sulfur atom into H₂S, which desorbs from the catalyst, leaving behind a regenerated active site.

For the fourth reactant – 4,6-dimethyldibenzothiophene (4,6-DMDBT), which has two methyl groups near the vicinity of the sulfur atom – HDS proceeds via both a direct and an indirect route. Overall, the indirect route is considerably faster. The 4,6-DMDBT molecule is planar, and the two methyl groups block the access of the sulfur atom to the catalyst surface, thereby inhibiting direct HDS. In the indirect route, saturating one of

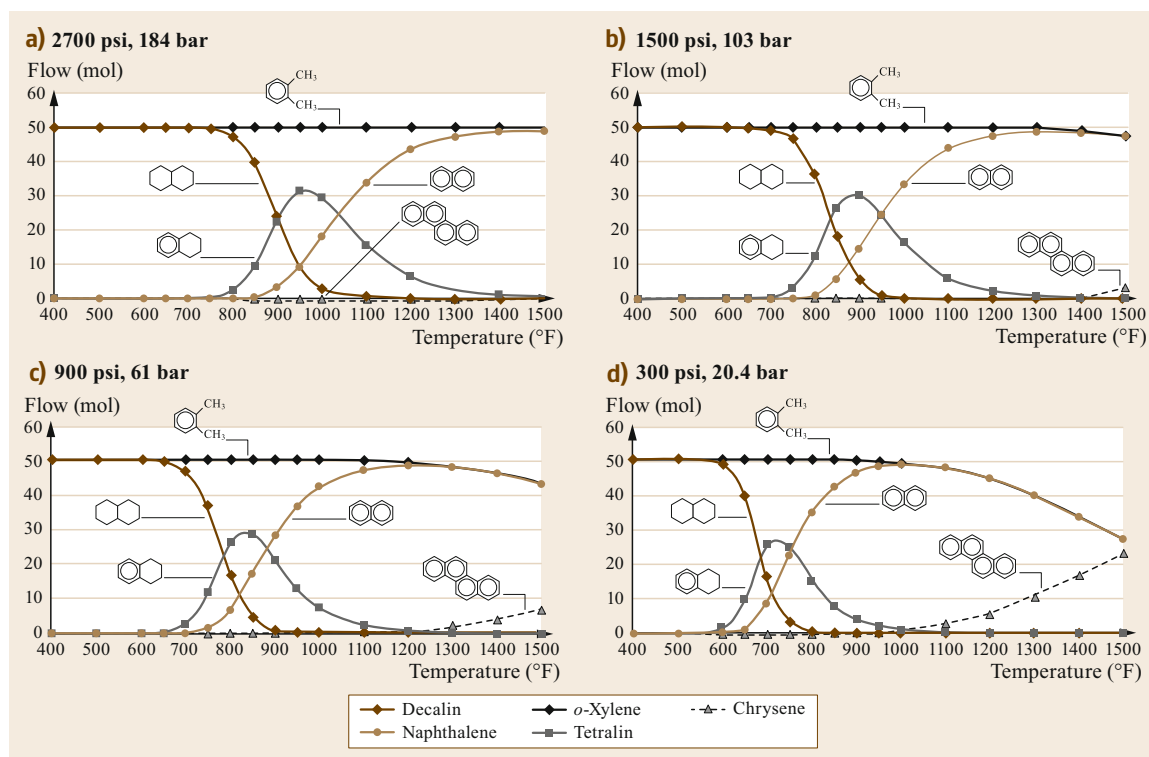

Fig. 1.21a-d Thermodynamic calculations illustrating the competition between saturation and condensation of polyaromatics. Data for the graphs were generated by Aspen Plus for a six-component system comprising naphthalene (C₁₀H₈), tetralin (C₁₀H₁₂), decalin (C₁₀H₁₈), *o*-xylene (C₈H₁₀), chrysene (C₁₈H₁₂), and hydrogen (not shown). The mol flow is the flow of a constituent at the reactor effluent (after [1.75])

Fig. 1.22 Zig-zag mechanism for the condensation of polyaromatics by sequential addition of 2- and 4-carbon units. Formulas for isomers shown are (A) naphthalene, $C_{10}H_8$; (B) phenanthrene, $C_{14}H_{10}$; (C) pyrene, $C_{16}H_{10}$; (D) benzo[e]pyrene, $C_{20}H_{12}$; (E) benzo[ghi]perylene, $C_{22}H_{12}$; (F) coronene, $C_{24}H_{12}$; (G) dibenzo[b,pqr]perylene, $C_{26}H_{14}$; (H) benzo[pqr]naphtho[8,1,2-bcd]perylene, $C_{28}H_{14}$; (I) naphtho[2'.8',2.4]coronene, $C_{30}H_{14}$; and (J) ovalene, $C_{32}H_{14}$. Note that the H/C ratio goes down as condensation increases, from 0.8 for naphthalene (A) to 0.4375 for ovalene (J)

Fig. 1.23 Mechanism for the addition of rings to an existing layer of coke

the aromatic rings that flank the sulfur atom converts the planar structure into a puckered arrangement with tetrahedral C–C bonds. This puckering rotates one of the inhibiting methyl groups away from the sulfur atom, giving it better access to the catalyst.

Making ultra-low-sulfur diesel (ULSD), in which the sulfur content is less than 10–15 wppm, requires severe hydrotreating, after which the only remaining sulfur compounds are the above-mentioned 4,6-DMDBT and other di- and trimethyl dibenzothiophenes. Because

the removal of sulfur from these compounds is more facile after prior saturation, the crossover phenomenon affects the production of ULSD significantly, so much that it governs the design of commercial units.

Hydrotreating: Nitrogen Removal by HDN

Figure 1.25 shows representative HDN reactions, and Fig. 1.26 presents the simplified mechanism for the HDN of quinoline [1.77]. Simple amines are rarely found in natural petroleum. As with sulfur removal

Fig. 1.24 Representative HDS reactions. For the hydrodesulfurization of 4,6-dialkylthiophenes, the indirect mechanism, which requires prior saturation, is preferred

Fig. 1.25 Representative hydrodenitrogenation (HDN) reactions. R = any alkyl group. Simple amines are rarely found in petroleum

Fig. 1.26 Mechanism for the HDN of quinoline (simplified)

from hindered DMBTs, the crossover phenomenon is important for deep HDN because nitrogen removal requires prior saturation of an aromatic ring adjacent to the nitrogen atom.

Hydrotreating: Oxygen Removal by HDO

In feeds to industrial hydroprocessing units, oxygen is contained in furans, organic acids, ethers, peroxides, cresols, and other compounds. Some are formed by reacting with air during transportation and storage of crude oil, distillates, and cracked stocks generated by delayed coking and FCC units (see below). For compounds such as light furans, hydrodeoxygenation (HDO) proceeds rapidly, so rapidly that it can cause problems with excessive heat release. Other compounds, such as cresols, are less reactive, even refractory. Oxygen compounds can form gums and polymers, which inhibit flow and increase pressure drop.

Feedstocks from biomass contain considerably more oxygen than conventional crude oil and petroleum distillates. While a conventional vacuum gas oil may contain 0.5 wt% oxygen, a biomass-derived oil (bio-oil) in the same boiling range might contain > 2% oxygen. Producing fuels from bio oils in conventional oil refineries requires extra hydrogen and presents processing and storage challenges. Large-scale hydrogen production generates large quantities of CO_2 . When assessing the environmental impact of replacing conventional crude oil fractions with bio oils, it is crucial to consider the hydrogen required for upgrading.

Hydrotreating: Trace Metal Removal with HDM

Metals such as nickel and vanadium are present in high-boiling fractions, mostly in asphaltenes. Asphaltenes are mixtures of waxy solids with porphyrins. Corrosion generates soluble iron, and entrained salt brings in alkali and alkaline earth salts, primarily carbonates and bicarbonates of sodium and calcium. Synthetic crudes from oil sands and oil shale tend to contain significant amounts of arsenic – up to 10 ppm. For hydrotreating, 50 ppb is a typical upper limit for arsenic. Silicones are added to crude oil to facilitate flow through pipelines. Silicones are also used to control foaming in delayed coking units.

All of these metals poison refinery catalysts. In hydrotreating, they are removed with grading material, including special wide-pore guard catalysts. Guard materials remove some contaminants by chemisorption. Other contaminants, such as Ni, V, and soluble Fe, are removed by hydrodemetalation (HDM). The products of HDM are metal sulfides, which deposit inside catalyst pores, blocking active sites. They can also cause pore-mouth plugging.

Conversion

Table 1.13 compares compounds with different hydrogen content. For any given class of hydrocarbons, *light*

Table 1.13 Molecular weight, H/C and boiling points for selected hydrocarbons

Compound	Molecular weight	Formula	H/C	Boiling point	
				(°C)	(°F)
Paraffins					
Methane	16.04	CH ₄	4.0	−164.0	−263.2
Ethane	30.07	C ₂ H ₆	3.0	−88.6	−127.5
Propane	44.10	C ₃ H ₈	2.67	−42.1	−43.7
Butane (iso)	58.12	C ₄ H ₁₀	2.50	−6.9	19.6
Octane (iso)	114.23	C ₈ H ₁₈	2.25	99.2	210.6
Cetane (n)	226.44	C ₁₆ H ₃₄	2.13	287.0	548.6
Aromatics					
Benzene	78.11	C ₆ H ₆	1.0	80.1	176.2
Naphthalene	128.17	C ₁₀ H ₈	0.8	218.0	424.4
Benzopyrene	252.32	C ₂₀ H ₁₂	0.6	–	–

means a lower molecular weight, lower boiling point, lower density, and a higher hydrogen-to-carbon ratio (H/C). Methane, the lightest hydrocarbon, has an H/C ratio of 4.0. Benzopyrene has an H/C ratio of 0.6. The H/C ratio of common crude oils ranges from 1.5 to 2.0, while the H/C ratio for asphaltenes is about 1.15.

Hydrotreating and hydrocracking increase the H/C ratio by adding hydrogen. Other conversion processes – FCC, thermal cracking, and deasphalting – increase the H/C ratio by hydrogen reappportionment (also called coke rejection) in which both lighter molecules with higher H/C and heavier products with lower H/C ratios are formed at the same time. In coking and FCC, the heavier product is coke, in which the H/C ratio is < 1.0. It is common to hear *carbon rejection* instead of coke rejection, but *carbon rejection* is misleading; no elemental carbon is removed.

Distillation is central to refining operations; products are defined, first and foremost, by their boiling point ranges (cut points). The goal of a conversion process is to reduce boiling point. Conversion means transforming low value material that boils above a particular cutpoint into high value material that boils below that particular cutpoint. A typical cutpoint for naphtha-oriented conversion is 400 °F (204 °C), while a typical cutpoint for diesel-oriented conversion is 650 °F (343 °C). The equation for conversion is simple

$$\text{Conversion} = \frac{P}{FF} \cdot 100\%$$

where P is the amount of material in the product that boils below the chosen cutpoint and FF is the total amount of fresh feed. In *true conversion* calculations, the amount of P in the FF prior to conversion is subtracted from the numerator.

Table 1.9 shows how boiling point can be reduced without breaking C–C bonds. Saturation, HDS, and HDN can achieve perhaps 10% conversion of vacuum gas oil into diesel and lighter material. To achieve the

degree of conversion shown in Table 1.10, C–C bonds must be broken.

Conversion: Thermal Cracking

Figure 1.27 outlines a mechanism postulated by *Greensfelder* et al. [1.78] for the thermal cracking or steam cracking of hydrocarbons. This chain-reaction mechanism includes the following steps:

1. *Chain initiation*: Radicals are formed due to direct thermal rupture of a chemical bond. Common initiators are organic molecules that contain S, N, or O, which are present in delayed coker feeds. Epoxides, which can be formed by reaction with oxygen during transportation and storage, are potent initiators. In steam cracker feed, heteroatom initiators are absent, so the chain reaction is initiated by the high-temperature rupture of a C–C bond.
2. *Propagation*: A radical abstracts hydrogen from another compound, turning it into a different radical.
3. *Radical addition*: A radical attacks an olefin group, forming a C–C bond and a larger radical.
4. *Radical decomposition (cracking)*: A radical decomposes into an olefin and a smaller radical.
5. *Cyclization*: Radicals with five or more carbons and an olefin group react with themselves to form ring compounds. At the high temperatures at which thermal cracking occurs, aromatics and polyaromatics are thermodynamically favored, so saturated or partially saturated ring compounds readily undergo dehydrogenation and form aromatics.
6. *Chain reaction termination*: Two radicals react to produce a saturated product.

The radical mechanism is consistent with the fact that thermal cracking produces significant amounts of hydrogen, methane, ethane, ethylene, and higher olefins.

Feeds to delayed coking units contain organic sulfur, nitrogen, and oxygen compounds, which form radi-

Fig. 1.27 Thermal cracking mechanism: radical chain reaction

cals more easily than hydrocarbons. These heteroatoms end up in two types of molecules – light ones (H_2S , ammonia, and water) and heavy ones, such as hindered dibenzothiophenes or carbazoles, from which they are harder to remove.

Steam-Hydrocarbon Reforming Chemistry

Steam-hydrocarbon reforming is commonly called SMR because methane is the most common feedstock. SMR produces hydrogen through the reaction of steam with light hydrocarbons at very high temperatures – around $1500^\circ F$ ($816^\circ C$). The product of the initial reaction is a mixture of H_2 , CO , CO_2 , residual methane, and traces of other hydrocarbons. The initial product goes to one or more shift reactors, where the reaction between H_2O and CO yields CO_2 and additional hydrogen

In older units, residual CO was removed by methanation over a nickel-based catalyst, and residual CO_2

was removed for example by adsorption with activated molten potassium carbonate (Benfield process). The product hydrogen contained up to 5% methane.

In newer units, pressure-swing adsorption (PSA) removes nearly all contaminants, yielding a product containing 99.99% hydrogen. A PSA unit employs a collection of solid adsorbents – molecular sieves, activated carbons, silica gels, and activated aluminas. For carbon, silica, and alumina, the separation is due to differential tendency to adsorb different gases. PSA cycles include pressurization, depressurization, and purging. The rejected gas, a low-BTU mixture containing methane, CO and CO_2 , is burned to provide some pre-heat duty.

Another important source of hydrogen is catalytic reforming.

Steam Cracking Chemistry

Olefin plants employ the steam-cracking process to produce ethylene and propylene feedstock for polymer plants. Steam cracking in olefin plants co-produces hydrogen. The reaction temperature is very high, at around

850 °C, and the residence time is very short, as fast as milliseconds, to improve yield and decrease oligomerization and coke formation. The reaction is stopped by rapid quenching. Steam cracking of heavier feed produces products rich in aromatic hydrocarbons suitable for blending into gasoline and fuel oil.

Conversion Chemistry: Catalytic Cracking

In refining, catalytic cracking falls into two categories: catalytic cracking in the absence of external hydrogen – primarily FCC – and catalytic cracking in the presence of external hydrogen – hydrocracking.

Catalysts for both kinds of catalytic cracking contain strong acid sites. The mechanism involves carbocations, also known as carbenium ions or carbonium ions. Acidity is provided by amorphous silica/alumina (ASA) or a crystalline zeolite. Hydrocracking catalysts are bifunctional because in addition to acid site, they contain metal sites, which catalyze hydrogenation.

Key features of catalytic cracking include a preponderance of branched-chain paraffin products and low yields of methane and ethane. Commercial catalysts for these and other processes are discussed in a subsequent section.

FCC units produce aromatics and other heavy products via cyclization, alkylation, and polymerization of intermediate olefins. As shown in Fig. 1.22, polyaromatics can grow into larger polyaromatics, which eventually can form coke. In hydrocracking units, abundant high-pressure hydrogen quickly saturates olefin intermediates, suppressing the growth of polyaromatic rings. For the hydrocracking of fluorene (C₁₃H₉), *Lapinas et al.* [1.79] proposed a mechanism that might apply generally to the hydrocracking of polyaromatics.

Figure 1.28 outlines the reaction sequence for hydrocracking a heptyl ethyl naphthalene isomer into lighter compounds. The reactions include:

- Removal of part of a side chain by dealkylation
- Saturation of an aromatic ring
- Isomerization of the saturated ring
- Opening the saturated ring
- Paraffin hydrocracking.

The first dealkylation reaction (1) removes hexanes through β -cleavage, leaving behind a methyl group. The ring itself remains intact due to resonance stabilization; one-ring aromatic compounds are especially stable. For mechanistic reasons, methyl and ethyl groups are not removed from aromatic rings by β -cleavage. This is consistent with the observation that acid-catalyzed cracking in hydrocracking and FCC units produces minimal methane and ethane. Hydrogenating aromatic rings (2) removes resonance, yielding a saturated ring which is susceptible to ring opening (3). Ring opening is followed by another dealkylation reaction (4), and paraffins are hydrocracked (5).

Comparison of Catalytic and Thermal Cracking

Table 1.14 compares catalytic and thermal cracking processes.

Alkylation Chemistry

In alkylation units, excess isobutane reacts with C₃–C₅ olefins to generate high-octane alkylate – a mixture of C₇–C₉ isoparaffins. Alkylate is a premium quality blend stock for gasoline. Alkylation reactions are catalyzed by strong Brønsted acids. Refineries employ either sulfuric acid alkylation (SAA) or hydrofluoric acid alkylation

Fig. 1.28 Reaction sequence for the hydrocracking of polyaromatics

Table 1.14 Comparison of product yields for catalytic and thermal cracking processes (after [1.9])

Process	Type	Product characteristics
FCC	Catalytic cracking in the absence of external H ₂	C ₁ and C ₂ : low Iso/normal paraffin ratio: high C ₃ and C ₄ olefin yields: can be significant H ₂ production: moderate Aromatics: higher than feed Coke formation: high Alkyl aromatics: β -scission next to the ring
Catalytic hydrocracking	Catalytic cracking in the presence of external H ₂	C ₁ and C ₂ : low Iso/normal paraffin ratio: high Olefins: removed by hydrogenation Aromatics: significantly lower than feed Coke formation: minimal Alkyl aromatics: β -scission next to the ring
Slurry-phase hydrocracking	Thermal cracking in the presence of external H ₂	C ₁ and C ₂ : high Iso/normal paraffin ratio: similar to feed Olefin production: moderate Aromatics: depends on feed (VR versus coal) Coke formation: low Alkyl aromatics: scission within the side chain
Coking and visbreaking	Thermal cracking in the absence of external H ₂	C ₁ and C ₂ : high Iso/normal paraffin ratio: similar to feed Olefin production: high Aromatics: moderate Alkyl aromatics: scission within the side chain
Steam cracking	Thermal cracking in the presence of steam	Olefin production: high H ₂ production: high Aromatics: high (in the pyrolysis oil) Coke formation: low

(HFA). In both processes, unreacted isobutane is recycled to maintain a high isobutane-to-olefins ratio (I/O), which typically is around 10. In one recently developed process, acidity is provided by a specific zeolite. In another, acidity is provided by an ionic liquid.

Alkylation reactions are highly exothermic. Temperatures are kept low. They range from 0 °C (32 °F) for SAA to around 30 °C (86 °F) for HFA. In HFA, temperature is controlled with refinery cooling water, but SAA requires refrigeration. The excess isobutane moderates temperature increase by absorbing reaction heat. Excess isobutane is the source of *t*-butyl ions to propagate the reaction and also dilutes the olefins, suppressing olefin polymerization.

The mechanism for alkylating butenes is shown in Fig. 1.29. In commercial units, the butene stream is predominantly 2-butene, but it also can contain isobutylene, and 1-butene [1.80]. Olefins are initially ionized by strong acid to form stable *t*-butyl cation via rearrangement, as shown in reaction 1.

Reactions 2–4 are the *alkylation* (addition) reactions. In reaction 2, the *t*-butyl cation reacts with isobutylene to generate the 2,2,4-trimethylbutane cation. Reactions 3a and 4a occur when the *t*-butyl cation encounters 2-butene and 1-butene. The products of 3a and

4a are secondary carbocations. They undergo *methyl shift* in reactions 3b and 4b to generate 2,2,4-trimethylpentane, a more stable tertiary carbocation. Reactions 3b and 4b do not proceed to completion, as indicated by the presence of 2,2,3-trimethylpentane and 2,2-dimethylhexane in the finished product.

Reaction 5 shows the *hydride transfer* reaction that converts isobutane into the *t*-butyl cation while generating finished products – iso-C₈ paraffins (alkylate). Reaction 6 indicates that unwanted side reactions can occur. These include olefin polymerization and follow-on alkylation, both of which form larger molecules, including sludge and acid-soluble oil (ASO).

Catalytic Reforming Chemistry

Figure 1.30 summarizes the reactions of catalytic reforming, the purpose of which is to transform C₆ to C₁₁ naphthenes and paraffins into aromatic compounds. The aromatics can go to chemical plants (Table 1.3) or be used as high-octane gasoline blend stocks. The process yields considerable amounts of hydrogen; in Fig. 1.30, 4 mol of hydrogen are produced from 1 mol of hexane through cyclization (ring closure) and aromatization. The hydrogen is used in hydrotreaters, hydrocrackers, isomerization units, and others.

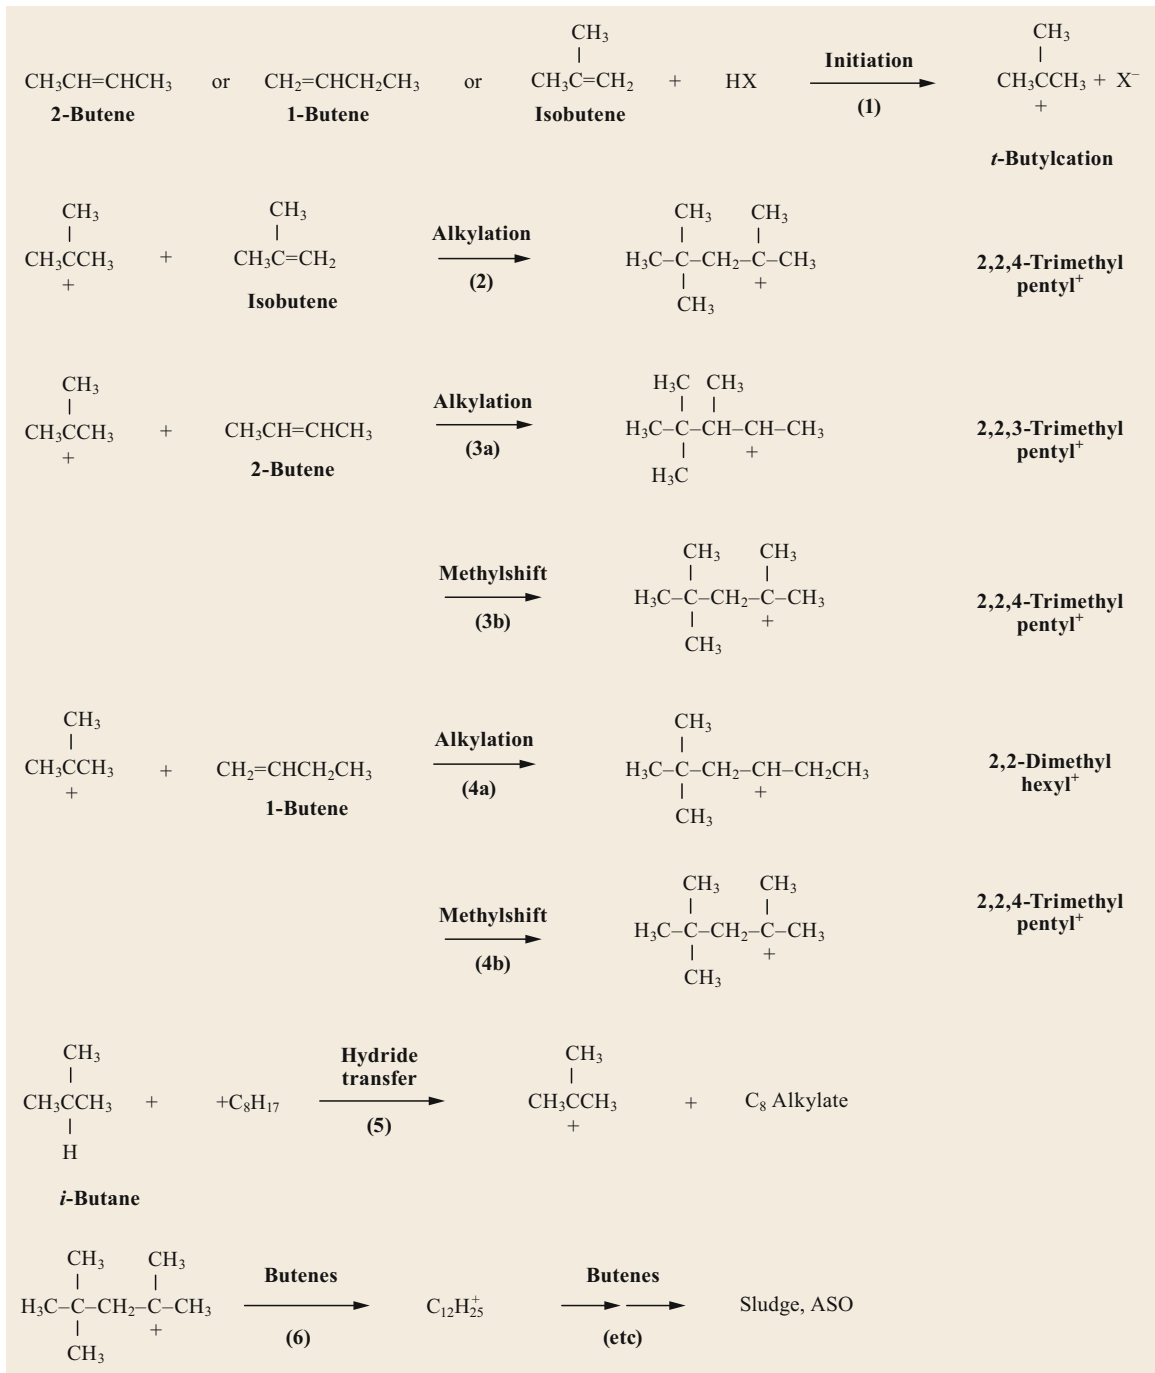

Fig. 1.29 Mechanism for acid-catalyzed alkylation of C₄ olefins, where X is HSO₄⁻ or F⁻

In contrast to hydrocracking, which operates at high hydrogen pressure and moderate temperature to saturate aromatics, catalytic reforming operates at low pressure and high temperature, which favors production of aromatics. In the example shown in Fig. 1.30,

low-octane *n*-hexane is isomerized over an acidic catalyst into 2-methylpentane (isohexane) of higher octane rating, which can further undergo cyclization to form methyl cyclopentane. The conversion of alkylcyclopentanes over a shape selective catalyst into cyclohexanes

Fig. 1.30 Catalytic reforming reactions for *n*-hexane

is a key step in the production of benzene and alkylbenzenes.

Paraffin Isomerization Chemistry

Paraffin isomerization reactions transform *n*-paraffins into *iso*-paraffins. Paraffin isomerization occurs in many conversion units. It is especially important in FCC, hydrocracking, and hydroisomerization to make lubricant (lube) base stocks. In C_4 isomerization units, *n*-butane is converted to isobutane in a two-stage process, which employs HCl-promoted AlCl_3 for the 1st stage and a supported noble metal catalyst in the 2nd stage. The isobutane product is the key feedstock for alkylation units, which produce high octane alkylates. C_5/C_6 isomerization produces isopentanes and isohexanes, which are high-octane components of gasoline.

Heavy *n*-paraffins are waxy. They solidify in cold weather, so during lube base stock production, they must be removed, either by extraction, conversion, or isomerization. In isodewaxing units, they are transformed into isoparaffins, with minimal cracking, over silica-alumina-phosphate (SAPO)-based catalysts. Compared to *n*-paraffins, isodewaxed products have considerably lower cloud and pour points; they flow more readily at low temperature.

The impact of heavy paraffin isomerization on melting point is illustrated in Table 1.15 for $\text{C}_{18}\text{H}_{38}$. Going from the *n*-isomer to the 3-methyl isomer lowers the melting point by 34°C . The melting points of com-

Table 1.15 Melting points of three C_{18} paraffins (after [1.62])

Compound	Melting point ($^\circ\text{C}$)
<i>n</i> -Octadecane	28
2-Methylheptadecane	6
3-Methylheptadecane	-6

pounds in mixtures differ from pure-compound melting points, and melting point is not the same as cloud point or pour point. Even so, the magnitudes of the changes in melting point are consistent with the changes in cloud and pour points.

Olefin isomerization converts straight-chain C_4 – C_6 olefins into the corresponding *iso*-olefins, which can be used as feeds to alkylation units (Sect. 1.11.3, *Alkylation Chemistry*).

Acid/Base Reactions:

Amine and Caustic Scrubbing

Several processes entail seemingly simple acid–base reactions. Treating with alkanolamines removes acid gases – H_2S and CO_2 – from fuel gas and off-gas streams. In refineries, H_2S -laden amines go to the sulfur recovery unit. There, the H_2S is stripped off with steam, and the amine is recirculated. The H_2S goes to a modified Claus unit, where it is converted into elemental sulfur.

Caustic scrubbers are used in several ways, including removing the last traces of H_2S from the hydrogen used for processes in which the catalysts are highly sulfur sensitive.

Modified Claus Process Chemistry

Modified Claus sulfur-recovery units burn hydrogen sulfide in enough air to form a mixture of H_2S and SO_2 in a 2 : 1 molar ratio. In downstream beds of alumina catalyst, H_2S reacts with SO_2 in the Claus reaction to form elemental sulfur and water. The product sulfur can include many different isomers of S_x

Claus Tail Gas Recovery Chemistry

Claus units achieve up to 96% conversion of H_2S into sulfur. The Claus tail gas contains SO_2 , SO_3 , COS , CS_2 ,

and volatile forms of sulfur. The carbon comes from CO_2 or methane, both of which can be present in the feed gas. Tail-gas treating units (TGTU) bring the total sulfur recovery up to $> 99.9\%$. Most tail-gas treating processes send the tail gas to a hydrotreater, which converts all sulfur-containing compounds into H_2S

In the SCOT process, offered by Shell Global Solutions, the H_2S is absorbed by an alkanolamine and returned to the front of the Claus furnace. In the LO-CAT process, offered by Merichem, H_2S is air oxidized to sulfur in an aqueous solution containing a chelated iron catalyst. For all tail-gas treatment processes, the last traces of unrecovered sulfur go to an incinerator, where they are converted by reaction with air into SO_2 and dispersed into the atmosphere.

Catalytic NO_x Removal Chemistry

Selective catalytic reduction (SCR) removes nitrogen oxides (NO_x) by reaction with ammonia to produce nitrogen via the following main reactions. Secondary reactions involve sulfur oxides and ammonium sulfates.

1.11.4 Petroleum Refining Processes

Separation

Separation processes in refineries are mainly based on volatility and solubility. They include distillation, extraction, and settling. Settling allows dirt and brine to disengage from the oil prior to shipment or processing.

Crude Oil Distillation

Figure 1.31 illustrates a crude oil distillation complex. As mentioned, when crude oil is extracted from underground, it is mixed with a variety of substances: gases, water, salt, and dirt. These must be removed before the crude can be transported effectively and refined without undue fouling and corrosion. Some cleanup occurs in oil fields and midstream processes such as the preparation of syncrudes. In refineries, crude desalting units provide subsequent cleanup.

A field separator at a well site is often no more than a large covered vessel that provides enough residence time for gravity separation into four phases: gases, crude oil, water, and solids. Generally, the crude oil floats on the water. The water is withdrawn from the bottom and is disposed at the well site. Gases are withdrawn from the top and piped to a natural gas processing plant or reinjected into the reservoir to maintain well pressure. Crude oil is pumped either to a refinery through a pipeline or to storage to await transportation by other means.

At the refinery, the crude is treated with hot water in one or more desalters. Desalters employ either chemical or electrostatic precipitators to remove dissolved salts and collect remaining solids. In chemical desalt-

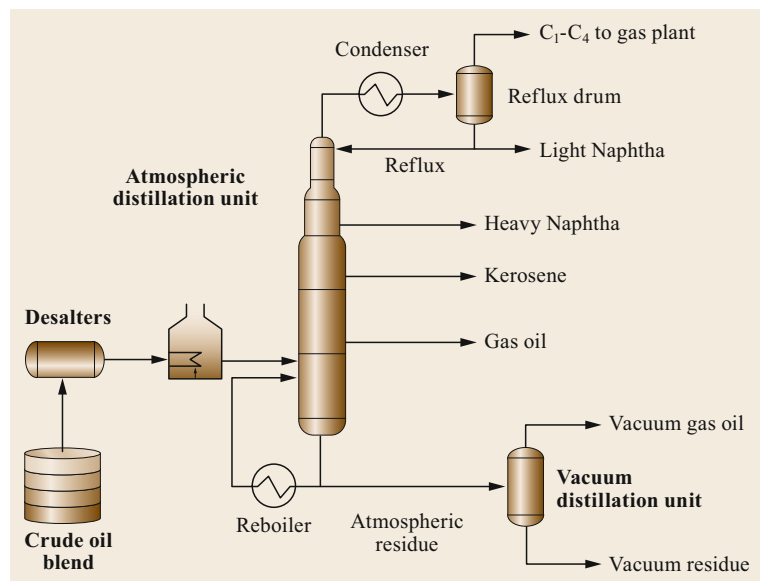

Fig. 1.31 Two-stage crude oil distillation unit with desalting, atmospheric distillation, and vacuum distillation

ing, water and surfactants are added to the crude, heated to dissolve salts and other impurities, and then sent to a settling tank, where the water and oil separate. In electrostatic desalting, chemicals are replaced with a strong electrostatic field at 12–35 kV, which drives the separation of water from oil. Coalescence is aided by passage through a tower packed with sand, gravel, and the like. Emulsion can be broken by adding chemicals, such as demulsifiers.

If the crude is not desalted, residual solids can clog downstream equipment and deposit on heat exchanger surfaces, thereby reducing heat-transfer efficiency. Salts can induce corrosion in major equipment and deactivate catalysts.

Before reaching the atmospheric distillation tower shown in Fig. 1.32, desalted oil goes through a network

of pre-heat exchangers to a fired heater, which brings the temperature up to 657–725 °F (347–385 °C). If the oil gets much hotter than this, it starts to crack, generating carbon. The carbon would deposit inside the pipes and equipment through which the oil flows.

As shown in Fig. 1.32, the hot crude enters the tower just above the bottom. Steam is added to enhance separation; it does so largely by decreasing the vapor pressure of hydrocarbons in the column. When it enters the tower, most of the oil vaporizes. Unvaporized oil drops to the bottom of the tower, from where it is drawn off. The vapors rise through the distillation trays, which contain perforations, bubble caps, downcomers, and/or modifications thereof. Each tray permits vapors from below to bubble up through the relatively cool condensed liquid on top of the tray. This vapor/liq-

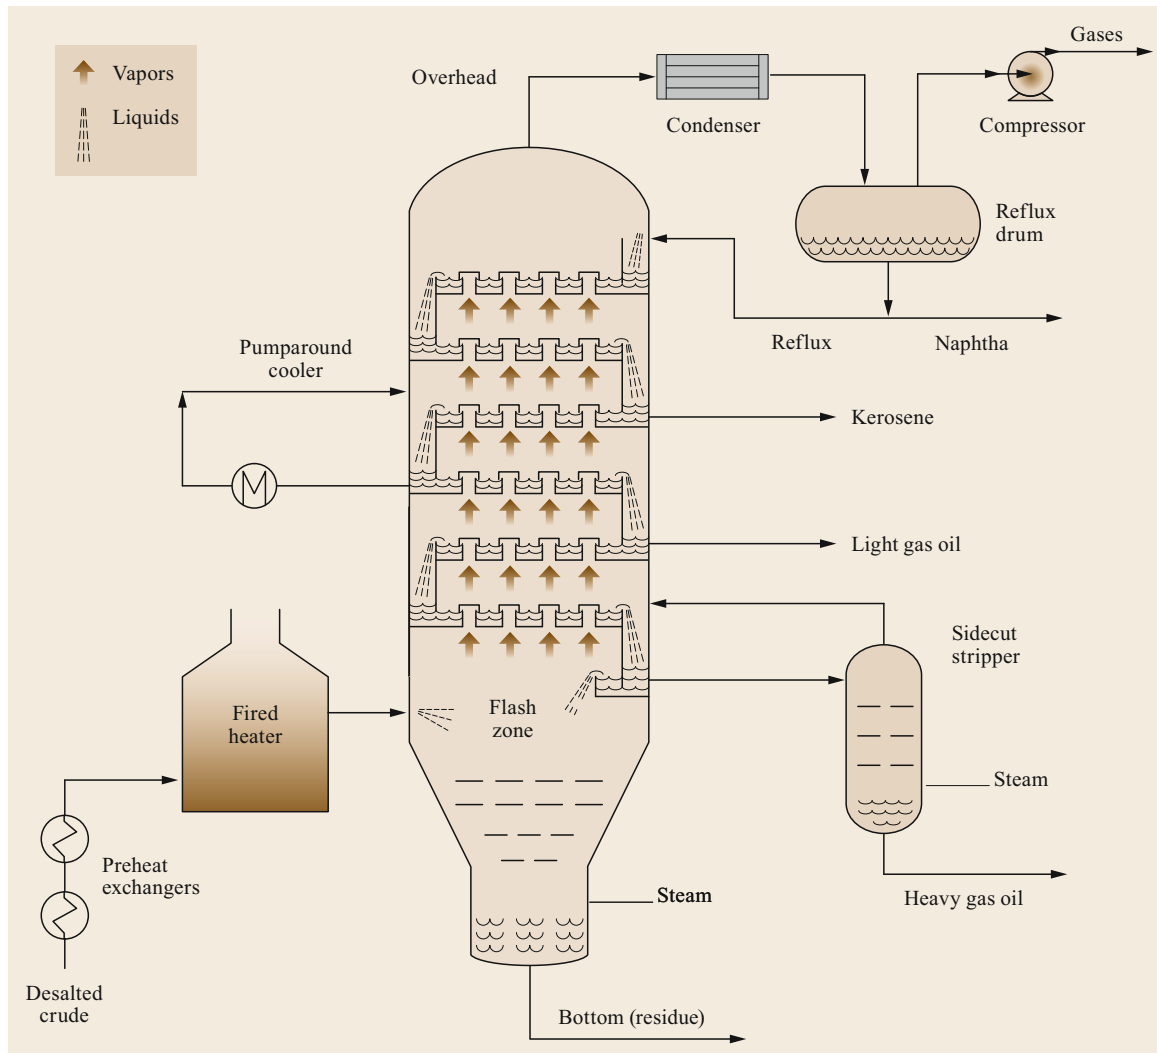

Fig. 1.32 Atmospheric distillation tower with bubble-cap trays, one pumparound, and three side draws

uid contact knocks heavy material out of the vapor. Condensed liquid flows down through a downcomer to the hotter tray below, where the higher temperature causes re-evaporation. A given molecule evaporates and condenses many times before finally leaving the tower.

Products are collected from the top, bottom, and side of the column. Side-draw products are taken from trays where the temperature corresponds to the cut-points for a desired product. Some of the side-draws can be returned to the tower as a pump-around or pump-back stream to control tower temperatures and improve separation efficiency. Reflux plays a major role in controlling temperature and enhancing separation at the top of the tower, where gases and light naphtha are drawn off overhead. Reflux ratio is the amount of reflux liquid returning to distillation tower to the amount of liquid withdrawn as product per unit time. With a higher reflux ratio, fewer theoretical plates are required. There is a reboiler at the bottom of tower to ensure that light components are not carried out of the bottom of tower.

Products from the crude distillation unit go to other process units, as shown in Table 1.16.

The bottom stream from the main fractionator (atmospheric distillation tower) is called atmospheric bottom, atmospheric residue, reduced crude, or long resid. It goes to a second fired heater, where the typical outlet temperature is about 750–775 °F (400–413 °C). From the second heater, the atmospheric residue goes to a vacuum distillation tower. Steam ejectors reduce the absolute pressure to about 7.0 psi (0.5 bar). Under this so-called vacuum, hydrocarbons vaporize at lower temperatures than atmospheric boiling points. For example, if the atmospheric equivalent boiling point of a com-

pound is ≈ 1050 °F (565 °C), then its boiling point under 40 mmHg vacuum is around 800 °F (427 °C). Hence, in a vacuum distillation unit, the molecule is far less likely to undergo thermal cracking and far more likely to undergo vaporization.

Solvent Refining

Solvent refining processes include solvent deasphalting, solvent extraction, and deoiling/dewaxing processes.

Solvent Deasphalting. Solvent deasphalting takes advantage of the fact that aromatic compounds are insoluble in paraffins. Unwanted deasphalting can occur during attempts to blend incompatible crudes and distillates.

Propane and *n*-pentane are used to precipitate asphaltenes from residual oils. The deasphalted oil (DAO) is sent to hydrotreaters, FCC units, hydrocrackers, or fuel-oil blending. In FCC units, DAO is easier to process than the corresponding straight-run residue. This is because the asphaltene content of DAO is very low. The asphaltenes in straight-run residue easily form coke and often contain catalyst poisons such as nickel and vanadium. Although DAO no longer contains asphaltenes, it still has a very high endpoint. Hence, DAO is harder to process than straight-run VGO and FCC cycle oils in hydrocrackers.

In traditional propane deasphalting, residual oil and propane are pumped to an extraction tower at 150–250 °F (65–120 °C) and 350–600 psig (2514–4240 kPa). Separation occurs in a tower, which may include a rotating disk contactor. Liquid products are evaporated and steam stripped to recover the propane solvent, which is recycled.

Table 1.16 Destinations for straight-run distillates. Resid is an abbreviation for residua, and 340+ etc. means everything that boils above 340 °C etc.

Fraction	Approx. boiling range		Next destination	Ultimate product(s) or subsequent destination
	(°C)	(°F)		
LPG	–42–0	–44–31	Sweetener	Propane fuel
Light naphtha	39–85	80–185	Hydrotreater	Gasoline, petrochemical plant
Heavy naphtha	85–200	185–390	Cat. reformer	Gasoline, aromatics
Kerosene	170–270	340–515	Hydrotreater	Jet fuel, No. 1 diesel
Gas oil	180–340	350–650	Hydrotreater	Heating Oil, No. 2 diesel
Atmos. resid	340+	650+	Visbreaker	FCC or hydrocracker feed, low-viscosity resid
			Resid hydrotreater	Resid FCC
			Ebullated bed hydrocracker	Naphtha, gas oils, FCC
Vacuum gas oil	340–566	650–1050	FCC	Gasoline, LCO, gases including C ₃ /C ₄ olefins
			Hydrotreater	Fuel oil, FCC, lubes
			Hydrocracker	Naphtha, jet, diesel, FCC, olefins, lubes
			Solvent refining	DAO, asphalt
Vacuum resid	540+	1000+	Coker	Coke, coker gas oil, coker naphtha, gases
			Solvent refining	DAO, asphalt
			Residue hydrocracker	Traditional hydrotreater, hydrocracker, heavy fuel oil

An advanced version of solvent deasphalting is *residuum oil supercritical extraction* or ROSE. The ROSE process was developed by the Kerr-McGee Corporation and is now offered for license by KBR. In this process, residue and solvent are mixed and the extractor temperature is typically maintained below the solvent's critical temperature. As the extraction temperature approaches the solvent's critical temperature, the DAO rapidly becomes less and less soluble in the solvent. Increasing the extraction temperature reduces the solubility of the heavier components of the feedstock, improving DAO quality but reducing DAO yield [1.81]. Liquid yields are higher under supercritical conditions, because the lighter part of the oil becomes more soluble. In addition to giving higher yields, the process is more energy efficient and has lower operating costs due to improved solvent recovery. The ROSE process can employ three different solvents, the choice of which depends upon process objectives:

- *Propane*: Preparation of lube base stocks
- *Butane*: Asphalt production
- *Pentane*: Maximum recovery of liquid.

Solvent Extraction. Solvent extraction removes aromatics and other impurities from lube base stocks and grease stocks. The feedstock is dried, and then contacted with the solvent in a counter-current or rotating disk extraction unit. The solvent is separated from the product stream by heating, evaporation, or fractionation. Remaining traces of solvent are removed from the raffinate by steam stripping or flashing. Electrostatic precipitators can enhance the separation of inorganic compounds. The solvent is then regenerated and recycled. Today, phenol, furfural, *N*-methyl-2-pyrrolidone (NMP) and cresylic acid are widely used as solvents. Liquid sulfur dioxide, chlorinated ethers, and nitrobenzene also have been used.

Solvent Dewaxing. This process removes wax (normal paraffins) from deasphalted oils. The main process steps include mixing the feedstock with the solvent, chilling the mixture to crystallize wax, and recovering the solvent. Commonly used solvents include toluene and methyl ethyl ketone (MEK). Methyl isobutyl ketone (MIBK) is used in a *wax deoiling* process to prepare food-grade wax, which is used to coat the paper used for milk cartons and other such products.

Visbreaking

Visbreaking is a mild form of thermal cracking that achieves about 15% conversion of atmospheric residue into gas oils and naphtha. At the same time, a low-viscosity residual fuel is produced. The main purpose of

visbreaking is not for conversion, but viscosity reduction for fuel oil. The two main types of visbreaking are *short-contact* and *soaker*. In short-contact visbreaking, the feed is heated to about 900 °F (480 °C) in furnace tubes (coils) and sent to a soaking zone reactor at 140–300 psig (1067–2170 kPa). The elevated pressure allows cracking to occur while restricting coke formation. To avoid over-cracking, the residence time in the soaking zone is short – several minutes (typically 1–3 min) compared to several hours in a delayed coker. The hot oil is quenched with cold gas oil to inhibit further cracking and sent to a vacuum fractionator for product separation. Soaker visbreaking keeps the hot oil at about 800 °F (430 °C) in a drum after the furnace for a longer time to increase the yield of middle distillates. Low-viscosity visbreaker gas oil can be sent to an FCC unit or hydrocracker for further processing, or used as heavy fuel oil.

Delayed Coking

Delayed coking is a cyclic process that employs more than two coke drums – typically at least four. The drums operate on staggered 18–24 h cycles. Each cycle includes preheating the drum, filling it with hot oil, allowing coke and liquid products to form, cooling the drum, and decoking the drum. As it is pumped into a drum, vacuum residue feed is heated to about 900–970 °F (487–520 °C). Thermal cracking begins immediately, generating coke and cracked products. Coke accumulates in the drum, while the vapors enter a product fractionator. Meanwhile, hot feed keeps flowing into the drum until it is filled with solid coke. At the end of a cycle, the top and bottom heads of the drum are removed. A rotating cutting tool uses high-pressure jets of water to drill a hole through the center of the coke from top to bottom. In addition to cutting the hole, the water also cools the coke, forming steam as it does so. The cutter is then raised, step by step, cutting the coke into lumps, which fall out the bottom of the drum.

Light products include coker naphtha, light coker gas oil (LCGO), and heavy coker gas oil (HCGO). All of these require further processing due to their high content of olefins, which makes them unstable and poorly suited for direct blending into finished products. The coker naphtha and LCGO are hydrotreated. The HCGO can go either to an FCC unit or a hydrocracker. Coke can account for up to 30 wt% of the product.

Fluid (Continuous) Coking

Fluid coking, also called continuous coking, is a moving-bed process for which the operating temperature is higher than the temperatures used for delayed coking. In continuous coking, hot recycled coke particles are combined with liquid feed in a radial reactor

at about 50 psig (446 kPa). Vapors are taken from the reactor, quenched to stop any further reaction, and fractionated. The hot coke goes to a surge drum, and then to a classifier where the larger coke particles are removed as product. The smaller coke particles are recycled to a surge drum (preheater), where they are mixed with fresh feed then sent to the reactor through a transfer line. Coking occurs both in the reactor and in the surge drum. Depending on the feed, 15–25% of the coke is burned with air to satisfy the heat requirements of the process, such as maintaining reactor temperature and sustaining thermal cracking reactions. Installation costs for fluid coking are higher than for delayed coking, but heat losses are lower. Fluid coking makes more fuel gas than delayed coking.

Flexicoking

Flexicoking is a version of fluid coking developed by ExxonMobil. Coke is gasified in an integrated steam air gasifier to produce clean CO and H₂ flue gas, instead of coke as product. Flexsorb hindered amine, also developed by ExxonMobil, is used to reduce H₂S to a low level.

Fluid Catalytic Cracking (FCC)

Fluid catalytic cracking (FCC) produces more than half the world's gasoline. It generates middle distillate streams (cycle oils) for further refining or blending. It also produces a large quantity of high-quality steam.

FCC Process Flow. A typical FCC unit (Fig. 1.33) comprises three major sections – riser/reactor, regenerator, and fractionation. In the riser/reaction section, preheated oil is mixed with hot, regenerated catalyst. The mixture acts as a fluid because the catalyst particles are quite small. The hot catalyst vaporizes the oil, and the vaporized oil carries the catalyst up the riser/reactor. The cracking reaction is very fast. It produces light gases, high-octane gasoline, and heavier products called light cycle oil (LCO), heavy cycle oil (HCO), slurry oil, and decant oil. It also leaves a layer of coke on the catalyst particles, rendering them inactive.

At the top of the riser, the riser outlet temperature (ROT) can reach 900–1020 °F (482–549 °C). The ROT determines conversion and affects product selectivity, so FCC operators control it as tightly as possible. Higher temperatures favor production of olefin-

Fig. 1.33 FCC process flow

rich light gases, especially propylene, at the expense of gasoline; many FCC units maximize refinery-grade propylene for purification and use in nearby olefin plants. Moderate temperatures favor gasoline production. Lower temperatures decrease gasoline yields and increase heavier products – LCO and HCO.

In the disengaging section, steam helps separate the now-deactivated catalyst from the reaction products. The catalyst goes to the regenerator, where the coke is burned away by fluidized combustion in the presence of air or oxygen-enriched air. The regenerated catalyst is hot, with temperatures up to 1350 °F (732 °C). It returns to the riser/reactor, where the cycle begins again.

In a 60 000 bbl/day unit processing a typical mixture of vacuum gas oils, the total catalyst in the unit (the *inventory*) is 400–500 t. To maintain activity, about 0.5–1 wt% of the inventory is replaced each day. If the feed to the unit contains significant amounts of residue, the replacement rate is higher. The discharged catalyst is cooled and shipped either to a land fill for disposal or to another refiner, which might need *conditioned* FCC catalyst.

Table 1.17 Representative FCC heat duty

Factor	Portion of total
Heat up and vaporize fresh feed	40–50%
Heat recycled oil	0–10%
Heat of reaction (endothermic)	15–30%
Heat steam	2–8%
Heat losses	2–5%
Heat air to regenerator temperature	15–25%
Heat coke from the reactor to regenerator temperature	1–2%
Total heat duty	500–1000 BTU/lb 1160–2325 kJ/kg

Table 1.18 Feeds and products for hydroprocessing units

Feeds	Products from hydrotreating	Products from hydrocracking
Heavy naphtha	Catalytic reformer feed	LPG
Straight-run light gas oil	Middle distillate fuels	Naphtha
Straight-run heavy gas oil	Diesel fuel	Naphtha
Atmospheric residue	Lube base stock, low-sulfur fuel oil, RFCC ^a feed	Naphtha, middle distillates, FCC feed, lube base stock
Vacuum gas oil	FCC feed, lube base stock	Naphtha, middle distillates, FCC feed, lube base stock, olefin plant feed
Vacuum residue	RFCC ^a feed	See note ^b
FCC LCO	Diesel blend stocks, fuel oil	Naphtha
FCC HCO	Blend stock for fuel oil	Naphtha, middle distillates
Visbreaker gas oil	Diesel blend stocks, fuel oil	Naphtha, middle distillates
Coker gas oil	FCC feed	Naphtha, middle distillates, FCC feed, lube base stock, olefin plant feed
Deasphalted oil	Lube base stock, FCC feed	Naphtha, middle distillates, FCC feed, lube base stock

^a RFCC = *residue FCC* or *reduced crude FCC*. This process is designed for feeds that contain high concentrations of carbon-forming compounds, ^b Traditional fixed-bed hydrocrackers cannot process vacuum residue. However, ebullated-bed and slurry-phase hydrocrackers can. Products from the latter include naphtha, middle distillates, and FCC feed

FCC Heat Balance. FCC units must be heat balanced, or they would not run. The burning of coke deposited on the catalyst in the regenerator provides all of the heat required by the process. In fact, FCC units are significant sources of high-quality steam for other refinery units. Table 1.17 gives a representative breakdown of FCC heat requirements.

Residue FCC. Some FCC units process significant amounts of residue. These units use catalyst coolers (e.g., steam coils) in the regenerator or a second-regeneration zone to remove excess heat from the unit. This is because residue generates substantially more coke than conventional FCC feeds, and excess heat is generated when the extra coke is burned off the catalyst. Steam for other process units is generated from the excess heat. The trace-metal content of residues can be very high. Trace metals destroy FCC catalysts, so removing them – usually with hydrotreating or solvent deasphalting – is essential.

Hydroprocessing

Hydroprocessing includes hydrotreating and hydrocracking. In hydrocracking, C–C bonds are broken, but in hydrotreating, for the most part they are not. The flow schemes for fixed-bed hydrotreating and hydrocracking units are similar. Hydrotreating is an essential precursor to fixed-bed gas oil hydrocracking. Feeds and products for typical hydrotreaters and hydrocrackers are shown in Table 1.18.

Figure 1.34 shows a fixed-bed hydroprocessing unit with two reactors, four flash drums, an amine unit, and emergency depressuring (EDP). The unit shown is a hydrocracker, as indicated by hydrocracking catalyst in the second reactor (R2). Preheated feed mixes with hy-

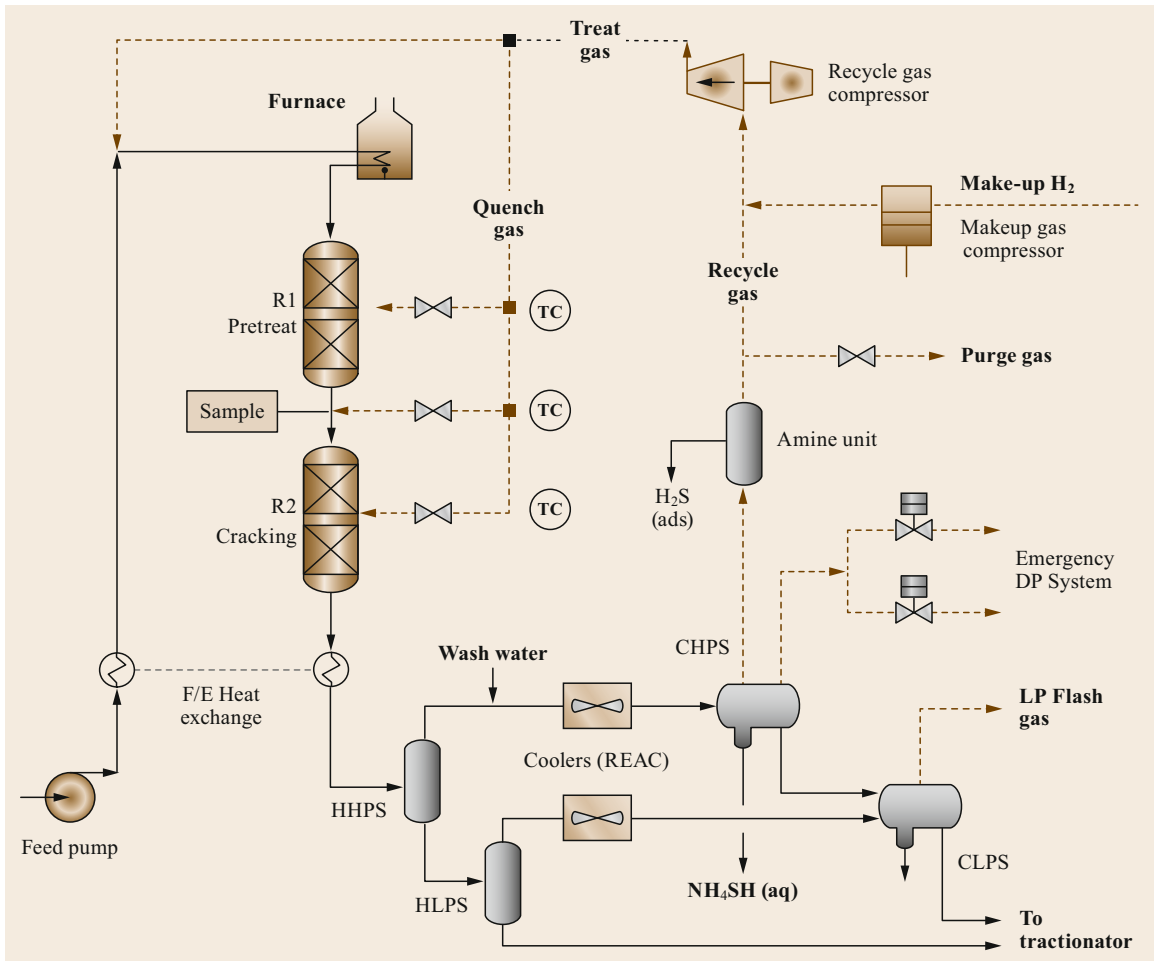

Fig. 1.34 Fixed-bed hydrocracking flow sketch with two reactors, four flash drums, amine unit, and emergency depressuring (EDP). F/E = feed/effluent, TC = temperature controller, HHPS = hot high-pressure separator, HLPS = hot low-pressure separator, CHPS = cold high-pressure separator, and CLPS = cold low-pressure separator. Hydrotreaters seldom include EDP

drogen and flows down through the catalyst-containing reactors. Some units mix hydrogen with oil and heat the mixture, as shown. In others, the hydrogen is heated first and mixed with preheated feed. Upon exiting the reactors, the reaction fluids go through a heat exchanger train to the separators (flash drum). Prior to the cold low-pressure separator, wash water is added to remove NH_3 which reacts with water and H_2S to form aqueous NH_4SH ; the aqueous NH_4SH is drained from the CHPS. The HHPS liquid flows to the HLPS, and then to the fractionator (not shown). The HLPS overhead goes to the CLPS. The CLPS overhead goes to a stripper, and the CLPS liquid goes to the fractionator. The emergency depressuring system, as shown, includes two independent lines. The hydrocracking chapter (Chap. 22) discusses process design in more detail.

Hydrotreating

Hydrotreating removes sulfur, nitrogen, and oxygen from organic sulfur, nitrogen, and oxygen compounds. The hetero atoms are transformed into H_2S , NH_3 , and H_2O , respectively. Under reaction conditions, these remain in the gas phase. But at lower temperatures, the H_2S and NH_3 combine and dissolve in process water to form aqueous ammonium bisulfide (NH_4SH). Ammonia also reacts with chlorides to form NH_4Cl ; chloride can come into the unit with makeup gas, feed, or wash water. These salts may deposit in air coolers and heat exchangers, blocking flow and – even worse – inducing corrosion. Fortunately, they are water-soluble, so they can be controlled by injecting wash water into the reactor effluent.

FCC Feed Pretreating. These days, most refiners pretreat FCC feeds in a fixed-bed hydrotreater. The hydrotreater removes trace metal contaminants such as nickel and vanadium. Nickel increases coke formation and decreases liquid yields. Vanadium reduces conversion, decreases liquid yields, and destroys the catalyst. In addition to removing Ni and V, the pretreater decreases concentrations of sulfur, nitrogen, and aromatics. In the FCC regenerator, sulfur on the coked catalyst is converted to sulfur oxides (SO_x) in the flue gas. Clean air regulations restrict SO_x emissions, which cause acid rain. Therefore, removing sulfur from the FCC feed – thereby reducing SO_x formation in the FCC regenerator – is highly beneficial. Removing nitrogen is beneficial, too, because basic feed nitrogen suppresses the activity of highly acidic FCC catalysts. Pretreating also saturates aromatics. As we have seen, saturating uncrackable aromatics converts them into crackable naphthenes, so pretreating increases FCC conversion, often by more than 10 vol.%.

FCC Gasoline Post-Treating. Conventional hydrotreating does a good job of removing sulfur from FCC gasoline. Unfortunately, it also does a good job of reducing octane by saturating C₆–C₁₀ olefins. In processes such as Prime-G+, offered for license by Axens,

full-range naphtha is split into light and heavy fractions. The light fraction contains most of the high-octane olefins but not much of the sulfur. After diolefins are removed via selective hydrogenation, the light cut is ready for gasoline blending. The heavy fraction contains most of the sulfur but not much of the olefins. It is hydrotreated conventionally. The ConocoPhillips S Zorb process uses selective adsorption to remove sulfur from FCC gasoline. The feed is combined with a small amount of hydrogen, heated, and injected into an expanded fluid-bed reactor, where a proprietary sorbent removes sulfur from the feed. A disengaging zone in the reactor removes suspended sorbent from the vapor, which exits the reactor as a low-sulfur stock suitable for gasoline blending. The sorbent is withdrawn continuously from the reactor and sent to the regenerator section, where the sulfur is removed as SO₂ and sent to a sulfur recovery unit. The clean sorbent is reconditioned and returned to the reactor. The rate of sorbent circulation is controlled to help maintain the desired sulfur concentration in the product.

Fixed-Bed Catalytic Hydrocracking

As with other conversion processes, hydrocracking breaks carbon–carbon bonds, thereby converting heavy hydrocarbons into lighter ones. An integral part of

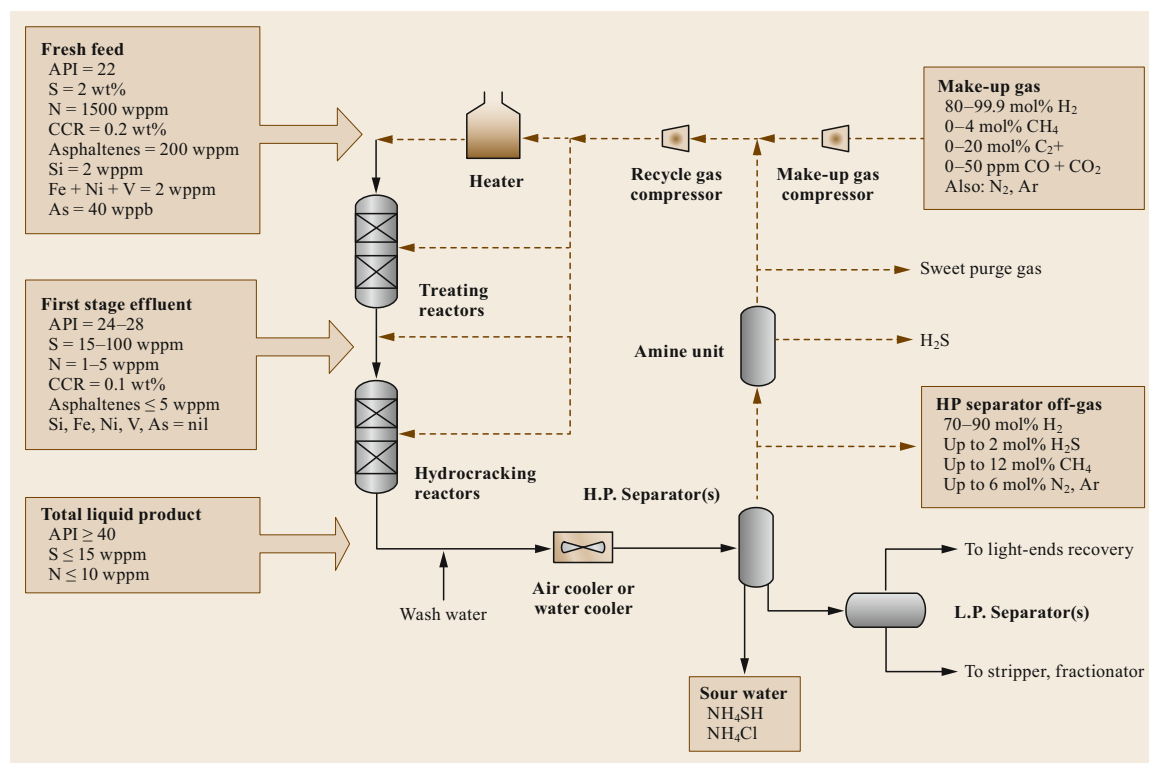

Fig. 1.35 Once-through hydrocracking process flow with selected stream properties

hydrocracking is hydrotreating, which in fixed-bed units removes almost all oxygen, sulfur, nitrogen, and trace elements from the feed before it reaches the cracking catalyst. Organic nitrogen poisons acidic cracking sites, so its removal is essential. Along the way, hydrocracking also isomerizes *n*-paraffins and saturates olefins and aromatics. With respect to equipment and process flow, fixed-bed hydrocrackers are similar to fixed-bed hydrotreaters.

Figure 1.35 shows a two-reactor once-through hydrocracker with four catalyst beds, along with some typical properties for feed and product streams. Figure 1.36 shows iconic examples of commercial hydrocracker configurations. The purpose of recycling unconverted oil is to increase overall conversion.

As shown in Table 1.19, a fixed-bed recycle hydrocracking unit can have significant product flexibility,

producing either large amounts of C₄-plus naphtha or large amounts of middle distillates in the same unit with the same catalyst, just by adjusting temperatures and cut points. In petroleum refining, this kind of process flexibility is unique.

Ebullated Bed Hydrocracking

In contrast to fixed-bed hydrocrackers, ebullated bed (e-bed) units can process large amounts of residual oils. Catalyst life does not limit these units, because fresh catalyst is added and spent catalyst is removed continuously. In such units, it is impossible to segregate catalysts, so the catalyst accomplishes both hydrotreating and hydrocracking. In e-bed reactors (Fig. 1.37), hydrogen-rich recycle gas is bubbled up through a mixture of oil and catalyst particles. This provides three-phase turbulent mixing, which is needed to ensure

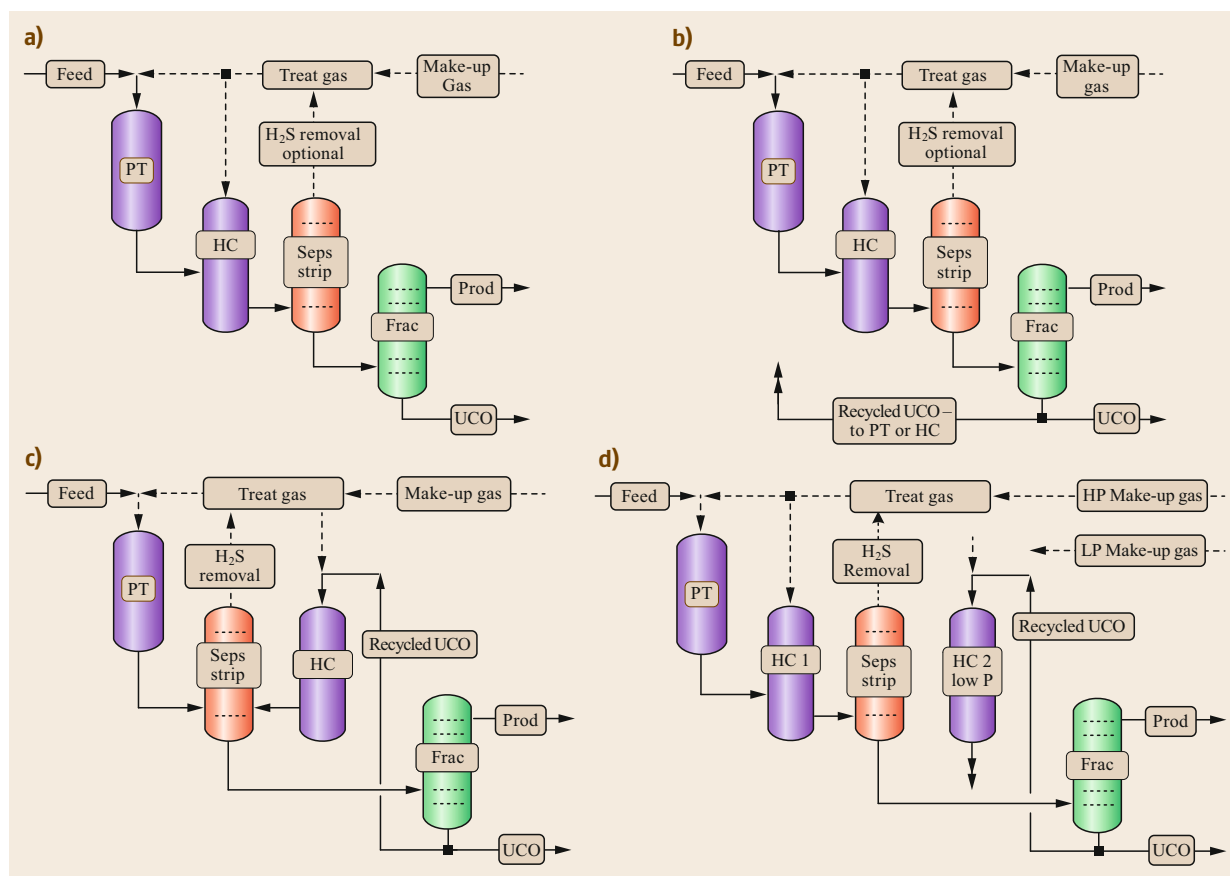

Fig. 1.36a–d Four simplified examples of hydrocracker flow configurations. (a) Once-through. (b) Series flow, in which reactants go directly from the pretreat section to hydrocracking section without intermediate stripping or fractionation, and in which unconverted oil (UCO) is recycled either to the first pretreat (PT) reactor or the first hydrocracking (HC) reactor. (c) Separate pretreat, where the products from the pretreat section are stripped and fractionated before going to the hydrocracking section. (d) Two-stage, in which UCO goes to a 2nd hydrocracking section. Some two-stage units have an independent recycle gas system, and hence can operate at lower pressure in a sweet environment free of H₂S, NH₃, and organic nitrogen

a uniform temperature distribution. The process can tolerate significant differences in feed quality, because in addition to manipulating temperature, operators can change catalyst addition rates. Catalyst consumption is determined by the concentrations of trace metals – particularly Fe, Ni, and V – in the feed.

At the top of the reactor, catalyst is disengaged from the process fluids, which are separated in downstream flash drums. Most of the catalyst is returned to the reactor. Some is withdrawn and replaced with fresh catalyst. When compared to fixed-bed processes, e-bed technology offers the following advantages:

- The ability to achieve more than 70 wt% conversion of atmospheric residue.

- Ample free space between catalyst particles, which allows entrained solids to pass through the reactor without accumulation, plugging, or build-up of pressure drop.
- Better liquid-product quality than delayed coking.

Disadvantages of e-bed technology versus fixed-bed processes include high catalyst attrition, which leads to high rates of catalyst consumption; higher installation costs due to larger reactor volume and higher operating temperatures; and sediment formation. Recent improvements include second-generation catalysts with lower attrition; catalyst rejuvenation, which allows the reuse of spent catalysts; improved reactor design leading to

higher single-train feed rates; and two-reactor layouts with inter-stage separation.

Slurry-Phase Hydrocracking

Slurry-phase hydrocracking can achieve up to 95 wt% conversion of vacuum residue, coal, or coal tar. Reaction temperatures are about 840 °F (450 °C) and pressures range from 2000 to 3000 psig (14 000–20 800 kPa). Slurry-phase hydrocracking employs finely divided solid additives, which are proprietary and not necessarily catalytic. Inside the reactor, the liquid/additive mixture behaves as a single phase due to the small size of the additive particles. The additives prevent bulk coking by providing highly dispersed nucleation sites for *micro coking*. The additive is not recovered. Instead, it ends up in a pitch fraction, which comprises roughly 5 wt% of the feed.

Slurry-phase hydrocracking has several advantages:

- It can achieve up to 95 wt% conversion of vacuum residue. It can also achieve high conversion of coal.
- In two-stage designs, which incorporate fixed-bed hydrotreating and hydrocracking, product quality is excellent.
- Feeds can include vacuum residue, FCC slurry oil, and even coal.
- The additive is low cost and disposable. Due to the micronic size of the additive, it flows like a liquid through the process.
- For a given volume of residue feed, total slurry phase reactor volume is lower than the reactor volume of e-bed processes.

A significant disadvantage is the production of low quality, refractory pitch. At high conversion, the pitch is so poor that it cannot be blended into bunker oil or asphalt; it has been blended with coal, sent to a metals reclaimer, or used in a cement plant as clinker.

LC-MAX Process

The LC-MAX process, developed by Chevron Lummus Global (CLG) and CB&I, is an innovative approach to residue hydrocracking. It combines two stages of LC FINING with solvent deasphalting (SDA). While the overall conversion of VR may be lower than that for slurry hydrocracking, all products, including the asphalt, can be sold conventionally. LC-MAX operates at lower pressures than slurry hydrocracking and therefore is less costly. LC-MAX also is more flexible: the product VGO is stable and can be sold as-is, sent to an FCC unit, sent to a conventional hydrocracking unit, etc.

Catalytic Reforming

The three major process flow schemes for catalytic reforming are:

Fig. 1.37 Ebullated bed hydrocracking process flow

- Semiregenerative
- Cyclic
- Continuous catalyst regeneration (CCR).

Figure 1.38 shows a fixed-bed semiregenerative reformer. Catalyst cycles last from 6 to 12 months. A cycle ends when the unit is unable to meet its process objectives – typically octane number and overall C₅-plus yields. At the end of a cycle, the entire unit is brought down and coke is burned off the catalyst. Desulfurized naphtha is mixed with hydrogen, heated to > 900 °F (> 480 °C), and passed through a series of fixed-bed reactors. The feed is spiked with an organic chloride, which converts to hydrogen chloride in the reactors. This provides the required catalyst acidity and helps minimize catalyst coking.

The major chemical reactions – dehydrogenation and dehydrocyclization – are endothermic and the reactors are adiabatic. Consequently, the temperature drops as reactants flow through a reactor. Between reactors, heat from fired heaters brings the process fluids back to desired reactor inlet temperatures (RIT). The last reactor effluent is cooled and sent to a separator, from which hydrogen-rich gas is recovered. Part of the hydrogen is recycled to the reactors. The remainder –

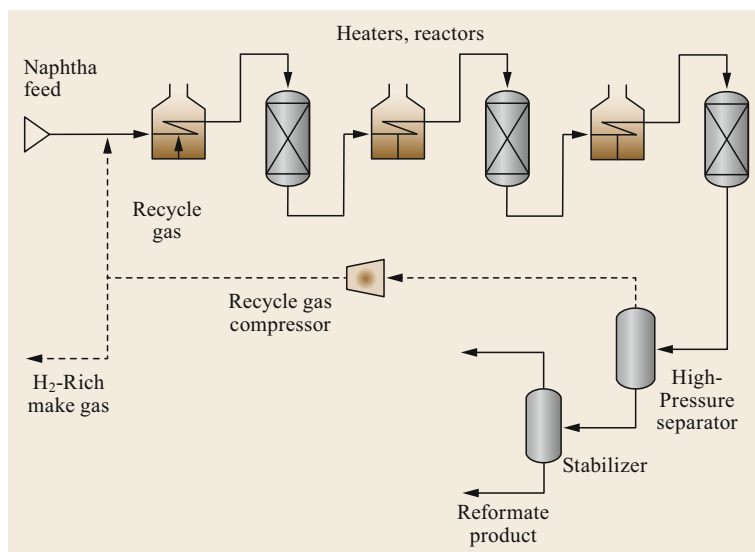

Fig. 1.38 Semiregenerative catalytic reforming process flow

the *net gas* – goes to a hydrogen header for distribution to hydrogen-consuming units. The liquid product flows to a stabilizer column, where entrained gases are removed, before going to the gasoline blender or aromatics plant.

A cyclic reformer has more reactors, and catalyst cycles are shorter, that is, 20–40 h. Shutdowns are staggered so that only one reactor is down at a given time.

The UOP Platforming process, which employed a platinum-based catalyst, was commercialized by UOP in 1949. In 1971, UOP commercialized the CCR Platforming process, shown in Fig. 1.39, which has several advantages. CCR means continuous catalyst regeneration. Hydrotreated feed mixes with recycle hydrogen and goes to a series of adiabatic, radial-flow reactors arranged in a vertical stack. Catalyst flows down the stack, while the reaction fluids flow radially through the catalyst beds. Heaters are used between reactors to reheat the reaction fluids to the required temperature. Flue gas from the fired heaters is typically used to generate steam.

A CCR reforming unit can operate at very low pressure (100 psig, 791 kPa). The low pressure improves yields of aromatics and hydrogen. It also accelerates coke formation, but that is okay in a CCR reformer, because the catalyst is continuously being regenerated.

Isomerization

As mentioned, isomerization units convert *n*-paraffins into isoparaffins and straight-chain olefins into isoolefins. Butane isomerization provides isobutane as the major feed for subsequent alkylation. Pentane/hexane isomerization improves the octane number of light naphtha for gasoline blending.

In butane isomerization, the feed contains *n*-butane, which typically contains some isobutane. The catalyst is highly sensitive to water, so the feed must be thoroughly dried. In the low-temperature first stage, the catalyst comprises aluminum chloride promoted by HCl. Hydrogen gas is added to inhibit olefin and coke formation. In the high-temperature second stage, the catalyst contains a noble metal such as platinum. Temperatures range from 230 to 340 °F (110–170 °C) and pressures range from 200 to 300 psi (14–20 bar). The reactor effluent goes to a flash drum, from which hydrogen is recovered and recycled. HCl is removed in a stripper column. The liquids go to a fractionator (deisobutanizer), which separates unconverted *n*-butane from the isobutane product. The *n*-butane is recycled and mixed with fresh feed.

In the Shell Hysomer process for pentane/hexane isomerization, the feed is combined with hydrogen-rich gas, heated to 445–545 °F (230–285 °C) and routed to the Hysomer reactor at 190–440 psi (13–30 bar). As with fixed-bed hydrotreating and hydrocracking, the process fluids flow down through the catalyst bed, where a part of the *n*-paraffins is converted into branched paraffins. The catalyst is comprised of a noble metal on a zeolite-containing support. The reactor effluent is cooled and sent to a flash drum, which separates hydrogen from the liquid product. The hydrogen is recycled. The liquid is fractionated, and the *n*-paraffins are recycled. The net conversion of *n*-paraffins into branched products can be as high as 97%, and the octane can be boosted by 8–10 numbers.

Often, the heat-exchanger and fractionation systems of isomerization units are integrated with those of other process units, such as catalytic reformers. In the

Fig. 1.39 CCR catalytic reforming process flow

Union Carbide total isomerization process (TIP), C₅/C₆ isomerization was integrated with molecular sieve separation, which provided complete conversion of *n*-paraffins. Other C₅/C₆ isomerization units presently used in the industry include the UOP Penex process, which improves octane ratings from 50–60 to 82–86 or higher.

The CDTECH ISOMPLUS process achieves near-equilibrium conversion of *n*-butenes into isobutylene, and *n*-pentenes into isoamylene over a zeolite catalyst.

Alkylation

During alkylation, an excess amount of isobutane reacts with light olefins such propylene, butylenes, and amylene in the presence of strong acids to form branched chain hydrocarbons. These hydrocarbons, often referred to as alkylate, have high octane values (motor octane number from 88 to 95 and research octane number from 90 to 98), nil benzene, nil olefins, nil sulfur, and low Reid vapor pressures (RVPs), making them an excellent contributor to the gasoline blending pool.

Alkylation employs either hydrofluoric acid or sulfuric acid. The process usually runs at low temperatures to avoid polymerization of the olefins. Temperatures for HF catalyzed reactions are approximately 100 °F (38 °C). For sulfuric acid, they are approximately 50 °F (10 °C). Figure 1.40 describes HF alkylation. HF is dangerous, and extra precautions are taken to ensure that it is always contained.

Both HF and H₂SO₄ require relatively expensive corrosion-resistant equipment. Safety in handling and operations is a major concern for both, which also face disposal issues associated with spent acids and acid-soluble oils. These problems can be diminished by two recently developed breakthrough processes: ionic-liquid alkylation and solid-acid catalyzed alkylation. The former (ionilkylation) was developed by China University of Petroleum – Beijing with PetroChina in

2006. The first commercial unit based on composite ionic liquid alkylation was started up in Dongying, Shandong, China in 2013. In 2016, Honeywell UOP announced commercialization of the ISOALKY process developed by Chevron. The latter (AlkylClean) was developed by CB&I, Albermarle Catalyst and Neste Oil, and the first commercial unit employing Albermarle's AlkylStar catalyst together with CB&I's novel reactor design was started up in Zibo, Shandong, China in 2015 (Chap. 17).

1.11.5 Petroleum Refining Catalysts

Several refining processes require catalysts. A catalyst is a material that facilitates and increases the rate of chemical reactions without being changed itself. Catalysts decrease energy requirements and reduce the size of process equipment.

In practice, catalysts do change as time goes by and more materials are processed. They degrade due to coking, attrition, feed contamination, and/or process upsets. Some catalysts last for years before they have to be replaced. In other processes, such as FCC and CCR catalytic reforming, they are regenerated and reused inside the process during normal operation (Sect. 1.9.3). In the FCC process, degraded catalyst is removed and replaced with fresh catalyst as needed. The chemistry of coke formation on catalysts is presented in Sect. 1.9.3.

Catalysts facilitate reactions by decreasing activation energies. Consider ammonia synthesis

The reaction is favored by thermodynamics, but molecular nitrogen is exceedingly stable due to the strength of the N≡N triple bond. To break the N≡N bond with heat alone requires 3000 °C (5400 °F). Before the catalytic Haber–Bosch process, ammonia was synthesized from

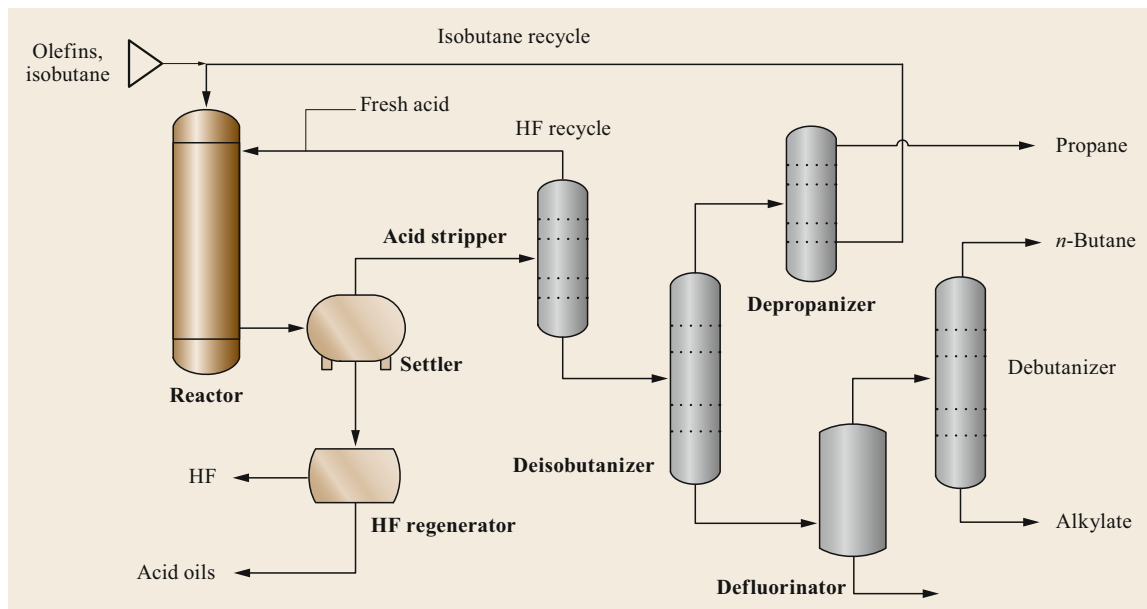

Fig. 1.40 HF alkylation process flow

nitrogen and hydrogen in electric arc reactors, which in essence generate mini-lightning bolts while consuming immense amounts of energy. In catalytic ammonia synthesis, the $\text{N}\equiv\text{N}$ bond is weakened when it adsorbs to the catalyst, allowing it to react with hydrogen at $< 750^\circ\text{F}$ ($< 400^\circ\text{C}$).

Most petroleum refinery catalysts are solids, with active metals supported on high-strength γ -alumina, silica, or aluminosilicates. The major exceptions are HF, H_2SO_4 , and ionic liquid alkylation catalysts, which employ liquid-phase acids. The separation of liquid and vapor products from solids is straightforward, so it is easier to recover the catalysts and regenerate or dispose of them.

FCC and hydrocracking employ solid-acid catalysts, primarily based on synthetic zeolites. Hydrocracking also employs amorphous silica-alumina (ASA) catalysts. Zeolites possess high surface area and high acidity, both of which contribute to their high activity. They also possess a mesopore structure, which affects feed flexibility and product selectivity.

Related materials are used in other processes. For example, metal-promoted silica alumina phosphates such as SAPO-11 are used to isomerize normal paraffins in catalytic dewaxing (CDW) units. Figure 1.41 shows six zeolite structures [1.12]. In cracking catalysts, HY zeolite is the most common, but beta and ZSM-5 are used as well. The building blocks of A, X, and other zeolites are tetrahedral units of Si and Al oxides. In the ultra-stable Y (USY) zeolites employed in cracking catalysts, the Si/Al ratio is > 10 .

The acidity of zeolites (and ASAs) comes from their structure [1.13]. Figure 1.42 shows how one can visualize these materials as a silica (SiO_2) superstructure, in which every so often an aluminum atom replaces a silicon atom. The silicon atoms have a valence of +4, and each one binds to four oxygen atoms.

The oxygen atoms in hydroxyl groups are Brønsted acids (proton donors). Replacing Si (+4) with Al (+3) creates electron-rich Lewis acid sites, which are associated with positive counter-ion such as Na^+ , K^+ , NH_4^+ , or H^+ . The counter ions can be swapped via ion exchange. For example, when Na-Y zeolite is exchanged with an ammonium salt, the Na^+ ion is replaced by NH_4^+ . When $\text{NH}_4\text{-Y}$ is heated to the right temperature, the ammonium ion decomposes, releasing NH_3 (gas) and leaving behind highly acid H-Y zeolite. A typical Si/Al ratio for a zeolite with high cracking activity is about 5. In hydrocracking catalysts with less activity but greater selectivity for production of middle distillates, the Si/Al might be about 30.

ZSM-5 is a shape-selective zeolite made by including a soluble organic template in the mix of raw materials. (Templates for this kind of synthesis include quaternary ammonium salts.) ZSM-5 enhances distillate yields in FCC units and CDW in hydroprocessing units, where due to its unique pore structure, it selectively cracks waxy *n*-paraffins into lighter molecules.

The ASA catalysts used for hydrocracking are less active, but they do a better job of converting straight-run VGO into diesel with minimal co-production of naphtha and lighter products. Figure 1.43 provides

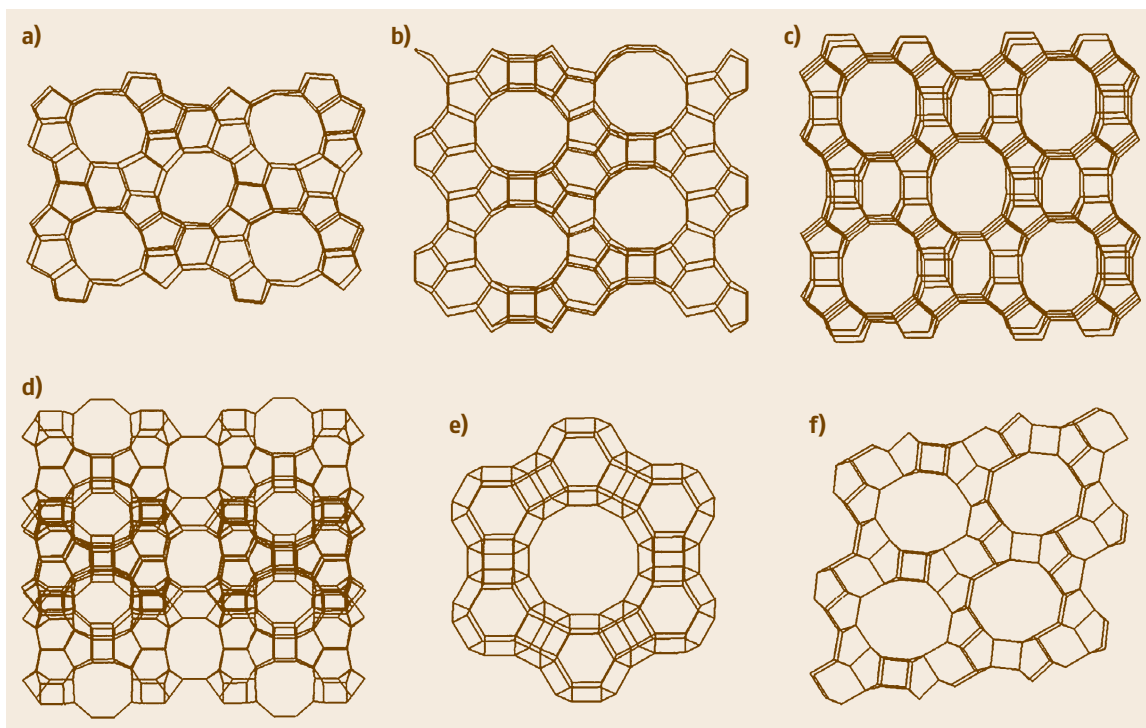

Fig. 1.41a–f Structures of zeolites ZSM-5 (a), mordenite (b), beta (c), MCM-22 (d), zeolite Y (e), and zeolite L (f)

a conceptual comparison of amorphous ASA catalysts with crystalline zeolite catalysts. The pore diameters of HY zeolite catalysts are uniform and relatively small – around 7.5 Å, give or take. Mesopores have larger diameters, which admit mid-sized molecules such as those found in vacuum gas oils. ASA catalysts include small, medium, and large pores. The width of ASA pores can exceed 100 Å. The larger pores can accommodate larger molecules. This explains why ASA catalysts do a better job of cracking feeds with very high endpoints. The pore diameter for ZSM-5 is 6.3 Å.

FCC Catalysts and Additives

Finished FCC catalysts are powders with the consistency of sifted flour. They are given their final form by spray drying, in which a slurry of catalyst components is converted into a dry powder by spraying into hot air. The method gives a consistent particle size distribution. The particles are roughly spherical, with bulk densities of 0.85–0.95 g/cm³ and average diameters of 60–100 μm.

The catalysts include four major components – one or more *zeolites* (up to 50%), a *matrix* based on non-crystalline alumina, a *binder* such as silica sol, and a clay-based *filler* such as kaolin. The zeolite is ultra-stable (US) H-Y (faujasite) or very ultra-stable (VUS) H-Y. The extra stability is provided by de-alumination

Fig. 1.42 Brønsted (B) and Lewis acid sites (L) in zeolites and ASAs

with hydrothermal or chemical treatment. The H-Y zeolite is sometimes augmented with ZSM-5 to increase propylene yield. To provide thermal stability and optimize the relative amounts of different active sites, a mixture of rare earths (RE) is incorporated into the zeolite structure by ion exchange. A lanthanum-rich mixture of RE oxides is added to provide thermal stability. The RE mixture can contain up to 8 wt% ceria, and up to 80% La₂O₃, up to 15 wt% Nd₂O₃, with traces of other RE.

Other components can be part of the core catalyst or introduced as external additives. The extra components can provide NO_x and/or SO_x reduction. Noble metal combustion promoters enhance the conversion of CO to CO₂ in the regenerator.

Catalysts for Fixed-Bed Reactors

Fixed-bed catalysts are shaped into spheres, cylinders, hollow cylinders, lobed extrudates, or pellets. Some look like small dog biscuits as shown in Fig. 1.44.

Fig. 1.43 Schematic comparison of amorphous alumina silica (ASA) and zeolite structures

Fig. 1.44 Catalyst loading scheme showing size/shape grading. Photo used with kind permission from Haldor Topsoe, Inc.

A cross-section of a lobed extrudate can look like a three-leaf or four-leaf clover without the stem. Compared to cylindrical extrudates, shaped extrudates have a higher surface-to-volume ratio, and the average distance from the outside of a particle to the center is shorter. This increases activity by decreasing the average distances traveled by molecules to reach active catalyst sites. To make extrudates, a paste of support material is forced through a die. The resulting spaghetti-like strands are dried and broken into short pieces with a length/diameter ratio of 2–4; for main-bed hydrotreating catalysts, diameters range from 1.3 to 4.8 mm. The particles are calcined, which hardens them and removes additional water and volatile molecules such as ammonia.

Spherical catalysts are made in one of several ways, including:

1. Spray-drying slurries of catalyst precursors
2. Spraying liquid onto powders in a tilted rotating pan
3. Dripping a silica–alumina slurry into hot oil. FCC catalysts are made by spray drying.

Pellets are made by compressing powders into dies.

Impregnation distributes active metals within the pores of a catalyst support. Like sponges, calcined supports are especially porous. Far more than 99% of the surface area is inside the pores. When the pores are exposed to aqueous solutions containing active metals, capillary action pulls the aqueous phase into them. After drying, the catalyst might be soaked in another solution to increase the loading of the same (or a different) active metal. Catalysts can also be made by co-mulling active metal oxides with the support. Co-mulling tends to cost less because it requires fewer steps. It also pro-

duces materials with different activities – sometimes higher, sometimes lower – than impregnation.

Eventually, refinery catalysts deactivate and must be replaced. The major causes of deactivation are process upsets, feed contaminants (trace metals, particulates, etc.) and catalyst coking; the latter is discussed above in some detail. In FCC, CCR processes, and

ebullated-bed hydrocracking, aged catalysts are continuously removed and replaced with fresh. But in fixed-bed units, catalyst replacement requires a shutdown. For a 40 000 bbl/day hydrocracker with an upgrade value of \$15–20/bbl, every day of down time costs \$600 000–800 000. Lost production during a 4-week catalyst changeout can amount to \$18–24 million.

1.12 Petroleum Products

Products from modern refineries comprise several individual streams, which are blended to meet specific requirements. Boiling ranges and carbon numbers for common petroleum products are summarized in Table 1.20. The values shown can vary from locale to locale, from refinery to refinery, and from season to season.

Developing petroleum product specifications involves cooperation between stakeholders, including equipment manufacturers, consumers, petroleum product suppliers, government agencies, environmental groups, and others. Specifications and test methods are published by ASTM International, the International Organization for Standardization (ISO), the European Union, Japanese Industrial Standards (JIS), and others. Many tests are developed by process licensors. For example, UOP's *Laboratory Test Methods* defines several hundred procedures for analyzing catalysts, chemicals, and fuels.

Table 1.21 lists some ASTM fuel specifications. Recent low-sulfur gasoline and diesel directives from the

US Environmental Protection Agency are incorporated into D975 and D4814, respectively.

Additives are essential components of finished fuels. They increase stability, improve flow properties, enhance performance, and reduce environmental impact. Cetane improvers are routinely added to diesel fuel, and additives that prevent intake-valve deposits are now required in all grades of gasoline in the United States.

1.12.1 Petroleum Gases

Methane, the main hydrocarbon ingredient of natural gas, is produced by certain refinery processes. It can be used as a refinery fuel and feedstock for hydrogen production by pyrolytic cracking and reaction with steam in SMR. Ethane is used as refinery fuel or as feedstock to produce hydrogen and ethylene, which is an important petrochemical. Propane is used as refinery fuel or as feedstock for propylene manufacturing. Liquefied refinery propane is called LPG (liquefied petroleum

Table 1.20 Boiling ranges and carbon numbers for petroleum distillates. Values vary seasonally and geographically

Product	Carbon number range	Boiling range (°C)	Boiling range (°F)	Primary uses
RFG (refinery fuel gas)	C ₁ and C ₂			Fuel
LPG (liquefied petroleum gas)	C ₃ (with some C ₄)			Fuel
Butanes, butenes	C ₄	–12 to –0.5	10–31	Fuel, chemicals, gasoline
Light naphtha	C ₅ (with some C ₄ and C ₆)	9–38	48–100	Gasoline, chemicals
Heavy naphtha	C ₇ –C ₁₂ (with some C ₆)	38–205	85–400	Gasoline, avgas, chemicals
Kerosenes	C ₉ –C ₁₈	180–280	300–540	Jet fuel, avgas, home heating
Gas oils	C ₁₆ –C ₂₆	121–370	250–700	Diesel fuel, fuel oil
Vacuum gas oils	C ₂₄ –C ₆₀	343 to > 593	650–1100	Fuel oil, lubricants
Residue	> C ₆₀	> 565	> 1050	Lubricants, asphalt, coke

Table 1.21 ASTM specification numbers for hydrocarbon fuels

Product	ASTM specification	Description
Gasoline	D4814	Standard specification for automotive spark-ignition engine fuel
Jet fuel	D1655	Standard specification for aviation turbine fuels
Kerosene	D3699	Standard specification for kerosene
Diesel	D975	Standard specification for diesel fuel oils
Fuel oil	D396	Standard specification for fuel oils

gas). LPG, which also contains minor amounts of butanes, can be used by other industries and domestic applications. Butanes can be blended into gasoline for regulating vapor pressure and promoting better starting in winter or cold weather areas.

Limited amounts of *n*-butane can be blended into gasoline or LPG. Significant amounts serve as feedstock to produce isobutane in isomerization units. Isobutane goes primarily to alkylation units, where it reacts with C₃–C₅ olefins to produce high-octane isoparaffins (isomerate) for gasoline blending. Isobutane is also converted into isobutylene for making polyisobutylenes, MTBE, ethyl tertiary butyl ether (ETBE), and various grades of butyl rubbers including chlorobutyl and bromobutyl rubbers for the tire industry.

1.12.2 Gasoline

Since the birth of modern automobile in 1886, the demand for gasoline to fuel automobiles with internal combustion engines has increased dramatically. The rate of the increase jumped in 1908, when the advent of the Model T made autos affordable for average people. It is estimated that the number of automobiles in the world exceeded 1 billion around 2010.

The typical boiling range of gasoline is from 100 °F (≈ 40 °C) to 400 °F (≈ 205 °C). The components have carbon numbers ranging from C₅ to C₁₂.

Octane and RVP

In a spark-ignition engine, some compounds start to ignite before the piston reaches the top end (highest compression ratio) near the spark plug. This premature ignition causes knocking, which reduces the power of the engine, increases engine wear, and can cause serious damage. Octane number or octane rating is a measure of the tendency of a fuel to knock. It is based

on a scale in which the octane number of *n*-heptane is designated as zero and the octane number of isooctane (2,2,4-trimethylpentane) is 100. When a fuel is tested in a standard single-cylinder engine, mixtures of isooctane and *n*-heptane of various percentages are used as reference standards for comparing the knocking of the test fuel with the percentage of isooctane in the mixture. ASTM D2699 and ASTM D2700 describe methods for measuring research octane number (RON) at 600 rpm to simulate low speed or city driving with load conditions and motor octane number (MON) at 900 rpm to simulate high-speed highway driving conditions.

In North America, the posted octane of gasoline is the arithmetic average of RON and MON: (R+M)/2. This is the number displayed on pumps at filling stations. Typical grades are *regular* with a posted octane of 87, *mid-grade* with a posted octane of 89, and *premium* with a posted octane of 91–93. In some locales, customers can dial in any octane they want between 87 and 93.

Another important property of gasoline is Reid vapor pressure (RVP) which is the vapor pressure of a motor gasoline measured at 100 °F in a volume of air four times the liquid volume. RVP indicates the ease of starting and vapor-lock tendency as well as explosion hazards and evaporation losses.

Gasoline Blend Stocks

Several refinery streams have the right vapor pressure, boiling range, sulfur content, and octane to end up in the gasoline pool. Table 1.22 shows properties for blend stocks from which gasoline might be made. Finished gasoline must have the proper octane while meeting RVP requirements. The octane of a particular grade is constant, but RVP requirements are seasonal.

In the summer, when outdoor temperatures can exceed 100 °F (38 °C), the RVP of gasoline must be low to avoid over-pressure in gasoline tanks, causing

Table 1.22 Gasoline blend stock composition and properties (after [1.82])

Component	API Gravity	RVP (psi)	Boiling range		RON	MON
			(°C)	(°F)		
<i>n</i> -Butane		52.0	−0.5	30	92.0	93.0
Light straight-run gasoline	78–79	11.0	30–80	85–176	61.6	66.4
Heavy straight-run gasoline	48	1.0	85–205	185–400	58.7	62.3
Light isomerate	80	13.5	30–80	85–176	81.1	83.0
Reformate	41–46	2.2–2.8	78–197	160–400	100.5	89.5
Hydrotreated FCC light gasoline	49.3	5.0	C ₆ –93	C ₆ –200	74.0	86.0
Hydrotreated FCC heavy gasoline	48.5	0.5	C ₅ –93	300–400	81.0	90.0
Alkylate, polymer gasoline	74	4.6	85–95	185–205	93.0	94.5
Ethanol	47.8	18.0	78	173	116.0	112.0
TAME ^a	53.5	1.5	86	187	112.0	98.0
MTBE ^b	59.7	8.0	55	134	115.0	97.0

^a *t*-Amyl methyl ether, ^b methyl-*t*-butyl ether. So-called polymer gasoline comes from oligomerization of C₃ and C₄ olefins.

vapor lock during ignition, and to limit hydrocarbon emissions; hydrocarbons react in the atmosphere with nitrogen oxides to produce ozone, a noxious component of photochemical smog. Summer RVP must be less than 6.9 psi in California; in urban areas along the east coast from Virginia to New Hampshire; and near Houston, Dallas, Chicago, and St. Louis. In other urban areas, the limit ranges from 7.0 to 7.8, and in most rural areas, the limit is 9.0. Summer RVP limits last from May 1 to September 15 for refineries and terminals, and from June to September 15 at filling stations; in California, switch-over dates start earlier and last longer. As weather gets colder, RVP must be higher; otherwise, engines might not start. Permissible winter RVP can reach 15 psi in especially cold and/or high-altitude areas.

A typical summer RBOB (reformulated gasoline before oxygenate blending) might contain 40% FCC gasoline, 25% straight run naphtha, 15% alkylate, 18% reformate, 0–2% butanes, and 0–2% other. During the winter, the butane content can be higher [1.83].

Aviation Gasoline

Gasoline used for piston-engine-powered aircraft is called aviation gasoline, or avgas, which has high octane number and low flash point to improve ignition characteristics on propeller aircraft. The flash point is the lowest temperature at which a liquid gives off enough vapor to ignite when an ignition source is present. As mentioned in the jet-fuel section, avgas can mean either Jet B or JP-4.

Gasoline Additives

A finished gasoline contains the base blend and small amounts of additives for corrosion inhibition, lubrication, and cleaning. Typical additives include metal deactivators, corrosion inhibitors, antioxidants, detergents, demulsifiers, anti-icing additives and oxygenates.

Table 1.23 lists additives used to prepare finished gasoline. Additive packages vary from season-to-season, region-to-region, and retailer to retailer. Aftermarket additives contain similar types of ingredients, and are more concentrated. They are packaged to be added by consumers to the gasoline in individual vehicles.

Reformulated Gasoline (RFG) in the United States

In the mid- to late twentieth century, making gasoline was a relatively simple task. If a mixture of components met specifications for volatility and octane, it could be shipped to retail outlets and sold as-was. If the octane was low, the problem could be fixed by adding a small amount of tetraethyl lead (TEL). Butanes could

Table 1.23 Additives used in gasoline

Additive type	Function
Oxygenates	Decrease emissions
Anti-oxidants	Minimize oxidation and gum formation during storage
Detergents	Clean fuel injector and minimize carbon deposit
Metal passivators	Deactivate trace metals that can accelerate oxidation
Corrosion inhibitors	Minimize rust and corrosion throughout the gasoline supply chain
Demulsifiers	Prevent the formation of stable emulsion
Anti-icing additives	Minimize ice in carburetors during cold weather
IVD control (detergent)	Control deposition of carbon on intake valves
CCD control	Control deposition of carbon in combustion chambers

be added or left out as needed to adjust volatility, especially during winter time or cold weather.

In 1970, gasoline blending became more complex. The US Clean Air Act required the phase-out of TEL because of its cumulative neurotoxicity and its damaging effect on catalytic converters, so refiners had to find other ways to provide octane. Regulations in other developed countries soon followed suit.

In 1990, the Clean Air Act (CAA) was amended. It empowered EPA to impose emissions limits on automobiles and to require reformulated gasoline (RFG). RFG was implemented in several phases. The Phase I program started in 1995 and mandated RFG for 10 large metropolitan areas. Several other cities and four entire States joined the program voluntarily. In the year 2000, about 35% of the gasoline in the United States was reformulated. Almost all US gasoline is now reformulated.

US Tier 1 reformulated gasoline regulations required a minimum amount of chemically bound oxygen, imposed upper limits on benzene and Reid vapor pressure (RVP), and ordered a 15% reduction in volatile organic compounds (VOC) and air toxics. VOC react with atmospheric NO_x to produce ground-level ozone. Air toxics include 1,3-butadiene, acetaldehyde, benzene, formaldehyde, and others.

The regulations for US Tier 2 gasoline, which took force in January 2000, were based on the EPA complex model, which estimates exhaust emissions for a region based on geography, time of year, mix of vehicle types, and – most important to refiners – fuel properties. As of 2006, the limit on sulfur in the gasoline produced by most refineries in the United States was 30 wppm. Tier 3 vehicle emission and fuel standards lowered the allowed sulfur content of gasoline to 10 wppm, beginning in 2017.

Oxygenates in Gasoline

In the United States, reformulated gasoline must include chemically bound oxygen. Initially, the oxygen could be supplied as ethanol or C₅–C₇ ethers. The most common were MTBE and *t*-amyl methyl ether (TAME). MTBE and TAME have excellent blending octanes and low vapor pressures. But due to leaks from filling station storage tanks, MTBE was detected in ground water samples in New York city, Lake Tahoe, and Santa Monica, California. In 1999, the Governor of California issued an executive order requiring the phase-out of MTBE. Eventually, ether blending was banned nationwide.

MTBE and ETBE still serve as high-value gasoline blend stocks in Europe, where ground water contamination is prevented by ensuring that tanks do not leak.

Now in the United States, ethanol must be added to automotive gasoline. In Brazil, obtaining fuel ethanol from sugar cane has been a highly successful, energy-efficient alternative to gasoline [1.84]. But in the United States, almost all fuel ethanol comes from American corn. All things considered, obtaining ethanol from corn is far less energy efficient than obtaining ethanol from sugar cane. According to one report [1.85], the energy balance for sugar cane ethanol is roughly four times greater than the balance for corn-based ethanol; energy balance is the difference between the energy expended to convert a crop into ethanol and the energy produced from burning the ethanol and flammable by-products such as corn stover. Getting ethanol from corn is more complicated. The starch in corn is first converted by enzymes into dextrose, which is then fermented by yeast into ethanol and CO₂. In contrast, the sucrose in sugar cane can be fermented directly. Land use is less for sugar cane ethanol. On average, an acre of sugar cane produces about twice as much ethanol as an acre of corn.

As a component of US gasoline, ethanol has some advantages. Its blended octane is high, and the corn ethanol requirement increases employment and farm income in corn-growing states. On the other hand, its high RVP reduces or even eliminates the blending of butane into gasoline. During the summer in urban areas, even pentane blending is limited by the ethanol requirement. It may or may not decrease American dependence on imported oil.

But ethanol in gasoline has significant disadvantages:

1. Ethanol increases the solubility of water in gasoline and also increases the solubility of polar hydrocarbons, additives, and lubricants in water. Spills of ethanol-containing gasoline are more likely to

introduce hydrocarbons into ground water. Water-contaminated gasoline is more likely to freeze, so aviation gasoline is exempted from the ethanol mandate.

2. Older motors are constructed with parts that degrade faster when exposed to ethanol.
3. The United States uses up to 45% of its corn crop to make fuel ethanol [1.86]. This has increased food costs, not just in the United States but also globally.
4. Water-use efficiency for corn ethanol production is improving dramatically [1.87], but the ethanol industry continues to impact ground-water levels, notably in the Ogallala aquifer, which spans eight Great Plains US states.
5. US Midwest farmers fertilize their fields extensively with ammonia, which reacts with air to form N₂O, a potent greenhouse gas. The ammonia is manufactured from hydrogen and nitrogen with the Haber–Bosch process; including the burning of natural gas to provide heat and steam for the process, making one ton of hydrogen produces up to 10 t of CO₂.

Butanol is a potential alternative to ethanol. Its heat content (i. e., fuel economy) is higher than for ethanol and only slightly less than conventional gasoline. Due to lower water solubility, butanol does not damage engines and has less tendency to separate polar additives from gasoline. It can be used directly as fuel without modification of vehicles designed for use with gasoline.

Gasoline (Petrol) in the EU

Transportation fuel specifications in the European Union are described by EN 228, *Specification for unleaded petrol (gasoline) for motor vehicles* (Table 1.24).

EU gasoline is cleaner than US EPA gasoline, it is easier to manufacture and regulate, and the allowed sources of oxygen are based on science rather than politics.

1.12.3 Naphtha

Light naphtha (LN) includes primarily C₅ and C₆ molecules and boils between 30 and 85 °C. The upper boiling point is lower if a refiner wishes to exclude benzene, which boils at 80 °C. Benzene is an air-toxic molecule, so its concentration in gasoline is limited to 1%. However, it is a valuable chemical and often undergoes purification in downstream units.

Heavy naphtha (HN) can include C₆–C₁₂ molecules. It boils between 80 and 210 °C. To exclude benzene and all other C₆ molecules, the initial boiling point is raised to 85 °C. Most HN goes to catalytic reforming or isomerization units.

Table 1.24 Specifications for unleaded petrol (gasoline) for motor vehicles in the EU (EN228)

Parameter	Limit
Octane	
RON (min)	95
MON (min)	85
Vapor pressure (kPa)	60.0 ^a
Volatility	
Vaporized at 100 °C (%)	46
Vaporized at 150 °C (%)	75
Hydrocarbon types	
Olefins	18 vol.% max
Aromatics	35 vol.% max
Benzene	1 vol.% max
Oxygen	3.7 wt%. Sources can include alcohols (with stabilizing agents) and ethers such as MTBE and ETBE
Sulfur	10 pmw max

^a Equivalent to RVP = 8.7 psi

Naphtha-range products – including reformates, isomerates, and alkylates – are high-octane gasoline-blend stocks. Straight-run naphtha is employed as a diluent in the bitumen mining industry, and as feed-stock for producing olefins via steam cracking. Naphtha serves as a solvent for paints, dry-cleaning, cutback asphalt, industrial extraction processes, and in the rubber industry.

1.12.4 Diesel

A diesel internal combustion engine uses heat from adiabatic compression to ignite a fuel/air mixture inside a piston. Wide-range diesel fuel boils between 150 and 410 °C (330–770 °F), and includes molecules with carbon numbers ranging from 8 to 21. The boiling range of automotive diesel is narrower, typically from 180 to 356 °C (365–680 °F). The initial boiling point is set by the flash point, which must be greater than 55 °C. The flash point corresponds to an initial true boiling point (TBP) of about 180 °C (356 °F). The upper distillation limit can be set by one of several properties. For Euro V diesel, the ASTM D86 95% boiling must be less than or equal to 360 °C (680 °F). This corresponds to a TBP final boiling point between 370 and 380 °C, depending on the nature of the blend components of the fuel and the other properties listed below.

Cetane Number and Cetane Index

The ignition quality of diesel fuels is related to cetane number, which is measured relative to standard mixtures of *n*-hexadecane (cetane), with a defined

cetane number = 100, and isocetane (2,2,4,4,6,8,8-heptamethylnonane), with a defined cetane number = 15. Previously, the low end of the scale was set by α -methyl naphthalene, with a defined cetane number = 0. Isocetane is preferred because it is less expensive and safer to handle.

Table 1.25 lists cetane numbers for selected pure compounds. As with octane, blended cetane numbers can differ significantly from those for pure compounds. Roughly speaking, there is an inverse, non-linear correlation between octane number and cetane number.

Cetane index is a number calculated from the average boiling point and specific gravity of diesel fuels. The results of cetane index calculations correspond to the results of cetane number measurements, but cetane index does not require an expensive engine test. Diesel engines can operate with fuels having cetane numbers between 40 and 55. For Euro V diesel, the minimum cetane *index* is 46 and the minimum cetane *number* is 51. The cetane number can be as high as 60 in premium diesel fuel (No. 1 diesel). Due to its higher heat content, the fuel economy of diesel is better than that for gasoline.

Other Important Diesel Fuel Properties

Other important diesel-fuel properties include flash point, cloud point, pour point, kinematic viscosity, lubricity – and of course sulfur. Cloud point and pour point indicate the temperatures at which the fuel tends to thicken and then gel in cold weather. In a diesel engine, viscosity not only measures the tendency of a fluid to flow but also indicates how well a fuel atomizes in spray injectors. Lubricity measures the fuel's quality as a lubricant for the fuel system, where it reduces friction between solid surfaces in relative motion. It indicates how the engine will perform when loaded.

Specifications for Euro V automotive diesel, as defined by EN 590, are presented in Table 1.26.

Diesel fuels used in railroad locomotives can have higher boiling final boiling points – up to 400 °C (752 °F) and lower cetane number (in the 1930s). Marine diesel oil contains some heavy fuel oil, unlike regular diesel fuels. Marine bunker fuels sometimes contain waste products such as used motor oil.

Diesel Additives

Diesel additives may contain a cetane number improver, such as alkyl nitrate, a lubricity agent, detergents to clean the fuel injectors and minimize carbon deposits, dispersants, and metal deactivators. Table 1.27 lists the common diesel additives and the reasons they are used.

Table 1.25 Cetane numbers for selected pure compounds

Compound	Type	Carbons atoms	Formula	Cetane No.
<i>n</i> -Decane	Paraffin	10	C ₁₀ H ₂₂	76

1.12.5 Kerosene and Jet Fuel (Turbine Fuel)

Prior to the invention of automobiles, kerosene for lighting and fuel oil for ships were the most marketable products of petroleum. Today, while a small amount of kerosene is burned in lamps, most of it is consumed in domestic heaters or furnaces and in jet engines [1.88]. Significant amounts are used as solvents for greases and insecticides.

At the front of a jet engine, a turbine sucks in air with a fan. The pressure of the air is raised by a compressor, which is powered by a turbine. Fuel is injected, and the air/fuel mixture is burned, generating exhaust gases that push through the fans of the turbine and exit through a nozzle at the back of the engine. As the jets of gas shoot backward, the aircraft is propelled forward. Turbine engines can operate with a wide range of fuels. Fuels with higher flash

Table 1.27 Diesel fuel additives

Additive type	Function
Anti-oxidants	Minimize oxidation and gum formation during storage
Cetane improver	Increase cetane number
Dispersants	Improve behavior in fuel injectors for cluster/aggregate formation
Anti-icing additives	Minimize ice formation during cold weather
Lubricity agent	Compensate for poor lubricity of severely hydrogenated diesel fuels
Detergents	Control deposition of carbon in the engine and clean fuel injector
Injector cleanliness agents	Clean deposits from fuel and lubricant
Metal passivators	Deactivate trace metals (e.g., Cu, Fe) that can accelerate oxidation
Smoke suppressants	Reduce black smoke from incomplete combustion
Corrosion inhibitors	Minimize rust throughout the diesel fuel supply chain
Cold-flow improver	Improve flow characteristics in cold weather
Demulsifiers	Allow fuel and water to separate
Stabilizers	React with weakly acidic components
Biocides	Kill bacteria in fuel system that cause clogging

points are less flammable and safer to transport and handle.

Kerosene, jet fuel, and turbine fuel have similar boiling ranges. The key product properties are flash point, freezing point, sulfur content, and smoke point. The freezing point is especially important at high altitudes where the outside temperature is very low. If jet fuel freezes, it cannot be pumped to the engine(s). Without functioning engines, airplanes cannot fly. The sulfur content is important, because sulfur compounds induce corrosion.

Originally, smoke point was a measurement of fuel quality in kerosene lamps. To get more light from a flat-wick lamp, one can turn a knob to lengthen the wick. But if the wick is too high, it gives off smoke. Per ASTM D1322, smoke point is the maximum height of smokeless flame that can be achieved with a calibrated wick-fed lamp, using a wick of *woven solid circular cotton of ordinary quality*. The smoke point of a test fuel is compared to reference blends. A standard 40 vol.%/60 vol.% mixture of toluene with 2,2,4-trimethylpentane has a smoke point of 14.7, while pure 2,2,4-trimethylpentane has a smoke point of 42.8. Clearly, isoparaffins have better smoke points than aromatics.

The primary sources of jet fuels are hydrotreated straight-run kerosene from an atmospheric distillation

unit and hydrocracker products with the right volatility. The boiling range specifications for different jet fuels are shown in Table 1.28. Military jet-fuel grades are designated with JP followed by a number, where JP stands for jet propellant. Civil grades are designated with *Jet* followed by a letter.

JP-1 was specified for military jets in 1944. It was pure kerosene, having a freezing point of -60°C . JP-2 and JP-3 also were developed during World War II; all three are obsolete today. JP-2 had higher freezing point and JP-3 had higher volatility than JP-1.

JP-4 is a present-day wide-cut fuel with a carbon number range of $\text{C}_4\text{--C}_{16}$, for broader availability. JP-5 is specially blended kerosene. JP-6 has a higher end-point than JP-4 with fewer impurities. JP-7 is used in supersonic jets requiring high flash point. JP-8 is kerosene similar to the Jet A-1 fuels used in civilian aircraft.

For civilian jet fuels, Jet A and Jet A-1 are kerosene-type jet fuels. The primary physical difference between the two is freeze point. Jet A has been used in the United States since the 1950s. Today, specifications for Jet-A and Jet A-1 are the same as those published by the International Air Transport Association (IATA). The freezing points of Jet A and Jet A-1 are -40 and -47°C , respectively. Both have minimum flash points of 38°C (100°F) with autoignition temperatures of 210°C (410°F). Both have a carbon number distribution between 8 and 16, similar to JP-8.

Jet B, also called aviation gasoline, is a lower-boiling fuel used for its enhanced cold-weather performance. Naphtha-type jet fuel has a carbon number distribution between 5 and 15, similar to JP-4.

Jet fuel additives include antioxidants, which are usually based on alkylated phenols to prevent gumming, antistatic agents such as dinonylnaphthylsulfonic acid to dissipate static electricity and prevent sparking, corrosion inhibitors, fuel system de-icing agents, biocides to remediate microbial growth in the fuel system, and metal deactivators to remediate deleterious effects of trace metals on the thermal stability of the fuel.

Table 1.28 lists specifications for common turbine fuels.

1.12.6 Heating Oils and Fuel Oils

Both heating oil and fuel oil are liquid petroleum products burned in furnaces or boilers to heat buildings or in generators to produce power [1.89].

No. 1 fuel oil is a volatile distillate similar to kerosene, but with higher pour points and end points. It is intended for vaporizing pot-type burners. It has a carbon number range of 9–16. No. 2 fuel oil is similar to

Table 1.28 Turbine fuel specifications

Specification	Jet A	Jet B	JP-4	JP-5	JP-8
Flash point, min (°C)	38	–	–	60	38
Freeze point, max (°C)	–40 (Jet A) –47 (Jet A-1)	–50	–58	–46	–47
API gravity	37–51	45–57	45–57	36–48	37–51
Distillation, °C					
10% max	205	–	–	205	205
20% max	–	145	145	–	–
50% max	–	190	190	–	–
90% max	–	245	245	–	–
EP	300	–	270	290	300
Sulfur, wt% max	0.3	0.3	0.4	0.4	0.3
Aromatics, vol.% max	22	22	25	25	25
Olefins, vol.% max	–	–	5	5	5

No. 1 but can contain cracked stocks; it has a carbon number range of 10–20. No. 3 fuel oil is for burners requiring low viscosity heating oil; it is merged with No. 2 in specifications. No. 4 fuel oil is usually a light residual oil used in a furnace that can atomize the oil and is not equipped with a preheater. It has a carbon number range of 12–70. No. 5 fuel oil has higher viscosities than No. 4, requires preheating to 170–220 °F (≈ 76 –104 °C) for atomizing and handling, and has a carbon number range of 12–70. It is also known as Bunker B fuel oil. No. 6 fuel oil is a high viscosity residual oil that requires preheating to 220–260 °F (≈ 104 –126 °C) for storage, handling and atomizing. No. 6 has a carbon number range of 20–70. It is specified by navy as Bunker C oil for ships.

Marine Diesel Oils

The fuel oils used in marine diesel engines have different classifications. Marine gas oil (MGO) is made from distillates only. It is roughly equivalent to No. 2 fuel oil. Marine diesel oil (MDO) is a blend of heavy gas oil that may contain very small amounts of black refinery fuel oil stocks, but needs not be heated for use in internal combustion engines. Intermediate fuel oil (IFO) is a blend of gas oil and heavy fuel oil, with less gas oil than marine diesel oil. Marine fuel oil (HFO) is roughly equivalent to No. 6 fuel oil (Bunker oil).

Major seaports, including those in the United States and the European Union, are imposing tighter emissions limits on sea-going ships and the fuels they burn. In 2012, a global treaty (MARPOL Annex VI) capped SO_x emissions at 1% in coastal waters and extended the coastal zone to 200 mile offshore around Canada and the United States. The SO_x limit was decreased to 0.1% on January 1, 2015, requiring even tighter limits on the sulfur content of marine fuels. Meanwhile, changes in vessels and the use of larger, more fuel-efficient vessels have decreased marine fuel consumption.

1.12.7 Lubricant Base Oils, Wax, Grease, and Specialty Products

Lube Base Oils

Refiners prepare lube base stocks from different crude oils by removing asphaltenes, aromatics, and waxes [1.90, Chaps. 33, 35]. Lube base stocks are hydrofinished, blended with other distillate streams for viscosity adjustment, and compounded with additives to produce finished lubricants. In the past, solvent-based technology was used to prepare lube base stocks. Propane deasphalting removes asphaltenes. Furfural and related substances extract aromatics, and MEK or MIBK remove wax. Wax removal technology was introduced in Sect. 1.9.3. With the advent of catalytic dewaxing (CDW), some or all of these solvent-based methods can be replaced with hydroprocessing. The first process for catalytic dewaxing, called MLDW, was developed by Mobil (now ExxonMobil) in the 1980s. The Mobil process employs ZSM-5, which selectively converts waxy *n*-paraffins into lighter hydrocarbons. The Isodewaxing process was commercialized in 1993 by Chevron. Isodewaxing is a hydroisomerization process, in which conversion of *n*-paraffins into smaller molecules is minimized. Instead, it reduces wax catalytically by isomerising *n*-paraffins into isoparaffins. Isodewaxing includes prior high-pressure hydrotreating and post-treating, which removes sulfur and nitrogen and saturates aromatics. The products have a high viscosity index (VI), low pour point, and excellent response to additives.

It is important to distinguish among lubricant products. Base stocks are products produced from the lubricant plant without any additives in the oil. Base oils are blends of one or more base stocks. Finished oils or formulated oils are blends of base oils with special additives.

Lubricant base stocks can be categorized into 5 groups [1.91]. The first three groups (I–III) are derived from mineral oils. Group I oils are manufactured by solvent extraction and hydro-finishing processes. They contain < 90% saturates and > 0.03% sulfur with a VI of 80–120. Common group I base oils are 150N (solvent neutral), 500N, and 150BS (bright stock). Group II oils are manufactured by hydrocracking or other catalytic processes, such as MLDW. They contain over 90% saturates and under 0.03% sulfur with VI of 80–120. Group II oils have superior antioxidation properties since virtually all hydrocarbon molecules are saturated. They are clear and water-white. Group III oils are manufactured by special processes such as hydrosomerization such as Isodewaxing and from base oil or slack wax. They also contain > 90% saturates and < 0.03% sulfur, but their VI is more than 120.

Synthetic lubricant base oils also have VI > 120. Group IV is specific to the base oils derived from poly alpha olefins (PAOs). Group V includes other synthetic base stocks, such as dibasic esters, aromatic esters, polyol esters, etc. Chapter 35 is dedicated to the production of synthetic lubricant base oils.

Finished lubricant oils with additives can be used as engine oils, transmission fluids, gear oils, turbine oils, hydraulic oils, metal cutting oils, paper machine oils and mixed with soaps as greases. Finished lubricants are formulated with base oil and special additives [1.14]. Detergents and dispersants are the dominant performance additives in motor oils. The additives are typically 5–20% of formulated engine oil or 55–70% of performance-package oil. The remaining additives include antiwear agents, ash inhibitors, friction modifiers, etc.

Petroleum Wax

Petroleum wax (paraffin wax) can come from atmospheric or vacuum distillates, which form wax with large crystals or plates with molecular weights between 300 and 450 (C_{17} – C_{35}). Such wax contains mostly normal paraffins and small amounts of isoparaffins, cycloparaffins and minute amounts of aromatics. Another source of wax is vacuum residue, which forms microcrystalline wax with molecular weights between 450 and 800 (C_{35} – C_{60}). Such wax contains mostly cycloparaffins with *n*-alkyl and isoalkyl side chains. Microcrystalline wax is often used in tire and rubber industries, candles, cosmetics, and for other purposes. The blending of paraffin and microcrystalline waxes is practiced in the tire and rubber industries.

Greases

Greases are made by blending detergents (salts of long-chain fatty acids) into lubricating oils at 400–600 °F

(204–315 °C). Antioxidants are added to provide stability. Some greases are batch-produced, while others are made continuously. The characteristics of a grease depend to a great extent on the counter-ion (calcium, sodium, aluminum, lithium, etc.) in the fatty-acid salt.

Specialty Oils

Other specialty products include white oil and insulating (electrical) oils. Naphthenic crude oils give white oil products of high specific gravity and viscosity, suitable for pharmaceutical uses. Paraffinic crude oils produce oils with lower gravity and viscosity suitable for lubrication purposes. Technical grade white oils are employed for cosmetics, textile machinery lubrication, insecticides, vehicles, paper impregnation, etc. Pharmaceutical (medical) grade white oils may be employed as laxatives or for lubrication of food-handling machinery. Insulating oils are highly refined fractions of low viscosity; they are stable at high temperature and have excellent electrical insulating properties. They are used in transformers, circuit breakers, and oil-filled cables, and for impregnating the paper covering of wrapped cables.

1.12.8 Cokes

Coke is a carbonaceous solid derived from coking or other cracking processes. Undesirable coke is deposited on catalysts used in certain oil refining processes, such as catalytic reforming, hydrotreating, and hydrocracking. In the FCC process, coke is not undesirable, it is essential, because burning the coke in the catalyst regenerator provides heat to run the unit.

The coke directly out of delayed coking units is often referred to as green coke. The most common grades of coke are fuel grade coke and anode grade coke. If the green coke contains low metals and low sulfur it may be calcined to remove residual hydrocarbons. Sulfur recovery is required during calcination. The calcined coke can be processed in an anode baking oven to produce anode grade coke or needle coke. Needle coke, named for its needle-like structure, is a high-value product that has a low thermal expansion coefficient, making it suitable for conversion into graphite anodes for the electric-arc furnaces mainly used in the specialty steel and aluminum smelting industries.

If the metals and sulfur contents in the green coke are too high, it will not be calcined and is used as fuel grade coke for burning. Fuel grade coke has as either desirable sponge coke or undesirable shot coke morphology (see Fig. 30.3). The formation mechanisms of sponge coke and shot coke are not well understood. However, low temperatures and high pressures promote sponge coke formation.

Sponge coke is named for its sponge-like appearance. It is produced from coker feeds with low-to-moderate asphaltene concentrations. Fuel coke with high heat and low ash content is used for power generation. Low ash content is important, because ash can foul boilers. When burning fuel coke, some form of sulfur capture is required to meet current emission standards. Fuel grade coke can be a feedstock for gasification, during which it is converted into synthesis gas – a mixture of CO and H₂.

Shot coke is undesirable because it tends to be unstable. It forms when the coking reaction is too rapid, as when the concentration of feedstock asphaltenes and/or coke-drum temperatures are too high. A block of shot coke is a cluster of discrete mini-balls with diameters 0.1–0.2 in. (2–5 mm). The clusters can be as large as 10 in (25 cm) across. If a cluster breaks apart when the coke drum is opened, it can spray a volley of hot mini-balls in every direction. Adding aromatic feeds, such as FCC decant oil, can eliminate shot coke formation. Other methods of eliminating shot coke – decreasing temperature, increasing drum pressure, increasing the amount of product recycle – decrease liquid yields, which is not desired.

Specialty carbon products made from petroleum include recarburizer coke, which is used to make special steels, and titanium dioxide coke, which is used as a reducing agent in the titanium dioxide pigment industry.

1.12.9 Asphalt

Asphalt is a sticky, black, and highly viscous liquid or semisolid form of petroleum. Also known as bitumen, it may be found in natural deposits or may be produced in refineries.

Asphalt base stocks can be produced directly from vacuum residue or by solvent deasphalting. Vacuum residue is used to make road-tar asphalt. To drive off

light ends, it is heated to about 750 °F (400 °C) and charged to a vacuum column.

In road-paving, the asphalt serves as a binder for aggregate, which can include stone, sand, or gravel. The aggregate comprises about 95% of the final mixture. Polymers are added to the binder to improve strength and durability. The recommended material for paving highways in the United States is Superpave32 hot-mix asphalt. Superpave was developed in 1987–1993 during a US\$50 million research project sponsored by the Federal Highway Administration.

Roofing asphalt is produced by bubbling air through liquid asphalt at 260 °C (500 °F) for 1–10 h. During this *blowing* process, organic sulfur is converted to H₂S and SO₂. Catalytic salts such as ferric chloride (FeCl₃) may be used to adjust product properties and increase the rates of the blowing reactions, which are exothermic. To provide cooling, water is sprayed into the top of the blowing vessel, creating a blanket of steam that captures sulfur-containing gases, light hydrocarbons, and other gaseous contaminants. These are recovered downstream. Cooling water may also be sprayed on the outside of the vessel. The length of the blow depends on desired product properties, such as softening temperature and penetration rate. A typical plant blows 4–6 batches of asphalt per 24 h day. There are two primary substrates for roofing asphalt – organic (paper felt) and fiberglass. The production of felt-based roofing shingles consists of:

- Saturating the paper felt with asphalt
- Coating the saturated felt with filled asphalt
- Pressing granules of sand, talc or mica into the coating
- Cooling with water, drying, cutting and trimming, and packaging.

If fiberglass is used as the base instead of paper felt, the saturation step is eliminated.

1.13 Characterization of Petroleum

As mentioned earlier, petroleum is a very complex mixture. In order to determine its value and processability, a battery of analytical tools, instruments, and methods have been developed to measure bulk properties and to determine detailed chemical composition. In fact, petroleum analysis has played an important role in petroleum research and development.

1.13.1 Crude Oil Assay

Both physical and chemical properties of crude oils vary with location, depth, and age of the oil field. They

are measured by testing laboratories according to the requirements of a crude oil assay (or crude assay). The assay can be performed on the whole crude oil or its distillation fractions. The assay can be an extensive (full) assay, especially for new crude oils, or an inspection assay that includes only selected tests. Full assay analyses are done by combining atmospheric and vacuum distillation runs. High quality assay data are used by producers, oil traders, and refiners, enabling them to predict the true value of an oil for a specific facility. Considerations include compatibility, processability, processing options, potential problems,

and expected product quality. In addition to quality, crude oil price is determined by many factors, including supply and demand, oil reserves and inventory, and the effect of world events. Two commonly used benchmark crude oils are West Texas Intermediate (WTI) and Brent (from North Sea).

For a whole crude oil, one of the most important properties is the yields of distillation fractions. The yields can be determined by distillation laboratory or by simulated distillation (SimDist) using gas chromatography (GC). The ASTM D 2892 (15/5 distillation) method is designed for atmospheric distillation to determine accurate boiling point and yields of distillation fractions using a 15 theoretical plate fractionation column with a 5 : 1 reflux ratio. The ASTM D 5236 (Hivac distillation) method is developed for vacuum distillation in a vacuum potstill to produce gas oil and traditional lube oils as well as vacuum resid. True boiling point (TBP) curve, i. e., a curve of accumulated volume or weight percent of distillates versus temperature, is created by combining atmospheric (ASTM D 2892) and vacuum (ASTM D 5236) distillation runs. SimDist uses a nonpolar GC column with a temperature program, typically from -50 to 350°C at $8^{\circ}\text{C}/\text{min}$. Products are measured with a flame ionization detector (FID) which response is proportional to the number of carbon atoms present and closely approximates weight percent. SimDist data are compared with a full assay TBP curve to determine true distillation curve and predict distillate yields. It provides a quick and robust method for obtaining distillation data with much less sample, time, and effort.

The full assay contains a vast amount of data, including API gravity, sulfur content, nitrogen content, metal content, salt content, total acid number, micro carbon residue, viscosity, refractive index, aniline point, freeze point, cloud point, pour point, smoke point, and more. The refinery may set up a testing grid of the above tests for each distillation fraction. There is no standard testing grid. Requirements vary from refinery to refinery. The extent of assay depends on customer need and affordability.

For manufacturing lubricant base oils, assay is used for identifying economically attractive crude oils based on the yield and quality [1.15]. The assay processes

include atmospheric distillation, vacuum distillation, extraction, and dewaxing to produce lubricant base stocks. Modeling uses assay information to predict process response for desired lube products and to investigate process variables and operating optimization for distillation, extraction, and dewaxing. This allows refiners to assess manufacturing flexibility. Plant tests for products include blending into formulated lubes for further testing. Periodic re-evaluation is performed to assess lube quality variation over time. Important lube qualities include viscosity, VI, sulfur, density, oxidative stability, refractive index, etc. The yield in the lube boiling ranges is also determined for economic evaluation.

1.13.2 Instrumental Analysis

With advances in instrumentation, many tests have been replaced by analytical instruments. For example, high temperature simulated distillation of whole crude oil by gas chromatography has been used as a replacement for assessing distillation yields without the use of a large-scale distillation apparatus with time-consuming, tedious, and very costly procedures [1.92]. In addition, the sample quantity is reduced by several orders of magnitude for handling and cleaning. There are numerous analytical instruments for testing other petroleum properties [1.93, 94].

To determine the composition of complex petroleum mixtures, it usually requires a battery of analytical techniques to detect specific features of the molecules, such as mass, elemental composition, boiling point, solubility, vibrational frequencies, nuclear magnetic resonance frequencies, etc. Modern instrumentation used to determine the petroleum composition for upstream, downstream, chemical and environmental applications includes elemental analysis, chromatography, mass spectrometry (MS), nuclear magnetic resonance spectroscopy (NMR), infrared spectroscopy (IR), and x-ray absorption spectroscopy [1.16]. The robust versions of selected instruments are used for routine analysis of process streams and products at refinery and chemical plant laboratories. More sophisticated and difficult-to-operate instruments are used in research and development laboratories for the development of new and novel technologies and problem solving.

1.14 Modeling

Ever-improving mathematical models are enhancing all aspects of petroleum technology. Three-dimensional imaging identifies geological formations most likely to contain oil and gas. Rigorous basin modeling optimizes

exploration and production. Global energy companies employ sophisticated planning models to quickly decide which feedstocks to buy, how to use them in numerous processing plants, and whether to resell them.

Rigorous equipment and piping models serve as the basis for designing piping networks and upgrading facilities in gas plants, refineries, and petrochemical plants; the use of such models has improved energy efficiency by up to 70% at some sites. Rigorous process modeling, based on molecular characterization, serves as the foundation for real-time online process optimization. The modeling and automation of product blending reduce product-quality giveaway, increasing profitability at relatively low cost, especially when no new equipment is required.

1.14.1 Basin Modeling

Basin and petroleum system modeling in the upstream sector aids the prediction of petroleum occurrence, migration, accumulation, and preservation. This helps with reducing exploration risk and highlights prospective exploration areas [1.95]. The four-dimensional models track migration through time, along with the composition and volumes of the entrapped fluids. They incorporate a broad spectrum of geoscience data from seismic measurements, well logs, stratigraphy, structure geology, and geochemistry.

1.14.2 Design Models

Equipment models based on rigorous thermodynamics, fluid dynamics, and other fundamental principles are employed in all sectors of process industries for many purposes, starting with process design. For existing petroleum and gas processing plants, rigorous models can aid the selection of feedstocks and enable optimization of operation conditions to give the most profitable balance between feed rate, process severity, catalyst life, and product yields. The models include equipment constraints and product property specifications; as mentioned, naphtha is not gasoline unless it meets gasoline specifications. Design models enable evaluation of possible revamps. No unit runs exactly as designed, in part because feedstocks are never the same as the design feed, and their qualities and availability always change. Other reasons for revamps include unexpected process bottlenecks and changes in market conditions, which change the relative value of products. The simulation results are compared with data from pilot plants as well as commercial practice.

1.14.3 Component Lumping

Lumping reduces the complexity of the astronomical number of molecular components in petroleum mix-

tures to a manageable size [1.96]. Hence, it enables one to simulate the reaction chemistry of complex mixtures with a hundred or so mathematical proxies instead of thousands of individual molecules. The first publications on lumping came from researchers at Mobil Oil, where the technique was called structure-oriented lumping (SOL). Similar techniques were developed at roughly the same time by Shell Oil; developers from Shell later formed DMC Corporation, which for a long time was the leading provider of lump-based online optimization services to refining and petrochemical companies, including Mobil.

At present, process models for middle distillate, VGO, and resid processing units rely on lumping extensively, with heavy dependence on bulk composition measurements. Models for catalytic reformers make little if any use of lumping. Lumping is not needed, because such units process mixtures containing only a small number of light compounds with less than 12 carbon atoms.

1.14.4 Real-Time Optimization

Real-time optimizers (RTO) based on rigorous process models are found in just about every olefin production plant in first-world countries. They are found in other chemical plants and many refineries, especially refineries operated by ExxonMobil. For an olefin plant, net benefits can exceed \$10–20 per ton of product [1.97].

In a fully rigorous conversion model, the number of lumps affects almost every piece of equipment in a unit. A VGO hydrocracker model might contain > 100 pieces of equipment, including pumps, compressors, heat exchangers, reactors, quench valves, flash drums, strippers, and distillation trays. For each piece, in addition to component information, pressure, temperature, and flow rate must be specified or calculated. In conversion units, the number of components affects the number of reactions. One modern hydrocracker optimizer includes 116 lumps and 240 reactions (Chap. 28). Even with an advanced computer, the execution time for an online version can exceed 10 min.

An RTO model must include a feed blending model. Feed quality and availability change frequently and often significantly, several times per week. In real time, it is impossible to determine detailed molecular compositions and distribute them into lumps. Therefore, the RTO described in Chap. 28 includes a feed adjustment block. The feed adjustment block is crucial, because it determines the fidelity of the entire RTO.

A feed adjustment block compares measured bulk properties of a candidate feed to the bulk properties

of a library feed. Each library feed includes a distribution of lumps, each of which is associated with a set of chemical and physical properties. The feed adjustment model develops a lump distribution for the candidate feed by skewing the lump distribution of a library feed until its bulk properties match (within an acceptable error range) the measured properties of the candidate feed.

In each optimization cycle, the program executes twice. The first time, it determines whether the plant is steady and detects gross errors. If process measurements are grossly wrong or if key data are missing, the optimizer might not run. If the plant is steady and measurements are reliable, the RTO imports price information for every input stream, product stream, and all utilities. It uses a sophisticated solver, which computes and automatically downloads optimal settings for every valve in the unit.

For fixed-bed catalytic units, the RTO must include a catalyst deactivation model [1.18]. Without considering deactivation, the RTO would select the heaviest possible feeds and push conversion to the limit, even if so doing would deactivate the catalyst immediately.

1.14.5 Planning and Scheduling

Petroleum companies strive to operate safely, reliably, and in compliance with the law. If a company is not

producing and/or processing petroleum due to a terrible accident or violating a regulation, it cannot make any money.

After safety, reliability, and legal objectives are met, feed selection and allocation determine profitability more than any other activity. In advanced companies, corporate planning models are linked to linear program (LP) models for individual refineries, and the LP models are linked to individual process unit optimizers (if they exist). At every level, the models include feedstock costs, information on how feedstock properties affect process unit capability, and product yields and prices.

If gasoline prices suddenly go up and diesel prices drop, the company may or may not make changes. If it has long-term contracts for feeds and separate long-term supply contracts, it may not be able to make significant changes in operation. If it buys crude on the spot market and sells products to the open market, it might be able to change operation, but the changes cannot be instantaneous. It can take days to readjust operating conditions in a single process unit, weeks to process on-site inventories, and a month to obtain pipeline crudes. Other companies also will make changes, increasing supply and thereby affecting prices.

The best planning models strive to account for the impact of a large company's decisions on the world market.

1.15 Petrochemicals

Refineries produce a very large quantity of commodity petrochemicals, which are used in subsequent chemical and pharmaceutical production. Primary petrochemicals can be divided into three groups as olefins, aromatics, and synthesis gas. Olefins are major source of polyolefins, such as polyethylene, polypropylene, and ethylene/propylene co-polymers. Ethylene and propylene are sources of other polymers, too. Ethylene reacts with benzene to make ethyl benzene, which leads to styrene and polystyrene. Propylene is oxidized to acrylic acid, which is used to make polyacrylates. Oxidation of propylene in the presence of ammonia produces acrylonitrile, which leads to polyacrylonitrile and several derivatives (Chap. 36). Aromatics are mainly benzene, toluene, and xylenes. They are solvents and feedstocks for a variety of chemicals. *p*-Xylene is a major feed for polyester production. Synthetic gas is used for making methanol and ammonia as well as synthetic fuels. Butyl rubbers made from C₄ olefins are basic ingredients for tires. Bromobutyl

(and chlorobutyl) is the key ingredient for tubeless tires due to its excellent air impermeability, UV resistance, and ozone resistance properties. High polymers can be further processed into plastics and engineering plastics.

Table 1.29 lists some of the refinery process units which produce petrochemicals. Figure 1.45 provides an example of the synergies between a refinery and a petrochemical plant.

Table 1.29 Sources of petrochemical feedstocks

Process unit	Petrochemicals
Natural gas processing	CO-based chemicals (synthesis gas, methanol, detergent alcohols)
Naphtha hydrotreating	Clean naphtha → olefin plants → polymers
FCC	Propylene and butylene → polymers
Hydrocracking	Unconverted oil → olefin plants → polymers
Catalytic reforming	Aromatics → solvents, polymers

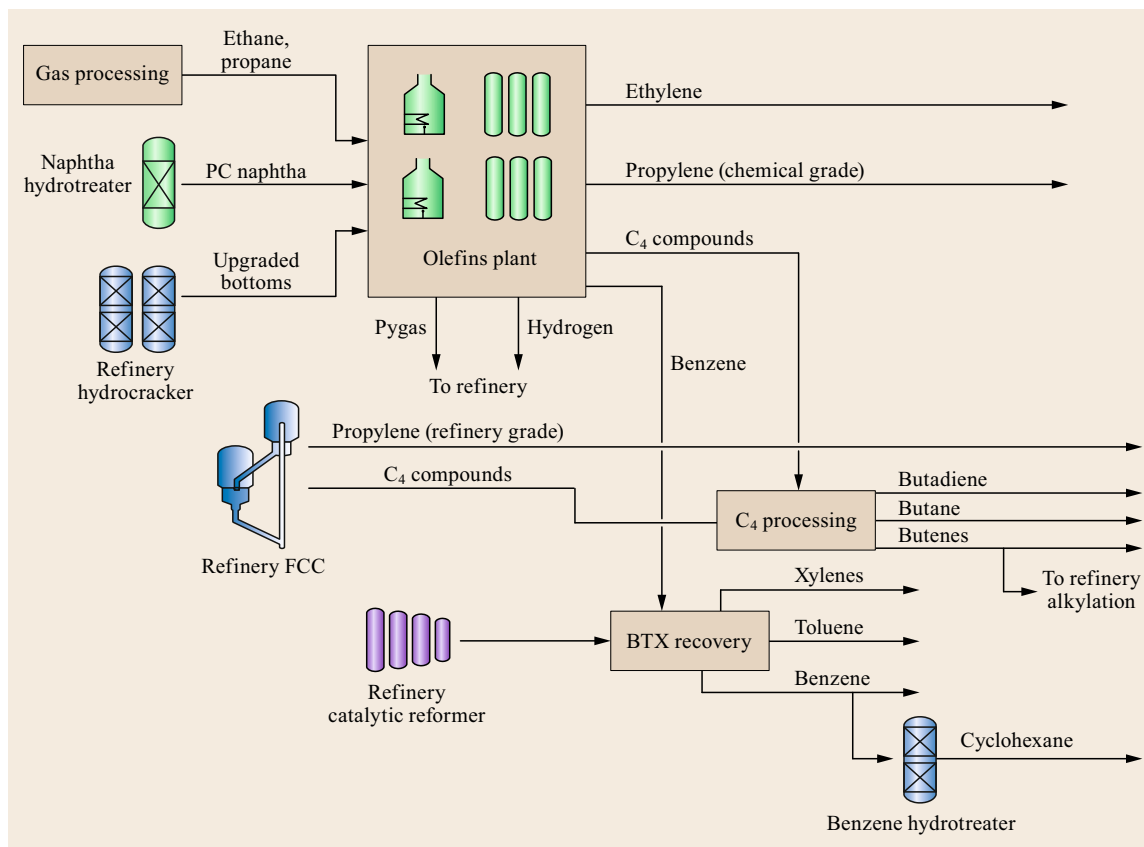

Fig. 1.45 Example showing interactions between a refinery and an olefins plant

1.16 Alternatives to Petroleum

Oil and gas reserves are finite. They are versatile, serving as sources of energy and raw materials for producing chemicals and consumer products. It will be difficult to replace them completely with any single alternative.

For decades, finding conventional crude oil has been getting harder. Even so, reserves are now increasing due to advances in technology, such as the recent advent of *fracking* technology to increase oil and gas production from tight formations and nonconventional reservoirs. Declining availability of conventional petroleum can be offset to some extent by nonfossil sources, but in the interim unconventional fossil resources are likely to carry most of the load. Liquid fuels are being produced from natural gas, bitumen, kerogen, and coal. Some of these, especially kerogen, contain daunting amounts of contaminants, so converting them into petroleum alternatives is costly and difficult.

1.16.1 Inexhaustible (Renewable) Energy Sources

Hydroelectric, wind, solar, and geothermal energy are carbon-neutral. They do not contribute to climate change, and they are practically inexhaustible. Importantly, capturing such energy is friendly to the environment, except perhaps when certain kinds of solar cells are employed. But, because they are carbon-neutral, they cannot serve as sources of carbon-containing chemicals.

1.16.2 Nuclear

Nuclear energy is finite, but with breeder technology, which converts ^{238}U and other nonfissile isotopes into useful nuclear fuel, it could provide our energy needs for thousands of years. Nuclear energy is carbon-

neutral. Hence, like the energy sources mentioned above, it cannot replace fossil resources as sources of petrochemicals.

1.16.3 Biomass (Renewable) Resources

Ethanol, cellulose, and vegetable oil do contain carbon, and already research is underway to develop bio-refineries [1.98].

Many countries offer incentives to add oils from plants to diesel fuels. Bio-oils, except biobutanols, are not suitable for direct use in existing gasoline engines, so they often are mixed in small amounts with conventional petroleum in existing refineries.

First-Generation Biofuel Technology

Brazil replaced most of its petroleum needs with ethanol from sugar cane, creating the world's first *biofuel economy* [1.84]. The key to Brazil's success was the demonstrated fact that the energy gain for ethanol from sugar is eight times; energy gain is the ratio of the energy obtained from product consumption divided by the non-solar energy required for manufacturing and collecting the product.

The United States now requires the blending of more than 10% ethanol into most of its gasoline. Most American fuel ethanol comes from corn, for which the energy gain ranges from 2.1 to 4.1 times [1.99]. Other aspects of corn ethanol are discussed in Sect. 1.12.2. First-generation biofuels derived from sugar cane or corn compete with food resources.

Another first generation biofuel is biodiesel consisting of methyl, ethyl or propyl esters of long-chain fatty acids. The esters are made by reacting lipids (vegetable oils, corn oil or animal fats) with an alcohol via transesterification.

Second-Generation Biofuel Technology

Second-generation biomass technology involves gasification or pyrolysis of nonfood sources. Raw materials for gasification technologies include forest and agricultural residues, waste wood, saw dust, energy crops, and black liquor from pyrolysis units. The product is syngas, which is converted via Fischer-Tropsch technology to alcohols and *n*-paraffins, which in turn are converted into gas oil, naphtha, and fuel gas.

Gasoline is produced from methanol through the MTG process developed at Mobil, now ExxonMobil. A useful byproduct is dimethyl ether (DME). Gas oil and naphtha can be converted into diesel and gasoline, respectively, with the conventional refining technology. Chemicals can be manufactured from methanol and DME. The fuel gas generates mechanical and electrical power via gas motors or gas turbines.

The same raw materials can be used for fast pyrolysis, which thermally decomposes organic material at elevated temperatures in the absence of oxygen. Pyrolysis oil is highly reactive and must be stabilized by hydrogenation prior to further processing in conventional crude oil refineries. The cost of hydrogenation is considerable, and producing the hydrogen in steam-methane reformers generates large amounts of CO₂.

1.17 Protecting the Environment

In addition to desired products, upstream, downstream, and petrochemical facilities produce wastes. If not contained or processed, these wastes can harm people and the environment. Waste control is a crucial consideration during process design and operation. Various treatment, capture, and disposal units are required, and emissions are constantly monitored.

As described in Chap. 2, despite concerted efforts to put safety first, preventable accidents still cause tremendous loss of life and environmental damage. Examples include the BP Texas City refinery explosion, the *Exxon Valdez* oil spill, and the recent *Deepwater Horizon* blowout in the Gulf of Mexico.

1.17.1 Air Quality

In the 1970s and 1980s, environmental laws compelled oil and gas companies to reduce emissions of SO_x,

NO_x, CO₂, and hydrocarbons. In the atmosphere, SO_x reacts with water vapor to make sulfurous and sulfuric acids, which return to Earth as dry or wet deposition (acid rain). Volatile hydrocarbons react with NO_x and sunlight to make ozone, a noxious component of photochemical smog. CO₂ is a major *greenhouse* gas responsible for climate change. To reduce these pollutants, the industry tightened its operations by:

- Reducing fugitive hydrocarbon emissions from valves and fittings
- Removing sulfur from refinery streams and finished products
- Adding tail-gas units to sulfur recovery plants
- Reducing the production of NO_x in fired heaters
- Scrubbing SO_x and NO_x from flue gases
- Reducing the production of CO₂ by increasing energy efficiency.

In several oil fields, companies keep CO₂ out of the atmosphere by pumping it into oil wells to maintain reservoir pressure, thereby enhancing production.

Sulfur Recovery

Natural gas can contain significant amounts of hydrogen sulfide. Some gas processing plants in Alberta, Canada, recover more than 2000 t of sulfur per day using the Claus process. Sulfur is recovered by a much smaller Selectox unit on Platform Irene off the coast of California [1.100]. For the most part, sulfur is recovered from petroleum in refineries. Conversion processes, hydrotreaters, and sweetening units remove chemically bound sulfur, which can end up as SO_x, H₂S, NH₄SH, or NaSH.

Fuel-oil fired heaters and the regenerators of FCC units are major sources of refinery SO_x and NO_x emissions. The most obvious solution to reduce SO_x emissions from a heater is to use low-sulfur fuels. Unfortunately, although that solution requires no investment in processing, it would probably be the most expensive due to the relatively high cost of buying low-sulfur crudes for the entire refinery and/or hydrotreated VGO just for the FCC.

A large fraction of the sulfur in the feed to an FCC unit ends up in coke on the catalyst. SO_x are formed in the regenerator when the coke is burned away. Therefore, removing sulfur from the feed, usually by hydrotreating, decreases SO_x emissions. FCC feed pretreating has other substantial benefits. Removing basic nitrogen decreases deactivation of acid sites on the FCC catalyst, which allows the FCC to reach a given conversion at lower temperatures. The saturation of aromatics in the feed pretreater provides the biggest benefit, because it converts hard-to-crack aromatics into easier-to-crack naphthenes. This alone can justify the installation of an FCC feed pretreater.

SO_x transfer additives, first developed by Davison Chemical, react with SO_x in the FCC regenerator to form sulfates. When the sulfated additive circulates to the riser/reactor section, the sulfate is reduced to H₂S, which is recovered by amine absorption and sent to the sulfur plant. In some units, these additives reduce FCC SO_x emissions by more than 70%. Consequently, if a pre-treater or post-treater still must be installed, its size can be reduced. The chemistry of SO_x transfer is summarized below.

FCC Regenerator (Oxidizing Environment).

FCC Riser-Reactor (Reducing Environment).

where MO is a weakly basic metal oxide such as MgO or La₂O₃.

Flue-gas scrubbing is a refiner's last chance to keep NO_x and SO_x out of the air. In wet flue-gas desulfurization, gas streams containing SO_x react with an aqueous slurry containing calcium hydroxide Ca(OH)₂ and calcium carbonate CaCO₃. Reaction products include calcium sulfite (CaSO₃) and calcium sulfate (CaSO₄), which precipitate from the solution. NO_x removal is more difficult. Wet flue-gas scrubbing removes about 20% of the NO_x from a typical FCC flue gas. To remove the rest, chemical reducing agents are used. As mentioned above, in the SCR process, anhydrous ammonia is injected into the flue gas as it passes through a bed of catalyst at 500–950 °F (260–510 °C). The chemical reaction between NO_x and ammonia produces N₂ and H₂O.

When sulfur-containing feeds pass through hydrotreaters or conversion units, most of the sulfur is converted into H₂S, which eventually ends up in off-gas streams. Amine absorbers remove the H₂S, leaving only 10–20 wppm in the treated gas streams. H₂S is steam-stripped from the amines, which are returned to the absorbers. The H₂S goes to the refinery sulfur plant.

Claus Process

At the sulfur plant, H₂S is combined with sour-water stripper off-gas and sent to a Modified Claus unit. (The Modified Claus process includes a combustion furnace. The original Claus process did not. In common usage, both the modified and original versions are called Claus. Additional information is given in Chap. 20.) Almost every refinery in the world uses some version of this process to convert H₂S into elemental sulfur. H₂S and a carefully controlled amount of air are mixed and sent to a burner, where about 33% of the H₂S is converted to SO₂ and water. From the burner, the hot gases go to a reaction chamber, where the reactants and products reach equilibrium. In several units, the air is enriched with oxygen to increase plant capacity. Elemental sulfur is produced by the reversible reaction between SO₂ and H₂S. Ammonia comes in with the sour-water stripper off-gas. In the Claus process, it is thermally decomposed into nitrogen and water.

In the Claus burner, combustion temperatures reach 2200 °F (1200 °C). Much of the heat is recovered in a waste-heat boiler, which generates steam as it drops the temperature to 700 °F (370 °C). Next, the process gas goes to a condenser, where it is cooled to

about 450°F (232°C). At this temperature, sulfur vapors condense, and the resulting molten sulfur flows through a drain to a heated sulfur-collection pit. At the bottom of the drain, a seal leg maintains system pressure and keeps unconverted gases out of the pit. Uncondensed sulfur and other gases flow to a series of catalyst beds, which recover additional sulfur by promoting the Claus reaction between left over H₂S and SO₂. With fresh catalyst and a stoichiometric gas composition, the cumulative recovery of sulfur across four condensers is about 50%, 80%, 95%, and 96–98%, respectively.

Claus tail-gas treating units (TGTU) bring the total sulfur recovery up to > 99.9%. Most tail-gas treating processes send the tail gas to a hydrotreater, which converts all sulfur-containing compounds (SO₂, SO₃, COS, CS₂, and various forms of S_x) into H₂S. The carbon for CS₂ and COS comes from CO₂ and/or hydrocarbons in the feed gas. In the SCOT process, offered by Shell Global Solutions, the H₂S is absorbed by an amine and returned to the front of the Claus furnace. In the LO-CAT process, offered by Merichem, H₂S is air oxidized to sulfur in an aqueous solution containing a chelated iron catalyst. For all tail-gas treatment processes, the last traces of unrecovered sulfur go to an incinerator, where they are converted into SO₂ and dispersed into the atmosphere.

1.17.2 Wastewater Treatment

Wastewater treatment purifies process water, runoff, and sewage. Purified wastewater streams are re-used in the refinery as much as possible. Wastewater streams may contain suspended solids, dissolved salts, phenols, ammonia, sulfides, and other compounds. The streams come from just about every process unit, especially those that use wash water, condensate, stripping water, caustic, or neutralization acids.

Primary treatment uses a settling pond to allow most hydrocarbons and suspended solids to separate from the wastewater. The solids drift to the bottom of the pond, hydrocarbons are skimmed off the top, and oily sludge is removed. Difficult oil-in-water emulsions are heated to expedite separation. Acidic wastewater is neutralized with ammonia, lime, or sodium carbonate. Alkaline wastewater is treated with sulfuric acid, hydrochloric acid, carbon dioxide-rich flue gas, or sulfur.

Some suspended solids remain in the water after primary treatment. These are removed by filtration, sedimentation, or air flotation. Flocculation agents may be added to consolidate the solids, making them easier to remove by sedimentation or filtration. Activated sludge is used to digest water-soluble organic compounds, either in aerated or anaerobic lagoons. Steam-stripping is

used to remove sulfides and/or ammonia, and solvent extraction is used to remove phenols.

Tertiary treatment processes remove specific pollutants, including traces of benzene and other partially soluble hydrocarbons. Tertiary water treatment can include ion exchange, chlorination, ozonation, reverse osmosis, or adsorption onto activated carbon. Compressed oxygen may be used to enhance oxidation. Spraying the water into the air or bubbling air through the water removes remaining traces of volatile chemicals such as phenol and ammonia.

1.17.3 Solid Waste Handling

During drilling and production operations, oil-bearing cuttings from wells present environmental challenges. Onshore, the cuttings can be stored onsite in clay-lined pits. Offshore, contaminated cuttings may have to be shipped to shore for treatment. If the cuttings meet certain criteria, they are discharged to the seabed whenever possible but often are dumped into the sea. Other wastes are transported to waste treatment facilities. In the oil sands fields in Alberta, Canada, bitumen is washed away from the inorganic substrate with hot water. The water goes into huge tailings ponds. The ponds emit considerable amounts of CO₂, and they contain significant amounts of trace contaminants.

Refinery solid wastes may include spent catalyst and catalyst fines, acid sludge from alkylation units, and miscellaneous oil-contaminated solids. All oil-contaminated solids are treated as hazardous and sent to sanitary landfills.

Recently, supercritical extraction with carbon dioxide has been used with great success to remove oil from contaminated dirt, including cuttings from oil-well drilling.

1.17.4 Fugitive Emissions

Fugitive emissions are comparatively small amounts of gaseous, liquid, and solid wastes, which come from process equipment during industrial activities. Even small quantities of leaked gases, such as benzene, can cause serious damage to health and environment when the emissions are continuous or chronic. Flammable chemicals can accumulate to form explosion hazards. One recent study showed that fugitive emissions were equivalent to 0.17 wt% of a refinery's throughput.

Leaks from high-pressure equipment usually occur through valves, connections, or mechanical seals. Other emissions come from storage tanks and waste treatment facilities. Operators regularly check for leaks with gas detectors and take appropriate corrective action.

Fugitive emissions can be hard to detect, and the sizes of leaks can vary with processing intensity and ambient conditions. Work continues on developing improved methods for discovery and analysis. One new technology is differential absorption, which measures concentrations of atmospheric hydrocarbons hundreds of meters from a facility. Opacity meters measure particulate emissions, and IR imaging can detect otherwise invisible gases escaping from leak sources.

1.17.5 Improving Energy Efficiency and Safety with Automation

The ever-increasing development and use of better instruments and analyzers, engineering models, and real-time online optimization continue to improve the efficiency and safety of petroleum processing plants. Examples are provided on the websites of companies

1.18 Conclusion

The petroleum industry is huge and complex. It is one of the most important industries on planet Earth. To understand the industry, one must gain familiarity with the underlying science and engineering used to find and recover crude oil and natural gas and to transform them into useful products. These technologies can also be applied to gases and liquids from coal, shale, and renewable biomass.

Research and development aimed at improving or modifying existing petroleum technologies and developing new ones start with physical testing and chemical characterization.

Three-dimensional imaging exhibits geological formations most likely to contain oil and gas. Rigorous basin modeling optimizes exploration and production. Modern production technology includes enhancements in horizontal drilling, offshore platform design, and in-situ SAGD. The application of hydraulic fracturing to previously unrecoverable oil from tight reservoirs transformed the United States into the world's leading oil producer.

Midstream technology includes transportation, trading, and upgrading oil sand bitumen into syncrude. Sophisticated computer models enable global energy companies to quickly decide which oils to buy, how to allocate them between numerous processing plants, and whether to resell them.

such as Applied Manufacturing Technologies (AMT), Aspen Technology, Honeywell, Invensys, Yokogawa, and others. A paper by *Hampton* and *Robinson* provides an example of using advanced regulatory control to improve the safety of a hydrocracking unit [1.101].

1.17.6 Conservation

Conservation also decreases the demand for petroleum and other fossil hydrocarbons while reducing pollution. According to the Rocky Mountain Institute [1.102], with modest investment in proven, widely applied technology, the United States could increase the efficiency of power production by 30%.

Figure 1.6 demonstrates that prices have a tremendous effect on energy consumption. We can save energy not just by traveling less, turning off lights and driving less, but also through innovation.

Crude oil goes to refineries, which rely on distillation, treating, conversion, extraction, and blending to produce fuels, hydrogen, lubricants, construction asphalt, solvents, and bulk chemicals (sulfur, ammonia, and CO₂). Refineries supply raw materials for chemical and pharmaceutical plants, which generate thousands of materials we use to enrich our daily lives – coatings, polymers, rubbers, fibers, plastics, cosmetics, pharmaceuticals, and many others.

Ever-improving mathematical models enhance all aspects of petroleum technology. Model-predictive control (MPC) stabilizes operations and reduces product-quality giveaway, increasing profitability at relatively low cost, especially when no new equipment is needed. The simple return on investment for an MPC project can be 3–4 months. Rigorous reaction models, based on molecular characterization, serve as the foundation for real-time online economic optimization, in some cases for entire refineries.

One cannot over-emphasize the importance of safety and environment protection. The root causes of many infamous industrial catastrophes and accidents were the failure of corporate executives, line managers, front-line engineers, and operators to learn and understand technology fundamentals.

Safety and the Environment

2. Safety and the Environment

Paul R. Robinson

Introduction

Safety, reliability, and protecting the environment are inextricably linked. In modern industry, they are prerequisites to profit. Company executives frequently tout their strong commitment to worker health and safety. Their commitment derives to a large extent from strict legislation. Health and safety rules address personal protection equipment, toxic substances, equipment maintenance, worker training, and compliance monitoring. Environmental regulations fall into five main categories: air pollution, waste water, solid wastes, spills, and fugitive emissions. Harm from chronic exposure to pollutants accumulates with time. Harm from major accidents causes tremendous short-term destruction, which often is followed by damage that lingers for years. Many of the worst industrial incidents occur in the coal, oil, and chemical industries. This chapter describes and analyzes numerous examples, many of which are infamous. In most, human misbehavior is the root cause. Misbehavior by unit engineers and operators includes ignoring safety rules, changing procedures without proper management of change, and sabotage. Misbehavior by management includes failing to provide proper training, postponing maintenance, approving substandard equipment, distracting workers (sometimes just with their presence) during safety-sensitive tasks, and understaffing turnarounds with exhausted personnel. Accidents can teach hard lessons. But not everyone learns such lessons, and those who do learn sometimes forget. Others choose to ignore the lessons, because they got away with ignoring them before. Things have gotten better – in developed countries, coal mining companies no longer employ children – but there's still room for improvement.

Process knowledge is the key to ensuring safety and protecting the environment. The purpose of this chapter is to impart knowledge, with focus on the impact of hydrocarbon processing on workers, the public, and the planet we share.

Hopefully, after reading this chapter, managers will be less inclined to:

- Underfund training
- Postpone maintenance
- Purchase substandard equipment
- Understaff operations during critical periods
- Disregard procedures recommended by licensors, industry committees, and their own companies.

2.1 Introduction and History

In developed countries, the quality of human life revolves around the exploitation of coal, petroleum, and natural gas. In 2016 [2.1] these fossil resources provided about 86% of the nonfood energy consumed by people. Oil and gas also serve as organic sources of chemicals. Table 2.1 gives a high-level overview of how petroleum derivatives are transformed into thousands of consumer products [2.2].

The negative impact of exploiting fossil hydrocarbons is both obvious and subtle. Major disasters – mine explosions, oil well blowouts, toxic chemical spills, etc. – generate tremendous immediate damage with aftereffects that can linger for months. They get considerable attention, but as the aftereffects diminish, they tend to fade from memory. Less attention is

Due to lack of knowledge, elected officials seem to believe that there are no right answers. They make serious mistakes about building pipelines, forcing ethanol in gasoline, exempting the fracking industry from clean water legislation, eliminating funding for the cleanup of hazardous sites, and other important matters.

Due to lack of knowledge (and common sense) large numbers of people allow themselves to be convinced that water burns, that batteries can capture lightning, that ultrasound removes sulfur from gasoline, and other misbegotten assertions. Instead of asking challenging questions and checking references, they squander money on schemes that turn charlatans into billionaires.

Can one chapter in one book improve industrial safety and change the way decisions-makers view the environment? One can only hope.

given to long-term exposure to chronic leaks and fugitive emissions, which can cause even greater harm than spectacular accidents.

In developed countries, health, safety, reliability, and protecting the environment are inextricably linked. In today's litigious society, they are prerequisites to profit. Modern executives behave accordingly. Shrugging while saying *It's a dangerous business* has been replaced by Zero-Zero-Zero campaigns aimed at achieving zero injuries, zero loss of containment, and zero unplanned shutdowns. The slogan for ExxonMobil's program is Nobody Gets Hurt [2.3]. Shell preaches Goal Zero [2.4], and employees who violate Lifesaving Rules may be discharged. KBR promotes Zero Harm 24/7 [2.5]. Chevron's ten Tenants of Operation [2.6]

Table 2.1 Overview of the transformation of refinery products into consumer goods

Refinery products	Refinery products to petrochemical plants	Intermediates from petrochemical plants	Fiber precursors	Consumer goods (partial list)
Fuels	Propylene	Acetic acid	Acrylics	Adhesives and sealants
● Gasoline	Isobutane	Acrylonitrile (AN)	Graphite fibers	Antifreeze
● Jet fuels	Butadiene	Acrylonitrile butadiene styrene	Nylons	Carpets
● Diesel	Butenes	Acrylonitrile styrene (AS)	Polybutadiene (PBR)	Construction chemicals
● Fuel oils	Benzene	Alcohols	Polyesters	Corrosion control chemicals
Heating Oils	Xylenes	Cyclohexane	Polyethylene (PE)	Cosmetics
Lubricants	Naphthas	Dimethyl terephthalate (DMT)	Polyethylene terephthalate (PET)	Electronics
Solvents	Middle distillates	Ethanolamine	Polyvinyl chloride (PVC)	Fabrics
Cokes	Hydrocracker bottoms	Ethoxylate	Styrene butadiene resin (SBR)	Fertilizers
Asphalts	Vacuum residue	Ethylene glycol (EG)	Thermosetting resins	Fishing rods
Carbon dioxide		Ethylene oxide (EO)		Flavorings, fragrances, food additives
Sulfur		Formaldehyde		Inks, dyes and printing supplies
Ammonia		Linear alkyl benzene (LAB)		Kevlar
		<i>n</i> -Hexene		Life sciences chemicals
		Phenol		Packaging, bottles, and containers
		Polyol		Paint, coatings, and resins
		Polypropylene (PP)		Pesticides
		Polystyrene (PS)		Pharmaceuticals
		Propylene oxide		Polymers
		Purified terephthalic acid (PTA)		Specialty chemicals
		Styrene monomer (SM)		Surfactants and cleaning agents
		Vinyl acetate monomer (VAM)		
		Vinyl chloride monomer (VCM)		

are prefaced by two statements: *Do it safely or not at all. There is always time to do it right.* These particular companies have departments dedicated to health, safety, and the environment (HSE) led by executives who report directly to the CEO or COO, not just to someone in human resources. The 0-0-0 initiatives are not just for show. They reflect a sincere belief that the energy business doesn't have to be deadly. HSE rules are strictly enforced. This approach requires investment, but the return on such investments is enormous in many measurable ways.

Vox populi – the voice of the people – instigated the regulations that play such a critical role in protecting workers and the environment. Worker safety and environmental movements [2.7, 8] are international, with long and interesting histories.

2.1.1 History of Labor Legislation and Decrees

Worker-protection rules go back to 15th Century England, when provisions were made to prevent abuses in the *truck system* – the paying of wages in goods in-

stead of money. Similar reforms were implemented in Switzerland in the 17th Century.

Efforts to improve the plight of coal miners go back as far as 1775, when an Act of Parliament partially emancipated colliers, coal-bearers, and salters in Scotland [2.9]. According to the Act, the workers were in a *de facto state of bondage*. (They had been since 1606, when an Act of the Scottish Parliament bound them to the mines.) In 1799, another Act explained and amended the 1775 Act, abolishing bondage totally.

In 1802 in England, the Health and Morals of Apprentices Act limited working hours for apprentices to twelve per day and abolished night labor. It required basic education and the provision of clothing and adequate sleeping accommodations. The Factory Act of 1819 limited working hours to twelve per day and prohibited employment of children under nine years of age.

In 1841 in France, a law prohibited employing children under eight years of age and prohibited night labor for any child under 13. In 1848, the working day was limited to 12h for adults in factories. The law was amended in 1885 to include factories with motor power

or furnaces, and to workshops employing more than 20 people.

The first labor law in the Netherlands, passed in 1874, applied only to children working in factories; then as now, it was deemed appropriate for children to do chores on family farms. In 1889, the law was extended to all industries except agriculture, forestry, and fishing. It prohibited the employment of children under 12. In 1895, a law established standards for space, lighting, ventilation, and sanitation. And in 1897, a decree limited working hours according to age and sex, with special provisions for certain industries and pregnant women.

The American Colonies were largely agrarian. Slaves provided labor in southern plantations. Industry was conducted for the most part by master and journeyman craftsmen, supported by apprentices and indentured servants [2.10]. Recorded labor disputes included a 1636 fishermen's strike on an island near Maine, prosecution of strikers in 1677 in New York City, and a 1746 strike by carpenters in Savannah, Georgia.

The United States Congress passed the first federal law governing mine safety in 1891 [2.11]. The law established ventilation requirements for underground coal mines and prohibited owners from employing children under 12. Owners had resisted acting voluntarily, arguing that doing so would put them at a competitive disadvantage.

In 1910, after a decade in which coal mine fatalities exceeded 2000 annually, Congress established the Bureau of Mines to conduct research and reduce accidents in the coal mining industry. Violations of regulations were rampant until 1941, when Congress empowered federal inspectors to enter mines. Over the years, regulations improved, culminating in the Federal Mine Safety Act of 1977, which was amended by the MINER Act of 2006.

US child labor laws lagged the rest of the world by decades. According to the 1890 US Census, about 1.12 million children between six and ten years old were engaged in so-called *gainful occupations* out of a total population of 63 million [2.12–14]. According to the 1900 US Census, the number had increased to 1.75 million children out of a total population of 76.2 million. About 16.7% of children under ten were working, and 18% of children between 10 and 15 were employed full time. Child labor on family farms was expected, but the increase of 50% in under-ten employment for wages, mostly in factories, alarmed many Americans. Attempts at reform were thwarted by the Supreme Court. In 1912, a law established the United States Children's Bureau in the Department of Commerce and Labor. In 1916, the Keating–Owen Act prohibited interstate shipment of goods manufactured or processed by child labor. The

bill passed 337 to 46 in the House and 50 to 12 in the Senate. But in 1918, in a 5-4 decision, the law was ruled unconstitutional by the Supreme Court. In 1938 – after years of court decisions overturning attempts at labor reform – and 118 years after the first child labor law in England – Congress passed the Fair Labor Standards Act (FLSA) [2.15]. The FLSA banned oppressive child labor, set a minimum wage of 25 cent/h, and limited the work week to 44 h. After surviving several Supreme Court challenges, notably the *United States versus Darby Lumber Co.* case in 1941, the FLSA remains in force today.

2.1.2 History of Environmental Laws and Decrees

As humans living on an ever-more-crowded planet, our main reason for abating pollution is self-preservation. While addressing waste in *What Is Life? Margulis and Sagan* [2.16] remind us that *every species or organism produces wastes that are incompatible with its own existence.*

In *The Closing Circle* [2.17], Barry Commoner generalized this principle with his Four Laws of Ecology. The first two are especially relevant: (1) Everything is connected to everything else. What affects one organism affects all. (2) Everything must go somewhere. There is no *waste* in nature and there is no *away* to which things can be thrown.

Fallout from open-air nuclear testing appeared all across the planet. Radioactive isotopes showed up in food, water, and the bones of animals. For the first time, it became clear that certain events have long-lasting global impact. On January 15, 1958, Nobel Laureate *Linus Pauling* presented to the United Nations a petition protesting further nuclear testing [2.18]. The document was signed by 9235 scientists from many countries. The nuclear powers, including the Soviet Union, the United States, and the UK, voluntarily stopped open-air testing that same year. The Soviet Union announced the resumption of open-air testing in August 1961, adding urgency to efforts to conclude a test-ban treaty. In July 1963, the Nuclear Test Ban Treaty was signed, outlawing atmospheric testing but allowing underground testing.

In 1962, *Rachel Carson* published *Silent Spring* [2.19]. Among other things, she presented evidence linking dichlorodiphenyltrichloroethane (DDT) to declines in the bald eagle population, due to the thinning of egg shells. She used the DDT linkage to tell a broader story: what affects one organism can affect all. According to data recently cited by PAN [2.20], an antipesticide organization, DDT breakdown products are still being found in food supplies and human blood.

In response to the efforts of outspoken organizations and people such as Carson, Commoner, and Pauling, the United States formed the Environmental Protection Agency (US EPA). Signed into law by President Nixon in 1970 [2.21], EPA was an amalgamation of departments, bureaus, and agencies taken from the Interior Department; the Department of Health, Education, and Welfare; the Agriculture Department; the Atomic Energy Commission; the Federal Radiation Council; and the Council on Environmental Quality. One of the first actions promoted by EPA was the 1972 ban on DDT.

The history of environmental protection goes back (at least) to the 17th Century [2.22].

After the Great London Fire of 1666, King Charles II proclaimed that all buildings must be constructed from stone, and streets must be widened. The London Cooking Fire Bylaw of 1705 specifically prohibited open fires in the attics of thatched buildings [2.23].

In 1842, the Madras Board of Revenue started local forest preservation efforts in British India. In 1855, under Governor-General Lord Dalhousie, a large-scale, state-managed forest conservation program was established.

Other early examples of British legislation are the 1863 Alkali Acts [2.24], implemented to regulate emissions of hydrochloric acid from the Leblanc process, the leading process for making soda ash. Pressure for the Alkali Acts came from the urban middle class.

Parliament passed the Public Health Act of 1875 to combat the spread of diseases such as cholera and typhus, which percolated in the sewage that flowed

through public streets [2.25]. The Act required all new construction to include running water and internal drainage. It also regulated housing construction and required every public health authority to employ a medical officer and an inspector.

Previous attempts at reform were inhibited by the reluctance of factory owners to improve conditions voluntarily. The Act itself included a *grandfather* clause, which exempted existing facilities. Both factors – grandfather clauses and the reluctance of owners to seek ways to improve conditions voluntarily – continue to plague safety and environmental programs.

The emergence of great coal-burning factories and the concomitant growth in coal consumption increased air pollution in industrial centers enormously. Smoke, soot, and sulfur oxides led to the Great Smog of 1952, which is described in Sect. 2.2.

Conservation in the United States began with the establishment of national parks [2.26], such as the Hot Springs Reservation (1832) [2.27], Yellowstone (1872), Sequoia (1890), Yosemite Valley (1890), Mount Rainier (1899), and Crater Lake (1902).

Major US environment-related legislation includes the following:

- The National Park Service Organic Act (1916)
- Land and Water Conservation Act (1964)
- National Trails System Act (1968)
- National Wild and Scenic Rivers System Act (1968)
- National Environmental Policy Act (1969)
- Clean Air Acts and Amendments (1963 through 1970).

2.2 Pollution from Petroleum Production and Processing

This section describes the predominant gaseous, liquid and solid pollutants generated by the coal, petroleum, and petrochemical industries. It also explains why they can be harmful. Technology for abating these pollutants is described later.

2.2.1 Particulate Matter

The main sources of air pollution from petroleum refineries are listed in Table 2.2. Refineries can be significant sources of particulate matter (PM), which can irritate the respiratory tract. PM is especially harmful when it is associated with sulfur and nitrogen oxides (SO_x and NO_x).

PM from coal is coal dust. PM from refining comes mainly from two sources – delayed coking units and the regenerators of fluid catalytic cracking (FCC) units.

FCC regenerators also emit ammonia, which combines with SO_x and NO_x in the air to form ammonium sulfates and nitrates. According to the South Coast Air Quality Management District (AQMD) [2.28] in Southern California, 1 t of ammonia can generate 6 t of PM₁₀ – airborne particulates with particle diameters less than 10 μm. PM_{2.5} stands for airborne particulates with diameters less than 2.5 μm.

2.2.2 Carbon Monoxide

Carbon monoxide (CO) is formed by incomplete combustion in boilers, process heaters, power plants, and FCC regenerators. CO is toxic because it binds strongly to the hemoglobin in blood, displacing oxygen. It is colorless and odorless, so without a special analyzer, it is hard to detect. This adds to its danger. Un-

Table 2.2 Main sources of air pollution in hydrocarbon processing

Source	PM	SO ₂	CO	VOC	NOx	Hg	VTCs

PM = particulate matter

SO₂ = sulfur dioxide

CO = carbon monoxide

VOC = volatile organic compounds

NOx = nitric oxide (NO) and nitrogen dioxide (NO₂)

Hg = mercury

VTCs = volatile toxic chemicals

der particular conditions in refinery hydroprocessing units, the nickel on NiMo catalysts can react with CO to form nickel carbonyl, an exceptionally hazardous gas.

2.2.3 Hydrogen Sulfide and Sulfur Oxides

Hydrogen sulfide (H₂S) is a pervasive hazard in petroleum production, petroleum refining, and natural gas processing facilities. Sour natural gas can contain several percent H₂S, which is recovered by amine adsorption and converted into elemental sulfur. In developed countries, H₂S recovery must be more than 99% – more than 99.8% in some instances.

Workers are most likely to be exposed due to leaks or when taking samples of sulfur-containing gases or liquids. Sample-taking stations should be well ventilated and equipped with several fixed-in-place toxic-gas monitors. In addition to the fixed monitors, mobile pocket-sized monitors are worn by all workers. Sample-taking procedures include the buddy system: one person takes the sample while another watches. In the past, workers died when rushing forward to help a stricken companion, so the watchers stand at a safe distance with quick access to a radio and/or self-contained breathing apparatus (SCBA).

The impact of H₂S depends on its concentration and duration of exposure [2.29]. At 0.01–1.5 ppm, the characteristic rotten-egg odor is detectable. The odor becomes offensive at 3–5 ppm, where prolonged exposure causes nausea, tearing, asthma, and headaches. Above 20–30 ppm, the odor is said to be sweet or

sickly sweet. Above 100 ppm, olfactory nerves are paralyzed and H₂S can no longer be smelled. Exposure to more than 700–1000 ppm causes immediate collapse and death after one or two breaths.

H₂S is flammable. The explosive range is 4.5–45.5% in air.

Despite periodic training, some workers choose to ignore regulations. During a startup attended by the author in 2015, the buddy system was not used for taking samples of H₂S-containing gas, even though there were six or seven idle workers sitting in a lounge in the control center. The reason given for failure to follow procedure – i. e., to use the buddy system – was: *It is cold outside*.

Sulfur dioxide (SO₂) and sulfur trioxide (SO₃), collectively known as SOx, are produced by the burning of sulfur-containing coal and fuel oil. SOx also are produced by burning coke off of catalysts in FCC regenerators.

2.2.4 SMOG: Nitrogen Oxides, VOC and Ozone

NOx are formed in fired heaters, power plants, and FCC regenerators. NOx also damage respiratory tissues and contribute to acid rain.

Ozone (O₃), a nasty component of smog, is generated by reactions between oxygen, hydrocarbons and NOx. The reactions are initiated by sunlight. In the troposphere, ozone reacts with volatile organic hydrocarbons (VOC) to form aldehydes, peroxyacetyl nitrate (PAN), peroxybenzoyl nitrate (PBN) and a number of

other substances. PAN irritates nasal passages, mucous membranes, and lung tissue. Collectively, these compounds are called *photochemical smog*. They harm humans, animals, and plants, and they accelerate the degradation of rubber and construction polymers. In some areas, smog looks like a brownish cloud just above the horizon. It makes for spectacular sunsets, but nothing else about it is good.

2.2.5 Acid Deposition

In the atmosphere, SO_x and NO_x react with water vapor to make sulfuric and nitric acids. The acids return to Earth as dry particulates or dissolved in moisture – rain, fog, or snow. Acidic moisture, commonly called *acid rain*, poisons trees and contaminates lakes and rivers. In humans, gaseous SO_x and NO_x molecules are trapped by mucous in the upper respiratory track, but dry particulates can penetrate deep into lungs. Experts estimate that SO₂ can remain in the air for 2–4 days. During that time, it can travel 600 mi (1000 km) before returning to the ground. Consequently, SO₂ emissions have caused a number of international disputes. Before 1990, acid rain from neighboring countries caused the death of about a third of the trees in Germany forests. In the past, the United States and Canada argued bitterly about the cross-border impact of SO_x emissions from US power plants and copper smelters; the passage and enforcement of clean-air legislation in both countries has reduced the problem dramatically.

2.2.6 Stratospheric Ozone

The previous section mentions the harmful effects of ground-level ozone. But in the stratosphere, located about 6–30 mi (10–50 km) above the ground, an *ozone layer* protects organisms from harmful ultraviolet-B (UV-B) solar radiation [2.30].

In the 1980s, scientists noticed that the ozone layer over Antarctica was thinning [2.31]. Researchers linked several man-made substances to ozone-layer depletion, including carbon tetrachloride (CCl₄), chlorofluorocarbons (CFCs), halons, methyl bromide, and methyl chloroform. These chemicals leak from air conditioners, refrigerators, insulating foam, and some industrial processes. Winds carry them through the lower atmosphere into the stratosphere, where they react with strong solar radiation to release chlorine and bromine atoms. These halide atoms initiate chain reactions. Scientists estimate that a single chlorine atom can destroy 100 000 ozone molecules.

In 1987, 27 countries signed the Montreal Protocol, which recognized the international consequences of

ozone depletion and committed the signers to limiting production of ozone-depleting substances. Today, more than 190 nations have signed the Protocol, which now calls for total elimination of certain ozone-depleting chemicals.

The 1998 and 2002 scientific assessments of stratospheric ozone firmly established the link between decreased ozone and increased ground-level UV-B radiation. In humans, UV-B is linked to skin cancer. It also contributes to cataracts and suppression of the immune system. The effects of UV-B on plant and aquatic ecosystems are not well understood. However, the growth of certain plants can be slowed by excessive UV-B. Scientists suggest that marine phytoplankton, which are the foundation of the ocean food chain, are under stress from increased UV-B.

In the United States, production of halons ended in January 1994 [2.32]. In January 1996, production virtually ceased for several other ozone-depleting chemicals, including CFCs, CCl₄, and methyl chloroform. January 1, 2010 saw a ban on production, import, and use of HCFC-22 and HCFC-142b, except for continuing servicing needs of existing equipment. In 2015, the production, import, and use of all HCFCs were banned, except for continuing servicing needs. In 2020, there will be no production or imports of HCFC-22 and HCFC-142b, achieving a total reduction of 99.5%.

New products less damaging to the ozone layer are replacing chlorofluorocarbons. For example, computer makers now use ozone-safe solvents to clean circuit boards, and automobile manufacturers use HFC-134a, an ozone-safer refrigerant, for air conditioners in new vehicles.

Studies indicate that the Montreal Protocol has been effective. Stratospheric concentrations of methyl chloroform are falling. Concentrations of other ozone-depleting substances, such as CFCs, are also decreasing. According to the US EPA [2.33], the ozone layer has not grown thinner since 1998 and appears to be recovering. Antarctic ozone is expected to return to pre-1980 levels sometime between 2060 and 2075.

2.2.7 Greenhouse Gases and Climate Change

For a thorough but succinct overview of the technology and politics of climate change, please refer to *Energy and Climate: Vision for the Future*, by Michael B. McElroy [2.34].

According to the US Environmental Protection Agency [2.35]:

The Earth's climate is changing. Temperatures are rising, snow and rainfall patterns are shifting, and

more extreme climate events – like heavy rainstorms and record high temperatures – are already happening. Many of these observed changes are linked to the rising levels of carbon dioxide and other greenhouse gases (GHGs) in our atmosphere, caused by human activities.

The Inter-government Panel on Climate Change (IPCC) estimates that if present trends continue, sea level will rise by about 1 meter by 2100 [2.36]. That could displace up to 100 million people from coastal areas, contaminate ground water and increase storm-surge damage. By putting more thermal energy into the oceans and atmosphere, warming will strengthen storms and continue to distort weather patterns, threatening certain crops.

Two important climate-change concepts are radiative forcing and global warming potential (GWP) [2.37].

Radiative forcing is the change in net irradiance (expressed in W/m^2) due to a change in an external driver of climate change, such as a change in the concentration of carbon dioxide or the energy output of the Sun. Radiative forcing is computed with all other tropospheric properties held fixed at their unperturbed values. Typically, radiative forcing is defined as the change relative to conditions in 1750 or 1850 and usually refers to a global and annual average value.

Global Warming Potential (GWP) is an index based upon radiative forcing of a unit mass of a given well-mixed GHG in the present-day atmosphere integrated over a chosen time horizon, relative to that of carbon dioxide. The GWP calculation includes the combined effects of residence time in the atmosphere and the

relative effectiveness of a gas in absorbing outgoing infrared radiation.

How Do We Know Global Temperatures Are Rising?

We have been collecting direct temperature readings since the 1800s. At the behest of Alexander von Humboldt, ships from many nations began collecting temperature and salinity data before 1804. Land-based data are now being gathered from more than 4300 stations around the globe. Thousands of buoys and floats measure ocean temperatures, both at the surface and down to 4000 m. The Goddard Institute for Space Studies (GISS) estimates that the global mean temperature of the Earth's surface increased by about $1.2^\circ C$ between 1880 and 2016 (Fig. 2.1) [2.38]. The figure also shows, for subsequent discussion, atmospheric carbon dioxide (CO_2) data from Figure 2.5.

Temperatures for the past 2000 years are estimated from tree-ring measurements and coral growth. Ocean surface temperatures back to 800 000 BCE are inferred by measuring isotope ratios in ice cores [2.39]. When water evaporates, lighter molecules – those containing ^{16}O and simple hydrogen – vaporize more readily, enriching the remaining water in heavier molecules – those containing ^{18}O and/or deuterium. The extent of the difference depends on temperature. Evaporation is greater in equatorial regions. As air masses move poleward, water vapor condenses into rain. Condensation preferentially removes deuterium and ^{18}O , further enriching the remaining vapor in lighter isotopes. In higher-latitude regions, the deuterium/hydrogen and $^{18}O/^{16}O$ ratios in rain (and snow) are significantly lower than in equatorial rains. There is more ^{18}O and deuterium in ice

Fig. 2.1 Change in global mean surface temperature and concentration of atmospheric carbon dioxide since 1880. The base period for temperature is the average for 1951–1980

during warm periods, because higher temperatures put more water vapor into the air, and more water containing heavy isotopes reaches higher latitudes.

Rock cores provide another isotopic proxy for ancient temperatures. The $^{18}\text{O}/^{16}\text{O}$ ratio in surface water depends on temperature, and it determines the $^{18}\text{O}/^{16}\text{O}$ ratio in the shells of the foraminifera growing in that water. When the organisms die, their remains sink to the bottom and become incorporated into sedimentary rock. The cores are dated radiometrically, typically with the $^{234}\text{U}/^{230}\text{Th}$ method [2.40].

When coupled with information from other sources, isotope data from the EPICA Dome C ice core indicate the following:

- Around 125 000 years ago, when average surface temperatures were $4\text{ }^{\circ}\text{C}$ higher than now, the average global sea level was 4 m to 6 m higher.
- Around 20 000 years ago, when average surface temperatures were $12\text{ }^{\circ}\text{C}$ lower than now, the average global sea level was 120 m lower [2.41].

What Is the Greenhouse Effect?

Scientists have been discussing climate change and the greenhouse effect for more than 200 years. Humboldt postulated human-induced climate change in 1800. Jean Baptiste Joseph Fourier (1768–1830) recognized that the Earth's atmosphere retained solar radiation, likening the effect to that of a black box in which the top panel is replaced by a pane of glass.

In 1862, John Tyndall, a prominent Irish physicist, conducted experiments which showed that certain gases, including water vapor and CO_2 , absorb IR radiation [2.42]. He concluded that in the atmosphere, such gases helped to warm the Earth by capturing escaping heat. He wrote:

As a dam built across a river causes a local deepening of the stream, so our atmosphere, thrown as a barrier across the terrestrial rays, produces a local heightening of the temperature at the Earth's surface.

Visible light enters a greenhouse through transparent glass. Inside, the light is absorbed by plants and other objects and then reradiated as heat, i. e., infrared (IR) radiation. Ordinary glass is mostly opaque to IR, so reradiated heat is trapped inside the greenhouse, causing temperatures to go up.

An interesting analogy comes from the American Chemical Society [2.44]:

Think of yourself under a blanket in a cold room. You represent the Earth, a warm body giving off energy [...] The blanket represents the atmospheric layer of greenhouse gases. As the heat energy leaves your body it is absorbed by the innermost fibers of the blanket. As they give off some of that energy, they warm the next layer of fibers and so on and on until some energy leaves the outermost cold fiber layer and is lost to the room. Just as the Sun continually warms the Earth, you continually produce energy through respiration. You will finally reach a balance where the energy leaving the blanket is equal to the energy you produce and your skin will remain at a constant temperature, just like the surface of the Earth.

Greenhouse Physics

GHG molecules are analogous to fibers in our imaginary blanket. IR radiation causes them to vibrate. They re-radiate vibrational energy in all directions. Some is absorbed by other GHG molecules, some goes back to the Earth's surface, and some escapes into space.

The wavelengths of light emitted by an object depend on the object's temperature [2.45]. As shown by Figure 2.2, the effective temperature of solar radiation when it reaches the Earth is around $5800\text{ }^{\circ}\text{C}$. The Sun emits a broad spectrum of radiation with peak intensities at wavelengths in the visible range between 0.4 and $0.7\text{ }\mu\text{m}$. The Earth re-emits that energy into space at an average temperature of $-18\text{ }^{\circ}\text{C}$ as IR radiation with peak intensities at wavelengths above $10\text{ }\mu\text{m}$ [2.46].

Continuing with the blanket analogy: what if the blanket has gaps or holes? Water vapor is the most

Fig. 2.2 Temperature and frequency of light emissions from the Sun and Earth (after [2.43])

abundant GHG and absorbs the most heat. It has gaps because it does not absorb at all IR wavelengths. Other GHGs reinforce absorption at wavelengths where water vapor absorbs, but in some cases they also fill the gaps left by water vapor. Figure 2.3 illustrates this plug-the-gap phenomenon for CO₂.

Which Gases Are Greenhouse Gases?

N₂ and O₂ are the main constituents of the Earth's atmosphere (see Table 2.3). They are not GHGs, because they are transparent both to visible and IR radiation. Other non-GHGs are H₂ and noble gases.

Table 2.4 presents current atmospheric concentrations, residence times, and 100-year global warming potentials for CO₂, CH₄, N₂O, and three selected fluorinated gases, all of which are significant GHGs [2.47]. The table also mentions water vapor, the most abundant GHG.

Table 2.5 gives a breakdown of anthropogenic GHG emissions.

Carbon Dioxide (CO₂). Figure 2.4 presents a simple view of the global carbon cycle. Most atmospheric CO₂ is natural. In the short-term carbon cycle, significant amounts of CO₂ are exchanged with the biosphere, soil and the hydrosphere.

Dissolved in water, CO₂ forms carbonic acid (H₂CO₃), bicarbonate (HCO₃⁻), and carbonate (CO₃²⁻). Sea water is slightly alkaline, with a surface pH of 8.2, so it readily reacts with H₂CO₃. Corals, foraminifera, and other marine organisms incorporate carbonates into aragonite shells. The extent to which H₂CO₃ forms inorganic bicarbonate (HCO₃⁻) and carbonate (CO₃²⁻) in deeper water depends on water acidity and depth [2.49]. The long-term carbon cycle includes silicate weathering, in which silicate rocks are dissolved by carbonic acid (H₂CO₃) or converted into carbonate rocks. Eventually, volcanic action releases CO₂ from carbonate rocks. The long-term cycle also includes fossil-fuel formation from dead organic matter, a process which takes hundreds of millions of years.

When something happens to upset the balance, exchange processes move the system toward a new steady state. But the movement is not instantaneous. Since the

advent of the industrial revolution in the mid-eighteenth century, humans have been upsetting the short-term carbon cycle by burning fossil fuels and biomass, by making cement, and by altering land use with deforestation, agriculture and soil degradation. It takes time for the biosphere and hydrosphere to take up excess CO₂. Uptake by surface waters is governed by equilibrium. It takes hundreds if not thousands of years for surface-ocean CO₂ to move into deeper waters. The ultimate CO₂ buffer is weathering, but weathering takes even longer.

During 2002–2011, about 46% of anthropogenic CO₂ remained in the atmosphere. The remainder went into terrestrial biomass (28%) and the oceans (26%) [2.50]. In recent years, humans sent as much as 7.4 Gt of carbon into the air, mostly as CO₂. This amount can be more than 80 times greater than the carbon from volcanic activity [2.51].

Says John Higgins of Princeton University [2.52]:

The earth can take care of extra carbon dioxide when it has hundreds of thousands or millions of years to get its act together. In contrast, humankind is releasing carbon dioxide today so quickly that silicate weathering can't possibly respond fast enough [...] The earth has these long processes that humankind has short-circuited.

Another CO₂-related concern is ocean acidification. Between 1751 and 1996, the pH of the surface ocean has dropped from about 8.25 to 8.14 [2.53]. This increase in acidity is dissolving coral reefs [2.54].

Methane (CH₄). Methane is emitted during the production and transport of coal, petroleum, and natural gas. Methane also is produced by termites, livestock, agricultural practices, and the anaerobic decay of mu-

Table 2.3 Average concentrations of non-greenhouse gases in dry air

Gas	Vol%
N ₂	78.08
O ₂	20.95

Fig. 2.3 Filling gaps in IR absorption by water vapor with CO₂

Table 2.4 GHG concentrations, residence times, and GWP for a 100-year horizon

Gas	Formula	Current atmos. concentration	Residence time (years)	GWP versus CO ₂ , 100-year horizon
Water vapor	H ₂ O	≈ 1% at sea level ≈ 0.4% throughout the troposphere	N/A	N/A
Carbon dioxide		400 ppm	^a	1
Methane ^b	CH ₄	1.8 ppm	12.4	28–36
Nitrous oxide	N ₂ O	320 ppb	121	265–298
HCF-134a	CH ₂ FCF ₃	0.01 ppb	14.6	1300
Halon 1301	CBrF ₃	0.003 ppb	65	7140
Sulfur hexafluoride	SF ₆	0.008 ppb	3200	23 900

^a CO₂ is not destroyed in the atmosphere. Instead, it cycles between the biosphere, soil, and hydrosphere. The global carbon dioxide cycle is illustrated in Fig. 2.4.

^b CH₄ has direct and indirect effects. It absorbs IR radiation and generates O₃, which itself is a GHG.

Table 2.5 Global anthropogenic emissions of greenhouse gases [2.48]

nicipal wastes in landfills. Table 2.6 provides a breakdown.

Nitrous Oxide (N₂O). Nitrous Oxide is emitted by excessive use of ammonia fertilizers and by certain chemical manufacturing plants. It also is produced during combustion of fossil fuels and solid waste. Table 2.7 provides a breakdown.

Fluorinated Gases. Fluorinated Gases include hydrofluorocarbons, perfluorocarbons, sulfur hexafluoride, and other compounds. They are emitted during industrial, commercial and household use. They do

not occur naturally. Some are used as substitutes for ozone-depleting substances such as chlorofluorocarbons (CFCs).

How Do We Know Greenhouse Gas Concentrations Are Higher Now than Before?

We have been measuring atmospheric GHG concentrations in several stations at different latitudes since 1959, and we are measuring GHG concentrations in air bubbles trapped in ancient ice cores. Figure 2.5 shows atmospheric CO₂ measurements from several sources – from ice core samples that are as old as 800 000 years and, since 1959, from surface measurement stations.

Table 2.6 Sources of methane emissions [2.55]

Natural	
Biomass burning	10
Atmospheric deposition	9

Prior to the 1800s, the peak atmospheric CO₂ concentration was <280 ppm except for a brief excursion to nearly 300 ppm at around 331 000 BCE. In 1878, the concentration topped 290 ppm and has been rising ever since. In 2015, the annual average at the Mauna Loa station in Hawaii topped 400 ppm.

How Do We Know People Are Responsible for the Recent Increase in GHGs?

As shown, by 2015, atmospheric CO₂ had increased to 400 ppm compared with 280 ppm in pre-industrial times. The increase cannot be explained by natural causes. When we add the observed CO₂ increase in the atmosphere to the observed increase in the oceans, the sum is approximately equal to all of the coal, oil, and natural gas burned since the nineteenth century [2.57].

The ¹³C/¹²C ratio in atmospheric CO₂ has been dropping steadily. This shows that atmospheric CO₂ is being diluted with CO₂ that contains less ¹³C. Both fossil fuels and old trees are low in ¹³C; we have been burning the former and destroying the latter at unprecedented rates. The ¹³C/¹²C ratio for oceanic CO₂ has dropped, too, with the greatest depletion in surface water. Radioactive ¹⁴C in atmospheric CO₂ also is getting lower. Fossil fuels contain no ¹⁴C; the CO₂ produced from their use contains no ¹⁴C. The carbon in old trees does contain ¹⁴C. The conclusion is clear: the extra CO₂ in the air comes from fossil fuels.

Finally, the annual mean CO₂ abundance in the northern hemisphere is higher than in the southern hemisphere. The difference has increased in recent years. This is consistent with the fact that most fossil fuel burning occurs in the northern hemisphere.

Global Energy Balance

Ultimately, we are concerned about GHGs because they play a major role in the global energy balance. The

Fig. 2.5 Measurements of CO₂ in ice core air bubbles. Ice core data come from EPICA Dome C and Vostok Station, Antarctica (back to 800 000 BCE); Law Dome, Antarctica (back to 1010 CE), and Siple Station, Antarctica (back to 1744 CE) [2.56]

balance is affected by many phenomena, including the following:

- Solar irradiance: determined by the ellipticity and obliquity of Earth's rotation and the Sun's surface temperature
- Volcanic aerosols: direct and indirect effects
- Tropospheric aerosols: particulates produced by burning
- Cloud cover
- Greenhouse gases: water vapor, CO₂, CH₄, N₂O, fluorinated gases, ozone
- Oceans: composition and circulation
- Snow and ice albedo
- Black carbon: from forest and grass fires, burning biomass for fuel, and fossil fuels
- Plants: growth, death, decomposition
- Land use: deforestation, cultivation, ruminants.

Figure 2.6 illustrates the relative impact of various phenomena on global energy. For each factor, the starting point is the 1880 value. Data for the plots are from GISS CMIP5 simulations [2.58] with the following exception: black carbon is split into natural (40%) and human (60%) components per *Ramanathan and Carmichael* [2.59].

Section A shows the impact of solar irradiance. Black carbon is a highly absorptive component of fine particulate matter. About 40% comes from open burning (forest and grass fires), about 20% comes from burning wood and other biofuels, and about 40% comes from burning fossil fuels. Stratospheric aerosols come from volcanoes. Major eruptions hurl immense quantities of particulates (aerosols) into the stratosphere, where they cool the Earth by reflecting sunlight back into space. The figure does not show the impact of the 1815 eruption of Mt. Tambora in Indonesia, which caused the *year without a summer* (1816) in the northern hemisphere. But it does show the impact of Krakatoa (Indonesia, 1882), Mt. Agung (Indonesia, 1963–64), Mt. St. Helens (USA, 1980) and Mt. Pinatubo (Philippines, 1991). Volcanoes also emit CO₂, SO₂, and halogens. As mentioned, on average, global anthropogenic CO₂ emissions are ≈80 times greater than CO₂ from volcanic emissions.

Section B shows the impact of eight anthropogenic factors. Greenhouse gases include anthropogenic CO₂, CH₄, N₂O, and fluorinated gases. Black carbon is mentioned above. Tropospheric ozone forms with photochemical smog. Snow albedo is reduced when fouled by soot from coal combustion. Direct tropospheric aerosols reflect sunlight back into space. Indirect effects include inducing cloud formation.

Section C compares forcings for greenhouse gases with all forcings, all natural forcings and all human

forcings. The data come from models, but the models match enormous amounts of data from many sources with high fidelity. It is difficult to view Figure 2.6 without concluding that GHGs impact the global heat balance in a major way.

Figure 2.7 and Table 2.8 illustrate a representative energy balance for the Earth; the balance changes seasonally [2.60]. Incident solar radiation is 340.4 W/m². Of this, 77.0 and 22.9 are reflected directly back into space by the atmosphere and surface, respectively. The fraction of reflected light is called the albedo, which in this case is 0.29. Clouds and aerosols account for most atmospheric reflection. Ice, desert sands, and other light-colored materials account for most surface reflection.

Of the non-reflected portion (240.4 W/m²) 32% is absorbed by the atmosphere and 68% is absorbed by the surface. The surface receives 485.2: 163.3 from the Sun and 321.9 re-radiated from GHGs. The surface re-emits this energy as IR radiation, thermals and evaporation. Thermals are rising masses of air, which distribute heat in the troposphere. Evaporation includes transpiration from plants. It generates clouds, in which latent heat is released via condensation to form rain or snow.

Of the re-emitted energy, 40.1 goes directly to space and the remainder goes to the atmosphere. The atmosphere and clouds emit 199.8 into space and recycle 321.9 to the surface.

Total outgoing radiation is 239.9. This is 0.2% less than incoming radiation. The imbalance increases temperature. Temperature change is easy to measure, but it is moderated by the properties of water. That marvelous substance is present on Earth in three phases. Liquid water has a high heat capacity, and both evaporation and freezing absorb considerable latent heat without a change in temperature. Small changes in temperature can correspond to large changes in heat. It's the heat that matters.

What Can Be Done About Climate Change?

Climate always will be changing. The real questions are: do you believe the science, which implies that human behavior is accelerating global warming? If so, do you believe the problem warrants action? If so, what should we do to minimize the damage that our actions are likely to cause during the remainder of the twenty-first century?

The *we* in this case means individuals, not just governments or companies. Unlike other matters discussed in this chapter, the problem is not specific to one technology, one company, or one industry. Everyone has an impact. In metabolizing food, an average human consumes 100 W of energy – the same as a typical light bulb – just by being alive. But we consume far more

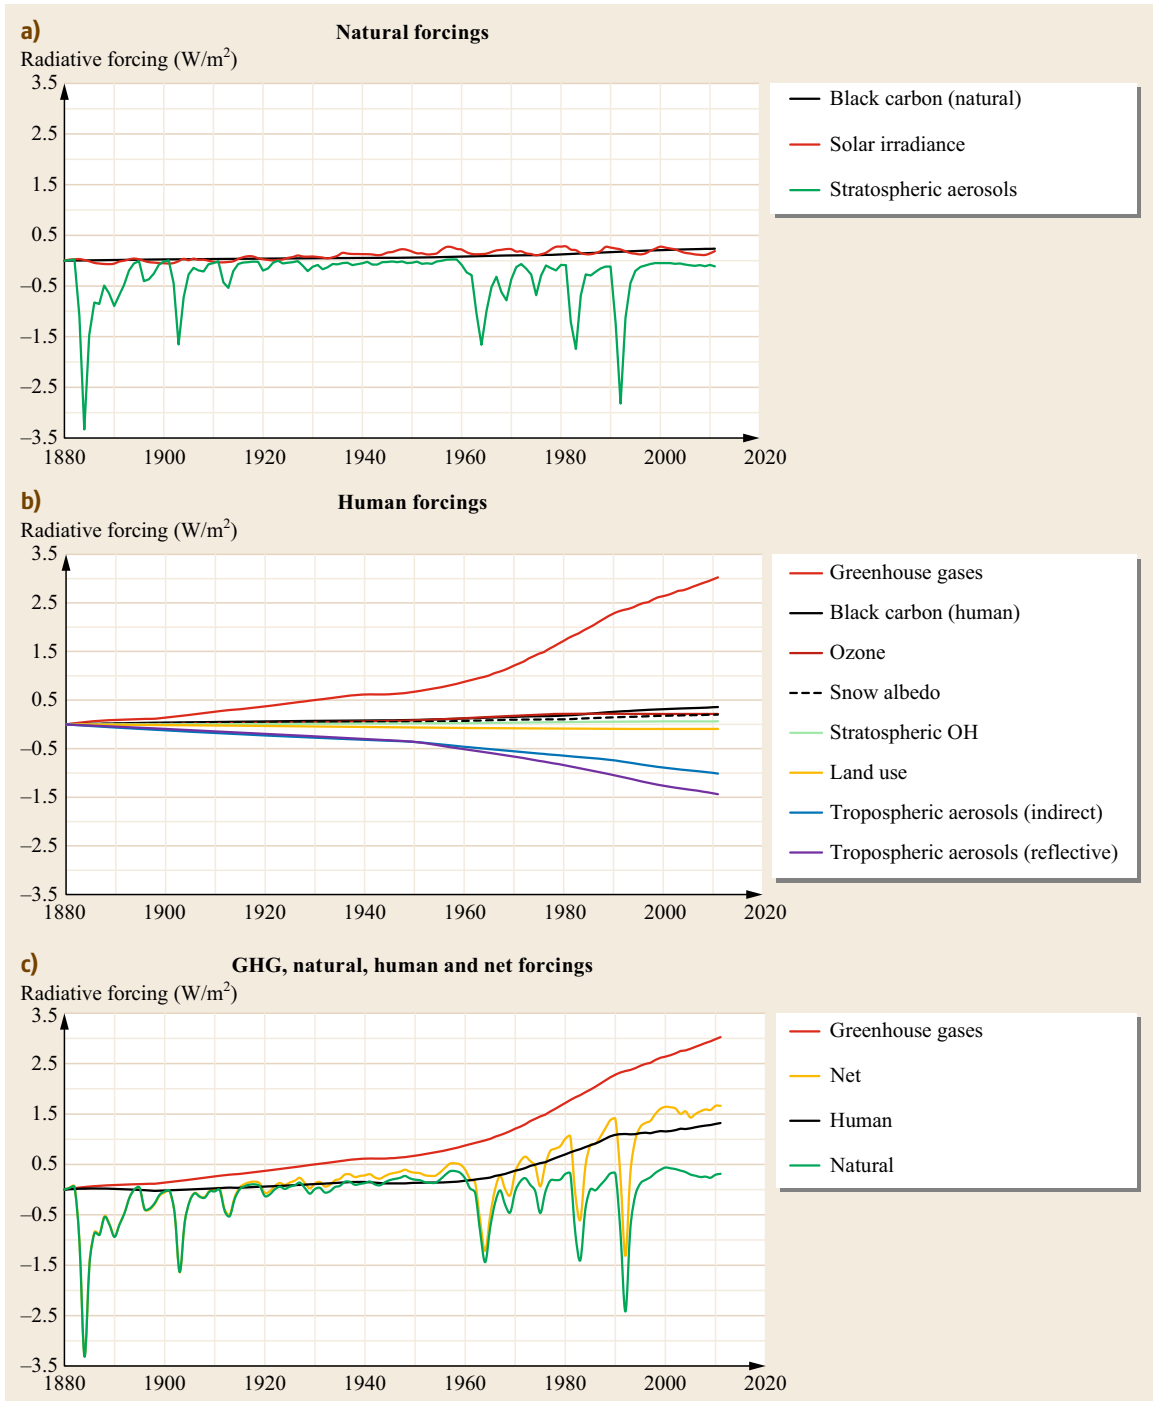

Fig. 2.6a–c Radiative forcings in W/m^2 for natural and human phenomena. with the following exception: black carbon is split into natural (40%) and human (60%) components per *Ramanathan and Carmichael* [2.59]

than a single light bulb. In 2013, average per capita energy consumption was 9210 W in the United States, 5150 W in Germany, 2965 W in China, 810 W in In-

dia, and 290 W in Bangladesh [2.61]. Especially in the United States, the world's 2nd-largest consumer, there is ample opportunity to conserve; Figure 1.5 in the

Fig. 2.7 Representative energy balance for the Earth. Accompanies Table 2.8. Incoming sunlight (340.4 W/m^2) exceeds outgoing radiation (339.8 W/m^2) by 0.21%

Table 2.8 Energy budget for the Earth. Accompanies Figure 2.7

	W/m^2		Percent of incoming	
Incoming sunlight (340.2 W/m^2)		340.4		100.00
Total reflected light:		99.9		29.35
● Reflected by clouds, aerosols, other	77		22.62	
● Reflected by the surface (ice, sand, other)	22.9		6.73	
	W/m^2		Percent of absorbed	
Absorbed by the Earth:		240.2		100.00
● By the atmosphere	77.1		32.07	
● By the surface	163.3		67.93	
IR Radiation				
Total outgoing IR radiation:		239.9		99.88
● From the atmosphere	169.9		70.73	
● From clouds	29.9		12.45	
● Directly into space	40.1		16.69	
From the surface to the atmosphere:		445.1		185.30
● GHGs	340.3		141.67	
● Hot-air thermals	18.4		7.66	
● Evaporation	86.4		35.97	
From the atmosphere to the surface		321.9		134.01
Net absorbed	0.5		0.21	

first chapter of this book describes how price shocks have led to significant reductions in energy consumption.

But the world population is rising and the economies of India and other developing countries are

growing. These factors alone are offsetting GHG reductions in developed countries. To make substantial long-lasting impacts will require low-cost infrastructure improvements, such as replacing consumption of fossil fuels – especially coal – with wind and solar energy.

More expensive endeavors – hydroelectric projects and nuclear power plants – also reduce fossil fuel consumption, but they have greater impact on other aspects of the environment.

Major projects require means but also will. In many quarters, will is lacking. Key decision-makers doubt the veracity of climate-change science. In the United States in 2017, the administration seemed to believe that the problem would go away if the terms *climate change* and *global warming* were deleted from government web sites.

In the end, regardless of whether you believe human-induced climate change is something to be concerned about, taking care of Planet Earth is the right thing to do. There is no Planet B.

2.2.8 Wastewater

Bitumen recovery processes such as SAGD (steam-assisted gravity drainage) and cyclic steam stimulation (CSS) require tremendous amounts of water [2.62]. SAGD produces wastewater contaminated with fines, trace metals, and hydrocarbons. At present, only a fraction of wastewater is recovered. Most goes to large tailing ponds, where the oil undergoes oxidation, generating significant amounts of CO₂ [2.63]. Environment Canada tolerates the tailings ponds.

Refineries and chemical plants generate contaminated process water, oily runoff, and sewage. Water is used by just about every process unit, especially those that require wash water, condensate, stripping steam, caustic, or neutralization acids. Contaminated process water may contain suspended solids, dissolved salts, water-soluble chemicals, phenols, ammonia, sulfides, and other compounds. As much as possible, wastewater streams are purified and reused. Present requirements ensure that the water going out of a U.S. or EU refinery processing plant is at least as clean as the water coming in.

Wastewater regulations and cleanup are described below.

2.2.9 Solid Waste

Solid wastes from coal and petroleum processing may include the following:

- Coal fines
- Cuttings from oil-well drilling
- Used drilling mud
- Spent catalyst and catalyst fines
- Acid sludge from alkylation units
- Sludge from the bottom of storage tanks
- Miscellaneous oil-contaminated solids.

Wastes that cannot be recycled are cleaned on site, sent to landfills, or transported to reclamation facilities. Some of the technology used for cleanup and reclamation is discussed in Sect. 2.6.

2.2.10 Oil Spills

Large spills of oil from tankers and pipelines can cause tremendous damage to the environment. Small spills come from leaks in tanks or mishaps during the loading or unloading of trucks, ships, or rail cars. Technology for cleaning up spills is discussed in Sect. 2.6.6.

2.2.11 Fugitive Emissions

Fugitive emissions are comparatively small amounts of gaseous, liquid, and solid wastes, which come from process equipment during industrial activities. Even small quantities of leaked gases, such as benzene, can cause serious damage to health and the environment when the emissions are continuous or chronic. Flammable chemicals can accumulate to form explosion hazards. One recent study showed that fugitive emissions were equivalent to 0.17 wt% of a refinery's throughput.

Leaks from high-pressure equipment usually occur through valves, connections, or mechanical seals. Other emissions come from storage tanks and waste treatment facilities. Operators regularly check for leaks with gas detectors and take appropriate corrective action.

Fugitive emissions can be hard to detect, and the sizes of leaks can vary with processing intensity and ambient conditions. Work continues on developing improved methods for discovery and analysis. One new technology is differential absorption, which can be used to measure concentrations of atmospheric hydrocarbons hundreds of meters from a facility. Opacity meters measure particulate emissions, and IR imaging can detect otherwise invisible gases escaping from leak sources.

2.2.12 Fracking

Fracking, discussed in Sect. 14.3.2, warrants a separate section in this chapter, because its widespread use is relatively recent, and because of unresolved questions about its impact on the environment. The economic impact of fracking is global. It dropped the price of oil, causing it to fall by more than 50% in less than two years while transforming the United States into the world's leading producer of oil and gas.

Fracking Technology

For decades, oil and gas companies knew of seemingly inaccessible hydrocarbons trapped in shale for-

mations with low permeability. Hydraulic fracturing (*fracking*) [2.64] increases permeability. Fracking involves pumping slurries of water, sand, and chemicals at high pressure into a hydrocarbon-containing formation. The pressure fractures the surrounding rock, and the sand props open the resulting passages. The chemicals can include acids, which dissolve particulates; silicones, which enhance flow; and surfactants.

Fracking isn't new. It was first applied in 1947 in Grant County, Kansas [2.65]. But now it is being employed in a new way. In the 1980s, George P. Mitchell started experimenting with different fracking techniques in the depleted Barnett Shale formation in Texas. By drilling horizontal wells and fracking directly under the densest rock, Mitchell got phenomenal results. His method transformed the Barnett Shale into a major gas field. Since then, similar methods have been applied to several other formations, including the Eagle Ford in Texas, the Bakken in North Dakota, and the Marcellus and Devonian, which at different depths underlay significant regions of Tennessee, Kentucky, Ohio, West Virginia, New York and Pennsylvania. The Marcellus shale alone contains around 500 trillion cubic feet of natural gas.

Fracking Exemption to the US Safe Drinking Water Act

Fracking requires immense amounts of water. In 2010, the US Environmental Protection Agency estimated that 70–140 billion gal of water are used to fracture 35 000 wells in the United States each year [2.66]. For coal-bed methane wells, fracturing uses 50 000–350 000 gal per well. For deeper horizontal shale wells, fracturing uses 2–10 million gal per well. In some cases, up to 90% of the water remains underground [2.67]. The rest comes back with the oil and gas, accompanied by natural underground water.

Typically, the wastewater is dark, thick, and smells of sulfur [2.68]. It contains dissolved minerals and chemicals. It tends to have high salinity, and sometimes it contains low levels of radiation. The wastewater goes

to a settling pit, where entrained oil disengages and floats to the surface. The oil is skimmed off and sold. The water is trucked to disposal wells and injected deep underground for permanent storage.

The Energy Policy Act of 2005 exempted fracking fluids from the United States Safe Drinking Water Act (SDWA) [2.69], except when diesel fuels are used. The Act did not exclude fracking wastewater, which is still covered by the SDWA. The *fracking loophole* was created, in part, so that service companies wouldn't have to disclose the chemical composition of their frack water. The problem is that if an incident forces chemicals into an aquifer, responders may be unprepared to take action. They won't know in advance what the contaminants might be, and they won't know at all until they analyze samples and/or get answers from the responsible company. Citizen's groups are deeply concerned. Several times between 2009 [2.70] and 2013 [2.71], legislation was introduced to close the fracking loophole. As of February 2017, the loophole was still open.

Fracking Induced Earthquakes

According to Scientific American [2.72], researchers at the United States Geological Survey (USGS) and other institutions have linked earthquakes to hydraulic fracturing and injecting wastewater from oil and gas operations into deep wells. Earthquake rates have skyrocketed in Oklahoma and Texas. Before 2008, not a single earthquake had been recorded by the USGS in the Dallas–Fort Worth area. Since then, nearly 200 quakes have shaken the cities and their immediate suburbs. The largest measured 5.6 on the Richter scale. Oklahoma has seen a 160-fold spike in quakes. Some damaged buildings and highways and sent people to hospitals. In 2014, Oklahoma's earthquake rate surpassed California's. Certain states have started to limit the amount of wastewater sent underground. But quakes could continue even if injections were stopped, because pressure changes can migrate for years, inducing changes in faults farther and farther away from the points of injection.

2.3 Significant Accidents and Near-Misses

As mentioned, safety, reliability, and protecting the environment are inextricably bound. The worst industrial accidents are deadly both to people and their surroundings. Several such accidents are reviewed in this section. Some are described by *Incidents that Define Process Safety* [2.73], a fine book assembled by John Atherton and Frederic Gil. At the front of that book is

a quote from Jesse C. Ducommun, a director of American Oil Company and a process safety pioneer. In 1961, he said:

It should not be necessary for each generation to re-discover principles of process safety which the generation before discovered. We must learn from the

experience of others rather than learn the hard way. We must pass on to the next generation a record of what we have learned.

George Santayana said: *Those who cannot remember the past are condemned to repeat it.* (Experience has taught me that there is truth in Kurt Vonnegut's rejoinder: *I've got news for Mr. Santayana: we're doomed to repeat the past no matter what.* In other words, there will always be people who ignore the past and others who don't care to learn.)

Reviewing incidents tells us that the following factors are common root causes:

1. *Absences of Regulations.* Workers and managers behave as they always have, either because they don't know there's a problem with a particular practice or there is no incentive to change.
2. *Design Flaws.* Flaws in design include flaws in procedures. Many are caused when equipment or procedures are exposed to a previously unknown physical phenomenon. Others result from willful misconduct – cutting corners to reduce costs or avoid delays.
3. *Poor Maintenance.* Poor or nonexistent maintenance plays a role in several of the incidents below, including one of the worst (Bhopal). According to the U.S. Coast Guard's National Response Center, equipment failure caused about half of the roughly 7600 accidental chemical releases reported by refineries during 2001 to 2010. Factories are scheduling fewer maintenance shutdowns, known as turnarounds, while increasing burdens on aging equipment. This is sometimes called *run to failure* – pushing equipment until it breaks [2.74].
4. *Ignorance.* The examples reveal two sources of ignorance: (a) an accident was the first of its kind and could not have been predicted by the people at hand, and (b) lack of training.
5. *Lack of Preparation.* Accidents can get worse when people are not prepared to respond.
6. *Willful misconduct.* Examples of willful misconduct abound. One of the most famous was the decision by senior managers to launch the Space Shuttle Challenger on January 28, 1986, despite vehement opposition from Roger Boisjoly and other engineers. Crucial O-ring seals failed, and the Challenger and its crew were destroyed. The Chernobyl nuclear reactor meltdown (see below) also was caused by willful misconduct.
7. *Did-it-before syndrome (DIBS).* People learn from experience. When they get away with shortcuts, with flouting rules over and over again, they come to

believe that flouting rules is acceptable. Eventually, they conclude that their way is better. They may be correct. If so, they are obliged to take proper steps to modify the rule.

8. *Malicious acts.* These include illegal midnight dumping; cover-ups; sabotage; and acts of war.

2.3.1 Coal Mining: Explosions and Black Lung Disease

Coal mine explosions and maladies such as black lung disease have plagued the energy industry since the start of the Industrial Revolution. In 1906, in a mine explosion in Courrières, France, 1099 people died, including children. Courrières was the worst mine accident in Europe. In April 1942, in a coal-mine explosion in Benxi, Liaoning, China, 1549 workers died in the worst coal-mine accident ever.

Mine explosions are caused by methane and/or coal dust. *Damp* is a catch-all term for gases other than air in coal mines. In addition to firedamp (methane), there is blackdamp (carbon dioxide), stinkdamp (hydrogen sulfide), and afterdamp (carbon monoxide). Firedamp is explosive in air at concentrations between 4 and 16%.

In May 1812, Sir Humphry Davy developed the Davy lamp, in which a low flame was surrounded by iron gauze. Due to the gauze, the lamp did not ignite ambient methane, but methane could pass into the lamp and burn safely within the flame. At first, the Davy lamp improved safety by eliminating open-flame lighting. But it led to the mining of areas that had previously been closed for safety reasons, sometimes with disastrous results [2.75].

Black lung disease is actually a set of maladies associated with coal dust [2.76]. It was not well understood until the 1950s. In the Federal Coal Mine Health and Safety Act of 1969, the US Congress set limits on coal dust exposure and created the Black Lung Disability Trust. Mining companies agreed to a clause that guaranteed compensation for workers or the families of workers who had spent 10 years doing mine work and could provide x-ray evidence of lung damage. Families of deceased miners were allowed to provide autopsy evidence. Financed by a federal tax on coal, by 2009 the Trust had distributed over \$44 billion in benefits to disabled miners or their widows.

2.3.2 Lakeview Oil Well: Blowout (March 1910–September 1911)

The Lakeview gusher [2.77] remains the largest accidental oil leak or spill in history. It released 1.2 million t of crude in 544 days. Drilling started in January 1909.

Initially, the only product from the well was natural gas. On March 14, 1910, pressurized oil blew through the well casing above the drill bit. At the time, blowout prevention technology didn't exist, so the well gushed unabated. The initial flow rate was 18 800 bbl/day. The peak flow rate was 90 000 bbl/day. The blowout created a river of crude, which crews contained with sand bag dams and dikes. About half of the oil was saved. The remainder seeped into the ground or evaporated. The Lakeview incident revealed the need for blowout prevention technology.

2.3.3 Texas City, Texas: Ammonium Nitrate Explosion (1947)

On April 16, 1947, the *SS Grandcamp* exploded in port at Texas City, Texas [2.78]. The ship was loaded with 7700 t of ammonium nitrate. The initial blast, together with fires and explosions on other ships and nearby oil-storage facilities, killed 581 people and injured up to 8000. The force of the blast was equivalent to 3.2 kt of TNT. At about 08:00 a.m., a fire was spotted in the cargo hold of the ship. For roughly an hour, attempts to extinguish the fire failed as a red glow returned after each effort to douse the fire. The cause of the initial fire remains unknown. The primary lesson from this disaster was to avoid storing large amounts of explosive chemicals in one place.

2.3.4 London: Killer Fog (1952, '56, '57, '62)

In December 1952, thick fog rolled across many parts of the British Isles. In the Thames River Valley, the fog mixed with smoke, soot and sulfur dioxide from the burning of coal, turning the air over London into a dense yellow mass. An unusual weather condition kept the air from moving. The smog was so thick that buses could not run without guides walking ahead of them carrying lanterns. Fog stayed put for several days, during which the city's hospitals filled to overflowing. According to the Parliamentary Office of Science and Technology [2.79], more than 3000 people died that month because of the polluted air. Similar, less-severe episodes occurred in 1956, 1957, and 1962. The 1956 event killed more than 1000 people.

London's deadly smog was caused by *usual-practice* pollution. Due to the widespread use of cheap, high-sulfur coal, London air had been bad for decades, but postwar growth made it worse than ever. In response to the incidents, Parliament passed Clean Air Acts in 1956 and 1962, prohibiting the use of high-sulfur fuels in critical areas.

2.3.5 Amoco Cadiz: Oil Spill (1978)

On March 16, 1978, the supertanker *Amoco Cadiz* was 3 mi off the coast of Brittany when its steering mechanism failed. The ship ran aground on the Portsall Rocks [2.80].

For two weeks, severe weather restricted cleanup efforts. The wreck broke up completely before any remaining oil could be pumped out, so the entire cargo – more than 1.6 million bbl of Arabian and Iranian crude oil – spilled into the sea.

The resulting slick was 18 mi wide and 80 mi long. It polluted 200 mi of coastline, including the beaches of 76 Breton communities. On several beaches, oil penetrated the sand to a depth of 20 in. Piers and slips in small harbors were covered with oil. Other polluted areas included the pink granite rock beaches of Tregastel and Perros-Guirec, and the popular bathing beaches at Plougasnou. The oil persisted for only a few weeks along exposed rocky shores, but in the areas protected from wave action, the oil remained as an asphalt crust for several years.

The *Amoco Cadiz* incident caused considerable loss of marine life. Cleanup activities on rocky shores, such as pressure washing, also caused harm. Two weeks after the accident, millions of dead mollusks, sea urchins, and other bottom-dwelling organisms washed ashore. Nearly 20 000 dead birds were recovered. About 9000 t of oysters died. Fish developed skin ulcerations and tumors.

Years later, echinoderms and small crustaceans had disappeared from many areas, but other species had recovered. Even today, evidence of oiled beach sediments can be seen in sheltered areas, and layers of subsurface oil remain under many impacted beaches.

From this disaster, the oil industry learned the need for prompt action and the relative efficacy of different techniques to sink, disperse, and recover spilled oil. It also gained experience in onshore cleanup.

2.3.6 Bhopal, India: Methyl Isocyanate Leak (1984)

In December 1984, up to 200 000 people were exposed to methyl isocyanate (MIC) in Bhopal, India and surrounding towns [2.81]. More than 2500 died. Thousands more suffered permanent lung and/or eye damage. All told, there were 524 000 personal injury claims, 2800 lost-cattle claims, 4600 business claims, and 3400 wrongful death claims. Eventually, Union Carbide, owner of the MIC plant, reached a US\$470 million settlement with the Parliament of India.

On December 2, 1984, a worker observed a buildup of pressure in a storage tank at the Union Carbide chem-

ical plant near Bhopal. The tank contained about 15 t of MIC, a chemical used to make pesticides. MIC is flammable, and at high concentrations it is deadly. At low concentrations, it causes lung damage and blindness. Several process and safety systems were out of service, any one which would have contained or destroyed the MIC:

1. The pressure increase was probably caused by water inside the storage tank. Water reacts with MIC to form methylamine and gaseous carbon monoxide. The reaction releases heat, which would have raised pressure by vaporizing MIC. Normally, a refrigeration unit would have controlled the temperature, but the cooler had been out of service for several months.
2. Eventually, the pressure rise popped a safety valve. When this happened, the vented gas should have been routed to a caustic scrubber, which would have absorbed and hydrolyzed the MIC, rendering it harmless. Instead, the vented gas went to the flare.
3. The flare should have converted the MIC into relatively harmless CO_2 , H_2O and N_2 . But the flare system failed, perhaps because it wasn't designed to handle such a large surge of gas.
4. If operators had noticed the leak immediately, they might have been able to stop the disaster before it did much damage. But the leak did not show up on control-room monitors because a critical panel had been removed. Instead, tons of MIC poured into the air and spread across the countryside, covering 25 mi^2 (65 km^2).

How did water get into the storage tank, where the MIC was kept under a blanket of dry nitrogen? Some experts suggest that the nitrogen was wet. Others guess that a water hose was inadvertently connected to the nitrogen line. A Union Carbide official suggested possible sabotage.

Even if the incident on December 2, 1984 was an act of sabotage, the MIC unit at Bhopal was a disaster waiting to happen. During a press conference, a Union Carbide executive acknowledged that the unit was in a state of sorry disrepair, and that its condition was so poor that it shouldn't have been running.

2.3.7 Nuclear Power Incidents: Context

This section sets the stage for descriptions of the incidents at Three Mile Island and Chernobyl. Table 2.9 provides a bare-bones introduction to relevant terminology.

Nuclear power plants generate heat from the enormous energy generated by nuclear fission. Two factors are essential to the success of nuclear power: generating

and controlling the heat, efficiently converting the heat into electrical power, and keeping radioactive isotopes inside the containment system.

Uranium and Its Hazardous Daughters

Modern nuclear plants are fueled by uranium-235 (^{235}U). Natural uranium is comprised of ^{235}U and two other isotopes, with the following abundances: ^{234}U (0.005–0.006%), ^{235}U (0.72%), and ^{238}U (99.274–99.275%). The isotopes contain 92 protons along with 142, 143, and 146 neutrons, respectively. Future plants may be fueled with plutonium (^{239}Pu) transmuted in nuclear reactors from ^{238}U , or with ^{233}U , transmuted from naturally occurring thorium (^{232}Th).

Many fission reactions produce more neutrons than they absorb. The extra neutrons can in turn induce fission in other fissile atoms, which generates more neutrons, and so on, in a chain reaction. Product isotopes are called *daughters*. Several daughters of ^{235}U fission are unstable and undergo subsequent nuclear reactions in *decay chains*. ^{90}Sr , ^{137}Cs , and ^{131}I are especially dangerous [2.82]. They are relatively abundant, comprising 4.5, 6.3, and 3 wt%, respectively, of all fission products in reactors.

Here are examples (excluding neutrinos) of primary fission reactions, including two which form ^{90}Sr and ^{137}Cs

In reactors, most ^{137}Cs is produced from three daughters: ^{137}Xe , ^{137}I , and ^{137}Te .

Decay of ^{90}Sr proceeds as follows

For ^{137}Cs , the decay is

Ba^* is an unstable version of Ba, which becomes stable after emitting a γ photon.

Carried aloft by dust, ^{90}Sr from the detonation of nuclear weapons in the atmosphere and from serious accidents was detected everywhere on the planet and continued to be found in soil and plants for more than 60 years afterwards. It goes from soil into growing plants and then into animal products, including milk. Chemically similar to calcium, strontium takes up residence in bones, where it can stay for years, greatly increasing the likelihood of cancer.

Table 2.9 A bit of nuclear physics

- By convention, the superscript which precedes the atomic symbol in nuclear notation is the *mass number* of the atom; it is not the *atomic mass*.
- The mass number is the sum of the number of *nucleons* – protons and neutrons.
- Atoms with the same number of protons but different numbers of neutrons are called *isotopes*. Isotopes of an element undergo the same chemical reactions.
- A *fissile* isotope is one which can undergo *nuclear fission*.
- Nuclear reactions can produce five types of radiation. Alpha (α) radiation is comprised of highly energetic helium nuclei (${}^4\text{He}$). Beta (β) radiation is comprised of highly energetic electrons (e^-). Gamma (γ) radiation is comprised of high-energy photons. Neutrons (${}^0\text{n}$) are released by many nuclear reactions. Neutrinos have no electric charge and are essentially massless; the nuclear reaction equations in this section do not show include neutrinos.
- In nuclear fission, a radioactive atom splits into two smaller atoms, all of which are heavier than an alpha particle (energetic ${}^4\text{He}$). The sum of the masses of all products (*daughter* atoms and neutrons) is less than the mass of the parent isotope. The difference is called the *nuclear binding energy*, which is released during the nuclear fission of heavy elements and the *nuclear fusion* of light elements.
- Binding energy is enormous. The amount can be calculated from the famous Einstein equation, $e = mc^2$, where e is energy, m is rest mass, and c is the speed of light. During the fission of one mole (235.043 g) of ${}^{235}\text{U}$, the products weigh about 0.2 g less than the uranium. The missing matter is converted into around 18 000 000 000 kJ of energy. In comparison, complete combustion of one mole of methane releases 810 kJ, about 222 billion times less energy!
- Half-life is the time it takes for half of a radioactive isotope to transform spontaneously into something else via radioactive decay.

${}^{137}\text{Cs}$ spreads more readily because much of it comes from gaseous ${}^{137}\text{Xe}$ and ${}^{137}\text{I}$. As it decays, ${}^{137}\text{Cs}$ emits an energetic – and mutagenic – gamma ray. It is chemically similar to sodium – its salts are highly soluble in water – so it can end up nearly everywhere. Most of the γ radiation at the Chernobyl and Fukushima accident sites came from the decay of ${}^{137}\text{Cs}$.

${}^{131}\text{I}$ is volatile because it finds its way into gaseous I_2 . As it decays to ${}^{131}\text{Xe}$, its half-life is 8.0 days, easily long enough to be spread hundreds of miles by winds. When inhaled or ingested it concentrates in the thyroid, where it can cause cancer.

Nuclear Power Plants. In natural uranium, chain-reaction fission does not occur. ${}^{238}\text{U}$ is mildly radioactive and relatively benign; it is present in nuclear power plants but does not undergo fission except indirectly. It also captures more neutrons than it releases. Most of the remaining neutrons are too fast to be captured by ${}^{235}\text{U}$. These challenges are met in two ways; isotopic enrichment and high-energy neutron moderation.

Most of the world's nuclear power plants employ light-water reactors (LWR). There are three kinds of LWR: pressurized water reactors (PWR), boiling-water reactors (BWR), and supercritical-water reactors (SCWR). Regular water (light water) is a preferred cooling medium and an excellent neutron-energy mod-

erator. But it also absorbs neutrons. Due to the latter, LWR require a higher concentration of fissile targets. This is accomplished by enriching uranium – increasing the ${}^{235}\text{U}$ content from the natural abundance (0.72%) to 3–5%. Chemical separation of isotopes is not possible, so separation is accomplished by mass-based techniques such as gas centrifugation.

Unenriched uranium fuels pressurized heavy-water reactors (PHWR) and graphite reactors. Heavy water is deuterium oxide (D_2O); it is a good coolant and neutron energy moderator, but it is a poor neutron absorber. In graphite reactors, such as the ones at Chernobyl, regular water is the coolant and graphite is the moderator. Graphite is flammable. At Chernobyl, graphite did not cause the incident, but burning graphite sent radioactive material into the atmosphere.

Most commercial land-based nuclear power plants, such as the one at Three Mile Island, contain pressurized-water reactors (PWR). PWR have multiple coolant loops as shown in Fig. 2.8. In the primary loop, nuclear heat generates super-heated water at 150–160 bar and 300°C . Through heat exchangers, heat from the primary-loop is transferred to the secondary loop, where it converts water into steam. The steam drives turbines to produce electricity. The primary and secondary loops exchange heat but not water; water in the secondary loop is not radioactive.

Fig. 2.8 Illustration of a pressurized large light water reactor (LWR) [2.83]

Fuel Elements. In reactors, fuel elements contain the uranium. Pellets of uranium dioxide (UO_2) are contained inside long tubes of zirconium (Zr) alloy.

Control Rods. In the reactor core, the fuel elements are surrounded by water or graphite and interspersed with control rods. The rods contain moderating elements, such as cadmium or boron, which regulate the chain reaction by absorbing neutrons. Operators control the reactor by raising or lowering the rods. The control rods can be attached to their hoist system by electromagnets. If electrical current is lost, the rods fall by gravity all the way into the core, completely shutting off fission.

Heat Control Is Crucial. There are two ways to control heat in a nuclear reactor – with control rods, which govern the production of heat, and with coolant. Both at Three Mile Island and Chernobyl, loss of coolant damaged equipment, which in turn led to loss of control of the nuclear reactions.

2.3.8 Three Mile Island: Nuclear Reactor Meltdown (1979)

On March 28, 1979, at the Three Mile Island PWR-based nuclear power plant near Middletown, Pennsylvania, the TMI-2 reactor partially melted down [2.84]. The accident began with failure of the reactor cooling system. The failure caused the turbine generator and the reactor to shut down automatically. Pressure began to rise in the nuclear portion of the plant. This activated a pressure relief valve, which should have shut automatically when the pressure returned to acceptable levels. But the valve failed to close, allowing water to bleed from the primary coolant loop. Alarms sounded, but due to lack of information, the operators did not know the reactor was losing water. They responded inappropriately, reducing the flow of water to the reactor core. The nuclear fuel overheated, and due to the high temperature, the zirconium alloy (zircalloy) fuel rod cladding ruptured, allowing the fuel pellets to melt.

Afterwards, inspections showed that half of the core had melted. In the end, things could have been much

worse. The reactor building remained intact and contained nearly all hazardous materials. A modest amount of radioactive gas was released, but due to dilution with air, ambient radiation levels hardly exceeded background.

After the accident, the US Nuclear Regulatory Commission (NRC) required several changes in the design and operation of US nuclear plants, which were implemented at all other PWR power plants.

The most significant health consequence of the Three Mile Island incident was its psychological impact, mostly on people in the surrounding area but also in the rest of the United States. Since the incident, the construction or expansion of nuclear power plants slowed to a crawl.

2.3.9 Chernobyl: Nuclear Reactor Fire (1986)

On April 26, 1986, a disaster occurred at the Chernobyl nuclear plant near Pripyat, Ukraine. According to official government figures, more than 4000 people who took part in the cleanup died, and 70 000 were disabled by radiation. About 3.4 million of Ukraine's 50 million people, including some 1.26 million children, were affected by the disaster [2.85].

The literature contains many summaries of the causes and lingering impact of the Chernobyl nuclear disaster. The International Nuclear Safety Advisory Group (INSAG) published a thorough report in 1986 and followed it with a revision in 1992 [2.86]. The INSAG documents remain the most generally accepted. The oft-vilified Anatoly Dyatlov, who was the Deputy Chief Engineer at the plant when the incident occurred, challenged the INSAG report. An English version of his perspective appeared in 1995 [2.87]. There are numerous summaries and timelines on the Internet, but they often disagree with each other and the INSAG document. A factual summary of health effects was published by the World Nuclear Association in 2009 [2.88]. Other articles on health effects are outlandish. For this chapter, choices had to be made. Please accept apologies for any errors, for which the author accepts complete responsibility.

SCRAM stands for *safety critical reactor axe man*. It is a term from the early days of nuclear power development, when graphite control rods were raised and lowered into the core of a reactor with a rope on a pulley. The axe man stood ready to cut the rope in an emergency, dropping all control rods all the way in, shutting down the reactor.

Before the accident, Anatoly Dyatlov was seeking ways to solve a nagging problem at the Chernobyl power plant. After a planned shutdown or emergency

SCRAM the cooling water pumps stopped due to lost electrical power. Backup power was supplied by diesel generators, but starting the diesels took almost a minute. During the delay, residual heat remained in the reactor. To Dyatlov, this delay was unacceptable. He thought of a solution. During the loss of power, the plant's steam turbines kept spinning for several minutes due to their massive inertia. Dyatlov calculated that, as the turbines slowed down, they could produce enough power to run the water pumps until the diesels were up and running. He designed a complex network of switches to keep the current steady as the turbines lost momentum.

Dyatlov talked to the Chief Engineer of the plant, who gave him permission to run his *electrical engineering* experiment. The test began on April 25, 1986, as Unit 4 was shutting down for long-delayed maintenance. With Dyatlov's approval, the operators decided to run the test manually instead of using the unit's *unimaginative automatics*.

At 02:00 p.m., in violation of one of the most fundamental nuclear power safety practices, the operators switched off the emergency cooling system. Just after midnight on April 26th, they switched off the reactor's power-density controls.

Under manual operation, the reactor became unstable. At 01:07 a.m., power output suddenly dropped to 0.03 GW, far less than the specified minimum of 0.70 GW. To generate more power, the operators increased heat by raising the graphite control rods to the maximum height allowed by regulations. Dyatlov ordered them to raise the rods further. When the operators balked, Dyatlov insisted, and the operators complied.

At 01:23 a.m., the power output seemed to be stable at 0.2 GW. The operators then violated THE most important nuclear power safety practice by disabling the emergency SCRAM. In this case, the SCRAM was not a man with an axe, but an automatic interlock designed to stop the reactor whenever the neutron flux exceeded a safe limit. (In today's nuclear power plants, it is physically impossible to disable this control.)

Now the experiment could begin. To see how long the electricity-generating turbine would spin without a supply of steam, operators closed the valve that channeled steam from the reactor to the turbine. Steam that should have been taking heat out of the reactor was now trapped inside.

In less than 45 s, the reactor started to melt. Super-hot pellets of uranium-oxide fuel deformed, rupturing their zirconium-alloy containers, and came into direct contact with cooling water. The water flashed into steam, causing the first of two explosions that blew the top off the reactor. The second blast was caused by a H₂-CO-air explosion. The H₂ and CO were generated

by reactions of zirconium and graphite with superheated steam

About 15 t of radioactive material from the reactor core rocketed into the atmosphere, where it spread across Europe. More than 36 h after the accident, plant personnel told local officials about the accident. About 14 h after that – 50 h after the accident – radiation from the explosion was detected by technicians at the Forsmark nuclear power plant in Sweden. That measurement was the first notification to the world outside the Soviet Union that something had happened in Pripjat.

At the site, more than 30 fires broke out, including an intensely hot graphite fire that burned for 14 days. About 250 people fought the various blazes. During 1800 helicopter sorties, pilots dropped 5000 t of lead, clay, dolomite and boron onto the reactor. Near term, the explosion and high-level radiation killed 31 people, including operators, firefighters, and helicopter pilots.

During a trial that ended in August 1987, the Chernobyl plant director (Brukhanov) was convicted and sentenced to 10 years in a labor camp. The Chief Engineer (Fomin), and Dyatlov received shorter sentences. The two operators were acquitted, but both of them died soon afterwards. More than 60 other workers were fired or demoted.

Long-Term Consequences

In June 1987, 14 months after the disaster, some 27 villages within the restricted zone were still heavily contaminated, because the cleanup operation had stopped. Nearby cities and towns were reporting dramatic rises in thyroid diseases, anemia, and cancer. Hardest hit were children.

According to Gernadij Grushevoi, cofounder of the Foundation for the Children of Chernobyl, the long-term danger is also critical in Belarus. In 1992, in testimony at the World Uranium Hearing [2.89], he said:

[...] 70 percent of the radioactive stuff thrown up by the explosion at Chernobyl landed on White Russian territory. There is not a centimeter of White Russia where radioactive cesium cannot be found.

The Rest of the Plant Kept Running for Nine Years

The three remaining nuclear reactors (Units 1, 2 and 3) continued to run. Despite ambient radiation levels nine times higher than widely accepted limits, workers lived in newly built colonies inside the *dead zone*. In 1991, Unit 2 was damaged beyond repair by a fire in the turbine room. That left Units 1 and 3, which kept going for

the next nine years. They kept going because the power was needed, and no funds were available to build a replacement.

On December 14, 2000, the plant was shut down. The shutdown was expedited by the European Commission, which approved a US\$585 million loan to help Ukraine build two new power plants, and by the European Bank for Reconstruction and Development, which provided US\$215 million.

2.3.10 Sandoz, Switzerland: Chemical Spills and Fire (1986)

On November 1, 1986, a fire broke out in a riverside warehouse at the Sandoz chemical plant in Schweizerhalle, Switzerland. While extinguishing the flames, firemen sprayed water over exploding drums of chemicals, washing as much as 30 t of pesticides, chemical dyes, and fungicides into the Rhine River. Up to 100 mi (160 km) downstream from Schweizerhalle, the Rhine was sterilized. All told, more than 500 000 eels and fish were killed. More than 50 million people in France, Germany, and The Netherlands endured drinking water alerts [2.90].

Afterwards, while checking the Rhine for chemicals as it rolled through Germany, officials discovered high levels of a herbicide (atrazine) that wasn't on the list provided by Sandoz. Eventually, Ciba-Geigy admitted that it had spilled atrazine into the river just a day before the Sandoz fire. As monitoring continued, more chemicals were discovered, alerting German authorities to the fact that many different companies were secretly discharging dangerous chemicals into the river. BASF admitted to spilling more than 1 t of herbicide, Hoechst discovered a chlorobenzene leak, and Lonza confessed to *losing* 2000 gal (4500 l) of chemicals.

Recovery

In response to the Sandoz disaster, companies all along the Rhine joined the Rhine Action Program for Ecological Rehabilitation, agreeing to cut the discharge of hazardous pollutants in half by 1995. Although many experts thought the target could never be reached, samples showed that from 1985 to 1992, mercury in the river at the German town of Bimmen-Lobith, near the Dutch border, fell from 6.0 to 3.2 t, cadmium from 9.0 to 5.9 t, zinc from 3600 to 1900 t, and polychlorinated biphenyls (PCBs) from 390 to 90 kg.

In December 1990, for the first time in 3 years, a large Atlantic salmon was fished from the Sieg River, a tributary of the Rhine in west-central Germany. The catch proved what officials had hoped: if you clean up your mess and clear the way, someday life will return. The event gave impetus to the Salmon 2000 project, and

further success followed. In 1994, researchers found recently hatched salmon in the Sieg, and in 1996 a salmon was hooked near Baden-Baden. In 1998, encouraged by the success of the Rhine Action Program, targets were set to designate a large protected ecosystem from streams in the Jura Mountains, the Alps, the Rhine mountains, the Rhineland-Palatinate, the Black Forest, and the Vosges to the mouth of the Rhine in The Netherlands. Meanwhile, not all of the Rhine's pollution problems have been solved. One of the most serious is a huge basin in the Netherlands, into which toxin-laden mud dredged from the Port of Rotterdam has been dumped since the 1970s. Contamination levels are falling, but several toxins are very stubborn.

All along the Rhine, the main source of remaining pollution comes from farm fertilizers, which seep into the river every time it rains.

2.3.11 Exxon Valdez: Oil Spill (1989)

On March 23, 1989, the 987-foot supertanker *Exxon Valdez* left port carrying more than 1.2 million bbl of Alaskan North Slope crude. The ship was headed south toward refineries in Benicia and Long Beach, California. At 10:53 p.m., it cleared the Valdez Narrows and headed for Prince William Sound in the Gulf of Alaska. To avoid some small icebergs, Captain Joseph Hazelwood asked for and received permission to move to the northbound shipping lane. At 11:50 p.m., just before retiring to his cabin, the captain gave control of the ship to the third mate, Gregory Cousins, instructing him to steer the vessel back into the southbound lane after it passed Busby Island.

Cousins did tell the helmsman to steer to the right, but the vessel didn't turn sharply enough. At 12:04 a.m., it ran aground on Bligh Reef.

Captain Hazelwood returned to the bridge, where he struggled to hold the tanker against the rocks. This slowed the rate of oil leakage. He contacted the Coast Guard and the Alyeska Pipeline Service Company. The latter dispatched containment and skimming equipment. According to the official emergency plan, this equipment was supposed to arrive at a spill within 5 h. In fact, it arrived in 13 h – 8 h late.

The *Exxon Baton Rouge* was sent to offload the spilled cargo and to stabilize the *Valdez* by pumping sea water into its ballast tanks. The oil transfer took several days. By the time it was finished, more than 250 000 bbl of oil had spilled into the Sound. Eventually, 33 000 birds and 1000 otters died because of the spill.

Eleven thousand workers treated 1200 mi (1900 km) of shoreline around Prince William Sound and the Gulf of Alaska, using 82 aircraft, 1400 vessels, and 80 mi (128 km) of oil-containing booms.

In response to the disaster, the US Congress passed the Oil Pollution Act of 1990. The Act streamlined and strengthened the ability of the US Environmental Protection Agency (EPA) to prevent and react to catastrophic oil spills. A trust fund, financed by a tax on oil, was established to pay for cleaning up spills when the responsible party cannot afford to do so. The Act requires oil storage facilities and vessels to submit plans to the Federal government, telling how they intend to respond to large oil discharges. EPA published regulations for above-ground storage facilities, and the US Coast Guard published regulations for oil tankers. The Act also requires the development of area contingency plans to prepare for oil spills on a regional scale.

Captain Hazelwood was tried and convicted of illegally discharging oil, fined US\$50 000, and sentenced to 1000 h of community service. Exxon spent US\$2.2 billion to clean up the spill, continuing the effort until 1992, when both the State of Alaska and the US Coast Guard declared the cleanup complete. The company also paid about US\$1 billion for settlements and compensation.

On July 10, 2004, USA Today reported [2.91]:

Not one drop of crude oil spilled into Prince William Sound from oil tankers in 2003 – the first spill-free year since the ships started carrying crude from the trans-Alaska pipeline terminal in 1977.

2.3.12 Arabian Gulf War: Intentional Oil Spill, Oil Well Fires (1991)

Mina Abdulla Spill

On January 25–27, 1991, during the occupation of Kuwait, Iraqis pumped 4–6 million bbl of oil from stations at Mina Al-Ahmadi into the Arabian Gulf. They did so to foil an expected beach invasion by allied troops. The size of the spill was 16–25 times greater than the *Exxon Valdez* spill. On January 27, allied bombers stopped the spill by destroying the pumping stations.

Ad Daffi Bay and Abu Ali Island experienced the greatest pollution. The spill damaged sensitive mangrove swamps and shrimp grounds. Marine birds, such as cormorants, grebes, and auks, were killed when their plumage was coated with oil. The beaches around the shoreline were covered with oil and tar balls.

Despite the ongoing war, the cleanup of the oil spill proceeded rapidly. Kuwaiti crude is rich in light ends, and water in the Arabian Gulf is relatively warm. For these reasons, about half of the spilled oil evaporated, leaving behind a thick emulsion, which eventually solidified and sank to the bottom of the sea. Another 1.5

million bbl were recovered by skimming. Operators of sea-water cooled factories and desalination plants were concerned that the oil might foul their intake systems. To prevent this, protective booms that extended 3 ft (1 m) below the surface were installed around intakes in Bahrain, Iran, Qatar, Saudi Arabia, and the United Arab Emirates.

Oil Well Sabotage

On February 23–27, 1991, retreating Iraqi soldiers damaged three large refineries and blew up 732 Kuwaiti oil wells. Fires started on 650 of the wells. Up to 6 million bbl of oil per day were lost between February 23 and November 8, 1991. Crews from 34 countries assembled to fight the oil-well fires. Initially, experts said the fires would rage for several years. But due to the development of innovative firefighting technology, the job took less than 8 months.

The oil-well fires burned more than 600 million bbl, enough to supply the United States for more than a month. The firefighting effort cost US\$1.5 billion. Rebuilding Kuwait's refineries cost another US\$5 billion. In all, Kuwait spent between US\$30 and US\$50 billion to recover from the Iraqi invasion.

2.3.13 Tosco Avon Hydrocracker: Deadly Pipe Rupture (1997)

On January 21, 1997 a temperature excursion led to the rupture of a reactor outlet pipe at the Tosco Avon Refinery in Martinez, California. The consequent release of hydrogen and hydrocarbons ignited on contact with air, causing an explosion and fire. One worker was killed and 46 others were injured. There were no reported injuries to the public [2.92].

Context

Fixed-bed catalytic hydrocracking converts vacuum gas oil, and other petroleum fractions with similar boiling ranges, into diesel, jet fuel, gasoline and other products. See Chap. 22 for detailed information. Commercial fixed-bed units employ two kinds of catalyst – hydrotreating and hydrocracking – which usually are loaded into separate reactors.

Hydrotreating catalysts remove sulfur, nitrogen and other contaminants, converting the organic sulfur and nitrogen into H_2S and NH_3 respectively. It is especially important to remove the organic nitrogen, because it neutralizes the acid sites of hydrocracking catalysts, suppressing their activity. Ammonia also inhibits cracking, but to a significantly lesser extent. Nitrogen slip (N-slip) is the amount of organic nitrogen remaining in the feed after it undergoes hydrodenitrogenation (HDN). For high-activity cracking catalysts, typical N-

slip targets range from 4 to 40 ppmw. Above about 200 ppmw, cracking catalysts might have nil activity.

Active catalyst particles have diameters ranging from 1.3 to 3.2 mm and lengths ranging from about 4 to about 12 mm with a median between 5 and 6. They are tiny compared to the reactors into which they are loaded. The diameters of large reactors can reach 6 m; reactor heights can exceed 30 m. Most reactors have multiple beds, with quench zones in between. In the quench zones, hot fluids from the bed above mix with relatively cold hydrogen-rich quench gas. The cooling is required, because hydrotreating and hydrocracking are highly exothermic. If not controlled, temperatures can run away, becoming high enough to melt through inches of steel.

Figure 2.9 compares hydrocracking with combustion. Combustion requires oxygen, fuel, and heat. Hydrocracking requires hydrogen, oil, and heat. If one of the three is removed, the reaction stops. A wood fire can be smothered with a blanket or carbon dioxide, or cooled with water or carbon dioxide. The fastest and most effective way to stop a hydrocracker temperature excursion is to remove hydrogen by depressuring the unit through emergency depressuring (EDP) valves. Typically, there are two EDP valves. One depressures the unit at an initial rate of 7 bar/min (100 psi/min). The other depressures the unit up to three times faster.

Either EPD valve can be activated manually. All hydrocracking process licensors specify automatic depressuring at low rate when a reactor temperature (or any two reactor temperatures) reaches some limit, typically 427–440 °C (800–825 °F). High-rate depressuring is activated automatically at some higher temperature. If temperatures exceed the metallurgical limit, typically 465 °C (870 °F), the steel degrades. Certain events, such as a power failure or loss of the recycle gas compressor, automatically initiate high-rate depressuring. Alert operators act before limits are reached, by adjusting quench flow and furnace firing. Early action forestalls emergency action.

Fig. 2.9 Reaction triangles for combustion and hydrocracking, showing factors required for the chemical reactions. Removing any one factor stops the reactions

The Incident

Figure 2.10 shows the reactor layout for the Tosco Avon hydrocracker. The unit has three parallel Stage 1 hydrotreating reactors with six beds each, and three parallel Stage 2 cracking reactors with five beds each. The effluents from the Stage 1 reactors are combined and sent to a stripper. The stripper removes light gases, including methane, ethane, propane, and H_2S . The stripper liquids go to three parallel Stage 2 hydrocracking reactors. There are multiple temperature indicators (TI) at the top and bottom of each bed, spaced in a pattern that allows operators to evaluate horizontal temperature differences. Large differences indicate maldistribution of flow.

On January 19, two days before the fatal event, operators managed to defeat a temperature excursion in Reactor 1, without depressuring, by aggressively manipulating quench flow. The outlet pipe temperature indicator (TI) exceeded $482^\circ C$ ($900^\circ F$) versus the metallurgical limit of $465^\circ C$, and the center TI in Reactor 1 Bed 4 (R1B4) reached $537^\circ C$ ($998^\circ F$) versus a specified maximum of $440^\circ C$. Specifications have safety margins, but at such high temperatures, there is little doubt that the metal was compromised. During the ex-

cursion, an operator went outside to get TI readings from a field panel underneath the outlet pipe. The panel TIs could measure higher temperatures than the control-room readings.

Table 2.10 shows a timeline for the accident on January 21. The problem began several hours earlier when one of the Stage 1 hydrotreating reactors was brought down to repair a leak. Stories differ about whether the total unit feed rate was kept the same or reduced, and whether or not Stage 1 reactor temperatures were adjusted to compensate for the change in rate. Regardless, N-slip rose, and due to N-poisoning, cracking diminished. By 10:00 a.m., cracking had nearly stopped. Almost no light products were being formed, and the exotherms in the Stage 2 reactors were very low. Also, only a few quench flows were above 10% of full rate. The lab reported an N-slip of 352 ppmw versus a target of 15 ppmw. At 11:30 p.m., operators responded, appropriately, by increasing Stage 1 temperatures to decrease N-slip.

The second most dangerous decision of the day was taken at 01:10 p.m., when Stage 2 temperatures were raised to *burn off* the nitrogen from the Stage 2 catalyst.

Fig. 2.10 Arrangement of reactors in the Tosco Avon hydrocracker

Table 2.10 Abbreviated timeline with comments for the Tosco Avon incident

04:50 a.m.	One of three Stage 1 hydrotreating reactors was brought down to repair a leak. Stories differ about whether the total unit feed rate was kept the same or reduced, and whether or not Stage 1 reactor temperatures were adjusted. Regardless, the extent of HDN was reduced.
10:00 a.m.	Nitrogen slip had risen from < 15 to 352 ppmw.
11:30 a.m.	Due to the high nitrogen slip and resulting inhibition of Stage 2 cracking activity, there was no temperature rise in one cracking reactor and very little rise in the other reactors. No light products were being formed. Stage 1 temperatures were raised to decrease nitrogen slip.
01:10 p.m.	Stage 2 hydrocracking reactor temperatures were raised to <i>burn off</i> inhibitory nitrogen. This was a horrendous mistake. Treating and cracking temperatures must never be raised at the same time. Figure 2.11 shows how very sensitive activity is to organic nitrogen.
05:38 p.m.	Nitrogen slip from Stage 1 was reported to be 47 ppmw. The actual nitrogen slip when the result was received was considerably lower than 47 ppmw. Since 10:00 a.m., the nitrogen slip had fallen 300 ppmw in 7.5 h, an average of 40 ppmw/h. If the lag time between taking a sample and getting results was 1 h as usual, the true nitrogen slip probably was < 10 ppmw at 05:38 p.m. and probably close to zero at 07:34 p.m.
07:34 p.m.	In Reactor 3, Bed 4 (R3B4), one TI jumped > 100 °C in 40 s, reaching 439 °C, 10 °C higher than allowed by procedure but not higher than in previous events.
07:34:20 p.m.	Quench to R3B5 opened 100%. Data logger temperatures cycled between –18, 649, and 343 °C. In well-run units, the associated uncertainty would have compelled operators to bring the unit down immediately (if it had not been depressured previously due to high temperature).
Before 07:37 p.m.	An operator went outside to verify temperatures at the field panel.
07:37–07:39 p.m.	All R3B5 outlet TIs were > 415 °C. One reached 679 °C.
After 07:40 p.m.	An operator phoned an instrument technician to work on the fluctuating data logger.
07:41:20 p.m. – 7 min after the first temperature jump	Explosion. The operator at the field panel died. A board operator activated the EDS.

Operating guidelines should have included the following prohibitions: During normal operation, never raise temperature in hydrotreating and hydrocracking catalysts at the same time. Never raise hydrotreating catalyst temperatures unless the cracking catalyst temperatures are at steady state, and vice versa. Figure 2.11 shows why. When concentrations of inhibitors are high, cracking reaction rates are not especially sensitive to modest changes. (Think of applying the brakes of an automobile, when the vehicle is stationary. Stepping harder on the brake pedal changes nothing.) However, at low inhibitor concentrations, small changes have a huge effect.

At 05:38 p.m., the reported N-slip was 47 ppmw. But surely the true N-slip at that time was considerably lower. How much lower we cannot know, but we can get an idea with a rough, linear approximation. On average, the N-slip had fallen 300 ppmw in 7.5 h, an average of 40 ppmw/h. If the lag time between taking a sample

and getting results was typical – say, about 1 h – the true nitrogen slip at 05:38 p.m. could have been < 10 ppmw, and it could have been close to zero at 07:34 p.m.

Recall: Due to the *burn off* decision, cracking reactor temperatures at 05:38 p.m. were higher and N slip was lower compared to conditions at 01:30 a.m. when the N-slip was 14 ppmw.

Figure 2.12 shows Reactor 3 temperatures during the Tosco temperature excursions. At 07:34 p.m., a temperature excursion struck R3B4 and cascaded into R3B5, peaking at 439 °C (823 °F). According to operating guidelines from the technology licensor, the unit should have been depressured when any bed TI reading reached 427 °C (800 °F). But instead of depressuring, operators made their most dangerous decision: to keep the unit running.

Instead, they did what they had done two days before and several times before that. They tried to control the excursion by cutting heater firing and manipulating

Fig. 2.11 Inhibition of hydrocracking by ammonia and organic nitrogen, where $K_{(\text{organic N})} = 7 \times K_{(\text{NH}_3)}$ by means of LHHW calculations. The trends are a function of percentage of inhibited catalyst sites at steady state, which is related to, but not the same as, the concentrations of ammonia or nitrogen in the feed

quench gas. As before, an operator went outside to get readings from the field panel beneath the reactor outlet pipe. Efforts to defeat the excursion with quench gas failed, the outlet pipe ruptured, and the operator died.

Surviving operators said they failed to depressure on January 21 because they didn't know whether or not an excursion was occurring. They had to reconcile temperature readings from three different sets of displays. Two sets were in the control room, and the other, as mentioned, was in the outside field panel. One control-room system was the data logger, which included most temperature readings. After the initial excursion, the data-logger readings started to fluctuate wildly, leading to further confusion.

In other refineries, uncertainty is not an excuse for unsafe behavior. Operators are told: Don't fly blind into a storm. When you don't know what's going on, assume the worse; bring the unit down.

Pipe Failure Analysis

Analysis of the ruptured pipe showed that the failure did not occur at weld, elbow or reducer. The pipe simply got too hot, reaching 1700 °F (927 °C). At the point of failure, the circumference of the 10 in (245 mm) diameter pipe expanded by 5 in (120 mm) before it failed. The wall thickness at the rupture was 0.3–0.4 in (7–10 mm), about 50% lower than the thickness of the rest of the pipe.

Root Causes and Recommendations

Root causes for the Tosco Avon accident include the following:

- *Management directives.* On July 23, 1992, the unit was depressured at low rate to stop an excursion. Due to a leak in the system, a grass fire started at

the flare. A source told the author that after this event in 1992, upper management strongly discouraged use of depressuring. A fire might spread into the nearby grassy hills and the John Muir Historic Site, creating a public relations nightmare. Fixing the flare would have required investment, which in those days at Tosco was not an option.

- *Confusion.* Operators used three different instrumentation systems to obtain temperature data. Not all the data were immediately accessible, and the data often disagreed. Monitoring points capable of reading the highest temperatures were underneath the reactors and not connected to the control room.
- *Inadequate supervision and process training.* Supervisory management and operator training were inadequate. Operators and engineers did not understand that a zero on the data logger indicated extremely high temperatures. They did not understand the sensitivity of cracking catalyst activity to changes in N-slip when the N-slip is very low.
- *Misunderstanding of sampling dynamics.* Operators and engineers did not comprehend the dynamics of sampling, i. e., the lag time between taking a sample, getting results, and what might have happened to the process in the meanwhile.
- *Poor procedure documentation.* Written procedures were outdated, incomplete, and contained in different documents in different locations.

The investigation team, led by EPA, developed recommendations for consideration by owners of all hydroprocessing facilities. These, with slight modifications by the author, are presented below:

- Management must ensure that operating decisions are not based primarily on cost and production.

Fig. 2.12 Reactor 3 temperatures during the TOSCO Avon incident. Temperature indicator Pt-133C2 jumped by 104 °C (186 °F) in 20 s, reaching 439 °C (823 °F). The excursion cascaded through the quench section into the next catalyst bed, causing a jump of 223 °F (124 °C) in 40 s at Pt-140C3, reaching 460 °C (860 °F)

- Facility management must set safe, achievable operating limits and not tolerate deviations from these limits.
- Management must provide an operating environment in which operators can follow emergency shutdown procedures without fear of retribution.
- Process instrumentation and controls should be designed to consider human factors consistent with good industry practice. Hydroprocessing reactor temperature controls should be consolidated with all necessary data available in the control room. Backup temperature indicators should be used so that the reactors can be operated safely in case of instrument malfunction.
- Each alarm system should distinguish between critical alarms and other operating alarms.
- Adequate operator supervision is needed, especially to address critical or abnormal situations.
- Facilities should maintain equipment integrity and discontinue operation if integrity is compromised.
- Management must ensure that operators receive regular training on process operations and chemistry. For hydrocrackers, this should include training on reaction kinetics and the causes and control of temperature excursions.
- Operators should be trained on the limitations of process instruments and how to handle instrument malfunctions.
- Facilities should ensure that operators receive regular training on the use of the emergency shutdown systems and the need to activate these systems.

2.3.14 BP Texas City Isomerization Unit: Explosion (2005)

On March 23, 2005, an explosion in an isomerization unit at the BP Texas City, Texas refinery [2.93], along with related explosions and fires, killed 15 people and injured another 180. A shelter-in-place order was issued, requiring 43 000 people to remain indoors.

Houses were damaged as far away as three-quarters of a mile. Resulting financial losses exceeded \$1.5 billion.

Context

The isomerization process converts straight-chain *n*-pentane and *n*-hexane into branched isomers with higher octane. The resulting isopentane and isohexane are blended into gasoline. Raffinates from the process are mixtures of straight-chain hydrocarbons. A raffinate splitter separates the light raffinate from the heavy raffinate. During normal operation, an automatic level controller maintains liquid level in the splitter by sending heavy raffinate to a storage tank when the level is too high. The level controller depends on feedback from a level transmitter. As a backup, level can be measured manually with a sight glass. The tower overhead is cooled and drawn off or sent back to the splitter for temperature control. If the tower pressure gets too high, three pressure relief valves can open, one at a time or in combination, sending vapors and liquids to an emergency blowdown drum. In the unit at BP Texas City, the blowdown drum should have been connected to a flare, but instead, it vented to the atmosphere.

The Incident

The accident occurred during the restart of the isomerization unit, after maintenance on the raffinate splitter. Before the restart, there were several unresolved safety-critical issues, including a faulty pressure control valve, a defective high level alarm in the splitter, a defective (opaque) sight glass used for level measurement, and an uncalibrated level transmitter. During the morning of March 23, operators noticed that the heavy raffinate storage tanks were nearly full. Consequently, the night-shift supervisor agreed that the startup should not continue until some liquid was withdrawn from the tanks. But the day-shift supervisor arrived late and did not receive a full status report. He did not hear about the raffinate tank level. Under his direction, the startup resumed at 09:30 a.m. To reduce level in the raffinate splitter, the level control valve was opened, sending liquid to the already-nearly-full heavy raffinate storage tank. At about 10:00 a.m., the level control valve was closed. As the startup proceeded, more raffinate entered the tower. Without a way to withdraw product, the tower overflowed. But the uncalibrated level transmitter indicated that the level was below 100%. The opaque sight glass was useless, so it wasn't possible to confirm the level visually.

As the startup proceeded, burners in the furnace were started to heat the inflowing raffinate. The procedure specified that the temperature of return flow to the tower should be raised to 135 °C (275 °F) at 10 °C/h (18 °F/h), but this time the procedure was altered. The return flow temperature was allowed to reach 153 °C

(307 °F) with an increase rate of 23 °C/h (41 °F/h). The defective transmitter was indicating a high (but supposedly still-safe) level of 93%. Heat was increasing, causing expansion of the raffinate. Pressure started to build, but the operations team thought the increase was due primarily to overheating, which was a known startup issue. The pressure was relieved and the furnaces were turned down.

At 12:42 p.m., the faulty level transmitter showed 78% as liquid was overflowing into the pressure-relief system. At 01:13 p.m., all three pressure relief valves opened, sending liquid to the blowdown drum. An operator opened the level control valve and shut down the furnace completely. But he did not stop the inflow of raffinate. In the blowdown drum, a *geyser* of hot hydrocarbon liquid vented directly into the air, then flowed down the outside of the drum, where it hovered above the ground and drifted away from the unit. It soon reached a pickup truck about 9 m (30 ft) away. Investigators concluded that heat or a spark from the truck must have ignited the hydrocarbons. The 15 people who died were in or around a nearby row of contractor trailers.

I was scheduled to be participating in a hydrocracker startup in the refinery on the day of the explosion. The startup was delayed. Otherwise, I might have been in one of the destroyed trailers.

Root Causes

According to the investigation report, the Texas City disaster was caused by organizational and safety deficiencies at all levels of the BP Corporation. Warning signs of a possible disaster were present for several years and were reported to officials by employees. But company officials did nothing. The extent of the safety culture deficiencies was further revealed when the refinery experienced two additional serious incidents just a few months after the March 2005 disaster. In one, a pipe failure caused a reported \$30 million in damage. The other resulted in property loss worth \$2 million.

The report cited the following local deficiencies at the Texas City refinery:

- A work environment that encouraged operations personnel to deviate from procedure
- Lack of a BP policy or emphasis on effective communication for shift change and hazardous operations (such as during unit startup)
- Malfunctioning instrumentation that did not alert operators to the actual conditions of the unit
- A poorly designed computerized control system that hindered the ability of operations personnel to determine if the tower was overflowing
- Ineffective supervisory oversight and technical assistance during unit startup

- Insufficient staffing to handle board operator workload during the high-risk time of unit startup
- Chronic worker fatigue, due to the lack of a human fatigue-prevention policy
- Inadequate operator training for abnormal and startup conditions
- Failure to establish effective safe operating limits.

The industry learned from the BP Texas City disaster, but not everyone learned, and some who might have learned forgot. Events five years later showed that within BP itself, key people had failed to learn or had forgotten key lessons from Texas City.

2.3.15 Deepwater Horizon Offshore Drilling Rig: Blowout (2010)

On April 20, 2010, a blowout on the *Deepwater Horizon* drilling rig killed 11 people and gushed 560 000–585 000 t of crude oil into the Gulf of Mexico. On July 2, 2015, a settlement was announced between BP, United States, and five US states. BP agreed to pay up to US\$18.7 billion in penalties [2.94, 95].

Context

The offshore drilling rig *Deepwater Horizon* floated in 5000 f (1500 m) of water 41 mi (66 km) from the coast of Louisiana just beyond the continental shelf in the Mississippi Canyon. Below the seabed was a large reservoir of oil and gas. The Macondo well, drilled from the rig through sub-surface rock to the reservoir, was 2.5 mi long.

During drilling, operators compare the amount of drilling mud going into the well to the *returns* – the amount coming back out. For this well, the returns exceeded the input, indicating intrusion from the formation. Depending on the size of the difference and the depth (pressure) of the well, this is often a danger sign.

As a well is drilled, the well bore is cased with steel pipe. Casing prevents the well from collapsing. As BP was drilling the last section, Halliburton (the drilling contractor) recommended liner/tie-back casing with four redundant barriers to flow. BP opted for one liner with fewer barriers to save US\$7 to 10 million. Cementing fills the otherwise empty annular space between well bore and the casing. If the annular space is totally blocked, oil and gas can flow out of the formation only through the casing. At the top of the casing, valves, blowout preventers, and so on, control the flow of oil and provide a route for future activities, such as perforation and well stimulation.

Figure 2.13 illustrates how centralizers improve cementing. They keep the casing from resting against the surrounding rock, which possibly could block the

flow of cement and jeopardize the well-completion process. According to industry acquaintances, poor cement jobs are the leading cause of postcompletion blowouts. Among other things, poor cementing can result from using low-quality cement and not using enough centralizers. A Halliburton model called for 21 centralizers. But there were only six on the rig. In short order, 15 more could be flown to the rig. A BP engineer informed management that it would take 10 h to install the extra centralizers. BP decided to install just six.

Before cementing, cement mixtures are prepared and tested in a laboratory. Three tests conducted by Halliburton showed that the Macondo well cement did not meet Halliburton's best practices and might not set properly. During Coast Guard hearings, BP said it hadn't seen the testing results.

To prepare a well for cementing, it is typical to conduct one last *bottoms up*, in which drilling fluid is pumped through the annulus all the way from the bottom of the well to the top. A bottoms-up is a common way to improve the success of cementing by removing pockets of gas and debris. BP opted to circulate only a fraction of the usual amount of fluid.

To test the integrity of cementing, two important tests are conducted: a positive-pressure test and a negative-pressure test. During the positive-pressure test, the pressure is increased in the steel casing and seal assembly to see if they are intact. The negative-pressure test determines the integrity of the cement at the bottom of the hole. Pressure is reduced to below atmospheric, and then suction is stopped. If pressure remains low, the test is deemed successful. If flow occurs or the pressure increases, it is likely that reservoir fluids are entering

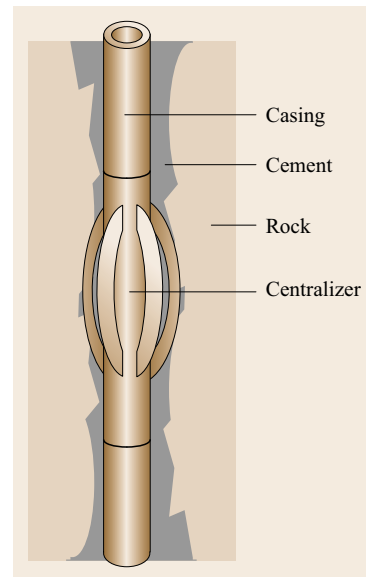

Fig. 2.13 Role of centralizers in oil well completion. The centralizer keeps the casing away from the rock while allowing cement to flow through. The drawing is, to say the least, not to scale

the well, probably through gaps in the casing and/or the cement. A failed negative pressure test requires remedial work to reestablish well integrity. If the remedial work is not done, the cement will fail and flow through the well will be impossible to control.

The Incident

At 7:00 a.m. on the day of the blowout, BP cancelled a scheduled *cement bond log*, a routine acoustical procedure which would have found spaces or weaknesses in the cement. The test would have taken 9 to 12 h and cost US\$128 000.

At about noon on the day of the blowout, the well had been cemented and other cement integrity tests were imminent. A helicopter arrived. Among its passengers were four VIPs from Houston – two from Transocean, the owner of the drilling rig, and two from BP. The executives were there to conduct a 24-hour *management visibility tour*. Their presence contravened two lessons that should have been learned from the BP Texas City disaster. During a highly critical activity, (1) nonessential personnel must be removed from the vicinity, and (2) supervisory oversight must be provided at all times by technically qualified personnel. Few activities are more critical than well completion, and few people are less essential than corporate executives. These particular VIPS were planning to stay on the rig overnight. They had to be fed, watered, and entertained. Their presence contributed to the flouting of Item (2) by monopolizing the time of highly capable experts, who otherwise might have been paying more attention to the drilling crew.

At 05:00 p.m., the rig crew began the negative-pressure test. The pressure repeatedly built back up after gases were evacuated. Between 06:00 and 07:00 p.m., the crew discussed how to proceed. A senior BP engineer insisted on another negative-pressure test. An assistant *tool pusher* said pressure could be measured through another line – the *kill line* – where the pressure did indeed stay low. For whatever reason, the crew decided that no flow through the kill line equaled a successful negative-pressure test.

The crew proceeded to replace dense drill mud, which had counteracted reservoir pressure during drilling, with sea water. Sometime later, people on the bridge of the rig felt a high-frequency vibration and heard a hissing noise. The senior BP engineer got a call from the assistant tool pusher, who told him that mud was coming out of the well and that gas was coming up too. The senior BP engineer grabbed his hard hat and stepped outside, where saw that mud and seawater were *blowing everywhere*. The assistant tool pusher called the senior tool pusher and said: *We have a situation [...] the well is blown out.*

Soon thereafter, at roughly 09:45 p.m., an explosion shook the rig, starting a fire. A second explosion followed, then several more. Meanwhile, people were being evacuated into life rafts. Others simply jumped into the water.

Eleven people died. Over the next several months, the blown-out well gushed 560 000–585 000 t of oil into the Gulf of Mexico, causing economic and ecological harm throughout the region, from Mexico to Florida.

Root Causes and Recommendations

The Presidential Commission appointed by President Barack Obama concluded with the following (author-abridged) observations:

- The explosion could have been prevented.
- The immediate causes were a series of mistakes made by BP, Halliburton, and Transocean. The mistakes revealed systematic failures in risk management. Tests and procedures were changed without consultation with technical experts.
- Deepwater energy exploration and production involves risks for which neither industry nor government was adequately prepared, but for which they can and must be prepared in the future.
- Regulatory oversight of leasing, energy exploration, and production require reforms, even beyond the significant reforms already initiated since the Deepwater Horizon disaster.
- Those in charge of oversight must have political autonomy, technical expertise, and authority to fully consider environmental protection concerns.
- Regulatory oversight alone will not be sufficient to ensure adequate safety, so the oil and gas industry will need to take its own, unilateral steps to increase safety throughout the industry, including self-policing mechanisms that supplement governmental enforcement.
- The technology, laws and regulations, and practices for containing, responding to, and cleaning up spills lag behind the real risks associated with deepwater drilling into large, high-pressure reservoirs of oil and gas located far offshore and thousands of feet below the ocean's surface. Government must close the gap, and industry must support rather than resist that effort.
- Scientific understanding of environmental conditions in sensitive environments in deep Gulf waters, along the region's coastal habitats, and in areas proposed for more drilling, such as the Arctic, is inadequate. The same is true of the human and natural impacts of oil spills.

2.3.16 Lac-Mégantic Quebec, Canada: Oil Train Derailment (2013)

At about 11:00 p.m. on July 5, 2013, a 74-car freight train carrying Bakken crude oil stopped in Nantes, Quebec. Nantes is about seven miles west of Lac-Mégantic. The train was owned by the MM&A, the Montreal, Maine and Atlantic Railway, for which Nantes is a crew-change point [2.96].

The train was named MMA-2. With a length of 1433 m (4700 ft), it stretched for almost a mile. Pulled by five locomotives, it weighed more than 11 000 tn sh. Each of the 72 tank cars carried about 30 000 gal (714 bbl) of crude oil. The oil was produced in North Dakota with hydraulic fracturing and was being shipped to the Irving Oil Refinery in Saint John, New Brunswick.

While riding in his usual taxi from the train to his usual hotel, the train engineer expressed concern about the lead locomotive, because it was smoking and leaking oil. Per MM&A policy, he had left the engine running, mainly to power the compressor that maintained pressure in the air brakes.

At about 11:45 p.m., the troubled engine caught fire. Local residents called 911, and within 5 min, firefighters and police arrived. They saw dark smoke coming from the engine, where a broken piston had started a *good sized blaze*.

After dousing the fire, a Nantes Fire Department member contacted the rail traffic controller for MM&A in Farnham, Quebec, 125 mi away. The controller sent two maintenance workers to the scene. The workers concluded that it wasn't safe to restart the damaged engine, so they decided to leave it off. They set hand brakes to augment the air brakes.

Without the compressor, the air brakes slowly released. The hand brakes alone couldn't restrain the 11 000-ton train. The train began to roll toward Lac-Mégantic down a 1.2% grade. When it arrived at about 01:15 a.m., the train was traveling at high speed. It derailed. The oil spilled out. The consequent fire and explosion destroyed the center of the town and killed 47 people.

The glut of oil being produced from the Bakken Shale in North Dakota is putting tremendous stress on truck and rail transportation. Old and poorly maintained rolling stock has been pressed into service. Until the equipment is replaced with new equipment or a pipeline the stage is well-set for future accidents.

2.3.17 Tianjin, China: Storage Station Explosions (2015)

On Wednesday, August 12, 2015, at around 22:50 LT, flames were reported in a warehouse in the Binhai dis-

trict of Tianjin, China. Situated on Bohai Bay 150 km southeast of central Beijing, the Binhai New Area is a Special Economic Zone (SEZ), similar to those in Shenzhen and Pudong in Shanghai. Several international companies, including Motorola and Airbus, have constructed facilities in the Binhai SEZ; in 2009, Airbus opened an assembly plant there for A320 airliners [2.97].

The warehouse was owned by Ruihai Logistics. It occupied 46 000 m² (500 000 sq ft) and included multiple areas for storing containers of hazardous chemicals. A regulation specified that such warehouses must be located at least 1 km away from public facilities, but in this case the regulation was ignored. Local officials, including emergency responders, did not know for sure what was stored at the site. The situation was aggravated by major errors, including errors of omission, in customs documents.

According to postmortem reports, the warehouse held more than 40 kinds of hazardous chemicals, including toluene diisocyanate, *vast quantities* of calcium carbide (CaC₂), 800 t of ammonium nitrate, 700 t of sodium cyanide, and 500 t of potassium nitrate. CaC₂ reacts with water to form calcium hydroxide and acetylene, a highly flammable gas. Sodium cyanide reacts with water to form sodium hydroxide and hydrogen cyanide gas, which is both toxic and flammable. Ammonium nitrate is the chemical responsible for the massive explosion in Texas City, Texas in 1947.

First responders to the fire were unable to keep it from spreading. Unaware of what they were facing, they tried dousing the flames with water. The consequent explosion, possibly due to acetylene formed from CaC₂, was equivalent to 3 t of TNT. Less than 1 min later, the ammonium nitrate detonated, causing a blast equivalent to 20 t of TNT. The blaze continued for several days, in part because of a pause in firefighting due to lingering uncertainty about the kinds and quantities of chemicals at the site. On August 15, the spreading flames triggered eight more explosions, which, fortunately, were relatively minor.

Photographs showed extensive destruction around the warehouse, with a massive crater at the center. Seven nearby buildings were destroyed, and others were rendered structurally unsafe. More than 17 000 nearby apartment units were damaged; 6000 people were evacuated.

On August 18, the first rain after the fire coated nearby streets with white chemical foam. People complained that contact with the rain caused burning sensations and rashes.

Also on August 18, the Central commission for Discipline Investigation (CCDI) initiated an investigation of Yang Dongliang. Yang was Director of the

State Administration of Work Safety. He was China's highest-ranking work safety official. He had been Tianjin's vice mayor for 11 years. In 2012, he had issued an order that loosened rules for the handling of hazardous substances. On October 16, he was expelled from the Communist Party for corruption and other offenses.

On August 20, tons of dead stickleback fish washed up on the land about 6 km from the explosion site.

On August 25, another rain brought more complaints of skin burns, and white foam again appeared on the streets. The director of Tianjin's environmental monitoring center claimed that the foam was *a normal phenomenon when rain falls. Similar things have occurred before.*

According to a report issued on September 12, the human toll at Tianjin was 173 killed, 797 hospitalized, and 8 still missing.

2.3.18 Personal Observations

During the past several years, in my role as a technology consultant, I have witnessed shutdowns, near-misses, and loss of containment due to known (but unamended) process design flaws, inadequate maintenance, inadequate training, lack of technical supervision, contravention of procedures, and worker fatigue.

DIBS – did-it-before syndrome – played a role in three of the examples in this section, and in many of the examples described above. DIBS leads workers and managers to disregard safety rules and procedures, because they got away with doing so before.

Hydrocracker Startup: Loss of Containment

The refinery in which this incident occurred was owned by a company known for its dedication to safety. Behind the hydrocracker area in the control room was a large sign that said, in effect, *All employees are obliged to stop any operation he or she believes is unsafe.*

The subject of this example was a two-reactor hydrocracker with multiple beds in each reactor. Catalysts had been loaded and warmed to drive off water. At midnight, it was time for the initial wetting of the catalysts with oil. Initial wetting occurs once and lasts about an hour, but it releases heat due to enthalpy of adsorption (see Chap. 22). In multiple-bed hydrocrackers, wetting causes the Bed 1 outlet temperature to rise, within minutes, by as much as 50 °C. Wetting exotherms can be just as high in subsequent beds. Oil adsorbs heat, so the oil rate is kept high, usually between 50% and 70% of the design maximum. If the oil rate is lower, the temperature rise is higher. Needless to say, controlling feed rate is very important.

Operators can prepare for the exotherms with postquench. When oil reaches the inlet to Bed 1, they

start sending cold gas into the quench deck between Bed 1 and Bed 2. It can take 5–8 min for oil to pass through the bed. When the oil arrives at the Bed 1 outlet, it mixes with the cold postquench gas, which quickly drops the temperature. Without postquench – that is, if operators didn't add cold gas until they saw the exotherm – the temperature wave would pass through the quench box to the inlet of Bed 2 unabated. The heat of adsorption in Bed 2 would increase the temperature by another 50 °C. The total increase across Beds 1 and 2 could be 100 °C. And so on.

Figure 2.14 compares wetting with and without postquench. Without postquench, wetting heat accumulates. Industry experience shows that temperatures can get high enough to initiate cracking and even temperature excursions. After the catalyst is wet, temperatures quickly fall to prewetting level.

Just after midnight in the subject refinery, the hydroprocessing Area Manager, unit engineer, and I were discussing how to proceed despite some known problems. As at BP Texas City, there were three known problems in a separation tower: the level transmitter wasn't working, the sight glass was foggy, and the off-gas compressor wasn't working. There was no way to observe level or control pressure in the tower. Repair work couldn't start before 08:00 a.m., and then it would take an unknown time to fix the compressor. An in-house technician probably could repair the level controller in parallel with other work.

Two VIPs – the refinery Engineering Manager and Operations Superintendent – appeared in the control room and immediately started firing questions. They were concerned that wetting was being delayed. They asked the lead operator to show panel displays irrelevant to the job at hand. Observing the operator's distress, I directed the VIPs to a nearby conference room. The room contained an observation-only display, on which the VIPs could browse without disturbing the startup team.

The Area Manager decided to proceed despite the known problems. He concluded that with postquench operation, the catalyst wouldn't get hot enough to induce hydrocracking. When wetting was over, oil could be circulated for a few hours to flush particulates out of the catalyst. By then, it would be 07:00 a.m. and the unit could be brought down for repairs.

Wetting started at about 03:00 a.m. When liquid feed was introduced, a fourth problem became apparent: the feed pump valve was *sticky*, taking up to 3 min to respond to a change in setpoint. Inability to control feed was crucial, due to the impact of feed on the size of exotherms. The operator called across the control room to the Area Manager. *This is not safe!* he said. *This is not safe!* he said again. According

Fig. 2.14 Comparison of oil temperatures during initial catalyst wetting, with and without postquench. The black and gray segments are for temperatures in the quench boxes. The no Q trends do not include postquench

to company policy, instead of yelling, he should have brought the unit down immediately, without asking permission.

The Area Manager said: *We can't go back. It's okay. We've done this before.* During wetting, the oil flow was lower than specified. With less oil to pick up heat, exotherms were larger than ever before. Thanks to postquench operation, there was never any danger of a temperature excursion.

However, the tower overflowed, sending hydrocarbons to the flare. The flaring lasted 1 h or so, but it had to be reported to environmental authorities. The startup was delayed for days. Saving 5 h cost the refinery more than \$2 million.

The Area Manager had gotten away with operating the tower before without the overhead compressor. He had also gotten away with running without the tower level controller and without the sight glass. He had never run the unit before with all three problems at the same time, and he had never run before without reliable control of feed rate.

As for me: I was an outside consultant. I was consulted by the operator during the event, but not by the Area Manager. Later, I reported the event to my friend, a corporate subject matter expert. He was appalled.

Substandard Equipment.

Disabled Safety Interlock. Stagnation

A serious excursion was the latest of several in a new hydrocracker. The ultimate cause was a decision by the purchasing department to order substandard items for the associated hydrogen plant. One by one, the faulty items failed and were replaced with proper items. Dur-

ing its first 6 months of operation, the unit never ran continuously for more than 1 month.

Each hydrogen plant failure upset the hydrocracker. Some failures sent liquid into the suction of the hydrocracker recycle gas compressor (RGC), causing the RGC to shut down. The licensor's EDS interlock protocol gave operators 15 min to restart the compressor before automatically activating the low-rate depressuring valve. Each depressuring event shut the unit down for at least a day. To give themselves extra time to restart the RGC, the unit engineer and operators decided to disable the EDS/RGC interlock, assuming that temperature-triggered depressuring would be sufficient.

This demonstrated ignorance of several fundamental concepts. The most egregious were:

- Residence time has a significant impact on reaction rates.
- The flow of fluids is the only significant way to remove heat from a hydroprocessing reactor.
- With zero or low flow, bed outlet TI readings are meaningless.

It is crucial to understand the difference between TI readings and temperature. Chapter 22 explains why one never knows the highest or lowest temperature in a catalyst bed. When reactants are flowing through at 50–100% of design capacity, one sees how bed outlet TIs correspond to the temperatures above them. But when flow stops, no TI reading is relevant to any temperature more than a few inches away. Reactions do not stop when flow stops. Heat accumulates in catalyst beds, often without affecting the bed outlet TI readings. Without gas flow, hot oil pools due to gravity at

low points. Eventually, the pooling oil will reach one or more bed outlet TIs and/or reactor wall TIs, providing the first tangible indication that temperatures are too high. Undoubtedly, that is what happened in this unit. Table 2.11 shows a timeline for this incident. A visual representation is presented in Fig. 2.15.

After the first compressor failure, it took 144 min for some overheated oil to run down to the reactor outlet. At 17:38 LT, an upward spike in Reactor Outlet TI-3 triggered depressuring when it reached 440 °C.

TI-3 continued to rise until it reached 487 °C. Depressuring seemed to make things worse. It decreased TI-3, but as the pressure fell, the exiting gas pulled formerly stagnant hot oil through the reactor. Between 17:48 and 17:55 LT, Bed Outlet TI-1 jumped from 404 to 618 °C, an increase of 214 °C in 7 min.

The readings dropped after a restart of the RGC. But then, most likely due to the arrival of more overheated oil, TI-1 jumped back up to 618 °C, where it flatlined for more than 2.5 h. Actual temperatures were higher

Table 2.11 Timeline for personal observations, Example 2

16:14	Recycle gas compressor failed Pressure = 127 barg Maximum bed TI = 402 °C Reactor outlet TI = 398 °C
17:38	Reactor Outlet TI-3 exceeded 440 °C Automatic low rate depressuring
17:44	Reactor Outlet TI-3 continued up to 478 °C
18:00	Recycle gas compressor was restarted
18:27	A bottom reactor wall temperature reached 436 °C
19:17	Recycle gas compressor failed
18:20–20:54	Bed Outlet TI-1 jumped 214 °C in 7 min, stayed > 618 °C for 154 min
20:28	Recycle gas compressor was restarted successfully
18:56–22:30	Bed Outlet TI-2 reached > 618 °C, fell, rose to > 550 °C until 22:30

Fig. 2.15 Pressure, recycle gas flow, and selected temperatures. Bed Outlet TI-1 flatlined at 618 °C, because 618 °C is top-of-range. Actual temperatures were far higher, as evidenced by the fused catalyst in the bed when the reactor was unloaded

than 618 °C, which is top-of-range. It was thought that the TI-1 reading was faulty, but it wasn't; it returned to reading on-scale at 20:54 LT. A second attempt to restart the RGC succeeded. TI-1 readings started to fall. But as they did, Bed Outlet TI-2 rose above 550 °C and stayed there for another 2 h.

Afterwards, the unit ran at reduced rates for 6 months, with strict adherence to licensor-suggested temperature limits. The limits were kept lower than usual due to fears that the reactor outlet pipe had been compromised. During the subsequent turnaround, workers found that the reactor internals were damaged. They also found partially fused silica balls near the reactor wall. Pure silica melts at about 2000 °C. Impurities drop the fusion temperature considerably. But even so, it must have gotten incredibly hot in that reactor.

Botched Refinery Maintenance

Refineries schedule maintenance shutdowns for several units at once, often more than a year in advance. Each process unit depends on several others, serving as a destination for some streams or as a source of feedstock for other units. When a hydrocracker comes down, the need for hydrogen goes down, and major units normally fed by the hydrocracker have to be run differently. Product tanks are filled and arrangements are made with other refiners to maintain supply customers. Construction is scheduled to coincide with maintenance shutdowns. To minimize downtime, equipment replacements must be ready to install, catalysts must be on site, oil inventories must be adjusted, and maintenance contractors are hired to conduct repairs, provide maintenance, unload and load catalysts, and so on. An unplanned shutdown is far more expensive, because other units are not prepared for an outage, and arrangements have not been made with suppliers and customers. Restarting may be delayed because key subcontractor personnel are busy elsewhere.

The following instance was caused (mainly) by a decision to reduce the number of crews employed to service heat exchangers. In shell-and-tube exchangers, one gas or liquid stream is pumped through a bundle of parallel tubes. As it flows through a bundle, the *tube-side* fluid exchanges heat with *shell-side* fluid, which flows in the opposite direction, inside the shell but outside the tubes. During this turnaround, a key activity was the long-delayed cleaning or replacement of fouled tubes. Due to the shortage of people, exchanger maintenance was taking a lot longer than expected. It became clear that the preordained schedule could not be met, given the original scope of work. For a large and important set of exchangers at the hydrocracker, the feed/effluent exchanger (F/E), the crew cleaned only some tubes – the ones most badly fouled. Upon

restart, flow in the F/E followed the path of least resistance – preferentially through the just-cleaned tubes. Within weeks, under-performance of the F/E required an unplanned hydrocracker shutdown and caused costly changes in the operation of other units. The shutdown, service work, and subsequent restart required about two weeks at a cost of more than US\$1 million per day – a steep price to pay for saving less than \$50 000 by reducing tube-cleaning costs.

The decision to clean only some tubes in the F/E displayed fundamental ignorance. Not knowing about the crew's decision revealed slipshod management. No wonder. The refinery was chronically understaffed. During maintenance shutdowns, engineers had to work as many as 30 consecutive 14-hour days. Staffing decisions are made by refinery management, who are ultimately responsible for the consequences.

Fatigue-Related Near Miss

Despite the harsh comments in the BP Texas City report about worker fatigue and insufficient training, a small but significant number of US refineries remain understaffed, especially for shutdown and startup activities. Those refineries aren't alone. Many US service companies also are understaffed, especially during *turnaround season* in March through May. Refineries want to complete maintenance before June, so they can be up and running throughout the summer, when gasoline consumption is highest. A smaller turnaround season occurs near the end of the year.

Members of a vendor technical service team had been working long hours during the spring startup season, often more than 100 h per week. In addition to spending 12–14 h per day supervising startups, team members were required to handle questions from other customers, write proposals, and prepare for upcoming customer visits. Four hours of sleep per night was the rule, not the exception.

The group had always been busy, but the workload increased after the business unit was reorganized. The main reason was a switch from a VP of Technical Service who controlled the team's workload by screening sales-support work, to a non-technical GM of Sales who did not understand the service end of the business and insisted on chasing every apparent opportunity, no matter how unlikely.

One night, while driving from a refinery to his hotel, a team member fell asleep and drove off a country road. He wasn't injured. For that and other reasons, he didn't report the incident until several months later, when another member of the team persuaded him to complain.

In response to the complaint, which included mention of possible consequences, a high-level manager said: *What are you, a lawyer? Mister HSE?* followed

by *Why didn't you say something sooner?* The manager later admitted knowing about the overwork for several months. *We didn't add people*, the high-level manager said, *because we might have had to lay them off if business slowed down*. Within a year of the reorganization, 60% of the original team had left, primarily due to overwork.

The high-level manager's response to what could have been a fatal accident was completely inconsistent with company policy. Accidents and near-miss reports were supposed to be treated seriously, no matter how or when they were reported. The fact that the manager knew about the overwork for so long – and did nothing – is astounding.

2.3.19 Lessons

Lessons are learned from such events. But not everyone learns. Many of those who do learn forget. Or worse, they decide that the lessons don't apply to them.

DIBS

I believe that DIBS – did-it-before syndrome – is a fundamental characteristic of human behavior. People ignore safety rules because they got away with ignoring them before, not just in the workplace, but in homes and public places, especially on the highway.

Statistics on road accidents provide a down-to-Earth example, especially for North Americans. In the United States, the National Highway Traffic Safety Administration (NHTSA) conducts periodic surveys of speeding attitudes and behaviors. The most recent survey was conducted in 2011. The corresponding report was issued in 2013 [2.98]. Data were collected via telephone interviews with 6144 US households, with allowances made for land-line versus cell-phone use. The report classified 30% of US drivers as nonspeeders, 40% as sometime speeders, and 30% as speeders. About 9% had been stopped for speeding, and about 6% had received speeding citations. Here are a few survey results:

- 82% of respondents agreed that driving at or near the speed limit makes it easier to avoid dangerous situations.
- 79% agreed that driving at or near the speed limit reduces their chance of having an accident.
- 17% said that driving at or near the speed limit annoys them.

Other reports [2.99–101] provide the following statistics for the United States:

- Registered drivers = 212 million
- Registered vehicles = 269 million

- Crashes causing only property damage = 4.1 million
- Injury-causing crashes = 1.6 million
- Fatal crashes = 32 719
- Speeding-related fatalities = 9613
- Speeding related crashes in which the driver was alcohol-impaired = about 42%
- Speeding related crashes in which the people killed were wearing restraints = about 50%
- Average miles driven per year per vehicle = 13 476
- Average length of trip = 9.75 mi
- Average trips per year = 1360
- Speeding tickets per driver per year = 0.17
- Average speeding ticket cost = \$152.

Using these data, one can calculate the following:

- Accidents per trip = 0.156%
- Injuries per trip = 0.061%
- Deaths per trip = 0.00037%.

Speeding gets us where we want to be faster, and the risks are very low. The most likely negative consequence is a speeding ticket, for which the cost is tolerable. The average driver takes 460 trips without a fender-bender, 1640 trips without an injury, 80 000 trips without dying, and 270 000 trips without dying due to speeding. So we speed, even though we know speeding is dangerous.

In hydrocarbon industries, consequences of accidents can be far worse, threatening the lives, health and prosperity of thousands of people. In well-run facilities, the personal financial cost of breaking a rule can far exceed the cost of a speeding ticket; it can get a worker fired.

But as described in several of the examples above, workers, managers and executives – knowingly and willfully – continue to break critical rules. Why? Is it simply because the rules are inconvenient? Do they believe the rules don't apply to them? Or is it DIBS – concluding that their way is better, because they've behaved that way before with no negative consequences?

How can DIBS be diminished? Experience shows that threats are effective at decreasing DIBS. If people can lose a job or go to jail for violating a rule, they take the rule more seriously, whether or not they agree with it.

MOC

Perhaps a DIBS practitioner is correct. Maybe his/her way really is okay, or even better. Management of Change (MOC) [2.102] is a formal process by which procedures can be improved. With design models, a written document, and perhaps a formal presentation,

the originator presents an idea to everyone involved. For a minor, localized change in procedure, the MOC process can be quick, requiring approval from two or more colleagues and subsequent documentation. For a significant change in hardware or general operating procedures, an MOC committee is formed, which usually includes peers, supervisors, and internal experts. The committee might also include one or more outside consultants. Implementation might require detailed design, budget approval, and development and review of operating procedures.

Ineffective MOC is one of the leading causes of serious incidents, according to the US Chemical Safety and Hazard Investigation Board (CSB) [2.103]. CSB stated:

In industry, as elsewhere, change often brings progress. But it can also increase risks that, if not properly managed, create conditions that may lead to injuries, property damage or even death.

Changes subject to MOC procedures can include:

- Personnel changes, including reorganization, staffing, and training
- Equipment changes, including revamps, communications devices, control hardware, and control software
- Procedure changes, including maintenance schedules and procedures for normal operation, startup, and shutdown
- Material changes, including significant changes in catalysis, chemicals, and feedstock.

Comparison of Examples

The Lakeview blowout occurred before the advent of blowout-prevention technology. Blowouts were known before, but it's difficult to say what might have been done to prevent this one, other than not drilling the well at all.

The Texas City ammonium nitrate explosion also was due to ignorance. The dangers of having so much ammonium nitrate in one place were not then understood.

Lack of prompt official response to the London killer fog could be due in part to culture. In 1952, not very long after World War II, Londoners had learned to accept discomfort, including perhaps noisome smog, as minor compared the blitz.

In 1978, the world simply was not prepared for oil spills as large as the *Amoco Cadiz*. The main lesson learned there was that quick response is critical. By the time help finally arrived, the ship was destroyed and its entire cargo was in the sea.

At Bhopal, management was abysmal, as evidenced by the horrid lack of maintenance. As stated by a Union

Carbide executive, the plant should not have been running.

Chernobyl was caused by contravention of procedures by managers who didn't understand nuclear technology. Three major safety rules were violated when operators:

1. Shut off the emergency cooling water system
2. Raised the control rods too high
3. Disabled the emergency SCRAM.

Any one of the idled systems, if left in place, might have prevented the accident.

Chemical companies all along the banks of the Rhine secretly dumped wastes into the river to avoid having to spend money on proper disposal infrastructure.

On the *Exxon Valdez*, Captain Hazelwood violated a US Coast Guard guideline when he left the third mate in charge before the ship reached open water. Despite the eight-hour delay in expected response time, action by Alyeska and Exxon was relatively fast. Most of the oil stayed inside the ship until it was offloaded. Consequently, instead of losing the entire cargo of 1.2 million bbl, only 250 000 bbl spilled into the sea.

In the Gulf War, retreating Iraqis took *scorched earth* during a war to a new level. Due to strong incentives to develop new technology, putting out the oil fires took far less time than anyone expected.

The Tosco Avon disaster was caused by management-induced DIBS. Engineers and operators were not sufficiently trained. Management refused to invest in proper instrumentation. Management refused to fix the problem that had caused a fire during the 1992 depressuring event. Management strongly encouraged operators to avoid depressuring. Operators became so accustomed to defeating excursions without depressuring that it never occurred to them to act correctly, even when temperatures far exceeded metallurgical limits. Obviously, nobody understood the relationship between N-slip and hydrocracking catalyst activity.

At BP Texas City, operators proceeded with the startup despite the lack of reliable level measurement, reflecting a combination of inadequate training, inadequate technical supervision, and probably DIBS.

Similar factors played a role in the *Deepwater Horizon* incident. Fatal mistakes included the use of an insufficient number of centralizers and the assumption that pressure in the kill line was indicative of pressure in the well. The drilling crew did not understand the significance of several consecutive failed negative pressure tests. The visit of nonessential VIPs during the most critical phase of well completion distracted key tech-

nical personnel, who certainly would have understood the significance of the tests.

The train derailment in Lac-Mégantic was caused by faulty maintenance, the failure of the engineer to tell MM&A about the failing locomotive before it caught fire, and the failure of authorities to act to ensure that oil transportation infrastructure is safe. Government refusals to permit pipelines also are to blame. Pipelines are far more efficient – and thousands of times cleaner and safer – than railroad trains.

All four of my personal examples occurred during startups. All were influenced by cost-cutting and/or unreasonable schedules.

Of all the examples in this section:

- Seven occurred during a startup or shutdown.
- Nine were caused in large part by contravention of procedures. Of these, three involved willful disabling of safety interlocks.
- Eight were caused by shortcuts and cost-cutting understaffing, inadequate training, buying sub-standard equipment, or taking shortcuts to save time. In each case, the supposed savings were miniscule compared to the cost of the incident.
- All but three were due in part to management malfeasance.

General Observations

In this section, I mention other safety-related issues that are general and not related to a single event. Management of change is outlined above.

Whistleblowing. In the above examples, rogue managers would have been chastised (or fired) if their behavior had been reported and verified.

Over the years, the US Congress has passed at least seven laws to protect environmental whistleblowers from retribution from their employers. Even so, according to Seebauer [2.104]:

Studies confirm the intuitive perception that whistleblowers tend to face hostility within their organizations and commonly leave their jobs, either voluntarily or otherwise. Lengthy and costly litigation often follows.

Seebauer goes on to say:

Some employers are happy to hire workers who demonstrate such a strong commitment to high ethical standards. Nevertheless, there is no guarantee of employment, especially in a slow market. The whistleblower may lose seniority and retirement benefits, and must often move to another city. The needs of family members must be considered.

When faced with these realities, insiders are reluctant to report environmental wrongdoing.

Smart companies encourage whistleblowing. They send employees to courses that teach them about safety and environmental protection. They establish internal whistleblower hotlines and encourage employees to use them when they think their concerns haven't properly been addressed by the normal chain of command. They recognize that, in today's litigious society, whistleblowers can save a company billions of dollars in fines and cleanup costs.

Automation. Control systems aren't perfect. I have seen more than one process unit in which an advanced control application is so bad that the operators won't use it. On the other hand, safety-related interlocks must *never* be disabled. They are there for good reasons. Operators, engineers, and managers should be trained to understand exactly how the interlocks work and why they are critical.

Personal Protection Equipment. One of the first things a person learns in the oil and gas business is the importance of personal protection equipment (PPE). In the bad old days, it wasn't uncommon to see bare-headed workers in short-sleeved shirts building scaffolding in a refinery. That doesn't happen now. We are required to wear appropriate PPE at all times.

PPE includes fire-resistant clothing, hard hats, safety glasses, steel-toed shoes, gloves, and toxic gas detectors. Harnesses are used to protect against falls. Using fresh-air breathing equipment or self-contained breathing apparatus (SCBA) improves safety in confined spaces and in areas that might be contaminated by hazardous gases and particulates. In recent years, communication between outside and inside workers has been enhanced by allowing communication via inherently safe radios. Laboratory workers face unique hazards; hard hats are seldom needed in labs, but for some analytical procedures, special gloves and full-face shields protect against hazardous substrates, solvents, and acids.

Pocket-sized toxic gas detectors are important PPE. They sound an alarm when CO or H₂S reach dangerous levels. Some sites require all workers to wear H₂S monitors at all times when they are *inside the gate*. Four-gas monitors detect H₂S, CO, combustible hydrocarbons, and oxygen.

In the United States, the Occupational Safety and Health Administration (OSHA) sets standards for PPE [2.105, 106]. The first standards were adopted in 1971. A major revision was issued in 1994, after OSHA discovered gaps in the existing standards. Data indi-

cated that injuries were occurring at the same rate, whether or not employees were wearing PPE. Some regulations were so restrictive that they discouraged innovation. Present regulations are based on the effectiveness of PPE. Recent improvements are addressing the main cause of worker noncompliance before the revision: some PPE was cumbersome, uncomfortable, and even impractical.

Confined Spaces. People enter tanks, reactors, and other confined spaces to perform maintenance. Oxygen levels can become too low even if air is circulating. Required PPE for confined space entry includes fresh-air breathing equipment and a harness that allows colleagues to lift the worker out if necessary. Modern video technology enables outside personnel to monitor people inside directly.

2.4 Agencies Protecting Safety and the Environment

2.4.1 Environment Protection Agencies

This section focuses almost exclusively on US environment protection agencies and laws. Please understand that to include similar detail for other countries would have been infeasible in the space allotted for this chapter.

In 1970, the United States formed the Environmental Protection Agency (EPA) [2.21] and the Occupational Safety and Health Administration (OSHA). Together, these agencies are responsible for dramatic improvements in air and water quality and increases in workplace safety throughout the United States. EPA's mission is:

to enforce federal laws to control and abate pollution of air and water, solid waste, noise, radiation, and toxic substances. Other missions include administering the Superfund for cleaning up abandoned waste sites, and awarding grants for local sewage treatment plants.

After its creation, EPA quickly took the following actions:

- Established ten regional offices throughout the nation
- Established National Ambient Air Quality Standards, which specified maximum permissible levels for major pollutants
- Required each state to develop plans to meet air quality standards
- Established and enforced emission standards for hazardous pollutants such as asbestos, beryllium, cadmium, and mercury
- Required a 90% reduction in emissions of VOC and CO by 1975
- Published emission standards for aircraft
- Funded research and demonstration plants
- Furnished grants to states, cities, and towns to help them combat air and water pollution.

EPA's law-enforcement efforts are supported by the National Enforcement Investigation Center in Denver, Colorado, which gives assistance to federal, state, and local law enforcement agencies. This unit has clamped down on the *midnight dumping* of toxic waste and the deliberate destruction or falsification of documents.

Today, almost every US state has an environmental agency. Arguably, the most famous of these is the California Air Resources Board (CARB), which pioneered regulations to mitigate smog in Los Angeles. In addition to administering state programs for improving air and water quality, the Texas Commission on Environmental Quality (TCEQ) participates in making plans to prevent and react to industrial terrorism.

Most countries have environmental agencies. As shown in Table 2.12, some are combined with public

Table 2.12 Environmental agencies around the world

Country	Agency
Australia	Department of the Environment
Austria	Ministry for the Environment
Brazil	Ministry of Environment
Canada	Environment Canada
Europe	European Environment Agency
Finland	Ministry of the Environment
Indonesia	Kementerian Lingkungan Hidup
India	Ministry of Environment and Forests
Japan	Ministry of the Environment of Japan
Kuwait	Environment Public Authority
Malaysia	Department of Environment
Mexico	Secretariat of Environment and Natural Resources
Norway	Ministry of the Environment
Saudi Arabia	Presidency of Meteorology and Environment
Singapore	National Environment Agency
South Africa	Department of Environmental Affairs and Tourism
Thailand	Ministry of Natural Resources and Environment
United Kingdom	Environment Agency
United States	Environmental Protection Agency

health departments, some are combined with energy agencies, and at least one is coupled with tourism. In addition to handling internal issues, these agencies administer their country's participation in international treaties, such as the Kyoto Protocol [2.107].

2.4.2 Worker Safety

Pollution control and safety are two sides of the same coin. In the United States, the Occupational Safety and Health Administration (OSHA) is part of the US Department of Labor. Its legislative mandate is to assure safe and healthful working conditions by:

- Enforcing the Occupational Safety and Health Act of 1970
- Helping states to assure safe and healthful working conditions
- Supporting research, information, education, and training in occupational safety and health.

OSHA can levy fines against unsafe people and companies. Not surprisingly, a large percentage of the safety infringements cited by OSHA have caused environmental damage or put the environment at risk. For example, in 1993 OSHA fined the Manganas Painting Company for exposing workers and the environment to lead during sandblasting operations. The proposed fines totaled US\$4 million. The contractor appealed, but in February 2002, it pleaded guilty to dumping 55 t of lead-containing sandblasting material, in violation of the Resource Conservation and Recovery Act (RCRA) [2.108].

Under the Occupational Safety and Health Act, employers are responsible for ensuring a safe and healthy workplace. One key requirement is that all hazardous chemicals must be properly labeled. Workers must be taught how to handle the chemicals safely, and material safety data sheets must be available to any employee who wishes to see them.

Material Safety Data Sheets (MSDS)

Material safety data sheets (MSDSs) play a major role in improving worker safety by providing standardized and readily available information on potentially hazardous substances. MSDS include the following information.

Material Identification. The name of the product and the manufacturer's name, address, and emergency phone number must be provided.

Hazardous Ingredients. The sheet must give the chemical name for all hazardous ingredients comprising

more than 1% of the material. It must list cancer-causing materials if they comprise more than 0.1%. Listing only the trade name, only the Chemical Abstract Service (CAS) number, or only the generic name is not acceptable.

If applicable, exposure limits are listed in this section of the MSDS. The OSHA permissible exposure limit (PEL) is a legal, regulated standard. Other limits may also be listed. These include recommended exposure limits (REL) from the National Institute for Occupational Safety and Health (NIOSH) and threshold limit values (TLV) from the American Conference of Governmental Industrial Hygienists (ACGIH). Sometimes, short-term exposure and/or ceiling limits are shown. The ceiling limit should never be exceeded.

Physical Properties. These include the appearance, color, odor, melting point, boiling point, viscosity, vapor pressure, vapor density, and evaporation rate. The vapor pressure indicates whether or not the chemical will vaporize when spilled. The vapor density indicates whether the vapor will rise or fall. Odor is important because a peculiar smell may be the first indication that something has leaked.

Fire and Explosion Hazard Data. This section provides the flash point of the material, the type of extinguisher that should be used if it catches fire, and any special precautions.

The flash point is the lowest temperature at which a liquid gives off enough vapor to form an explosive mixture with air. Liquids with flash points below 100 °F (37.8 °C) are called flammable, and liquids with flash points between 100–200 °F (37.8–93.3 °C) are called combustible. Flammable and combustible liquids require special handling and storage.

The four major types of fire extinguishers are Class A for paper and wood, Class B for flammable liquids or greases, Class C for electrical fires, and Class D for fires involving metals or metal alloys.

Health Hazard Data. This section defines the symptoms that result from normal exposure or overexposure to the material or one of its components. Toxicity information, such as the result of studies on animals, may also be provided. The information may also distinguish between the effects of acute (short-term) and chronic (long-term) exposure. Emergency and first-aid procedures are included in this section.

Reactivity Data. This section includes information on the stability of the material and special storage requirements.

Unstable chemicals can decompose spontaneously at certain temperatures and pressures. Some unstable chemicals decompose when they are shocked. Rapid decomposition produces heat, which may cause a fire and/or explosion. It also may generate toxic gas. Hazardous polymerization, which is the opposite of hazardous decomposition; it can produce enough heat to cause a fire or explosion.

Concentrated acids and reactive metals are hazards when mixed with water. They should be stored separately in special containers.

Spill, Leak, and Disposal Procedures. This part of the MSDS gives general procedures, precautions and

methods for cleaning up spills and disposing of the chemical.

Personal Protection Equipment Requirements.

This section lists the protective clothing and equipment needed for the safe handling of the material. Requirements can differ depending on how the chemical is used and how much of it is used.

Protective equipment and clothing can include eye protection (safety glasses or face shields), skin protection (clothing, gloves, shoe covers), self-contained breathing equipment, and/or forced-air ventilation (fume hoods).

2.5 Key Regulations

In this section, important environmental legislation is described. Most examples come from the United States, but there is an excuse: for several decades, the United States has pioneered environmental regulations, and many countries have followed suit. Recently, the European Commission took the lead in promoting climate-control treaties, including the Rio and Kyoto Protocols.

2.5.1 Clean Air Acts

The first clear-air acts in the English-speaking world were implemented by Parliament in 1956, in response to the *deadly fog* incidents around London.

Since 1963, the United States government has passed several clean-air acts, including:

- Clean Air Act of 1963
- Motor Vehicle Air Pollution Control Act of October 20, 1965
- Clean Air Act Amendments of October 15, 1967
- Air Quality Act of November 21, 1967
- Creation of EPA: Clean Air Act of 1970
- Clean Air Act Amendments of 1975, 1977, and 1990.

For convenience, the entire package often is called just the Clean Air Act (CAA). A good source for general understanding is the Plain English Guide to the Clean Air Act, available from the US EPA web site [2.109]. The Guide shows how the CAA has led to significant improvements in human health and the environment. For example, since 1970:

- The six most commonly found air pollutants have decreased by more than 50%

- Air toxics from large industrial sources, such as chemical plants, petroleum refineries, and paper mills have been reduced by nearly 70%
- New cars are more than 90% cleaner and will be even cleaner in the future
- Production of most ozone-depleting chemicals has ceased.

At the same time, the US economy and associated energy consumption has grown significantly:

- The US GDP has tripled
- Energy consumption has increased by 50%
- Vehicle use has increased by almost 200%.

Under the CAA, EPA's role is to set limits on certain air pollutants, including ambient levels anywhere in the country. EPA limits emissions of air pollutants from point sources like chemical plants, utilities, and steel mills. Individual states or tribes may have stronger air pollution laws, but they may not have weaker pollution limits than those set by EPA.

EPA assists state, tribal, and local agencies by providing research, expert studies, engineering designs, and funding to support clean air progress. EPA must approve state, tribal, and local air pollution reduction plans. EPA can issue sanctions against states which fail to comply; if necessary, it can take over enforcing the CAA in noncomplying areas.

The CAA required EPA to set National Ambient Air Quality Standards (NAAQS) for pollutants considered harmful to public health and the environment. EPA set are two types of standards – primary and secondary. Primary standards protect against adverse health effects. Secondary standards protect against damage to

farm crops, vegetation, and buildings. Because different pollutants have different effects, the NAAQS are also different. Some pollutants have standards for both long-term and short-term averaging times. The short-term standards are designed to protect against acute, or short-term, health effects, while the long-term standards were established to protect against chronic health effects. NAAQS are shown in Table 2.13 [2.110].

Hazardous air pollutants (HAPs) are regulated, too. Table 2.14 lists 20 *core* compounds selected from the 188 HAPs regulated under Section 112 of the Clean Air Act.

Compliance with air quality standards is monitored by the Office of Air Quality Planning and Standards (OAQPS) [2.111]. OAQPS evaluates the status of the atmosphere as compared to clean air standards and historical information, using measurements acquired from many hundreds of monitoring stations across the United States.

Reformulated Gasoline (RFG) in the United States

In 1970, gasoline blending became more complex. The US Clean Air Act required the phase-out of tetraethyl lead, so refiners had to find other ways to provide octane. In 1990, the CAA was amended. It empowered EPA to impose emissions limits on automobiles and to require reformulated gasoline (RFG) [2.112]. RFG was implemented in several phases. The Phase I program started in 1995 and mandated RFG for ten large metropolitan areas. Several other cities and four entire States joined the program voluntarily. The current phase began in 2000. RFG is used in 17 States and the District of Columbia. In 2015, about 35% of the gasoline in the United States was reformulated.

Tier 1 reformulated gasoline regulations required a minimum amount of chemically bound oxygen, imposed upper limits on benzene and Reid vapor pressure (RVP), and ordered a 15% reduction in VOC and air toxics. Air toxics include 1,3-butadiene, acetaldehyde, benzene, and formaldehyde.

The regulations for Tier 2, which took force in January 2000, were based on the EPA Complex Model, which estimates exhaust emissions for a region based on geography, time of year, mix of vehicle types, and – most important to refiners – fuel properties. As of 2006, the limit on sulfur in the gasoline produced by most refineries in the US was 30 ppmw.

Initially, the oxygen for RFG could be supplied as ethanol or C₅–C₇ ethers. The ethers have excellent blending octanes and low vapor pressures. But due to leaks from filling station storage tanks, methyl-*t*-butyl ether (MTBE) was detected in ground water samples in New York City, Lake Tahoe, and Santa Monica, California. In 1999, the Governor of California issued an executive order requiring the phase-out of MTBE as a gasoline component. That same year, the California Air Resources Board (CARB) adopted California Phase 3 RFG standards, which took effect in stages starting in 2002. The standards include a ban on MTBE and a tighter cap on sulfur content. In the United States, Tier 3 vehicle emission and fuel standards lowered the allowed sulfur content of gasoline to 10 ppmw as of January 2017.

Conservation, Efficiency, and Renewable Fuel Mandates

The *Energy Policy Act of 2005* [2.113] was signed into law by President George W. Bush on August 8, 2005. The Act addresses energy production and use in the

Table 2.13 National Ambient Air Quality Standards (NAAQS) pollutants

Pollutant	Primary/secondary	Averaging time	Level	Form
Carbon monoxide	Primary	8 h	9 ppm	Not exceeded more than once/year
Carbon monoxide	Primary	1 h	35 ppm	Not exceeded more than once/year
Lead	Both	Rolling 3 month	0.15 μg/m ³	Not to be exceeded
Nitrogen dioxide	Primary	1 h	100 ppb	98th percentile of 1 h daily max concentrations, averaged over 3 years
Nitrogen dioxide	Both	Annual	53 ppb	Annual mean
Ozone	Both	8 h	0.075 ppm	Annual fourth-highest daily max 8 h concentration, averaged over 3 years
Particulates, PM _{2.5}	Primary	Annual	12 μg/m ³	Annual mean, averaged over 3 years
Particulates, PM _{2.5}	Secondary	Annual	15 μg/m ³	Annual mean, averaged over 3 years
Particulates, PM _{2.5}	Both	24 h	35 μg/m ³	Annual mean, averaged over 3 years
Particulates, PM ₁₀	Both	24 h	150 μg/m ³	Not to be exceeded more than once/year, on average, over 3 years
Sulfur dioxide	Primary	1 h	75 ppb	99th percentile of 1 h daily max concentrations, averaged over 3 years
Sulfur dioxide	Secondary	3 h	0.5 ppm	Not exceeded more than once/year

Table 2.14 Twenty of the hazardous air pollutants regulated by the Clean Air Act

Volatile organics (VOC)	Inorganics (Metals)	Aldehydes
Benzene	Arsenic	Formaldehyde
1,3-Butadiene	Beryllium	Acetaldehyde
Carbon tetrachloride	Cadmium	Acrolein
Chloroform	Chromium	
Propylene dichloride	Lead	
Dichloromethane	Manganese	
Perchloroethylene	Mercury	
Trichloroethylene	Nickel	
Vinyl chloride		

United States. It provides tax incentives and loan guarantees for specific types of energy production. Topics include:

- Energy efficiency
- Renewable energy
- Oil and gas
- Coal
- Tribal energy
- Nuclear matters and security
- Vehicles and motor fuels, including ethanol
- Hydrogen
- Electricity
- Energy tax incentives
- Hydropower and geothermal energy
- Climate change technology.

It authorized the following tax reductions:

- \$4.3 billion for nuclear power
- \$2.8 billion for fossil fuel production
- \$2.7 billion to extend the renewable electricity production credit
- \$1.6 billion in tax incentives for investments in *clean coal* facilities
- \$1.3 billion for energy conservation and efficiency
- \$1.3 billion for alternative fuels (bioethanol, biomethane, liquified natural gas, propane)
- \$500 million Clean Renewable Energy Bonds for government agencies for renewable energy projects.

The Energy Independence and Security Act of 2007 required improved vehicle fuel economy. It also increased production requirements for biofuels, specifically biomass-derived diesel. To be biomass-based diesel, the fuel must reduce emissions by 50% versus petroleum-derived diesel. It increased the total target volume for ethanol, and specified that a large portion should come from noncorn sources. The Act motivates energy savings with improved standards for appliances and lighting, and in industrial and commercial buildings.

Gasoline (Petrol) in the EU

Transportation fuel specifications in the European Union (EU) are described by EN 228, *Specification for unleaded petrol (gasoline) for motor vehicles*. The present version is sometimes called Euro IV gasoline. Key specifications include the following:

- Octane: minimum research octane number (RON) and motor octane number (MON) are 95 and 85 respectively.
- Volatility: minimum percent vaporized at 100 and 150 °C are 46 and 75 respectively.
- Hydrocarbon types: the maxima for olefins/aromatics/benzene are 18/35/1 vol%, respectively.
- Oxygen: The maximum oxygen content is 3.7%. Oxygenates can include different amounts of methanol, ethanol (with stabilizing agents), isopropyl alcohol, butyl alcohols, ethers such as MTBE, and other mono alcohols.
- Sulfur: 10 ppmw.

EU gasoline is just as clean if not cleaner than EPA gasoline, but it is easier to manufacture and regulate. The allowable sources of oxygen are based on science.

Ultra-Low-Sulfur Diesel

At present, the most advanced specification for diesel fuel is Euro V, which is described in Table 2.15. Severe hydroprocessing is required to make Euro V from difficult feedstocks.

2.5.2 Rivers and Harbor Act, Refuse Act

One of the first environmental laws in the US was the Rivers and Harbor Act of 1899. It was passed to control obstructions to navigation. The Act required congressional approval for the building of bridges, dams, dikes, causeways, wharfs, piers, or jetties, either in or over a navigable waterway. The Act also made it illegal to discharge debris into navigable water without a permit. In 1966, a court held that the River and Harbor Act made it illegal to discharge industrial waste without a permit, not just directly into navigable waters, but also into associated tributaries and lakes. This led to the Refuse Act Permit Program of 1970, under which specific kinds of pollution are allowed under permits issued by the Army Corps of Engineers. Every application for a permit is reviewed by EPA. If EPA concludes that the discharge described in the application will harm the environment, the Army Corp of Engineers denies the permit.

The penalties for violating permits are severe, including stiff fines and jail time. A corporation that employs the guilty person can be fined up to \$1 000 000. False reports also can be punished by fines or im-

Table 2.15 Clean fuels: Specifications for Euro V diesel, (EN 590)

Property	Units	Low limit	Upper limit	Test-method

prisonment. In this context, *guilty person* refers to the corporate officer responsible for the facility from which the illegal discharge originates. In other words, a negligent act by a sloppy operator can send the Big Boss to jail.

2.5.3 Federal Water Pollution Control Act

The original Federal Water Pollution Control Act (FWPCA) was approved on July 9, 1956. The present Act includes the following:

- Pollution Control Act Amendments of July 20, 1961
- Water Quality Act of October 2, 1965
- Clean Water Restoration Act of November 3, 1966
- Water Quality Improvement Act of April 3, 1970
- Federal Water Pollution Control Act of 1972
- Clean Water Acts of 1977, 1981, and 1987.

The FWPCA of 1972 gave EPA greater authority to fight water pollution. While implementing the Act, EPA cooperates with the US Coast Guard and the Secretary of the Interior. Individual states have primary responsibility for enforcing water quality standards, but if the states fail to meet expectations, EPA can take civil or criminal action under the Refuse Act.

The FWPCA prohibits the discharge of harmful amounts of oil into navigable waters. If oil is spilled, the owner or operator is liable for cleanup costs. Initially, the bill authorized \$24.6 billion for water pollution control over three years. The goal of the law was to eliminate the pollution of US waterways by municipal and industrial sources by 1985.

2.5.4 Clean Water Acts, Water Quality Act

The main objective of the Clean Water Acts (CWA) of 1977, 1981 and 1987 is to maintain the *chemical, physical, and biological integrity of the nation's waters*. It seeks to have *water quality which provides for the protection and propagation of fish, shellfish and wildlife and provides for recreation in and on the water*. Under these Acts, each state is required to set its own water quality standards. All publicly owned municipal sewage treatment facilities are required to use secondary treatment for wastewater. To help states and cities build new or improved water treatment plants, Congress provides construction grants, which are administered by EPA. EPA allocates funds to states, which in turn distribute money to local communities.

Community programs are monitored by EPA. They must meet treatment requirements to obtain permits under the National Pollutant Discharge Elimination System (NPDES).

The Water Quality Act of 1987 requires discharge permits for all point sources of pollution. More than 95% of all major facilities now comply with five-year NPDES permits, which specify the types and amounts of pollutants that legally can be discharged. When permits are renewed, they can be modified to reflect more stringent regulations. Violators are subject to enforcement actions by EPA, including criminal prosecution.

The authority of the EPA was strengthened under the 1987 Water Quality Act. The allowable sizes of fines were increased, and violators found guilty of negligence could be sent to prison.

2.5.5 Marine Protection, Research, and Sanctuaries Act

The Marine Protection, Research, and Sanctuaries Act of 1972 gave authority to EPA to protect oceans from indiscriminate dumping. The Agency designates sites at which dumping is allowed and issues dumping permits. Fines can be imposed for illegal dumping.

2.5.6 Safe Drinking Water Act

Since the 1970s, the assurance of safe drinking water has been a top priority for EPA, along with individual states and over 53 000 community water systems (CWSs). The CWSs supply drinking water to more than 280 million Americans – about 90% of the population [2.114].

The Safe Drinking Water Act of 1974 was amended in 1977 and again in 1986. It empowered EPA to set national standards for drinking water from surface and underground sources. It also authorized EPA to give financial assistance to states, which are in charge of enforcing the standards. Aquifers are protected from wastes disposed in deep injection wells, from runoff from hazardous waste dumps, and from leaking underground storage tanks. In 1987, EPA also established maximum contaminant levels for VOC and 51 man-made chemicals. Standards for other chemicals were added as their toxicity was determined. At present, health and safety standards have been established for 91 microbial, chemical, and radiological contaminants.

2.5.7 Resource Conservation and Recovery Act (RCRA)

In the United States, solid wastes are regulated by the following:

- Solid Waste Disposal Act of 1965
- Resources Recovery Act of 1970
- Resource Conservation and Recovery Act of 1976 (RCRA).

In 1965, the Solid Waste Disposal Act provided financial grants to develop and demonstrate new technologies in solid waste disposal. The Resources Recovery Act of 1970 emphasized recycling and by-product recovery.

By 1976, problems caused by the accumulation of large quantities of hazardous waste prompted Congress to pass the Resource Conservation and Recovery Act (RCRA). This legislation gave EPA the responsibility of developing a *cradle to grave* approach to hazardous

waste, which culminated in the establishment of Hazardous Waste and Consolidated Permit Regulations (1980).

Under RCRA, hazardous waste is tracked from its source to every destination, including final disposal. Tracking is based on transportation manifests, other required records, and the issuance of permits.

EPA classifies wastes according to four measurable characteristics, for which there are standardized tests. The characteristics are:

- Ignitibility
- Corrosivity
- Reactivity
- Extraction procedure (EP) toxicity.

In 1980, the Waste Oil Recycling Act (WORA) empowered EPA to encourage the development of state and local programs for recycling waste motor oil. That same year, WORA was amended to strengthen its enforcement provisions.

A *generator* of hazardous waste is responsible for the following:

1. Determining if a waste is hazardous
2. Obtaining a facility permit if the waste is stored on the generator's property for more than 90 days
3. Obtaining an EP identification number
4. Using appropriate containers and labeling them properly for shipment
5. Preparing manifests for tracking hazardous waste
6. Assuring through the manifest system that the waste arrives at the designated facility
7. Submitting to EPA an annual summary of activities.

Prior to shipping hazardous waste, the generator must prepare a manifest which includes the following:

1. Name and address of the generator
2. Name of all transporters
3. Name and address of the facility designated to receive the waste
4. EPA identification number of all who will handle the waste
5. Department of Transportation (DOT) description of the waste
6. Amount of waste and number of containers
7. Signature certifying that the waste has been properly labeled and packaged in accordance with EPA and DOT regulations.

To send waste away from its site, the generator must use EPA-approved transporters. It must also keep records of all hazardous waste shipments and immedi-

ately report those that fail to reach the facility shown on the manifest.

A *transporter* of hazardous waste must:

1. Obtain an EPA identification number
2. Comply with the manifest system for tracking hazardous waste
3. Deliver the entire quantity of hazardous waste to the facility specified by the manifest
4. Retain copies of manifests for 3 years
5. Comply with Department of Transportation rules for reporting discharges and spills
6. Cleanup any spills that occur during transportation. All spills must be reported to both EPA and the DOT.

Any person who owns or operates a hazardous waste facility must receive a permit from the EPA. Standards for facilities that treat, store, or dispose of hazardous waste are designed to:

1. Promote proper treatment, storage, and methods of disposal
2. Provide states with minimum standards acceptable to EPA
3. Provide technical support to states that lack hazardous waste management programs.

The RCRA amendments of 1984 and 1986 extended the Act to cover underground storage tanks, especially those used for gasoline and other petroleum liquids. At the time, about 15% of the nation's 1.4 million gasoline storage tanks were leaking. Most of these leaks have since been repaired.

2.5.8 Superfund, CERCLA

Years ago, people were less aware of the dangers of dumping chemical wastes. On many properties, dumping was intensive and/or continuous. This created thousands of hazardous sites, many of which were uncontrolled and/or abandoned. On December 11, 1980, in response to public concern, Congress passed the Comprehensive Environmental Response Compensation and Liability Act (CERCLA) [2.115], which authorized EPA to locate, investigate, and remediate the worst of these hazardous sites.

CERCLA established the Superfund, which provides emergency cleanup funds for chemical spills and hazardous waste dumps. The Superfund allows the government to take immediate action to cleanup spills or dumps where the responsible party cannot be identified easily. The Superfund draws about 90% of its money from taxes on oil and selected chemicals. The remainder comes from general tax revenues.

Except in an emergency, state agencies are consulted before the federal government takes action. When it does so, it uses one of three approaches:

1. If the owner of the hazardous site cannot readily be identified, the federal government may proceed with the cleanup.
2. If the owner can be identified but refuses to clean the site, or if the owner's efforts are not up to par, the federal government can take charge of the cleanup. The owner must pay the cost, whatever it happens to be.
3. When the owner can be identified and decides to do the work, the federal government monitors the project and gives official approval when the work is completed according to standards.

CERCLA covers a wide range of sites. In addition to land-based dumps, it applies to spills into waterways, groundwater, and even the atmosphere. Initial funding for the Act was US\$1.6 billion over five years. In 1986, the Superfund Amendment and Reauthorization Act (SARA) extended the program by five years and increased the fund to US\$8.5 billion. It also tightened cleanup standards and enhanced EPA's enforcement powers. The Emergency Planning and Community Right-to-Know Act (EPCRA), also known as SARA Title III, encourages and supports emergency planning efforts at state and local levels. It also gives information to the public and local governments on potential chemical hazards in their communities. This legislation helped reduce pollution and improve safety all across the land.

In 1984, Hazardous and Solid Waste Amendments (HSWA) were passed because citizens were concerned about the potential contamination of groundwater by hazardous waste disposal sites.

In 1978, the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) of 1947 was amended to give EPA authority to control pollution from DDT, mercury, aldrin, toxaphene, parathion, and related chemicals. About one billion pounds of pesticides, fungicides, and rodenticides are used every year in the United States. While they contribute enormously to the success of agriculture, they can be harmful to animals, birds and humans if not used properly.

2.5.9 Toxic Substances Control Act (TSCA)

The Toxic Substances Control Act (TSCA) of 1976 gave EPA the authority to regulate the development, distribution, and marketing of chemical products. Manufacturers, importers, and processors must notify EPA within 90 days before introducing a new chemical to the

market. Certain tests (e.g., fish-kill tests) must be conducted to determine toxicity. Approved chemicals must bear warning labels.

Many chemicals are restricted or banned under TSCA:

- The manufacture, processing and distribution of completely halogenated chlorofluorocarbons (CFCs) is banned, except for a small number of essential applications.
- Chromium(VI) may not be used as a corrosion inhibitor in comfort cooling towers (CCTs) associated with air conditioning and refrigeration systems.
- Nitrosating agents may not be mixed with metal-working fluids that contain specific substances.
- The import, manufacture, processing, or distribution of PCBs is banned unless EPA agrees that the PCBs will be *totally enclosed*.

2.5.10 Asbestos School Hazard Abatement Act

The Asbestos School Hazard Abatement Act (SHAA) of 1984 was passed to encourage the removal of asbestos from schools. In 1986, the Asbestos Hazard Emergency Response Act was passed to correct deficiencies in the previous Act. The final rule, issued in 1987, required local education agencies to:

1. Inspect school buildings for asbestos-containing materials
2. Submit asbestos management plans to state governors
3. Reduce or completely eliminate all asbestos hazards.

2.5.11 Control of Dumping at Sea

On November 13, 1972, the Convention on the Dumping of Wastes at Sea was agreed in London by representatives of 91 countries, including all of the world's principle maritime nations. The list of substances that may not be dumped includes biological and chemical warfare agents, certain kinds of oil, certain pesticides, durable plastics, poisonous metals and their compounds, and high-level radioactive waste. Enforcement is left to individual countries.

2.5.12 Climate Control: Rio, Kyoto, and Paris

Rio Earth Summit

In 1992, during the *Earth Summit* in Rio de Janeiro, 154 nations plus the European community signed the United Nations Framework Convention on Climate

Change (UNFCCC). At the time, the Earth Summit was the largest-ever gathering of Heads of State. Effective on March 21, 1994, the UNFCCC called on industrial nations to voluntarily reduce greenhouse gas emissions to 1990 levels by the year 2000. As of May 2015, there were 196 Parties (195 countries and one regional economic integration organization) to the Framework [2.116–118].

In many respects, the Rio Declaration resembled the Declaration on Human Environment issued by the Stockholm Conference in 1972. The 27 nonbinding principles of the Rio Declaration included the *polluter pays* concept and the *precautionary principle*. The latter recommends that, before a construction project begins, an impact study should be conducted to identify and forestall potential harm to the environment.

The declaration asserted that present-day economic development should not undermine the resource base of future generations. It also affirmed that industrial nations pollute more than developing countries. (For example, on a per capita basis, the United States emits 25 times more CO₂ than India.) On the other hand, industrial nations have advanced technology and greater financial resources, which enable them to contribute more to environmental protection.

Kyoto Protocol

The Kyoto Protocol extended the UNFCCC. Adoption committed countries to accept that global warming is a fact, and that anthropogenic CO₂ is the primary contributor. It was concluded in December 1997 and took force in February 2005. As of 2015, it was accepted by 192 countries. Significantly, Canada withdrew its support in 2012, and the United States never adopted it. The Protocol obliges developed countries to reduce current greenhouse gas emissions while giving allowances to transitional (developing) countries. It discusses intergovernmental emissions trading; to many interests in the United States, the emissions trading concept is especially onerous.

Paris Accord

The Paris Accord was signed in November 2016 by 194 members of the UNFCCC. As of December 2016, it had been ratified by 127 countries. The main differences between the Paris Accord and previous agreements are its bottom-up approach and its flexibility. Countries set their own targets voluntarily. Targets are not legally binding. No distinct difference is made between developed and developing economies. The goal of the Paris Accord is to limit the increase in global average temperatures to 1.5 °C above pre-industrial levels. The NASA GISS model predicts that if the temperature increase

reaches 2.0 °C more than 150 million people could be displaced.

According to *Hirtenstein* [2.119], green technology does more than keep the planet clean, it also generates

jobs. The green workforce in the US rose to 8.1 million in 2015, and solar energy jobs overtook those in the oil and gas extraction sector. Similarly, more people work in renewable energy than in oil and gas in China.

2.6 Pollution Control and Abatement Technology

In response to environmental regulation, the petroleum industry reduced pollution by:

- Reducing fugitive hydrocarbon emissions from valves and fittings
- Removing sulfur from refinery streams and finished products
- Adding tail-gas units to sulfur recovery plants
- Reducing the production of NO_x in fired heaters
- Scrubbing SO_x and NO_x from flue gases
- Reducing the production of CO₂ by increasing energy efficiency.

The technology behind these actions is explained below.

2.6.1 Particulate Matter

In petroleum refineries, coking operations and FCC regenerators are the main sources of particulate matter (PM) emissions. Coke-derived PM can be reduced by building enclosures around coke-handling equipment – conveyor belts, storage piles, rail cars, barges, and calciners.

For flue gas from FCC regenerators, many licensors offer scrubbing technology. ExxonMobil offers wet-gas scrubbing (WGS), which removes particulates, SO_x and NO_x [2.120]. UOP and Shell Global Solutions offer third-stage separator (TSS) technology, which removes PM in conjunction with flue-gas power recovery [2.121].

2.6.2 Carbon Monoxide and VOC

CO from partial combustion in FCC regenerators is converted to CO₂ in CO boilers. Flue gas from other boilers, process heaters, and power plants can also contain some CO, which can be diminished by the installation of high-efficiency burners and/or the implementation of advanced process control.

Fugitive emissions (leaks) from storage tanks, sewers, process units, seals, valves, flanges, and other fittings [2.122] can contain both CO and VOC. Floating roofs can be added to open tanks, and tanks that already have a roof can be fitted with vapor recovery systems. Open grates above sewers can be replaced with

solid covers. Emissions from seals, valves, and so on, can be pinpointed with portable combustible-gas detectors. Repairs can then be made at convenient times, for example during a maintenance shutdown.

2.6.3 Sulfur Oxides

In the petroleum industry, most sulfur oxide pollution comes from gas processing plants and crude oil refineries.

Sources of SO_x

Sour-gas processing, fuel-oil fired heaters and FCC regenerator units are major sources of SO_x and NO_x emissions. The most obvious way to reduce SO_x from a heater is to burn low-sulfur fuels. Switching fuels requires no capital investment, but it is probably the most expensive solution due to the relatively high cost of low-sulfur fuels.

A large fraction of the sulfur in the feed to an FCC unit ends up in coke on the catalyst. SO_x are formed in the regenerator when the coke is burned away. Removing sulfur from FCC feed with a pretreater decreases SO_x emissions.

Flue Gas Desulfurization

Processes for removing sulfur oxides from stack gases include dry absorption, wet absorption, carbon adsorption, and catalytic oxidation.

Historically, wet flue-gas desulfurization processes used aqueous slurries of lime, dolomite, and/or sodium hydroxide. Sulfur oxides react with lime or limestone (CaCO₃) to produce calcium sulfate (CaSO₄) and calcium sulfite (CaSO₃), which precipitate from the scrubbing solution. The products move to a settling tank, in which the solid calcium salts separate from the solution as the scrubbed gas goes up the stack. After some time, the solids are removed and sent to a sanitary landfill. The solution is recycled, and fresh lime is added as needed.

The *dual alkali* approach starts with solutions or slurries of sodium hydroxide (NaOH), sodium carbonate (Na₂CO₃), or sodium bicarbonate (NaHCO₃). These compounds react with SO₂ to give sodium sulfite (Na₂SO₃) and sodium bisulfite (NaHSO₃), which

stay dissolved in the solution. Some of the sodium sulfite reacts with excess oxygen in the flue gas to give sodium sulfate. Sulfate and sulfite are removed by reaction with lime or limestone (CaCO_3). The sodium hydroxide solution is recycled. Makeup hydroxide is added as needed to compensate for losses. Selected dual-alkali reactions are shown below.

In a carbon adsorption process developed by Lurgi, hot flue gas first goes through a cyclone or dust collector for particulate removal. The gas is cooled with water and sent to an adsorption tower packed with activated carbon. The carbon adsorbs SO_x . Water is sprayed into the tower intermittently to remove the adsorbed gas as a weak aqueous acid. The scrubbed gas goes out the stack. The acid goes to the gas cooler, where it picks up additional SO_x by reacting with incoming flue gas. Cooler discharge is sold as dilute sulfuric acid.

In the Reinluft carbon adsorption process, the adsorbent is a slowly moving bed of carbon. The carbon is made from petroleum coke and activated by heating under vacuum at 1100°F (593°C).

Flue-gas scrubbing with catalytic oxidation (Cat-Ox) is an adaptation of the contact sulfuric acid process, modified to give high heat recovery and low pressure drop. In the Monsanto process, particulates are removed from hot flue gas with a cyclone separator and an electrostatic precipitator. A fixed-bed converter uses solid vanadium pentoxide (V_2O_5) to catalyze the oxidation of SO_2 to SO_3 . Effluent from the converter goes through a series of heat exchangers into a packed-bed adsorption tower, where it contacts recycled sulfuric acid. The tower overhead goes through an electrostatic precipitator, which removes traces of acid mist from the scrubbed gas. Liquid from the tower (sulfuric acid) is cooled and sent to storage. Some of the acid product is recycled to the absorption tower.

The Wellman-Lord process uses a solution of potassium sulfite (K_2SO_3) as a scrubbing agent. K_2SO_3 adsorbs SO_2 to give potassium bisulfite (KHSO_3). The bisulfite solution is cooled to give potassium pyrosulfite ($\text{K}_2\text{S}_2\text{O}_5$). This can be stripped with steam to release SO_2 , which is fed to a sulfuric acid plant.

FCC SO_x Transfer Additives

Arguably, SO_x transfer additives are the most cost-effective way to lower SO_x emissions from a full-

combustion FCC unit. These materials, first developed by Davison Chemical, react with SO_x in the FCC regenerator to form sulfates. When the sulfated additive circulates to the riser/reactor section, the sulfate is chemically reduced to H_2S , which is recovered by amine absorption and sent to a sulfur plant. Sulfur that would have gone up the stack as SO_x goes instead to the sulfur plant as H_2S .

FCC regenerator (oxidizing environment)

FCC riser-reactor (reducing environment)

In some units, SO_x additives can reduce FCC SO_x emissions by more than 70%. This can have a dramatic effect on the design and/or operation of upstream and downstream equipment – FCC feed pretreaters, FCC gasoline posttreaters, and flue-gas scrubbers for FCC regenerators.

Hydrogen Sulfide Removal

When sulfur-containing feeds pass through hydrotreaters or conversion units, some or most of the sulfur is converted into H_2S , which eventually ends up in off-gas streams. Absorbers containing aqueous solutions of alkanolamines, such as diethanol amine (DEA) or N-methyl diethanol amine (MDEA) remove the H_2S , leaving only 10–20 ppmw in the treated gas streams. H_2S is steam-stripped from the amines, which are returned to the absorbers. The H_2S is piped to the refinery sulfur plant, where it is converted into sulfur.

2.6.4 Nitrogen Oxides

In refineries and petrochemical plants, NO_x are formed in several ways. In high-temperature fired heaters, NO_x are produced by combustion. In FCC regenerators, NO_x are produced by combustion and from the nitrogen deposited with coke on spent catalysts. FCC NO_x emissions go up when:

1. The catalyst contains more combustion promoter
2. When oxygen in the flue gas goes up
3. At higher regenerator temperatures, and
4. At higher feed nitrogen contents.

Combustion promoter is a noble-metal material that accelerates the reaction between CO and O_2 to form CO_2 .

Dual-alkali flue-gas scrubbing as described in Sect. 2.6.3 only removes about 20% of the NO_x from a typical flue gas. Therefore, instead of simple scrubbing, chemical reducing agents are used. In selective catalytic reduction (SCR) processes, anhydrous ammonia is injected into the flue gas as it passes through a bed of catalyst at 500–950 °F (260–510 °C). The reaction between NO_x and ammonia produces N₂ and H₂O.

The MONO-NO_x process offered by Huntington Environmental Systems employs a nonnoble metal catalyst. For SO_x, NO_x and VOC removal, Ducon uses ceramic honeycomb or plate-type catalysts in which titanium dioxide is the ceramic and the active coatings are vanadium pentoxide and tungsten trioxide (WO₃). The working catalyst temperature ranges from 600–800 °F (315–427 °C). For NO_x abatement, Ducon provides complete ammonia injection systems with storage tanks, vaporizers and injection grids. Either anhydrous or aqueous ammonia can be used.

NO_x-removal catalysts are offered by Haldor-Topsøe, KTI, and others. The Thermal DeNO_x process offered by ExxonMobil is noncatalytic.

2.6.5 Wastewater

In large petroleum production operations and in refineries, the treatment of wastewater (Table 2.16) purifies process water, runoff from storms, and sewage. These may contain oil, suspended solids, dissolved salts, phenols, ammonia, sulfides, and other materials. They come from just about every process unit, especially those that use wash water, condensate, stripping water, caustic, or neutralization acids.

Primary Treatment

Primary treatment uses a settling pond to allow most hydrocarbons and suspended solids to separate from the wastewater. The solids drift to the bottom of the pond, hydrocarbons are skimmed off the top, and oily sludge is removed. Difficult oil-in-water emulsions are heated to expedite separation.

Acidic wastewater is neutralized with ammonia, lime, or sodium carbonate. Alkaline wastewater is treated with sulfuric acid, hydrochloric acid, carbon dioxide-rich flue gas, or sulfur.

Figure 2.16 shows a simplified sketch of an API oil-water separator. The large capacity of these separators slows the flow of wastewater, allowing oil to float to the surface and sludge to settle out. They are equipped with a series of baffles and a rotating endless-belt skimmer, which recovers floating oil. Accumulated sludge is removed through sludge hoppers at the bottom.

Secondary Treatment

A small amount of suspended solids remains in the water after primary treatment. These are removed by filtration, sedimentation or air flotation. Flocculation agents may be added to consolidate the solids, making them easier to remove by sedimentation or filtration. Activated sludge, which contains waste-acclimated bacteria, digests water-soluble organic compounds in either aerated or anaerobic lagoons. Steam-stripping is used to remove sulfides and ammonia, and solvent extraction is used to remove phenols.

Tertiary Treatment

Tertiary treatment removes specific pollutants, including traces of benzene and other partially soluble hydrocarbons. Tertiary processes include reverse osmosis, ion exchange, chlorination, ozonation, or adsorption onto activated carbon. Compressed air or oxygen can be used to enhance oxidation. Spraying water into the air or bubbling air through the water removes remaining traces of volatile chemicals such as phenol and ammonia.

2.6.6 Cleaning Up Oil Spills

Oil spills can be caused by natural seepage, leaky storage tanks, petroleum exploration and production ac-

Table 2.16 Refinery wastewater treatment

Designation	Source
Oil-free water	Oil-free storm runoff

tivities, the on-purpose flushing of fuel tanks at sea, and accidents such as those described in Sect. 2.2.

The cleanup of oil spills includes containment, physical and mechanical removal, chemical and biological treatment, and natural forces. Land-based spills are easier to clean than spills onto open water, which are spread quickly by currents and winds.

Natural Forces

Several natural forces tend to remove oil spills. These include evaporation, spreading, emulsification, oxidation, and bacterial decomposition.

Evaporation. A large portion of an oil spill may simply evaporate before other methods can be used to recover or disperse the oil. Rates of evaporation depend on the ambient temperature and the nature of the oil.

Spreading. The fact that spilled oil spreads quickly across the surface of water is a *good news, bad news* story. The good news is that spreading increases rates of evaporation and air oxidation. The bad news is that the more dispersed the oil becomes, the harder it is to collect.

As with evaporation, rates of oil-spill dispersion depend upon ambient conditions and the nature of the oil. Not surprisingly, oil disperses best in fast-moving turbulent water.

Oxidation. Freshly spilled crude oil has a natural tendency to oxidize in air. Sunlight and turbulence stimulate the process. Oxidation products include organic acids, ketones and aldehydes, all of which tend to dissolve in water. As a spill ages, oxidation slows as *easy* molecules disappear from the mix. Compared to other

natural forces, oxidation plays a minor role in removing oil spills.

Emulsification. When crude oil spills at sea, it emulsifies rapidly. Two kinds of emulsions are formed – oil-in-water and water-in-oil. Oil-in-water emulsions, in which water is the continuous phase, readily disperse, removing oil from the spill. However, this kind of emulsion requires the presence of surface-active agents (detergents).

The composition of water-in-oil emulsions varies from 30% to 80% water. These are extremely stable. After several days, they form *chocolate mousse* emulsions, which are annoyingly unresponsive to oxidation, adsorption, dispersion, combustion, and even sinking. The most effective method for mousse emulsions is physical removal. After a 40–50% loss of light-ends through evaporation, a spill of 200 000 bbl of oil can form 400 000–500 000 bbl of mousse.

Containment and Physical Removal

Booms. When oil is spilled on water, floating booms may be used for containment. A typical boom extends 4 in (10 cm) above the surface and 1 ft (30 cm) below. Foam-filled booms are lightweight, flexible, and relatively inexpensive. Typically used for inland and sheltered waters, they are made from polyvinyl chloride (PVC) or polyurethane. Rectangular floats allow them to be wound onto a reel for storage.

Inflatable booms use less storage space and can be deployed from ships or boats in open water. Towed booms (Fig. 2.17) are good for preventing dispersion of oil by winds and currents.

Beach booms are modified for use in shallow water or tidal areas. Water-filled tubes on the bottom of the

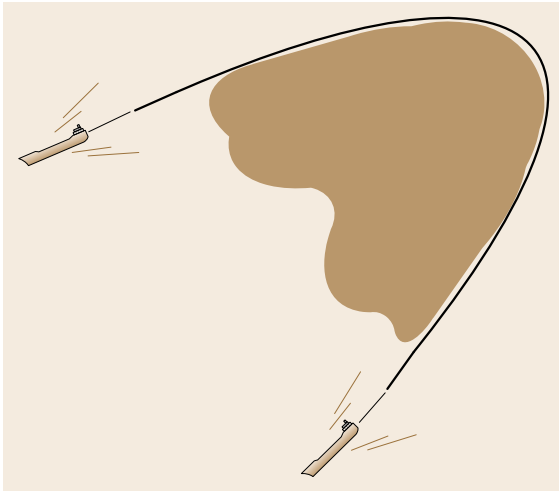

Fig. 2.17 Boom barrier towed by ships

boom elevate it above the beach when the water level is low and allow the boom to float when the water level rises.

Skimmers and Pumps. After a spill is contained, skimmers and pumps can pick up the oil and move it into storage tanks. Weir skimmers are widely used because they are so simple. Modern designs are self-adjusting and circular so that oil can flow into the skimmer from any direction. They can be fitted with screw pumps, which enable them to process many different types of oil, including highly viscous grades. Cutting knives keep seaweed and trash from fouling the pumps. Screw pumps can develop high pressure differentials, which gives them higher capacities than other kinds of pumps.

Another kind of skimmer is an oleophilic (*oil loving*) endless belt. The belt picks up oil as it passes across the top of the water. As the belt returns to its starting point, it is squeezed through a wringer. Oil recovered by the wringer flows into containers, where it is stored until it can be moved to a land-based processing facility.

Another method uses a subsurface impeller to create a vortex, similar to the vortex that forms as water flows out of a bathtub (Fig. 2.18). This funnels water down through the impeller and creates a bowl of oil in the middle of the vortex. A pump is used to remove oil from the bowl.

Adsorbents

Oil spills can be treated with absorbing substances or chemicals such as gelling agents, emulsifiers, and dispersants.

When applying adsorbents, it is important to spread them evenly across the oil and to give them enough

Fig. 2.18 Free vortex skimmer for oil recovery

time to work. When possible, innocuous substances should be used. Straw is cheap, and it can absorb between 8 and 30 times its own weight in oil. When it is saturated, the straw is loaded into boats with rakes or a conveyor system and transported to land. Oil can be recovered from the straw by passing it through a wringer.

Synthetic substances may also be used for adsorbing oil spills. Polymers such as polypropylene, polystyrene, and polyurethane have been used successfully. Polyurethane foam is especially effective. It can be synthesized onsite easily, even aboard a ship. It adsorbs oil readily and doesn't release its load unless it is squeezed. Best of all, a batch of polyurethane can be used again and again.

Dispersion Agents

Dispersion chemicals act like detergents. One part of the molecule is oil-soluble while the other is water-soluble. In effect, the oil dissolves in water and diffuses quickly away from the spill. Dispersants reduce the tendency of oil to cling to partly immersed solids, such as walls, docks, buoys and boats.

Nondispersive Methods

Nondispersive methods for removing oil spills include gelling, sinking, and burning.

Gelling. Fatty acids and 50% sodium hydroxide can be added to a spill to trigger a soap-forming reaction. The resulting gel does not disperse. Instead, it remains in place to block the spread of nongelled oil.

Oil Sinking. Sinking an oil spill keeps it from reaching shorelines, where it can devastate marine life. Sinking is best used in the open sea. In shallow water near the coast, it can cause more problems than it solves. Amine-treated sand is the most common sinking agent. To initiate sinking, a sand/water slurry is sprayed onto the oil slick through nozzles. The required sand/oil ratio is about 1 : 1. The oil sticks to the treated sand, which sinks toward the bottom of the sea; the oil-coated sand can remain in place for many years. According to others, it can damage fragile ecosystems on the ocean floor.

During a full-scale test 15 mi from the coast of Holland, Shell Oil used amine-treated sand to sink a 100-ton slick of Kuwaiti crude in less than 45 min. Oil removal exceeded 95%.

Other materials have been used for oil sinking. These include talc, coal dust, cyclone-treated fly ash, sulfur-treated cement, and chalk. In general, a 1 : 1 ratio of sinker weight to oil weight is needed to sink a fresh spill. If weathering takes place, the density of the oil increases and less sinking agent is needed. It has been estimated that the cost for sinking is similar to the cost for dispersion. However, in open seas under high winds and waves, it may be difficult to spread the sinking agent.

Burning. Freshly spilled crude oil in a confined area may be combustible. However, after several hours, the spill may have thinned due to spreading and the most volatile components may have evaporated. If so, it may not be possible to ignite the remaining material. The addition of gasoline or kerosene can restore combustibility.

Burning is not used much anymore. It seldom removes much oil, and it can generate concentrated, unpredictable pockets of atmospheric CO and SO₂, both of which are poisonous.

Cleanup of Oil-Contaminated Beaches

For cleaning oil from beaches, farm machinery and earthmoving equipment are used to good effect. In many cases, a layer of straw is spread across the oil. After a few days, the oil-laden straw is raked onto a conveyor, screened to drop out sand, and sent to a wringer. Recovered oil is trucked away to a refinery. The spent straw, which still contains some oil, can be blended with coal and burned in a power plant, or simply incinerated. The separated sand is washed and returned to the beach.

When beach pollution is severe, oily sand is removed with earthmoving equipment. When beach pollution is mild, sand removal may not be needed. Instead, detergents can be used. They must be used cautiously to minimize harm to marine life. Wave action does a great

job of mixing detergent into the sand. Usually, the detergent is applied about one hour before high tide. When the tide comes in, the washing begins. If high-tide washing is inappropriate, high-pressure hoses can be used. Hoses are also effective for cleaning oil off of walls and rocks.

Froth Flotation. In the froth-flotation process, oil-soaked sand from a polluted beach is poured into a vessel, where it is mixed with water and cleaned with a froth of air bubbles. Aided by chemical or physical pretreatment, the froth strips oil away from the sand. Due to its low density and the action of the bubbles, the oil floats to the top of the vessel, where it is drawn off and sent to a separating chamber, where entrained water is removed. Tests show that sand containing 5000 ppm of oil can be cleaned down to 130 ppm, generating effluent water with 165 ppm of oil. Usually, the cleaned sand is returned directly to the beach.

Hot Water Cleanup. When milder methods fail to give the desired degree of cleanup, hot water can mobilize some of the oil still trapped within the polluted sand. This method is used as a last resort because of the damage it does to intertidal ecosystems.

Amoco Cadiz Oil Spill Cleanup: A Case Study

As mentioned, for two weeks after the *Amoco Cadiz* ran aground off the coast of Brittany, severe weather restricted cleanup efforts. Eventually, the entire cargo – more than 1.6 million bbl of crude oil – spilled into the sea. The resulting slick was 18 mi wide and 80 mi long. The oil polluted 200 mi of coastline, including beaches, harbors and habitats for marine life.

A 2.5 mi permanent boom protected the Bay of Morlaix. Although it required constant monitoring, the boom functioned well because the bay was protected from severe weather and the brunt of the oil slick. In other areas, booms were largely ineffective due to strong currents, and also because they were not designed to handle such enormous amounts of oil. Skimmers were used in harbors and other protected areas. Vacuum trucks removed oil from piers and boat slips where seaweed was especially thick. *Honey wagons* – vacuum tanks designed to handle liquefied manure – were used to collect emulsified oil along the coast.

Oil-laden seaweed was removed from the beaches with rakes and front-end loaders. Farm equipment was used to plow and harrow the sand, making it more susceptible to wave and bacterial action. Prior to harrowing, chemical fertilizers and oleophilic bacteria were applied to the sand.

At first, authorities decided against using dispersants in sensitive areas and along the coastal fringe.

Meanwhile, the spill formed a highly stable water-in-oil emulsion (*mousse*). On the open sea, the French Navy applied both dilute and concentrated dispersants, but good dispersion was hard to achieve because in some places the mousse emulsion was several centimeters thick. If dispersants had been dropped from the air at the source of the spill – in days instead of weeks – the formation of mousse emulsion might have been prevented.

About 650 t of chalk was applied in an effort to sink the oil. But after one month at sea, the oil was so viscous that the chalk just sat on top of it. Rubber powder made from ground-up tires was applied to absorb the oil. The French Navy used water hoses to spread most of the powder. Some was applied manually from small fishing boats. Because it stayed on top of the oil, the rubber powder had little effect; wave action wasn't strong enough to mix it into the oil, most of which was trapped inside the chocolate mousse emulsion.

During the third and fourth months of the cleanup, high-pressure hot water (fresh water at 2000 psi, 80–140 °C) was very effective in cleaning oil from rocky shores. A small amount of dispersant was applied to prevent oiling of clean rocks during the next high tide. The mouths of several rivers contained oyster beds and marshes that required manual cleaning. Soft mud river banks were cleaned with low-pressure water. To improve oil-collection efficiency, a sorbent was mixed with water and poured in front of the wash nozzles. The oil was collected downstream by a local invention called an *Egmolap*. This device was good at collecting floating material in sheltered areas.

2.6.7 Solid Waste Recovery and Disposal

Contaminated solids are produced during the drilling of oil wells, the transportation of crude oil, and in oil refineries. All oil-contaminated solids are considered hazardous and must be sent to hazardous-waste landfills. The transportation and disposal of hazardous waste costs an order of magnitude more than the transportation and disposal of sanitary waste. Thus, there is a huge economic incentive to remove oil from contaminated solids before they leave a site.

Considerable amounts of solid wastes can be generated during oil drilling. Oil-contaminated cuttings must be cleaned before disposal. Table 2.17 shows the sources of solid wastes in a modern oil refinery. These data, provided by the American Petroleum Institute, are based on a typical 200 000 bbl/day high-conversion refinery. A plant this size produces about 50 000 t/yr of solid waste and about 250 000 t/yr of wastewater. As discussed above, all wastewater must be purified before it leaves the plant.

Table 2.17 Breakdown of refinery solid wastes

Solid Waste	Total (wt %)
Pond sediments	8.4
Sludge from biological treatment	18.9
Solid from DAF/IAF treaters	15.4
API separator sludge	13.2
Miscellaneous sludge	17.5
Off-grade coke	1.9
Spent catalysts	6.4
Slop oil emulsion solids	4.4
Spent solvents, chemicals	3.8
Contaminated soils and other solids	6.7
Heat exchanger cleaning sludge	0.1
Tank sludge	3.4

DAF = dissolved air flotation
IAF = induced air flotation

Supercritical Fluid Extraction

A supercritical substance exists as a single fluid phase. Simultaneously, it can have liquid-like solvating powers and gas-like diffusivity and viscosity; its surface tension is zero. Ammonia, argon, propane, xenon, water, CO, and CO₂ are used for supercritical fluid extraction (SFE). The phase diagram in Fig. 2.19 shows that the supercritical region for CO₂ lies above 88 °F (31 °C) and 1058 psig (7.4 MPa). The CO₂ triple point, where solid, liquid, and gas phases exist simultaneously, occurs at –69.9 °F (–56.6 °C) and 57.8 psig (0.5 MPa).

With nontoxic gases such as CO₂, the SFE process is simple. Untreated solids are placed in an extraction chamber and CO₂ is added. Pressurizing the CO₂ converts it into an effective solvent. By manipulating temperature and pressure, operators can extract the material of interest with high selectivity. After the extracted material dissolves in the CO₂, the mixture goes to a collection vessel, where the pressure is reduced. At low pressure, CO₂ loses its solvating power and separates from the extract. The CO₂ is recovered, condensed and recycled. In SFE with CO₂, no liquid solvents are used. The CO₂ is recycled, so the process is not considered to be a contributor to global warming.

SFE is common in the food, pharmaceutical and cosmetic industries, where it extracts caffeine from coffee beans, bitter from hops, tar and nicotine from tobacco, and other natural compounds from spices, flowers, aromatic woods, and medicinal plants.

Since about 1990, SFE with CO₂ has been used in oil fields to remove oil from drill cuttings. CO₂ is especially good for this purpose because it can be used on site. It is nontoxic (except when it suffocates), relatively unreactive, and it doesn't burn. On drill cuttings and other oil-contaminated soils and sands, it penetrates the mineral structure, removing both the free-oil phase and

Fig. 2.19 Phase diagram for carbon dioxide

the oil trapped in the solid matrix. The process removes more than 99.9% of the oil, leaving no toxic residue. The required time is short – about 10–60 min/batch.

Sludge

According to RCRA, oil-containing sludge from storage tanks and refinery water treatment facilities is by definition hazardous, and should be sent to a hazardous landfill. In most cases, a lot of the sludge can be dissolved with detergents or solvents (such as hot diesel oil) and blended into crude oil. Alternatively, dissolved sludge can go to delayed cokers, asphalt plants, carbon black plants, or cement kilns.

In one method, hot water and a chemical are circulated through the tank. On top of the water, a hydrocarbon such as diesel is added. The density difference between warm water and the hydrocarbons in the sludge causes the sludge to rise, allowing the chemical to strip out water and solids. The method recovers good-quality oil, which can be processed in the refinery, and leaves behind a relatively clean layer of solids on the tank bottom.

Tanks associated with slurry oil from FCC units present an interesting challenge. It can be very expensive to take these tanks out of service, the sludge is loaded with finely divided FCC catalyst particles, and slurry-oil sludge is difficult to dissolve. Recently, a process called Petromax has been used to liquefy slurry-oil sludge, allowing it to be pumped out of tanks with ordinary equipment, even while the tanks are still in use [2.123].

Some service companies use robots, cutting wands, and other sophisticated devices to clean tanks completely without sending people inside. These methods are especially valuable when the tank contents are toxic. One such company is Petrochemical Services, Inc., which pioneered the use of robots in tank-cleaning operations.

Blending mobilized sludge into crude oil is limited by specifications on basic sediment and water. This seems equivalent to moving waste from one place to another, but it really isn't. The dissolution of tank sludge separates useful oil from inorganic solids (sand, clay, salts, and metal oxides) and refractory organics (asphaltenes, long-chain waxy paraffins, kerogen, and coke).

Spent Catalysts

Many refinery catalysts are regenerated several times. The regeneration of FCC catalysts occurs in the (aptly named) regenerator. Catalysts from fixed-bed units can be regenerated in place, but usually they are sent off site to a facility that specializes in catalyst regeneration.

Eventually, even the hardiest catalysts reach the end of their useful life. When this happens, they are sent to a metals reclaimer, which recovers saleable products such as alumina, silica, MoO_3 , V_2O_5 , nickel metal, and various forms of cobalt.

The reclamation company makes money on both ends of the plant – from the refiner who must dispose of the catalyst, and from the customer who buys reclaimed products.

2.7 Summary

Safety, reliability, and protecting the environment are inextricably linked. In modern industry, they are viewed as prerequisites to profit. Company executives frequently emphasize their strong commitment to worker health and safety. Their commitment derives to a certain extent from strict legislation.

Health and safety rules address personal protection equipment, toxic substances, equipment maintenance, worker training, and compliance monitoring. Environment regulations fall into four main categories: air pollution (particulate matter, volatile hydrocarbons, and harmful gases), waste water, spills and solid wastes. Harm from chronic exposure accumulates with time.

Harm from major accidents causes tremendous short-term destruction, which often is followed by damage that lingers for years. Many of the worst peace-time accidents occur in coal, oil, and chemical industries. Such accidents can teach hard lessons. But as the examples show, not everyone learns the lessons, and those

who do learn lessons sometimes forget or choose to ignore them.

Things have gotten better. Before the 1970s, black lung disease, dead forests downwind from coal-fired power plants, and pools of poison around abandoned strip mines were just part of the price we paid for cheap power and minerals. Smoky flares in refineries were the rule, not the exception. They *smelled like money*. More often than not, news of a river catching fire caused laughter instead of outrage. Climate change was derided as just another bogeyman imagined by academics.

Today a majority of us believe that our fundamental rights include clean air, clean water, and a safe and healthy workplace. We are products of the same social movement that created EPA, OSHA, and similar agencies around the world. Government regulations are providing the Big Stick. The Carrot for all is a safer, cleaner world. We all have one life and one planet. We must ensure the health of both.

3. Molecular Science, Engineering and Management

Chang Samuel Hsu

All organic materials, living and nonliving are made of molecules. Hence, the composition and structure of the organic molecules, either in pure compounds or different in complex mixtures, determine the properties, behavior, and reactivity of the compounds and mixtures. Chemistry is a science to study the changes of molecules and the relationship of those changes with physics, mathematics, biology, geology, and other disciplines. Chemistry controls how molecules can be used in exploration/production, refining engineering/processing, chemical production, drug discovery, disease controls, etc.

Molecular engineering is the science of manufacturing molecules through transformation and/or combination of molecules by engineering processes. It is especially valuable in petroleum, where it impacts chemical engineering (downstream) and petroleum engineering (upstream), the two major disciplines in which molecules are handled in large scales. Molecular engineering can be guided, controlled, or predicted through molecular-based modeling.

Through knowledge of chemistry and the understanding of chemical processes, we can manage molecules more economically, while minimizing harm to life and the environment. Waste molecules must be properly handled and disposed. Hence, science, engineering, and management should be an integral part of handling molecules from the beginning to the end of all chemical and biochemical processes.

Detailed information on molecules often requires the use of sophisticated analytical instrumentation. Analytical devices and instruments play key roles in providing information of existing, unknown, or new molecules for the design and control of chemical processes. Analytical research and development have been driven by business needs, market demands, and governmental regulations.

In the oil industry, regardless of sector – upstream, downstream, petrochemical, environmental or modeling, molecular understanding of

petroleum and upgrading processes is important for science and technology development and the improvement of processes and products.

All organic materials, living and nonliving are made of molecules. Hence, the composition and structure of the organic molecules, either in pure compounds or different in complex mixtures, determine the properties, behavior, and reactivity of the compounds and mixtures. Physical properties include density, boiling point, melting point, mass (as aggregates of atoms), and energy (vibration, rotation, and intermolecular interaction). Chemical properties include reactivity, stability, and changes in molecules, and biological properties include toxicity, etc. Important behavior includes processability and disposal options of the feeds, intermediates, and products.

Chemistry is a science to study the changes of molecules and the relationship of those changes with physics, mathematics, biology, geology, and other disciplines. Chemistry controls how molecules can be used in exploration/production, refining engineering/processing, chemical production, drug discovery, disease controls, etc.

Molecular engineering is the science and technology of manufacturing molecules through transformation and/or combination of molecules by engineering processes. It encompasses chemical (including refining) and pharmaceutical research as well as material science. It is especially valuable for petroleum where it impacts chemical engineering (downstream) and petroleum engineering (upstream), the two major disciplines in which molecules are handled in large scales.

Through knowledge of chemistry and the understanding of chemical processes, we can manage molecules more economically, while minimizing harm to life and the environment. Waste molecules must be properly handled and disposed. Hence, science, engineering, and management should be an integral part of handling molecules from the beginning to the end of all chemical and biochemical processes.

Detailed information on molecules often requires the use of sophisticated analytical instrumentation. Analytical devices and instruments play key roles in providing information of existing, unknown, or new molecules for the design and control of chemical processes. Many physical and chemical devices can be used to monitor, analyze, and measure molecules in a pure form, bulk mixtures, or individual groups of components.

This chapter is derived mainly from the author's personal experience in and contributions to the development of petroleum mass spectrometry (MS). It is not intended to be an overview of all the molecular characterization techniques being developed and available. However, it provides evidence that molecular characterization can play important and critical roles in petroleum research and development. Many new technologies in molecular characterization and management (through modeling) continuously emerge, dealing with science understanding and leading to practical engineering improvements.

3.1 Analytical Endeavors in the Petroleum Industry

In the petroleum industry, the analytical endeavor can be generally divided into upstream and downstream applications. In upstream operations, the main goals are the discovery, recovery, and transportation of hydrocarbon resources. Certain individual molecules, most noticeably petroleum biomarkers, in crude oil or other fossil hydrocarbons (coal, oil shale, oil sands, tar sands, etc.) can provide key geochemical information to guide exploration and production. In downstream operations, refining processes involve large volumes of complex mixtures, such as crude oil or its distillation fractions. Molecular details are only obtained to assist the understanding or control of processes and their products.

In general, the higher the boiling point of the mixture, the more difficult it is to obtain the information of individual molecules due to the complexity of the mixtures. For example, it remains challenging to determine molecular compositions and structures of residua (*resids* in petroleum terminology) and asphaltenes reliably even using the most modern analytical techniques and instrumentation. But without an adequate or better understanding and knowledge of the molecules involved, existing refining or chemical processes cannot be optimized and new processes cannot be developed for upgrading resids and asphaltenes to high-value fuels and chemical products.

3.2 Analytical Tools

For pure compounds or simple mixtures, ^1H and ^{13}C nuclear magnetic resonance (NMR) spectroscopy and vibrational spectroscopy (infrared and Raman) can provide the unambiguous determination of molecular structures [3.1, 2]. When dealing with more complex mixtures, these spectroscopies can be coupled (hybridized) with chromatography (gas, liquid, or supercritical) either online or offline to separate individual components for molecular structural determination [3.1]. However, MS is much more convenient and effective when coupled with chromatography due to

its adaptability, sensitivity, and specificity. Therefore, MS has become the most commonly used analytical technology, either alone or coupled with chromatography, for detailed molecular characterization [3.1, 3]. Chromatography alone can also be used for identification purposes if authentic compounds are available for confirmation. Specific detectors are often used for the confirmation of the mass spectrometric identification of components containing heteroatoms, such as sulfur, nitrogen, oxygen, and phosphorus [3.1, 4].

3.3 Analytical Strategy

For complex crude oils, bulk properties such as distillation yield, density (API gravity), viscosity, CHNS (carbon-hydrogen-nitrogen-sulfur contents), metal content, ash content, and total acid number are measured by a series of physical tests, which are compiled into crude assays [3.5]. Overall functionalities are measured by spectroscopy on distillation fractions. Only in selected cases, when it is necessary to the understanding of crude oils or refining processes and/or identification of problem-causing materials, detailed molecular characterization is carried out.

In upstream, geochemists work with other geoscientists to study the paleotransformation of deeply buried organic deposits for local or integrated sedimentary basin assessment. A few target compounds, generally petroleum biomarkers, are analyzed in studies of geochemical processes to assist in exploration effort. Biomarkers are compounds that retain basic carbon skeletons of biological precursors and carry important geochemical information during organic sediment burial and subsequent transformation.

In downstream operations, crude oils are separated by distillation into different boiling fractions, including petroleum gas, naphtha, gasoline, jet fuel, diesel, gas oils, and resids. Lubricant base oils are produced through solvent-refining processes (deasphalting, extraction, dewaxing, etc.) of atmospheric or vacuum

resids, or by hydrorefining processes. The petroleum boiling fractions below gasoline have been well characterized. Hence, most of the refining research and developments today are in heavy hydrocarbon characterization for converting low-value residual oils and resids into high-value fuels and lubricant base oils to increase profit margins.

Many conversion processes involve the use of catalysts that are often expensive. Hence, modern research in the petroleum industry has also been on the development and application of novel catalysts to improve process performance, economic operations, and product quality. It is important for analytical scientists to cooperate with engineers or modelers for experimental design, information flow, and problem solving. Such cooperation leads to tool sharpening (development of new and improved analytical methodology or protocols).

The common problems of heavy petroleum fractions encountered in oil refineries include crude incompatibility, emulsions in desalters, corrosion, deposit/sediment formation in storage tanks and reactors, precipitation and fouling in heat exchangers, line blockage, carbon laydown, and catalyst fouling during upgrading processes, just to name a few. The characterization of foulants, undesired impurities, and off-specification products at the molecular level is a constant challenge to the scientists/engineers.

3.4 Chromatographic Systems

Several types of chromatographic systems are suitable for the analysis of organic molecules [3.6]. The most commonly used are gas chromatography (GC) and liquid chromatography (LC) [3.7]. Supercritical fluid

chromatography (SFC), which can have characteristics of GC and LC, is also used on many occasions. GC is generally used for separating nonpolar or low-polarity compounds with high and moderate volatility (boiling

points lower than 500°C) in gas and vaporized liquid mixtures, while LC is used for mixtures of polar compounds and high-boiling compounds in a liquid solution.

A GC system consists of an injector, an oven, and a detector. GC has become a mature, well-developed technology since the 1950s. The gaseous or liquid sample is introduced into an injector in a carrier gas like helium, hydrogen, or nitrogen. Injectors can be split/splitless, on-column, temperature programmable, etc. A dual injector is commonly available in modern GC systems. A single oven with a single column is usually used, but a dual oven with two columns can be found in comprehensive two-dimensional GC (GC×GC) [3.8]. Modern GCs use fused silica capillary columns typically 10–100 m long and ≤ 0.25 mm ID for the enhanced separation efficiency of the components based on diffusivity, although occasionally they use some packed columns for specific separation purposes. Other than for gas mixtures at room temperature, temperature gradient programs are often used for complex mixture analysis. However, the maximum temperature allowed for the column (and the oven) is generally not higher than 450°C due to the temperature limitations on stationary coatings for the separation of components based on diffusivity inside the column. There are many kinds of de-

tectors available. The most commonly used detectors in petroleum or petrochemical analysis include flame ionization (FID), sulfur specific (such as sulfur chemiluminescence, SCD), nitrogen specific (such as nitrogen chemiluminescence, NCD or nitrogen–phosphorus, NPD), and other element-specific (such as atomic emission, AED) detectors [3.4]. Since the 1960s, MS has been used as a GC detector, only for routine analysis without sophisticated instrument operations and spectral interpretations [3.9].

LC has been used for fractionating less volatile or nonvolatile complex mixtures based on solubility in different solvent systems [3.7]. Its separation efficiency is generally much less than GC for complex petroleum mixtures. Suitable detectors are also more limited. The detectors include mostly refractive index (RI), ultraviolet (UV), and evaporative low-angle light scattering (ELSD) for petroleum applications. The sample is generally dissolved in a solvent or solvent mixture that is compatible with the nonpolar or polar mobile phases. The column is packed with a suitable stationary phase. For petroleum fractions, the separation results in compound types grouped with numerous co-eluting components of various carbon numbers. When coupled with MS, it provides additional values for differentiating molecules with the same molecular formula but different functionalities [3.10].

3.5 Mass Spectrometry

Mass spectrometry (or spectroscopy) (MS) was invented, developed, and exclusively used by physicists at the turn of the last century for the studies of the basic properties of substances, which led to the discovery of elements and isotopes [3.11, 12]. After the first commercial instrument was delivered at Atlantic Richfield in 1942, it was used in the petroleum industry for the analysis of petroleum gases and light fuels during and after World War II. Since then, MS has become an indispensable and the most powerful analytical technique for molecular characterization [3.3, 13]. Its coupling with chromatography further enhances its capabilities in mixture analysis [3.9, 10, 14–16].

The four major components of a mass spectrometer are shown in Fig. 3.1 [3.17, 18]. A mass spectrometer is an analytical device for detecting and measuring vapor phase ions in vacuum, even though the ions can be generated in atmospheric pressure outside the mass analyzer. Hence, ion production in an ion source through various ionization techniques is essential. The sample can be introduced alone, such as in a batch inlet or in a direct insertion probe, or

through chromatography, most commonly GC and LC. A range of mass-resolving power is achievable by various types of mass analyzers, from unit mass resolution on a quadrupole mass spectrometer to ultrahigh resolution on a Fourier-transform ion cyclotron resonance mass spectrometer (FT-ICR MS). The ion detector is designed to be suitable or adaptable for the mass analyzer. For example, induced image current detection is associated with FT-ICR MS that is not suitable for electron multipliers for ion signal enhancement. Effective ion transmission between the components is also critical to a successful mass spectrometric experiment. There are numerous reference books for mass spectrometric operations. Although library or reference spectra are available for routine analysis, advanced data interpretation for much more complex high-boiling petroleum mixtures requires an in-depth training of professionals.

Petroleum is a mixture that is too complex for the characterization of individual molecules [3.19]. It is more practical to analyze distillation fractions, such as those produced during conventional refinery operations,

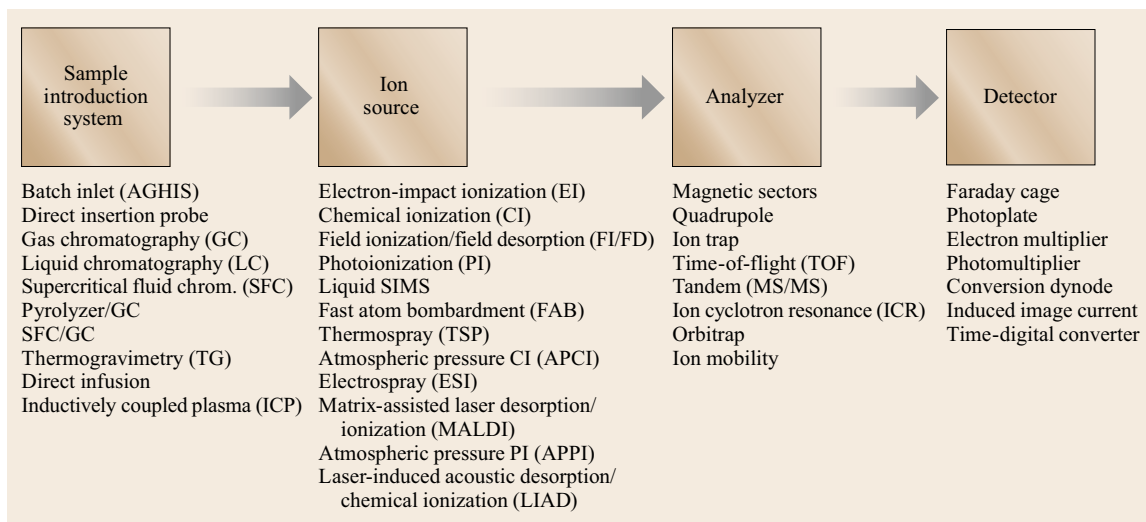

Fig. 3.1 An array of MS techniques has been developed for petroleum mass spectrometric analysis. (After [3.18])

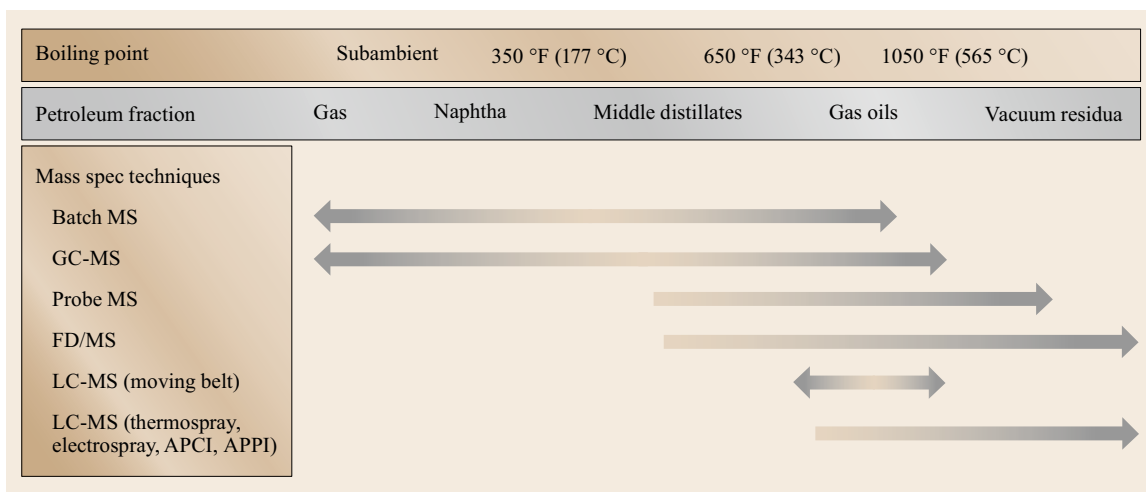

Fig. 3.2 Various petroleum fractions require different mass spectrometric modes of operation. (After [3.18])

namely, gas, naphtha, middle distillates, gas oils, and resids. For each fraction, various modes of mass spectrometric operations as shown in Fig. 3.2 are applied to obtain maximum molecular information [3.17, 18]. GC-

MS is the most powerful technique for mixture analysis including gas oils. For heavy fractions beyond gas oils, the use of direct insertion probe, direct liquid introduction, and field desorption (FD) is common.

3.6 Petroleum Biomarker Analysis

The most noticeable application of MS in upstream is petroleum biomarker analysis [3.18, 20–22]. As mentioned above, biomarkers are petroleum molecules that retain the basic carbon skeleton of biological origins through diagenesis. These molecules provide important geochemical information on source input (ma-

rine, lacustrine/terrestrial or paralic), age (Cretaceous, Jurassic, Devonian, etc.), maturity, alteration (such as biodegradation, oxidation and water washing), and depositional environment [3.23, 24]. They can be used for developing oil–oil and oil–source rock correlations for migration and accumulation studies, as well as en-

Fig. 3.3 Typical biomarker distributions in crude oils measured with GD-FID. (After [3.22]). The numbers on top of peaks are carbon numbers of *n*-paraffins, ●'s denote isoprenoid hydrocarbons

vironmental applications, including the identification of oil-spill sources, differentiation/correlation of oils, and monitoring the degradation process and weathering of oils under a wide variety of environmental conditions [3.25].

Limited analysis can be done by GC-FID, as shown in Fig. 3.3. The salient feature of the chromatogram is the presence of normal paraffins. Isoparaffins are also abundant. The ratio of C_{19} pristane (Pr) and C_{20} phytane (Ph) can be used as an indicator of whether the environment during deposition was reducing ($Pr/Ph < 1$) or oxidizing ($Pr/Ph > 1$). However, cyclic biomarkers that are rich in geochemical information cannot be analyzed with this method due to severe overlaps with other hydrocarbons and their low concentrations.

To detect the overlapping cyclic biomarkers as shown above, mostly 4-ring (steranes) and 5-ring (hopanes/triterpanes) cycloparaffins (see below), GC-MS is used [3.9]. Under 70 eV (high-energy) electron-impact ionization (EI) conditions, the 4-ring steranes yield a characteristic fragment ion at mass-to-charge ratio (m/z) at 217 while 5-ring hopanes (triterpanes) yield a characteristic m/z 191 ion. A mass spectrometer operated so as to record only these two masses

rather than a full scan from low to high masses can enhance the signals, yielding the m/z 191 and 217 mass chromatograms, as shown in Fig. 3.4. Hopanes (triterpanes) can be well resolved according to their carbon number. On the other hand, severe overlaps in carbon numbers are observed for steranes. However, the ratio of hopanes to steranes can be used as a source facies indicator [3.26]. In general, ratios below 4 generally indicate marine sources and greater than 15 indicate terrigenous/lacustrine sources. The medium ratios can be attributed to the paralic source inputs.

The overlapping steranes can be resolved by the use of tandem MS coupled with GC as GC-MS-MS [3.22]. Figure 3.5 shows the GC-MS-MS mass chromatograms displaying precursors (parents) of the m/z 217 ion characteristic to steranes. In the example shown, the second stage MS is fixed at m/z 217, while the first stage MS is stepped between m/z 372, 386, 400, and 414, the molecular ions of the C_{27} , C_{28} , C_{29} , and C_{30} steranes, respectively, to enhance the ion signals of fragmentation occurring between the two stages of MS. Not only steranes of different carbon numbers but also epimers of each carbon number are resolved for quantitation. The presence of trace amounts of C_{30} steranes as a marine source indicator that would be buried under C_{28} and

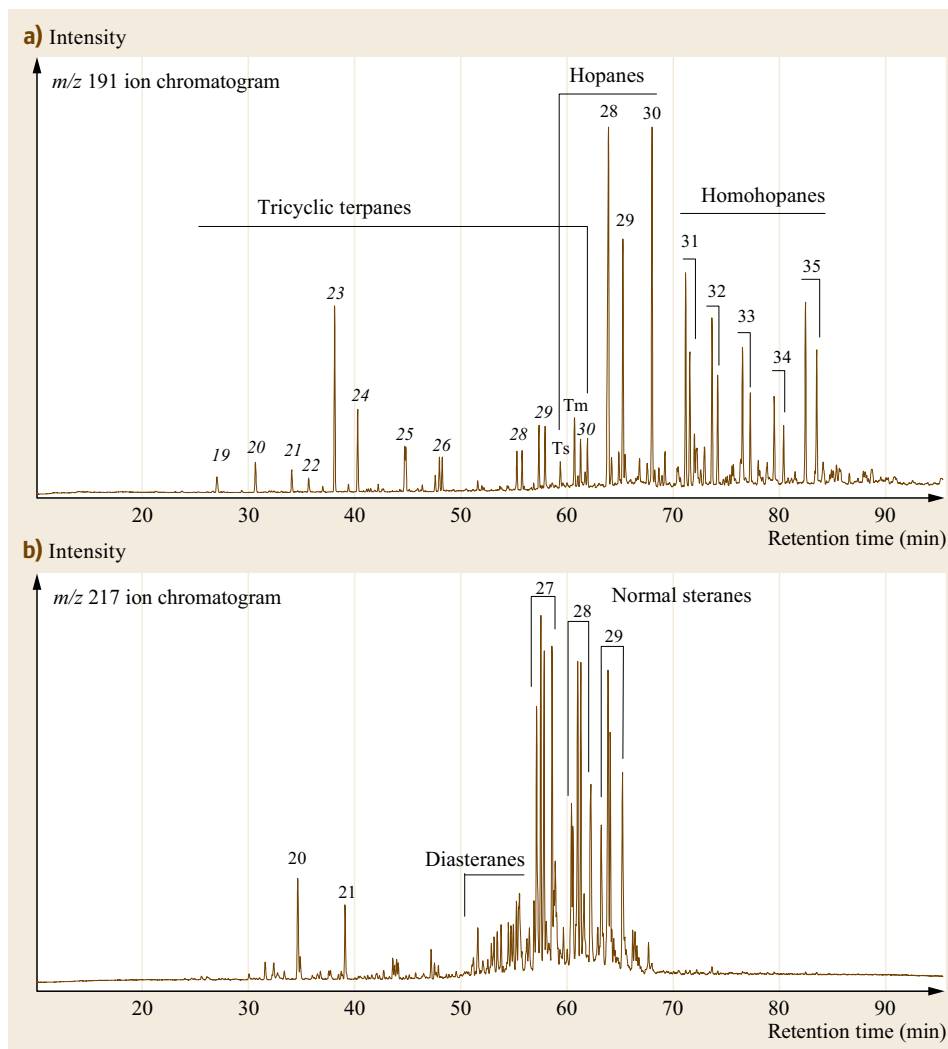

Fig. 3.4a,b GC-MS mass chromatograms of m/z 191 (a) and 217 (b) ions which display the distributions of hopanes and steranes, respectively. (After [3.22]). The *numbers* on top of the peaks are carbon numbers

C_{29} steranes in GC-MS runs can then be detected. For marine source oils and source rock extracts, the ratio of C_{28} -to- C_{29} steranes can be correlated with age reflecting different phytoplanktons appeared at different eras [3.22].

Instead of GC-MS-MS, comprehensive two-dimensional gas chromatography (GC \times GC) can also resolve the sterane and hopane biomarkers from co-eluting hydrocarbons appearing in the one-dimensional GC chromatograms. It was found that the reversed column arrangement, that is, a polar column as the first dimension and a nonpolar column as the second dimension would yield better results for acyclic and

cyclic paraffins, as shown in Fig. 3.6 as a contour plot of GC \times GC-FID chromatogram, than a normal column arrangement for which a nonpolar column is the first dimension and a polar column is the second dimension [3.27]. Steranes and hopanes are well resolved from each other and other paraffins and aromatics. Absolute quantitation is made possible by the use of a universal quantitation detector, FID [3.28]. However, the resolution of sterane epimers at each different carbon numbers still requires the use of MS. This may change when more polar GC columns that can withstand temperatures higher than 400 °C and resolve the epimers become available.

Fig. 3.5 GC-MS-MS mass chromatograms of precursor scans of m/z 217 ion resolve overlapping sterane epimers of different carbon numbers. (After [3.22]) A: C_{27} 13 β (H),17 α (H)-20*S*-diasterane; B: C_{27} 13 β (H),17 α (H)-20*R*-diasterane; C: C_{27} 13 α (H),17 β (H)-20*S*-diasterane; D: C_{27} 13 α (H),17 β (H)-20*R*-diasterane; E: C_{27} 5 α (H),14 α (H),17 α (H)-20*S*-cholestane; F: C_{27} 5 α (H),14 β (H),17 β (H)-20*R*-cholestane; G: C_{27} 5 α (H),14 β (H),17 β (H)-20*S*-cholestane; H: C_{27} 5 α (H),14 α (H),17 α (H)-20*R*-cholestane

The intensities of the peaks are represented by colors, with red to be the most intense and blue the least

3.7 Online LC-MS

For simple low-temperature distillation fractions, detailed molecular characterization of mixtures is possible for thorough separation of individual components. It is possible to resolve individual isomers in distillation fractions up to naphtha by GC. With the perfection of interface technology in the 1970s, GC-MS has become

common practice for analyzing mixtures containing components having sufficient partial pressure up to 450 °C under carrier gas flow [3.9].

The prediction of the octane number by quantifying individual isomers in motor gasoline [3.29] is an early example of *petroleomics*, defined as the identification

Fig. 3.7 Two m/z 380 mass chromatograms with a resolution window of 200 ppm by LC-MS. (Reprinted with permission from [3.31]. Copyright 1991 American Chemical Society)

of molecules in petroleum or its fractions for their contributions (roles) in properties and performance. The term was introduced at the *Hydrocarbon and Chemicals* workshop of 1999 American Society for Mass Spectrometry (ASMS) Conference and presented at 2003 Pittcon [3.30], to parallel *proteomics* as the identification of protein for their roles in physiological and pathophysiological functions. Beyond naphtha, the differentiation of isomers is less important because of their similarity in combustion characteristics as a transportation fuel (diesel and jet fuel).

For high-boiling complex mixtures with components having insufficient volatility under GC conditions, molecular characterization remains challenging. The separation of the components could rely on the difference in solubility. Hence, LC would become a logical choice [3.10, 32]. The separation of compound types according to the number of aromatic rings, as shown in Fig. 3.7, was performed with a solvent gradient program [3.31]. The pairs of C_nH_{2n-12} and C_nH_{2n-16}S compounds which have the same molecular formula, thus, exactly the same molecular weight, are not resolvable by any form of MS regardless how high the resolving power is, but they can be resolved by aromatic ring type LC separations. This approach was applied to look into the molecular transformation of feed and product for changes in compound types and carbon numbers through a hydrotreating process [3.33]. Due to poor resolving power inherent to LC for complex mixtures beyond naphtha, mass spectral analysis of sub-fractions within an LC peak by time slicing can provide elution characteristics of co-eluting compound types for

quantitation/estimation purposes [3.34]. This kind of analysis is commercially significant, because the results can be used to explain differences in the reactivity of feeds and the impact on the activity of catalysts in hydrotreating and hydrocracking units. Such differences cannot be explained only by looking at bulk properties, such as distillation behavior, density, and UV aromatics. Refiners who look only at bulk properties continue to make expensive feedstock and catalyst selection mistakes [3.35].

There are several interfaces available for coupling LC with MS [3.10]. Among them, the moving-belt interface, although difficult to operate and no longer commercially available, is the only LC-MS interface that has been able to analyze all types of hydrocarbons, including saturate hydrocarbons in middle distillates and gas oils online by EI [3.10, 31, 33] or field ionization (FI) [3.36, 37]. However, this interface is not suitable for distillate fractions beyond vacuum gas oil due to the temperature limitation of the polyimide belt that transport the analyte into the ion source. For resids and asphaltenes, a spray interface with atmospheric pressure ionization has been commonly used. However, challenges remain for their abilities of analyzing (ionizing) high-boiling saturated hydrocarbons. This is an active area of analytical research in the petroleum industry. In addition, repeatability and reproducibility of the results are of major concern.

For compound-type analysis, it is convenient to group members of homologous series. The adjacent members of a homologous series differ by a methylene group, CH₂. Hence, a mass scale in which the mass of

CH₂ defined as exactly 14, instead of the IUPAC mass of 14.01516 based on the ¹²C = 12.00000 mass scale, was proposed by *E. Kendrick* in 1964 [3.38]. Using the Kendrick mass scale, all members of a homologous series possess an identical mass defect regardless of the carbon number [3.34]. However, the use of the Kendrick mass scale suffered from measurement errors caused by the instability in mass measurements by high-resolution magnetic sector mass spectrometers that were com-

monly used until the 1990s [3.34]. The Kendrick mass scale has gained popularity after narrow measurement errors are obtainable with an ultrahigh resolution MS, such as FT-ICR MS. Through stable measurements in accurate mass for reliable elemental composition determination, compound distributions can then be conveniently expressed as double-bond equivalence (or *z*-number) versus the carbon number with peak intensity (ion abundance) as a third axis [3.18, 39].

3.8 Ionization for Molecules

MS is adapted for identifying and measuring individual components in a mixture based on their masses. However, it is only useful when the molecules can be ionized and subjected to electromagnetic separations for detection. Hence, ionization is an essential element of MS.

Ionization can be classified as universal and selective. Universal ionization, such as EI and field ionization (FI), ionizes all of the vaporized organic molecules. Chemical ionization (CI), photoionization (PI), and all of the atmospheric pressure ionization methods, including electrospray ionization (ESI), atmospheric chemical ionization (APCI), and atmospheric photoionization (APPI), selectively ionize certain classes of molecules, mostly aromatic, polar and metal-containing, for molecular weight and functional group studies.

Ionization can also be divided into vacuum and reduced pressure methods, such as EI, CI, FI, FD, and PI, and atmospheric pressure methods, such as ESI, APCI, APPI, and many others.

3.8.1 Ionization Under Vacuum and Reduced Pressure

Electron-Impact Ionization (EI)

EI was developed at the early stage of MS, replacing less controllable ionization by electrode discharge initially used in nascent MS [3.11]. It has been operated at high (50–70 eV) and low (10–12 eV) electron beam energies under vacuum ($\sim 10^{-6}$ torr). High repeatability and reproducibility can be achieved at electron beam energies greater than 50 eV, most commonly at 70 eV, also known as high-voltage EI (HVEI). Under carefully controlled ion source conditions with calibration reference materials, 70 eV EI mass spectra are highly reproducible, especially using magnetic sector instruments. Thus, over 200 000 HVEI mass spectra of pure compounds were compiled and are available in the data system of modern mass spectrometers for compound identification through a library search [3.40, 41]. A larger database of reference spectra for 662 000

spectra of 592 000 compounds with 565 000 searchable structures is available in McLafferty's book [3.42].

Low energy (< 15 eV) EI (low-voltage EI, LVEI) was used for aromatic and polar hydrocarbons that have a lower ionization potential than saturate hydrocarbons for differentiation between aromatics and overlapping cycloparaffins. For example, both tetracyclic paraffins and benzenes have identical molecular formulae at the same nominal mass. When EI is operated at proper low voltage, only benzenes are ionized, leaving tetracyclic paraffins unionized and not detected by MS. LVEI also produces fewer fragment ions than HVEI.

Chemical Ionization (CI)

For molecules that do not yield molecular ions under EI conditions, CI has been used. In CI, reactions between an excess amount of reagent gas ions and molecule generate molecular ions by charge exchange, or *pseudomolecular* ions through protonation, hydride abstraction, deprotonation (to form negative ions), and reagent ion adduction of the molecules under reduced pressure (~ 1 torr) [3.43]. Both positive and negative ions are generated at low internal energies, resulting in much less fragmentation compared to high-energy EI.

For hydrocarbon analysis, the most commonly used reagent gases are methane, isobutane, and ammonia for molecular weight determination [3.44]. Novel reagent gases, such as benzene [3.45], nitric oxide [3.46], carbon disulfide [3.47], and deuterated ammonia [3.48] were chosen for the studies of structure/functionality. The reagent gas ions are normally produced by a heavy-duty filament for nonoxidizing gases and Townsend discharge for oxidizing gases, such as oxygen and nitric oxide.

Field Ionization (FI)

Confusion in molecular weight can occur from the masses of pseudomolecular ions. For example, the protonated molecular ion, MH⁺, of a component will have the same mass as the hydride abstracted molecular ion, (M-1)⁺, of the component with molecular weight to

be two mass unit higher. Hence, it is often desirable to produce molecular ions by losing only one electron as surrogates of neutral molecules in a complex mixture for the determination of molecular weight distribution. This can be accomplished by FI, which uses a fine emitter or a sharp edge razor blade of the order of a few micrometers in diameter operated at 10–12 kV to create a high electric field of the order of 10^7 to several times 10^8 V/cm across the emitter and counter-electrode under vacuum ($\sim 10^{-6}$ torr) [3.49]. FI produces molecular ions from molecules at low internal energies through quantum tunneling [3.49, 50]. Figure 3.8 displays an FI mass spectrum of lubricant base oil containing only saturated hydrocarbons, yielding molecular ions at even masses, except for isoparaffins that yield a fragment ion unless lowering the emitter current [3.51, 52]. Based on the molecular ions, the distribution of saturated ring types (acyclic paraffins, 1-ring cycloparaffins, 2-ring cycloparaffins, etc.) can be discerned. Figure 3.9 shows the carbon number distributions of each ring type between a hydrotreating feed and its product. Since lubricant base oils are extracted from crude oil distillate without conversion thermally or catalytically, the distribution profiles of sterane and hopane biomarkers

remain visible. The red curves are for the feed and the blue curves are for the product. It is apparent that the production of acyclic alkanes and 1-ring cycloparaffins is at the expense of higher rings cycloparaffins.

Field Desorption (FD)

For high-boiling and nonvolatile petroleum fractions, such as resids and asphaltenes, vaporization for FI becomes difficult, if not impossible. The sample is dissolved in a suitable solvent to be deposited onto a fine emitter which is inserted into the ion source through a vacuum lock. The solvent is evaporated, and a high electric field, as FI, is applied to the emitter deposited with the sample (in condensed phase) to desorb molecules as ionic species (different than field evaporation) into the mass analyzer. This technique is called FD [3.49, 50, 53].

3.8.2 Ionization Under Atmospheric Pressure

Electrospray Ionization (ESI)

As mentioned previously, LC is a suitable technique for the separation of less volatile or nonvolatile mixtures.

Fig. 3.8 Field ionization mass spectrum of a lubricant base oil

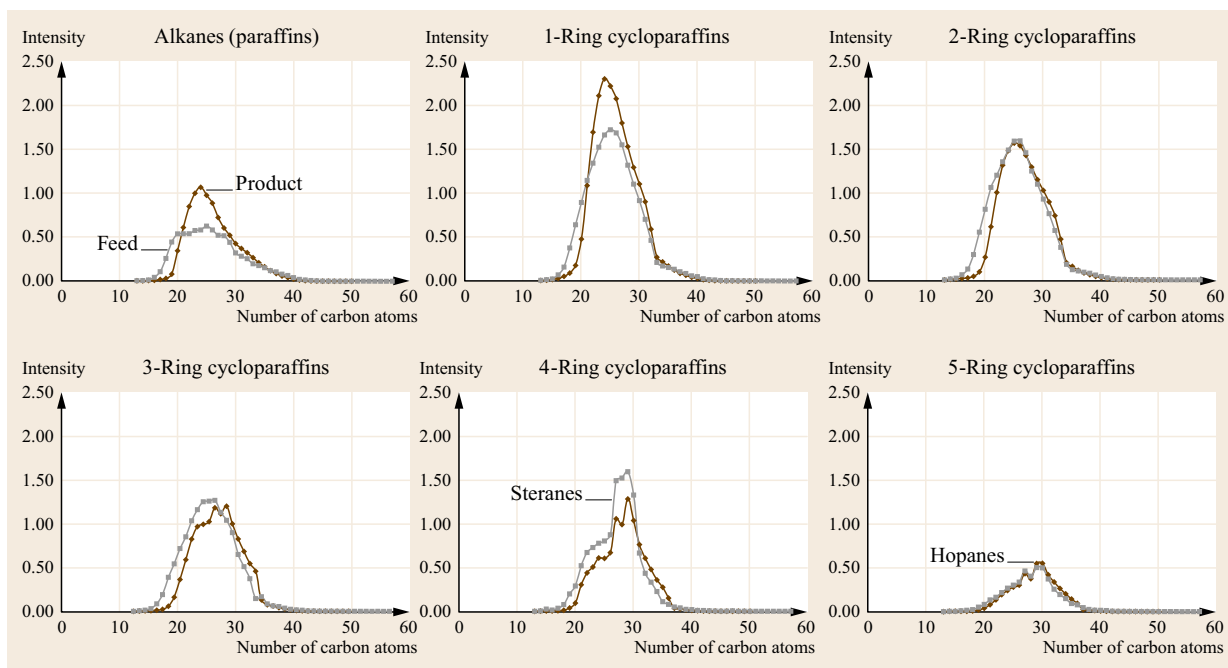

Fig. 3.9 Carbon number distribution of each saturated ring types can be obtained from molecular ions obtained in FI. The hydrotreating feed shown in gray, the product in brown

Many ionization methods, mostly gentle, were developed for the mass spectrometric coupling with LC. One example is ESI that was developed by Malcolm Dole in 1968 originally for the macromass analysis of high polymer (polystyrene) [3.54, 55] has become a common and convenient means of ionization for nonvolatiles. Electrospray also uses high voltage (> 10 kV) on a nebulizer but under nitrogen flow at atmospheric pressure, unlike FI and FD under mass spectrometric vacuum (on the order of 10^{-6} torr).

Although not successful in fully characterizing synthetic high polymers in Dole's effort [3.55], ESI has been adopted to biological systems for analyzing biomacromolecules as pioneered by late Nobel Laureate, *John Fenn* [3.56, 57]. Fenn's group also carried out exploratory experiments with ESI MS on crude oil, jet fuel, gasoline, and coal [3.58]. Their resulting mass spectra contain remarkable amounts of information on the composition and character of these sometimes very complex materials. Hence, it was suggested that ESI might have found a new arena in which to exercise its power [3.59]. Since then, ESI has also been popular in analyzing heavy petroleum resids (by distillation) and asphaltene (by solubility) fractions, including the derivatization of less polar or nonpolar compound classes to polar species suitable for ESI analysis [3.58, 60–64].

Because there is no effective chromatography to separate these extremely high-boiling mixtures into different classes or types of compounds, most of the LC ionization techniques are being used with direct liquid infusion. The resulting learning of detailed molecular composition comprises the basis for developing viable refining technologies. However, studies of resids that are fed to resid processing with resid fluidized catalytic cracking (RFCC) or resid hydrocracking have not yet been seen in the open literature. Such processes are strategically important, and it can be exceedingly profitable. Therefore, there are strong incentives to use the above-described analytical techniques to learn more about resids.

Thermospray (TSP)

There is another spray technique using heat without the use of an electric field, called thermospray (TSP), invented by *Marvin Vestal* in the early 1980s [3.65]. This can also be used for heavy petroleum fraction, as an example shown in Fig. 3.10 for the aromatic ring-type distributions in a 1120–1305 °F DISTACT fraction of a vacuum resid separated by LC [3.66–68].

The highest m/z value in typical spectra from the spray ionization of resids and asphaltenes is less than 2000 for ionic species confidently detected above noise threshold. Arguably, the heaviest molecule in petroleum

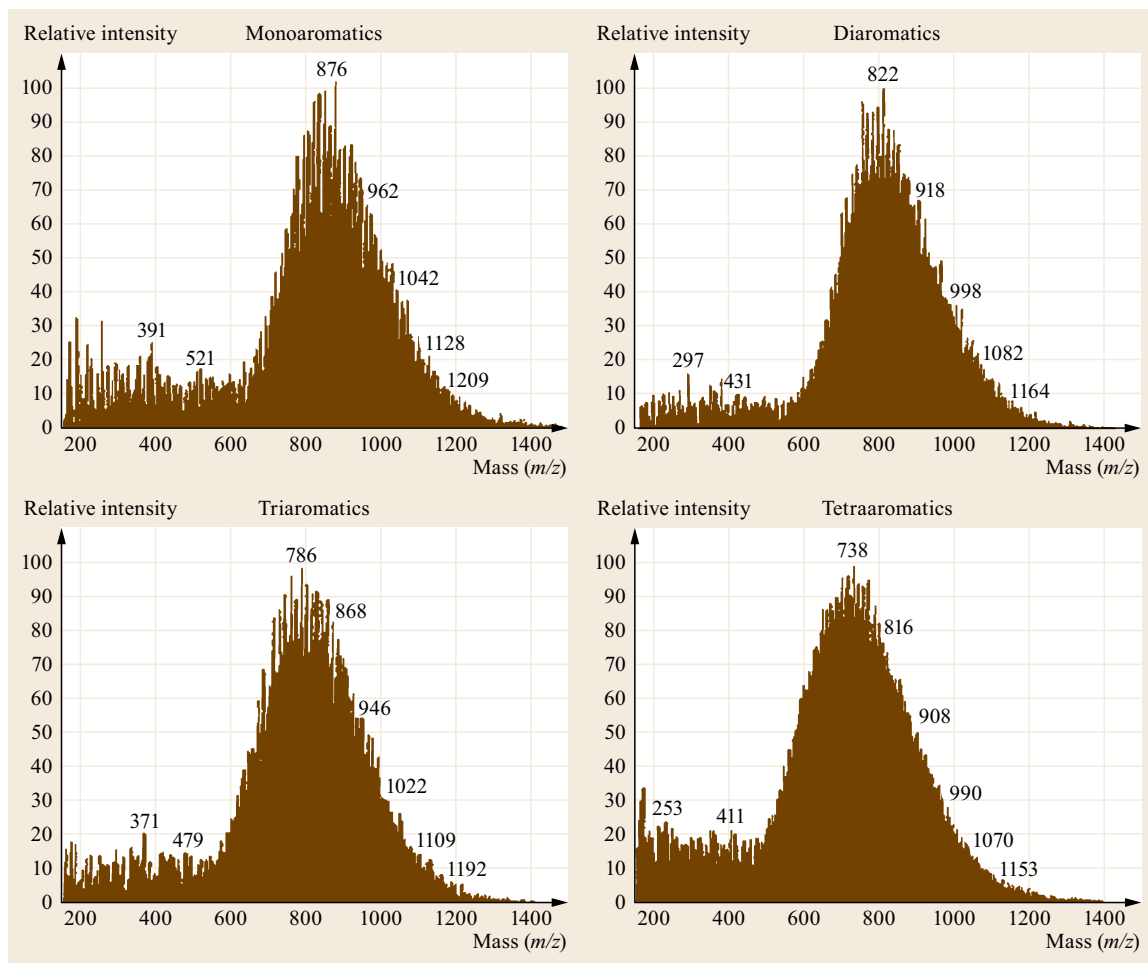

Fig. 3.10 Aromatic type distribution in the 1120–1305 °F DISTACT fraction of a vacuum resid by TSP. (After [3.68])

is less than 2000 without any possible aggregation in measurement, such as in vapor pressure osmometry (VPO). Mass spectrometric measurements, however, can suffer from deficiencies in ionization, ion transmission, and detection of heavier species. Some nonvolatile and nonionizable materials such as dissolved dust, coke, and tar particles will not be detected and analyzed by mass spectrometry. Under severe conditions, the sample can form char or coke or decompose preventing the analysis of heavy species.

Atmospheric Chemical Ionization (APCI)

With ever-increasing demand in proteomics, ESI has become commonly available in commercial instruments. However, ESI cannot be used to ionize all petroleum molecules unless they are aromatic or polar. Alternatively, atmospheric pressure chemical ionization (APCI) initially introduced by Horning for picogram-level detection [3.69] can provide an alternative for

analyzing the compounds [3.70] not amenable for ESI. For examples, the use of acetonitrile as a solvent for the APCI analysis of metalloporphyrins in the negative ion mode was found to be more sensitive than ESI [3.71, 72]. A recently developed version of APCI applying corona discharge at a high flow of nitrogen at atmospheric pressure, also called *atmospheric pressure gas chromatography* (APGC), provides a convenient ion source adaptable for both GC-MS and LC-MS operations. It has been demonstrated as an alternative ionization method for nonpolar sterane and hopane biomarkers [3.73].

Laser-Assisted Ionization

There are many other types of ionization methods performed under atmospheric pressure, most commonly laser-assisted ionization, such as APPI [3.74], matrix-assisted laser desorption/ionization (MALDI) [3.75], and laser induced acoustic desorption (LIAD) [3.76].

They are designed as selective ionization for specific compound types. APPI can be performed with or without dopants under vacuum-ultraviolet (VUV) laser light [3.77]. The most commonly used dopant for hydrocarbon analysis toluene that is added in excess is predominantly ionized by the laser. The analyte ions are formed by ion-molecule reaction between toluene ions and analyte molecules. Positive ions are formed through charge exchange, protonation, or hydride-abstraction, and negative ion are formed through deprotonation. Hence, APPI with dopants can be considered as laser-assisted APCI. MALDI and LIAD are performed with laser light before and after the sample matrix, respectively. They can produce interesting spectra depending on the matrix and gas environment. However, the reliability and applicability of the laser-

associated techniques, [3.78–81] particularly for repeatability and reproducibility in results, remain questionable.

Liquid Injection Field Desorption/Ionization

The incorporation of FI and FD operated under liquid flow, namely, liquid injection field desorption ionization (LIFDI), where the sample solution is delivered to the emitter inside the ion source without breaking the vacuum [3.82]. LIFDI should be capable of ionizing all types of hydrocarbon molecules, including nonpolar saturated hydrocarbons. Hence, this new method could be an ideal ionization technique for LC for overall molecular composition determination of resins and asphaltenes, compensates with other biased atmospheric pressure ionization (ESI, APCI, AAPI, etc.)

3.9 Mass Analyzers

Over the last 100 years, since the first mass spectrograph was constructed by Sir J. J. Thompson of the Cavendish Laboratory of the University of Cambridge, various types of mass analyzers were introduced (Fig. 3.1). They can be generalized as low- and high-resolution instruments. A high-resolution mass spectrometer consists of a mass analyzer capable of determining accurate masses of the components having the same nominal mass for the determination of elemental composition of the ionic species [3.83, 84]. The ability of elemental composition determination for molecular ions is of particular interest. The most commonly used mass spectrometers in the petroleum industry over the years for molecular characterization are briefly described below.

3.9.1 Magnet Sector Mass Spectrometers

Initial commercial single-focusing magnetic sector mass spectrometers were dominant in the 1940s and used in the petroleum industry during World War II for the quantitative analysis of organic gas and light fuel mixtures. In fact, it is the only type of mass spectrometer that provides data adopted by American Society for Testing Materials (ASTM) as standard quantitation methods, including ASTM D 2786 and ASTM D3239 for hydrocarbon mixtures up to gas oil [3.85]. Although obsolete, there are no substitute instruments for acceptable repeatability and reproducibility being manufactured.

For high resolution, a combination of electric sector with magnet in either Mattauch/Herzog or Nier/Johnson geometry provides double-focusing for sep-

arating overlapping components of the same nominal mass [3.11, 84]. The highest resolving power achievable by double-focusing mass spectrometers for a full scan mode is around 50 000. Reversed geometry double focusing-mass spectrometers are composed of the reversing Nier–Johnson geometry with a magnet (B) preceding the electric sector (E). They not only provide high resolution but also serve as a type of tandem mass spectrometers (MS/MS) to link between the precursor and product ions for structural determination and fragment ion kinetic energy release studies [3.86–89]. Due to high cost in maintenance and difficulty in construction and operation, double-focusing mass spectrometers have gradually been replaced by other types of high-resolution mass spectrometers capable of achieving resolving power up to several millions [3.18].

3.9.2 Quadrupole Mass Analyzers (QMS)

The quadrupole mass analyzer or spectrometer (QMS) consists of four hyperbolic rods parallel to each other with opposite rods connected electrically. When an oscillating radio frequency (RF) voltage is applied to one pair of rods and the other, both positive and negative ions are transmitted through the quadrupole rods with equal facility. When a direct current (DC) voltage is superimposed with the RF voltage, ions of different mass-to-charge ratios (m/z) are separated based on the stability of their trajectories by varying the DC and RF voltage ratio. At a certain value, only the stable ions can pass through and other ions with unstable trajectories colliding with rods. By scanning the DC/RF ratio, the

quadrupole can be used as a mass analyzer [3.90]. The resolving power of a QMS is as low as unit resolution (separated by nominal masses) accompanied with great sensitivity for the effective transmission of the ions. The coupling of GC with QMS has found great utility for mixture analysis from petroleum gas to gas oils.

A tandem triple-stage quadrupole mass spectrometer where the first (Q1) and third (Q3) quadrupoles function as mass scanning analyzers and the middle quadrupole (Q2) with RF serves only as a collision cell provides convenient MS/MS operations [3.91, 92]. Its operation modes can be: (1) precursor (parent) ion scan, (2) product (daughter) ion scan, (3) neutral loss scan (concurrent scan of Q1 and Q2 at a constant mass offset) and (4) full scan (with one of the Q1 and Q3 to be RF only as Q2). Triple-quadrupole MS/MS greatly improves the daughter ion mass resolution, which is poor in a reverse geometry double focusing MS due to kinetic energy release. The mass-scanning quadrupoles (Q1 and/or Q3) can be fixed at the nominal masses of interest, known as multiple-reaction monitoring, (MRM) to enhance the sensitivity of ion fragmentation pathways of interest. Unlike other types of MS/MS instruments, the precursor ion scan is unique to triple-quadrupole MS. When coupling with GC, precursor scans of triple quadrupole MS/MS greatly facilitate petroleum biomarker analysis, particularly for overlapping epimers, as described earlier for steranes [3.22].

3.9.3 Time-of-Flight Mass Spectrometers (TOF MS)

Time-of-flight MS (TOF MS) was developed in the late 1940s [3.93] and became prominent during the 1960s, but it was soon replaced by magnetic sector and quadrupole instruments with higher sensitivity and mass resolving power [3.11]. It regained popularity recently with greatly improved resolving power using orthogonal acceleration, reflectron technology and high-speed electronics [3.94]. It has an advantage of analyzing heavy molecules with no theoretical upper mass limit of ions.

In TOFMS, ions are separated by their velocities obtained from acceleration through an electric field (acceleration voltage) in the ion source. At a constant kinetic energy, the velocity of a singly charged ion is inversely proportional to the square root of its mass. Hence, the arrival time at the detector is proportional to the square root of m/z ratio of the ion. To reduce the energy spread, the ions into the mass analyzer are accelerated in a direction orthogonal to the ion path out of the ion source. To increase flight time for achieving higher resolution at a limited space inside the mass analyzer,

the ion flight path is lengthened using an ion mirror (reflectron) [3.95], multipath reflections [3.96], or spiral trajectory [3.97].

3.9.4 Quadrupole Time-of-Flight Mass Spectrometers (QTOF MS)

Quadrupole TOF MS (QTOF MS) can be considered as an instrument where the third quadrupole (Q3) of the triple quadrupole is replaced by the TOF mass analyzer. However, an additional quadrupole can be added for collision damping. With orthogonal injection (acceleration) of the ions, QTOF MS with a reflectron with two or more paths provides high-sensitivity and high-resolution/mass accuracy for both precursor and product ions with simplicity in operations [3.98, 99]. QTOF MS can be operated as a TOF MS by setting RF only on the quadrupole mass analyzer to transmit all ions through. Another advantage of QTOF MS is simultaneous high- and low-energy collisions producing similar mass spectra as HVEI and LVEI [3.73].

3.9.5 Fourier-Transform Ion Cyclotron Resonance Mass Spectrometry (FT-ICR MS)

The mass limitation encountered in high-resolution double-focusing magnetic sector instruments has been greatly reduced by using Fourier-transform ion cyclotron resonance mass spectrometry (FT-ICR MS). The resolving power of several millions, even capable of resolving mass difference less than an electron mass, can be achieved [3.18]. An ICR MS employs inherent resonance frequency of an ion in a fixed magnet field to determine m/z . The ions are introduced (transmitted) and trapped in electric trapping plates under the magnetic field. By applying an oscillating electric field orthogonal to the magnetic field, the ions are excited and rotated at their resonance frequencies. They circulate inside the trap as packets with larger radius to be closer to the detection electrodes, producing an induced current image from the induced decay detectable on a pair of electrodes. The frequency signals, which are sine waves on a time scale, are Fourier transformed to the frequency scale and then mass calibrated as a mass spectrum.

Modern FT-ICR MS was first recognized in 1994 as a powerful alternative to the high-resolution sector MS for resolving overlapping components, particularly hydrocarbons and their overlapping sulfur species of 3.4 mDa mass difference, in complex high-boiling mixtures that are of most interest in the petroleum industry [3.100]. Since then, numerous publications have appeared in the literature, mostly for asphaltene char-

acterization. Although previously unanalyzable polar species can be accurately mass measured for elemental composition determination, reliable and repeatable quantitation of the identified species remains a great challenge.

3.9.6 Other Mass Spectrometers

There are many other mass spectrometers, some of which are gaining popularity in the oil industry, such as the quadrupole ion trap [3.90] and the orbitrap [3.101]. Regardless of the type of mass spectrometer being used, the main purpose is to obtain the maximum molecular information and understanding in complex

petroleum mixtures for process and product improvements, problem solving, safety, and environmental compliance.

Recently, ion mobility analyzers have become commercially available associated with TOF and other types of mass analyzers [3.102]. They are improved versions of plasma chromatography [3.103] or ion drift MS to create mobility spectra, which was proposed for density measurements of gaseous ions [3.104]. Along with mass measurement by MS, ion mobility chromatography can be used for cross-sectional area measurements of ionic species [3.105, 106]. The cross-sectional area measurements are made by use of reference compounds with the known cross-sectional areas.

3.10 Data Interpretation and Management

The advent of modern high-speed computers greatly facilitates the instrument control and data acquisition of mass spectrometers and mass spectral data processing. Based on the needed information or desired results, a mass spectrometrists makes decisions of what instruments to be used and experiments to be performed. Data interpretation will be made to communicate with collaborative scientists and/or engineers to understand the underlying chemistry and evaluate/assess the process and/or products.

3.10.1 Molecular Isotopic Pattern Computation

The isotopes of elements were discovered by physicists in early mass spectroscopic studies [3.11]. Thus, MS is well suited for the isotopic pattern determination of molecules. Isotopic patterns can aid in compound identification and quantitation.

The earlier approach of calculating isotopic patterns of molecules involved the use of polynomial expressions to include probability theory and combinatorial analysis [3.11, 107]. For petroleum fractions containing components with the carbon number less than 90 and smaller numbers of heteroatoms including sulfur, nitrogen, and oxygen, the polynomial approach is adequate for isotopic distribution calculations. However, for much larger molecules, such synthetic polymers, the polynomial approach suffers from several limitations in the numbers of elements and carbon numbers being calculated. Another approach based on the Diophantine algorithm which can only have integer solutions was first proposed for eliminating the constraint in the number of elements and carbon numbers and providing simplicity in isotopic abundance calculations and monoisotopic

mass determinations of high-mass species [3.108]. This approach has been extended to polypeptides in proteomics [3.109] and biomedical research [3.110] dealing with biomacromolecules containing a larger number of carbon atoms and heteroatoms. No limitation in the number of elements has advantages of computing complex multielement catalysts or enzymes by mass spectrometric analysis.

3.10.2 Compound Identification and Type Analysis

A volatile component in light petroleum fractions can be analyzed by GC-MS. With EI, compounds can be identified individually by matching their mass spectra with reference spectra through library search. The best search system is published by *Pesyna* et al. [3.111] and *McLafferty* et al. [3.112]. If no matching spectrum can be found, the identification can be made by interpreting the mass spectral pattern based on the principles of organic chemistry [3.113, 114]. For higher boiling fractions, components are grouped together for characterization according to compound types. Several methods of compound-type analysis have been adopted by ASTM as semiquantitation methods of petroleum fractions.

3.10.3 Integration of Molecular Characterization Data for Kinetic Modeling

One of the ultimate goals for molecular characterization is its use in process control and performance assessment. It is desirable to develop process kinetic models based on the molecular information of the feed-

stock to predict processability and product yields under various refining conditions. A large volume of molecular characterization data are then integrated with the reaction chemistry network in the model for the prediction, control, and evaluation of the process and products. Hence, it can be considered as a form of molecular engineering for designing refining processes without a pilot plant. One successful example is the structural-oriented lumping (SOL) kinetic modeling method developed at ExxonMobil to describe molecular composition, reaction chemistry, and properties of complex hydrocarbon mixtures for predicting the yields of refinery processes [3.115]. Molecules are represented by structural vectors for computer manipulation. The method has been extended to molecules found in vacuum resid represented as multicore molecules

comprising single-core molecules found in lower boiling fractions. It includes two more vectors for nickel and vanadium, which poison the catalysts in VGO and resid conversion units [3.116]. SOL has been applied to steam cracking [3.117] and delay coking [3.118] processes to describe feedstock and reaction behavior for predicting product distributions. The predictions compare well with experimental results. SOL has been used for the prediction of the octane number of gasoline [3.119] and cetane numbers of diesel [3.120], providing true examples of petroleomics to relate molecular composition with properties, performance, and functions of refinery products [3.30]. Accurate quantitation is the key to the technical and economic success of molecular based models and this work is ongoing.

3.11 Molecular Engineering and Management Through Science and Modeling

Once the compounds in the petroleum mixture are identified, their physical and chemical properties that include thermodynamic and kinetic properties can be determined or predicted through science studies. Molecular composition in the petroleum fractions and process streams can be measured or estimated through quantitative analysis using sophisticated separation and analytical schemes. The molecular property database could be created for individual molecules, molecular groups, and structural types. Based on the property database of the molecules, all the possible reactions along with their rate constants of refining processes can be listed. To handle the huge amounts of data and information of the molecules involved in complex mixtures, model building based on modern sophisticated computers becomes necessary. To achieve this goal, the molecular structures need to be digitized as the digital expression for the

molecular composition model and the molecular level reaction network of every type (or group) of molecules for the kinetic model need to be established [3.115, 121]. Such kinetic modeling allows computers to perform dynamic calculations referring to the experimental conditions for the optimization and prediction of the yield and quality of products of the particular process. It can also be used for the development and application of new catalysts and new processes through the prediction on possible reaction routes. The visualization of the reaction network would also help users to understand and study the molecular conversion chemistry.

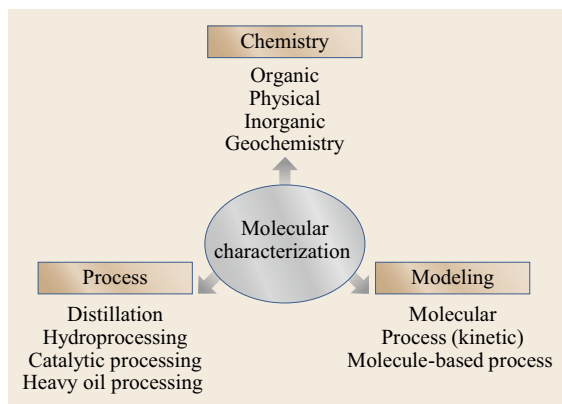

Molecular management for the overall optimization of the resource and refinery process would increase refinery profitability through feedstock selection, operation condition optimization, novel process development, product blending, and waste management.

3.12 Conclusion

In the oil industry, regardless of whether upstream, downstream, petrochemical, environmental, or modeling, molecular understanding of petroleum and upgrading processes is important for science and technology as well as the improvement of processes and products. Analytical devices and instruments play key roles in providing the information of existing, unknown or new molecules for the design and control of chemical processes. Analytical research and development have been

driven by business needs, market demands, and governmental regulations.

The value of molecular characterization is enhanced by integrating science (chemistry), engineering (processing), and management (modeling and chemometrics), as shown in Fig. 3.11. Molecule-based process kinetic modeling based on molecular characterization data and generalized rate constants in the reaction network for the simulation/optimization of refinery pro-

cesses and prediction of yields, properties, and performance of products has gained popularity, evidenced by

Fig. 3.11 Role of molecular characterization in molecular science (*chemistry*), molecular engineering (*process*) and molecular management (*modeling*) ◀

recent publications. Successful molecular engineering without a pilot plant studies would be a great savings for time and cost for designing new and improved processes. However, the calibration or correlation of the output with pilot plant results is always necessary to validate the process models.

Acknowledgments. The author would like to acknowledge valuable comments and suggestions from Fred W. McLafferty, R. Graham Cooks, and Paul Robinson. Discussion with Dr. Qing Wu of China National Offshore Oil Corporation (CNOOC) is also highly appreciated.

Petroinformatics

4. Petroinformatics

Manhoi Hur, Sunghwan Kim, Chang Samuel Hsu

Studies on petroleomics have been focused on advanced molecular-level characterization of compounds that could not be analyzed by conventional techniques. The next stage of the development would be more discussions on the information obtained and relationships with the properties and functions. The relationship between molecular composition and bulk properties or functions can be explicitly expressed by *petroinformatics*, which utilizes statistics, mathematics, and computational visualization technology to interpret or correlate analytical results with bulk properties and experimental data. This provides explicit or implicit information for underlying science and engineering.

In this chapter, several examples of petroinformatics are presented. Statistical methods, such as principle component analysis (PCA) for dimensionality reduction in multivariate analysis, and hierarchical clustering analysis (HCA), have been applied to interpret complex petroleum mass spectra obtained by ultrahigh-resolution Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR MS). The mass spectral peaks were statistically analyzed by Spearman's rank correlation, and by correlation diagrams showing relationships between composition and bulk properties. Additionally, the chapter demonstrates quantitative analyses for petroleum samples by PCA for multivariate analysis and *t*-tests for univariate analysis. Volcano plots are utilized to visualize the quantitative change or difference between samples in detail.

The software platform, which integrates data from many samples obtained from different analytical instruments, is a very important tool to achieve more comprehensive understanding of complex analytes such as crude oils. The learnings from other research fields, such as metabolomics, genomics, and proteomics, are important and valuable for the next steps of petroinformatics development, i. e., standardization of data and retrieval of its metadata information.

In modern society, information is generated by studies, experiments, surveys, experience and other communications. Information technology, or informatics, vastly improves access to such information by people who support education, research, practice, development, and decision making. Thanks to advances in computer technology, a huge amount of information from various sources can be digitized, integrated, stored, and pro-

cessed by computers with high speed and efficiency. *Petroinformatics*, which utilizes statistics, mathematics, and computational visualization technology to interpret or correlate analytical results with bulk properties and experimental data, is particularly needed for very complex petroleum mixtures, ranging from light gas to solid residue that can contain millions of molecules. Sophisticated analytical techniques generate data that often

require noise rejection algorithms, statistical analysis, and other resolution enhancement tools for obtaining useful information. Models that employ advanced mathematics and statistics are being built and developed for handling critical physical and chemical data.

Since the beginning of the petroleum industry, various physical testing methods have been established to measure bulk properties of crude oils, exemplified by the Crude Assay [4.1]. Mass spectrometry for molecular characterization was pioneered at the Atlantic Richfield Company (ARCO) during World War II [4.2]. For complex mixtures even in light boiling ranges, such as petroleum gas and naphtha, sensitivity matrices were used for resolving the overlapping ionic species obtained by mass spectrometry. These enabled researchers to determine the distribution of hydrocarbon compound types for the properties and thus quality and performance of the fuels [4.2, 3]. Gas chromatography (GC) was advanced for accurate quantitative measurement of separated components using a universal flame ionization detection (FID) [4.4, 5]. An early application was the octane number prediction of naphtha, the main gasoline component [4.6]. The successful coupling of gas chromatography and mass spectrometry (GC-MS) greatly expands analytical capabilities in the oil industry for determining and monitoring the properties and behaviors of petroleum fractions at the molecular level, enabling identification of optimal processing conditions and product quality control or prediction [4.4, 7].

The term *petroleomics* [4.8–13] was first introduced at a hydrocarbon and chemicals workshop of the American Society for Mass Spectrometry (ASMS) conference in the late 1990s. The concept parallels proteomics for the physiological and pathophysiological functions related to molecular composition and functional groups [4.14]. It has been greatly practiced by a research group at the National High Magnetic Field Laboratory (NHMFL) using ultrahigh-resolution Fourier-transform ion cyclotron resonance mass spectrometry (FT-ICR MS) for heavy oils and fractions [4.15] to partially resolve problems associated with heavy components. Since its first introduction as a tool for petroleum analysis [4.16], FT-ICR MS has been evolved along with electrospray ionization (ESI) [4.17–26], atmospheric pressure photo ionization (APPI) [4.27–34], atmospheric pressure chemical ionization (APCI) [4.35–37] and laser desorption ionization (LDI) [4.38–42] as a principal tool to analyze compounds with higher molecular weights (e.g., 400–500 Da) and polar functional groups (e.g., –OH, thiophene, pyridine). It has played a critical role for petroleomics in which molecular-level understanding is pursued to find correlation between chemical compositions and reactivity/properties of crude oils. FT-ICR

MS is a powerful technique by which over 10 000 compounds can be detected and identified from a single spectrum [4.15, 18].

Elemental compositions (formulae) of the compounds are determined from accurate mass measurement, and relative abundance observed from spectra can be visualized and studied by various tools such as Kendrick mass defect analysis [4.43–46], van Krevelen diagrams [4.47–49], double bond equivalence (DBE) versus carbon numbers (C#) plots [4.10, 20, 23, 50–52], and statistical methods [4.53–60]. Planar limits (or compositional boundaries) [4.51], tandem mass spectrometry [4.61], and atmospheric pressure hydrogen-deuterium exchange mass spectrometry [4.62–65] have also been used to gain additional information on the molecular structures of compounds comprising crude oils.

Although ultrahigh-resolution mass spectrometry is a powerful tool for the analysis of crude oil components, it has limitations. Only limited information on molecular structures can be obtained by this technique because numerous isomeric compounds of various structures have the same elemental composition. One of the biggest obstacles for quantitative analysis by mass spectrometry is nonuniformity of the ionization processes, resulting in low repeatability and reproducibility. Two compounds with a small structural difference can have big difference in ionization efficiency, in addition to ion transmission and detection efficiencies. Therefore, it is difficult to directly correlate the amounts of components in solution with the amounts observed in the gas phase inside the mass spectrometer. There have been many studies devoted to understanding the ionization processes, but it would take more time and effort to further understand the quantitative aspects of the ionization processes. Despite the limitations listed above, ultrahigh-resolution mass spectrometry has been a powerful tool to study heavy molecules of crude oils in general. Research employing this technique has been active, leading to numerous publications.

In fact, considering the heterogeneity and complexity of crude oil's composition, it is obvious that no single analytical technique can determine the structural identities of all the compounds present in crude oils. The process of finding structural identities of the compounds can be compared to a group of men with blindfolds trying to find the shape of an elephant. Since the elephant is so big, each man can only cover a limited area. To find the overall shape of elephant, the information obtained from each man has to be coordinated and integrated by talking to each other. The areas covered by the men have to be well organized by being well spread out and wide enough to cover the whole elephant. At the same time, some overlaps of the covering areas would

be necessary to link information provided by each man. Care should also be taken to identify missing areas.

By analogy, all the available tools have to be used to characterize crude oil samples, since each technique can only cover a limited area of overall crude oil compositions. If petroleum is separated into traditional saturates, aromatics, resins, and asphaltenes (SARA) fractions, different techniques have to be used to characterize each fraction, as illustrated in Fig. 4.1. Combining and coordinating information obtained from different sources is not an easy task, but there have been a few attempts to achieve that goal. To combine the information, it is important to understand the capabilities and limitations of various analytical techniques. For each property measurement, each analytical method gives different information. The research effort has to be devoted not only to investigate what information can be obtained from each technique, but also how the information can be integrated to find ultimate and accurate information.

Therefore, it is clear that more research has to be carried out to devise methods for combining information obtained from each analytical technique. This information-driven research is called *petroinformatics*. The concept of *petroinformatics* was first introduced at a petroleomics workshop of a Pacificchem conference in 2010 [4.66]. The focus of petroinformatics is gathering

Fig. 4.1 Analytical strategy for the determination of chemical composition in a crude oil

and combining the chemical composition information on crude oils obtained from various traditional and new techniques, such as FT-ICR MS, quadrupole time-of-flight mass spectrometry, gas chromatography time-of-flight, and nuclear magnetic resonance spectroscopy (NMR), to strive for an integrated oil analysis. The gathered information can be statistically processed and correlated with reactivity and properties of the crude oils. The statistical data analysis techniques for a large amount of data have been actively investigated and evaluated. In the end, the overall information can be combined with theoretical simulation to understand and predict crude oil processing.

This chapter describes how petroinformatics can enhance the understanding and applications of petroleum science and technology.

4.1 Petroleum Analysis and Statistical Approaches

To analyze and mine information from large-scale datasets, statistical methods have successfully been applied in biological and biomedical fields, such as microarrays, transcriptomics, metabolomics, and proteomics. Similar statistical methods in crude oil studies could provide viable means of data analysis. The current chapter describes the application of principal component analysis (PCA), hierarchical clustering analysis (HCA) combined with the heatmap visualization method, and correlations between chemical composition and crude oil properties using correlational diagrams. In addition, it introduces a quantitative analysis method for using PCA to characterize heteroatom classes or samples, aided by the *t*-test and its visualization, called volcano plots.

4.1.1 Data Preprocessing for Statistical Analysis

PCA has been used as an effective statistical method for understanding crude oils [4.61]. Twenty oil samples were analyzed by FT-ICR MS utilizing both positive (+)

and negative (−) APPI modes. Triplicate measurements enabled determination of statistical significance. Hence, in this study, a total of 60 mass spectra were obtained from the 20 samples in each ionization mode. All peaks were generated by an automated peak picking algorithm with a moving window of data points [4.54, 67], which provided quicker and more reliable peak picking for analyzing crude oil samples. The relative abundance of individual peaks was normalized to the sum of abundances throughout the peak list. Assignments of molecular formulas were performed for more than 95% of the total number of peaks above a predetermined signal-to-noise ratio. For each ionization mode, the resulting peak lists with elemental formula assignments of 20 samples were aligned into a single table for statistical analysis. Normalized abundances and peaks with the same elemental formulas found in different samples were aligned into single lines. Peak alignment was performed on the basis of the assigned elemental formulas matching with theoretical mass-to-charge values. When aligning peaks, the relative abundance of peaks not detected in samples was assigned as zero [4.68].

4.1.2 Comparison of Multiple Crude Oil Samples by PCA and HCA

Conventionally, data interpretation and spectral comparison of complex datasets are carried out by Kendrick mass defect [4.16, 42, 43] and van Krevelen diagrams [4.46–48]. They have been applied to ultrahigh-resolution mass spectra of one sample at a time magnificently. Also, even though a pair of atomic abundance ratios of selected elements in molecular formulas, such as H/C, O/C, S/C, etc. is cross-plotted as a van Krevelen diagram to facilitate the visualization of changes or differences at the molecular level, the extraction of information out of complex mass spectra remains difficult when multiple samples must be analyzed and compared. A van Krevelen diagram of petroleum spectra, for instance, presents only one sample at a time. Since a detailed comparison of multiple samples, such as 20 in our example, would require the generation and manual examination of 20 individual van Krevelen diagrams and Kendrick plots, principal component analysis (PCA) and hierarchical clustering analysis (HCA) combined with the heatmap visualization method are utilized to simultaneously analyze APPI FT-ICR mass spectra from these crude oil samples.

PCA, discussed under *PCA Applications of Positive/Negative APPI Data*, is commonly explained in the literature [4.69–71] as the number of variables (eigenvectors) through linear combination of the original variables, e.g., the number of peaks observed in a mass spectrum to be transformed by PCA into principal components. Principal components (PCs) as the new variables are descriptive of the variance, or crucial difference, among the oil samples in question and those PCs are ordered by their contributions (eigenvalues) to the variance of peaks observed. Thus, the first PC generated by PCA describes more of the variation in the peaks observed than the second PC. Also, these PCs can be represented by two plots called loading and score. A loading plot contains the original variables and a set of coefficients, while a score plot can be described as a linear combination of PCs with a new set of coefficients. Both loading and score plots are frequently used to visualize the PCA results [4.61].

HCA, discussed under *Applications of HCA and Heatmaps to samples from Positive/Negative APPI Modes*, is one of the cluster analyses that generate clusters of related objects, in which a series of partitioning calculations are performed to group objects. In this study, both ward linkage [4.72] and Kendall rank correlations [4.73] were utilized to create clusters. A ward linkage is a least squares method, computed by the fol-

lowing equation

$$\sum_{i=1}^n (X_i - \bar{X})^2, \quad (4.1)$$

where X represents the value of an object and \bar{X} is the estimated mean value of the cluster. The Kendall tau (τ) is computed by the following equation

$$\tau = \frac{n_c - n_d}{\frac{1}{2}n(n-1)}, \quad (4.2)$$

where n_c and n_d are the concordant and discordant count numbers respectively, and n is the number of samples. Thus, two clusters in perfect positive correlation will be presented as $\tau = 1$. On the other hand, $\tau = -1$ represents a perfect negative correlation.

PCA Applications of Positive/Negative APPI Data
PCA Interpretation of Positive APPI Data. The score plot shown in Fig. 4.2a was constructed with PC-1 and PC-2 variables from each of the samples. The 20 samples were roughly split into three groups. In Fig. 4.2b, the loading variables for PC-1 and PC-2 are presented. For easy recognition and evaluation, the compound class distribution was color coded. In the loading plot as shown in Fig. 4.2b, N_1 class compounds are marked in gray, and HC class compounds are shown in dark green. Sulfur-containing classes such as S_1 , S_2 , and N_1S_1 are located mostly on the right side of the loading plot. It shows that the group I samples are rich in sulfur. Group II samples are rich in HC, O_1 and O_2 class compounds, and group III samples are rich in N_1 and N_1O_1 compounds. Thus, PCA can be used to describe the similarities and/or differences between complex spectra.

We use biplots, which superimpose score and loading plots, shown in the Figs. 4.3–4.5 for three groups of compound types, for easy visualization of the relationships between the samples and their observed peaks. Figure 4.3 is for HC, O_1 and O_2 class compounds, Fig. 4.4 is for N_1 and N_1O_1 class compounds, and Fig. 4.5 is for S_1 and S_2 class compounds. It can be seen that X01, X12 and X16 in Fig. 4.3 all contain high concentrations of nitrogen as shown in Table 4.1, while X02, X03, X11, X13, X17, X18 and X19 in Fig. 4.3 contain high concentrations of sulfur.

PCA can show good correlation between the spectral results and the bulk properties. For example, A.J.G. Barwise [4.74] previously reported a correlational relationship between bulk sulfur and vanadium contents in crude oil samples. Thus, the comparison of samples displayed in Figs. 4.3–4.5 (group I versus group II and III) and their properties listed in

^a Unconventional, bitumen from oil sand

^b Data not available

in Fig. 4.6a,b respectively. The division between groups in the score plot was not as distinct as that observed for the positive APPI mode.

Fig. 4.5 Biplots of the score and loading plots displayed in Fig. 4.2 for S_1 and S_2 class compounds. Reprinted with permission from [4.55]. Copyright (2010) American Chemical Society

Among the 20 samples, X03 was the only unconventional oil that was a bitumen extracted from oil sands. It was well separated from all other samples in the score plot, situated at lower right corner. Comparing with the loading plot, it shows that S_xO_y ($x \geq 1$ and $y \geq 1$) compounds were uniquely abundant in X03. Hence, PCA can identify unique components in the samples.

By eliminating X03, the source and score plots of the remaining 19 conventional oils are shown in Fig. 4.7a,b. The division between three main groups becomes clear as shown in Fig. 4.7a. The distribution of compound classes can be seen in the loading plot of Fig. 4.7b. The group consist of sulfur-containing classes (N_1S_1 and S_1O_1) primarily located on the right side of the figure, nitrogen-containing classes (N_1 and N_1O_1) at the top, and oxygen-containing class such as O_2 class on the left side.

Applications of HCA and Heatmaps to Samples from Positive/Negative APPI Modes

HCA is useful to show relationships among samples based on selected clusters of peaks. The samples were divided into two main clusters, as shown in Fig. 4.8.

Each cluster can be further divided into several layers of subclusters.

Figure 4.8a displays the first layer of four subclusters: A, B, C and D of HC, O_1 and O_2 peaks shown in Fig. 4.3. The physical and chemical properties of the bulk oils corresponding to these clusters are listed in Table 4.1. The figure reveals that subclusters A and B contained higher amounts of vanadium and $> 1\%$ sulfur, while subclusters C and D contained lower or negligible amounts of vanadium and $< 1\%$ sulfur. All of the subcluster B samples contained no less than 90 ppm vanadium, and subcluster A contained samples with moderate amounts of vanadium ranging from 10 to 60 ppm. Thus, HCA can reveal relationships between crude oil samples by correlating the measured peaks to gross properties.

Similarly, Fig. 4.8b displays two first-layer subclusters, A' and B' of sulfur-containing S_1 , S_2 , and N_1S_1 classes shown in Fig. 4.5. Subcluster A' contained $> 1\%$ sulfur and significant amounts of vanadium, while subcluster B' contained less than 1% sulfur and small or negligible amounts of vanadium. Table 4.3 lists the oil samples in each of the subclusters.

4.1.3 Correlation Between Chemical Composition and Physical Properties of Crude Oils

The following studies show the peaks measured by FT-ICR MS can be associated with chemical and physical properties of crude oils. The peaks were statistically analyzed by Spearman's rank correlation; utilized and graphically presented correlations are based on Circos diagrams [4.75]. Many peaks correlate strongly with sulfur, total acid number (TAN), and vanadium contents.

Statistical Analysis for Correlation Study

Prior to statistical analysis, peak lists with elemental formula assignments were aligned into a single table for each set of data. Further information can be found in Sect. 4.1.1. In this study, Spearman's rank correlation was utilized, [4.76] since the Spearman correlation does not require prior knowledge of a probability distribution. In the literature [4.76, 77], it is commonly explained that the original two variables were converted into ranks at the first step. After the ranks were determined based on size, variables were sorted by size and ranked according to their order. If a variable had

a smaller value, it had a lower rank, and if a variable had a larger value, it had a higher rank. When variables were of equal size, they had an equal rank. After ranking, a correlation value was then computed on the ranks. The first original variable was the relative abundance of peaks in the samples and the second original variable was a selected property of the crude oils. If there were no tied ranks, the correlation coefficient (ρ , Spearman's rho) was computed as follows

$$\rho = 1 - \frac{6 \sum_i (x_i - y_i)^2}{n(n^2 - 1)},$$

where x_i and y_i are the ranks of relative abundance and properties of crude oil respectively, for each set. If there were tied ranks, the following equation was used for the computation

$$\rho = \frac{\sum_i (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_i (x_i - \bar{x})^2 \sum_i (y_i - \bar{y})^2}}.$$

Our correlation studies used bulk properties of samples shown in Table 4.2.

Visualization/Interpretation of the Correlation Diagrams

Correlation diagrams were designed by Hur et al. [4.56] based on the Circos diagram [4.75], which was originally developed for comparative genomics. It is a very effective visualization tool for large amounts of data. Peaks with statistical significance (ρ -values < 0.05) were used to construct the diagram as shown Fig. 4.9, which serves as an example to explain how to interpret the diagrams. Correlation diagrams contain four bands: the chemical, or heteroatom, class band; the C# (number of carbon) versus DBE (rings plus double bonds to carbon) band for each class; the distribution of ρ band; and the correlation circle band. DBE values were calculated from chemical formulas using the following equation

$$\text{DBE} = c - h\frac{1}{2} + \frac{n}{2} + 1$$

(for the ions $\text{C}_c\text{H}_h\text{N}_n\text{O}_o\text{S}_s^+$ or $\text{C}_c\text{H}_h\text{N}_n\text{O}_o\text{S}_s^-$).

In Fig. 4.9, the peaks with the same C# are shown on a line in the band, and C# for the lines increased in a clockwise direction. In addition, the minimum and maximum values of C# are marked for each class. *Triangle dots* closer to the center have lower DBE values than outside *triangle dots*. The correlation circle is located at the center. The correlation circle shows not only the whole distribution of the correlation coefficient (ρ), but it also shows lines linking a property with observed peaks color-coded according to their ρ values. Colors in *red* and *orange* show a strongly positive correlation, *light green* a weak correlation, and *green* and *blue* a strong negative correlation. A more detailed distribution of the ρ band is presented in the band just outside of the circle.

Correlation with Sulfur and Vanadium Contents.

Correlation between peaks observed in (+) mode APPI spectra is presented in Fig. 4.9. The diagram shows that sulfur-containing classes such as S, S₂, OS, and NS were dominant. The correlation circle band was dominated by either *red* or *orange*, indicating a very strong positive correlation. This means that sulfur-containing compounds show a strong positive correlation with the sulfur content of the samples, which agrees with what is expected from crude oils. In Fig. 4.9, the classes that do not contain sulfur yield an apparently negative correlation with sulfur content. This could be due to the higher sensitivity of sulfur-containing compounds with (+) mode APPI detection. The negative correlation shown here could be the result of suppressed ionization when sulfur-containing compounds exist in large amounts in the sample. In addition, since a correlation

Fig. 4.9 A Circos diagram showing correlations with sulfur of oil components observed in (+) APPI FT-ICR mass spectra. Reprinted with permission from [4.56]. Copyright (2010) American Chemical Society

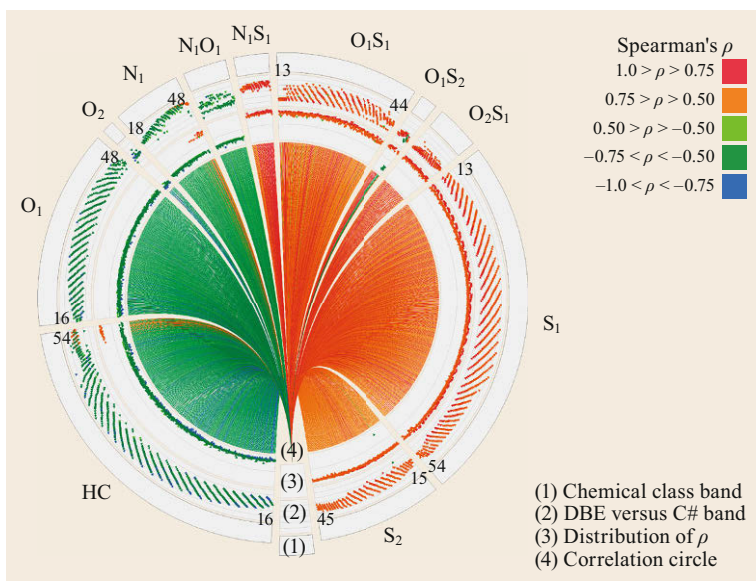

Fig. 4.10 Correlation with vanadium of oil components observed in (+) APPI FT-ICR mass spectra. Reprinted with permission from [4.56]. Copyright (2010) American Chemical Society

with SO class compounds showed DBE dependence, the SO compounds with relatively high DBE values had stronger correlation than those with lower DBE values in the *DBE versus C# band*. Hence, this result shows that information obtained from the ultrahigh-resolution mass spectra correlates well with sulfur contents of crude oils.

The vanadium contents were determined using the American Society for Testing and Materials (ASTM) method [4.78]. Figure 4.10 shows the correlations between peaks observed in (+) APPI mass spectra and the vanadium contents of the oil sample. A strong correlation between vanadium content and sulfur-containing compounds was observed. Clearly, the correlation diagram for vanadium content is very similar to Fig. 4.9 for sulfur-containing classes. This relationship has been previously reported [4.74]. The S_1 class compounds with relatively low DBE numbers presented stronger correlations with vanadium content in the *DBE versus C# band* of Fig. 4.8. The trend of a stronger correlation for lower DBE compounds was independent of C#. Table 4.4 presents the average DBE values of S_1 class compounds in two different ranges of Spearman coefficient values (ρ). The average DBE with a ρ value between 0.75 and 1.0 was computed to be 4, but those with a ρ value between 0.5 and 0.75 had an average DBE of about 11. It shows that S_1 class compounds with a lower degree of aromaticity and/or unsaturation were more strongly linked with vanadium content. Further studies are required to understand why this correlation exists.

Correlation with Total Acid Number (TAN). TAN values were commonly determined by titration [4.79],

Table 4.4 Average DBE values for S_1 class compounds in different ranges of ρ values

Spearman correlation coefficient (ρ)	$0.5 < \rho < 0.75$	$0.75 < \rho < 1.0$
Average DBE (\pm standard deviation)	4.0 (± 2.7)	10.8 (± 3.6)

which the oil industry uses to indicate the acidity of crude oils. The number is defined as the amount of KOH (in mg) needed to neutralize 1 g of crude oil. Since negative mode analysis is more suitable for acidic compounds, negative APPI spectra were used for the correlation with TAN as shown in Fig. 4.11. Strong correlations ($\rho > 0.5$) between TAN and O_2 and O_4 classes were observed. This is reasonable, since both naphthenic and aromatic acids contribute to the acidity of crude oils. The DBEs of the O_2 class correlated with the TAN widely from 1 to 17, with higher C# more strongly. The peaks in the O_4 class correlated positively with TAN at relatively low DBE values, 3–5. Hence, O_4 class compounds are likely to be dicarboxylic naphthenic acids. The DBE values ≥ 4 can also be aromatic.

4.1.4 Quantitative Comparisons by Statistical Analysis

Principle component analysis (PCA) for dimensionality reduction in multivariate analysis is useful to make grouped samples into score plots based on the molecular composition. Hierarchical clustering analysis (HCA) has been applied successfully to interpret complex petroleum mass spectra obtained by Fourier

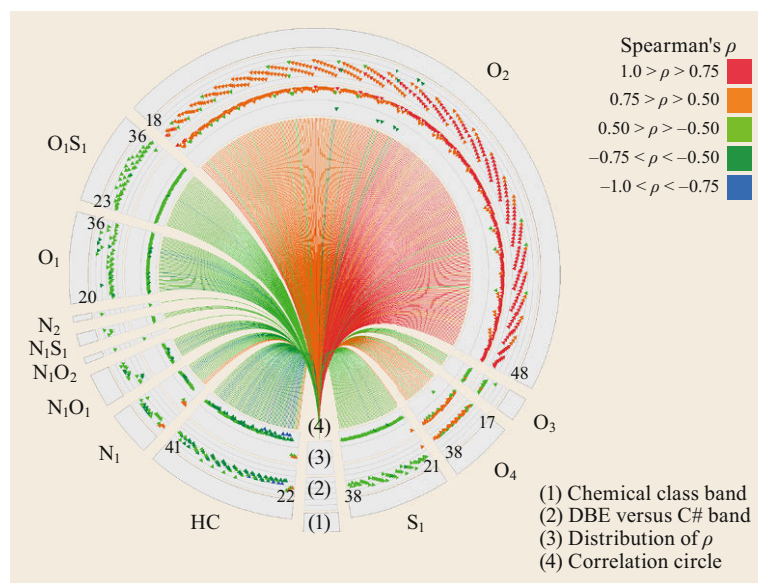

Fig. 4.11 Correlation with TAN of oil components observed in (–) APPI FT-ICR mass spectra. Reprinted with permission from [4.56]. Copyright (2010) American Chemical Society

Fig. 4.12 Quantitative changes on PCA scores with changes in ratios of samples A and B, created by mzCruiser software

transform ion cyclotron resonance mass spectrometry (FT-ICR MS). This method has been used to group and compare samples based on the selected peaks that had been grouped by PCA. However, PCA and HCA have not been combined with conventional visualization methods such as DBE versus C# plot and van Krevelen diagram. Also, they do not explain how much difference in abundance there is between heteroatom classes or samples by quantitative analysis.

This section demonstrates a quantitative analysis for comparing two petroleum samples by PCA and *t*-test. As an illustration, two crude oils (samples A and B from North Sea offshore reservoirs provided by SINTEF in Norway) were mixed in different ratios from 0 to 100% of sample A (or sample B) at 20% increments. The resulting six crude oil mixtures were measured by Witt and Timm [4.80] in replicate using APPI positive ion mode for the determination of composition ratios in simulated binary and even ternary crude oil mixtures [4.80].

The six mixtures are separated on the score plot shown in Fig. 4.12. Each mixture was separated and changed constantly on PC-1 as *x*-axis and PC-2 as *y*-axis according to the ratio of samples A and B. This shows that the quantitative change of sample A or B is identified by PCA. It also indicates how the abundance of peaks is changed according to the change of ratio of samples A and B by 20%, because the PCA has the strongest linear trend along the principal component with the highest variance on PC-1.

Volcano plots are utilized to identify the quantitative change of samples in detail. Such graphics are generated by plotting statistical significance, called *p*-value, on the *y*-axis, and the degree of changes, called fold change (FC or \log_2 FC), on the *x*-axis. The degree of change between two samples can be determined by the abundance ratio of chemical components observed in the spectra.

For the pooled *t*-test analysis, the degree of change is generally computed with the \log_2 scale because the abundance of compounds can vary by orders of magnitude [4.81] and it has been commonly used to present spectral data for statistical analysis [4.54, 55, 82]. One of the reasons for using \log_2 scale rather than \log_{10} scale is to increase dynamic range of graphical presentation or statistical interpretation. If x_i is the abundance of the *i*-th compound in the spectra repeated for n_0 times and if y_i is the abundance of the *i*-th compound in the spectra repeated for n_1 times, then \bar{x}_i and \bar{y}_i are defined as

$$\bar{x}_i = \frac{1}{n_0} \sum_{j=1}^{n_0} x_{ij} \quad \text{and} \quad \bar{y}_i = \frac{1}{n_1} \sum_{k=1}^{n_1} y_{ik} \quad (4.3)$$

Thus, the degree of change of the *i*-th compound, \log_2 FC_{*i*}, in \log_2 scale is computed by (4.4), and FC_{*i*} is calculated by (4.5)

$$\begin{aligned} \log_2 \text{FC}_i &= \log_2(\bar{y}_i) - \log_2(\bar{x}_i) \\ \text{or } \log_2 \text{FC}_i &= \log_2\left(\frac{\bar{y}_i}{\bar{x}_i}\right) \end{aligned} \quad (4.4)$$

Fig. 4.13 Volcano plots and quantitative changes in major classes (HC-R, S₁-R, HC, N₁-R, O₁-R, S₁, and N₁S₁). As the ratio of sample A increases, the positive and negative fold change changed constantly in major classes. Volcano plots were generated by mzCruiser software

$$FC_i = 2^{\log_2 FC_i} \tag{4.5}$$

For the hypothesis testing, null and alternative hypotheses are stated in the following (4.6)

$$H_0 : \mu_x = \mu_y, \quad H_a : \mu_x \neq \mu_y, \tag{4.6}$$

where μ_x and μ_y are the population mean of x and y respectively. In the hypothesis testing, it is always assumed that $\mu_x = \mu_y$, and the sampling distribution is examined on the basis of this assumption. Within this sampling distribution, one will determine whether or not a sample statistic is unusual. Here it can be assumed that population standard deviations σ_x and σ_y have the

same value, therefore the sample variances s_x^2 and s_y^2 can be pooled to obtain an estimate of the common population variance σ^2 . The pooled estimate of σ^2 is denoted by s_p^2 and is a weighted average of s_x^2 and s_y^2 . The standardized test statistic can be then calculated by the following equation

$$t_i = \frac{(\bar{y}_i - \bar{x}_i) - (\mu_{\bar{y}i} - \mu_{\bar{x}i})}{\sqrt{s_{p,i}^2 \left(\frac{1}{n_1} + \frac{1}{n_0} \right)}}, \tag{4.7}$$

where $s_{p,i}^2$ is the pooled sample variance of the i -th compound x_{ij} and y_{ik} in (4.3); each n_0 and n_1 is the number of x and y replicate spectra obtained from the same sam-

ple. Then, the significance level (p -value) presented in ordinate (typically the $-\log_{10}$ of the p -value) is calculated by the following (4.8)

$$p\text{-value} = 2 \text{Prob}(T > |t|), \quad (4.8)$$

where T is a random variable, t is the standardized test statistic obtained from (4.7) and Prob is the probability. As a consequence, chemical components with statistical significance are located in the upper part of the volcano plot. Positive/negative \log_2 FC (4.4) was used as the abscissa for representing the degree of change on the volcano plots. Each dot that represents a chemical component can be color coded by its heteroatom class, DBE, or other parameters. This approach can be very effective for finding unique biomarkers or specific compounds in the samples.

Volcano plots based on \log_2 scale have been used for analyzing biological data since 2003 [4.83] (e.g., microarray [4.83, 84] and metabolomics [4.85]). Fold changes are the preferred quantification parameter (or variable) of differential expressions, which are basically the ratios of the measurement of the same species between two samples. However, the ratios are not symmetric around 1, making it problematic to perform statistical analysis. Thus, we choose logarithms (e.g., \log_2) because logs of the ratios are symmetric around 0.

Figure 4.13 shows the volcano plots that illustrate the quantitative changes or degrees of difference in peak intensity ratios of various compound types (in color codes shown on top of the figure) when sample B is mixed with sample A. Each dot represents a component that is present in both samples to be compared. Sample B if compared to itself would have both p -value and fold change of 0 for unity ratios. The components in sample B (100% B) having more statistical significance in abundance than sample A and its mixtures are in left-hand side with negative fold change values. On the other hand, the components in sample A and its mixtures with sample B having more statistical significance in abundance are in the right-hand side with positive fold change values. When more sample A is added into sample B in the mixtures, both p -value and fold change will be increased in absolute values due to increasing difference in intensities between the pairs to be compared.

As the ratio of sample A increases, the positive/negative fold change was changed constantly in the major classes of HC-R, S₁-R, HC, N₁-R, O₁-R, S₁, and

Fig. 4.14 Average DBE distribution and quantitative changes in major heteroatom classes (HC-R, S₁-R, HC, N₁-R, O₁-R, S₁, and N₁S₁) among mixtures

Fig. 4.15 Average carbon number (C#) distribution and quantitative changes in major heteroatom classes (HC-R, S₁-R, HC, N₁-R, O₁-R, S₁, and N₁S₁) among mixtures

N₁S₁ that appeared in positive APPI spectra, where the classes with -R represent radical molecular ions ($M^{+\bullet}$) and the ones without -R represent protonated molecular ions (MH^+). Also, average DBE as shown by Fig. 4.14 increased linearly, and average carbon number (C#) as shown Fig. 4.15 decreased linearly. There are big differences between molecular ions and protonated molecular ions, such as S₁ and S₁-R, due to the difference in ionization processes. In summary, the t -test and volcano plot can be used to present quantitative changes in crude oil samples.

4.2 Emerging Technologies for Storing, Visualizing, and Processing Crude Oil Data

Several key technical challenges in crude oil studies have been discussed. Researchers in other -omics studies have been developing a variety of analytical approaches and techniques to understand life phenomena, such as DNA sequencing, by integrating all the information obtained from experiments including analytical results [4.86]. Those approaches can be utilized for oil analysis.

4.2.1 Development of a Data Analysis Platform with Mega Database

Various analytical platforms provide a wealth of metadata for samples. Development of new techniques for extracting information from the metadata for relationships between crude oil and its properties can further enlarge our understanding of crude oils. Sect. 4.1.3 showed, for example, the studies of correlations between FT-ICR MS peaks and crude oil properties [4.56]. Due to their practical importance, bulk properties are perhaps the most significant metadata for oil samples. Therefore, correlation studies between a significant number of crude oil samples and their metadata are important for oil research [4.87]. However, the amount of data from different analytical instruments is massive, and the amount of corresponding metadata (chemical-physical properties) is equally massive. Consequently, manual evaluation is impossible. But, an efficient software platform for this task has not been developed at this point. Hence, developing such a platform is of utmost importance.

The first step for the platform is to develop an appropriate database system. The database should contain data and metadata obtained from different analytical platforms, and it should be designed to integrate data with metadata. A categorized model of a database for data integration should be considered. This categorized model should be able to incorporate data and metadata from several different platforms. It would be helpful to explain the difference of metadata and actual data among platforms.

Even though some tools are commercially available in petroleomics, the integrated analysis software with database does not exist at this point. Ideally, tools can be combined with the database to store experimental data and their associated metadata. The tools should also include conventional visualization methods and statistical methods now being developed.

The integrated analysis tools that combine with database technology are expected to make significant contributions to oil studies.

4.2.2 Integration of Traditional Methods and Statistical Methods

There have been recent attempts to integrate traditional analysis approaches with statistical methods in petroleomics. Kendrick mass defect analysis, van Krevelen diagrams, H/C versus carbon number (C#) plots, and DBE versus carbon number (C#) plots have been used in crude oil analysis. Meanwhile, varieties of statistical analysis have been combined with the conventional visualization methods [4.88–90]. *Sleighter et al.* [4.89] used this approach to interpret the complex mixtures. In the study, groups of PCA variables from loading plots were selected and further analyzed by van Krevelen diagrams.

The two FT-ICR mass spectra obtained by NHMFL of the S_1 -R ions shown in Fig. 4.16 for Arab Heavy and NIST2717a are obviously different from visual inspection. However, the visual difference needs to be quantified digitally to display the difference in abundance ratios quantitatively, as exemplified by the volcano plot shown in Fig. 4.17 to compare the S_1 -R ions of these two oils.

In Fig. 4.17, the quantitative difference in abundance is presented as fold change in x -axis and the statistical significance is presented as p -value in y -axis. Each dot in Fig. 4.17 represents a S_1 class component that is present in both oils, with carbon number coded on the right-hand side of the figure. The S_1 components in Arab Heavy having higher statistical significance in abundance are located in left-hand side with negative $\log_2 FC$ values. Arab Heavy has higher probability to contain S_1 species of carbon numbers < 40 and > 60 . On the other hand, the S_1 components having higher statistical significance in abundance in NIST2717a are located in right-hand side with positive $\log_2 FC$ values, with most components in the carbon number range of 30–60. Hence, the statistical difference in compound abundances between the two oils can be easily discerned from the volcano plot.

The quantitative comparison (QC) plots for DBE versus C# and H/C versus S/C in van Krevelen diagram are shown in Figs. 4.18 and 4.19 respectively, which were presented by *Hur* at a petroleomics workshop of a Pacificchem conference in 2015 to integrate traditional analytical approaches with statistical methods [4.91].

To be more specific, in the DBE versus C# QC plot shown in Fig. 4.18, the negative fold change area in blue where S_1 -R class components of smaller carbon numbers (C# < 40 and DBE < 15) and larger carbon numbers (C# > 60 and DBE 5–25) in Arab Heavy are more

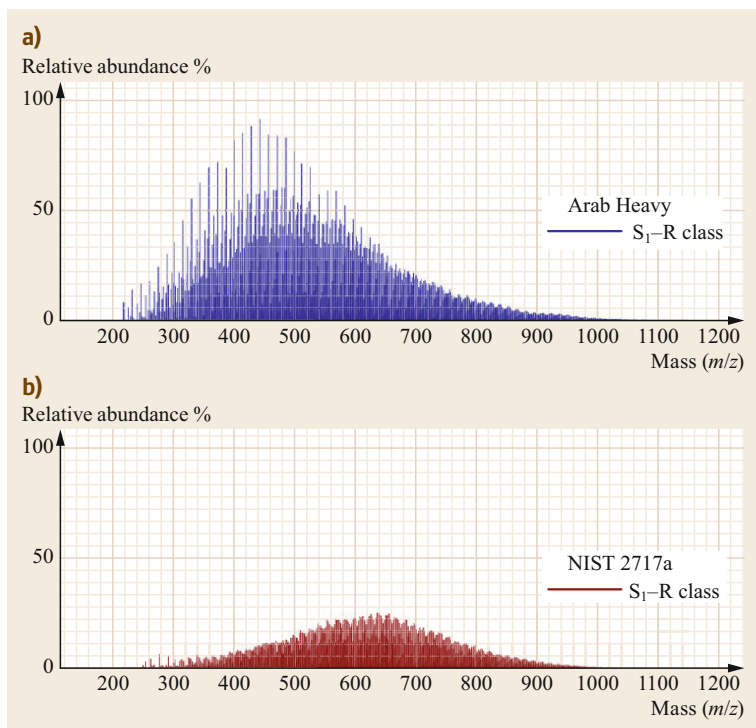

Fig. 4.16a,b Conventional comparison of two spectra of Arab Heavy (a) and NIST2717a (b) in S_1 -R class

Fig. 4.17 Comparison of two samples using a volcano plot in S_1 -R class, with carbon numbers (C#) indicated by colored dots. Arab Heavy oil has more low C# (< 40) and high C# (> 60) components in the S_1 -R class. Components in Arab Heavy oil have negative fold change values while those in NIST2717a, mostly in the C# range of 30 and 60 have positive fold change values

statistically abundant than in NIST2717a. On the other hand, the positive fold change area in yellow shows S_1 -R class components of larger DBE (DBE > 18) and carbon number between 30 and 60 are more statistically abundant in NIST2717a than in Arab Heavy. The gray area indicates not much difference between the two samples.

Similarly, Fig. 4.19 shows that aromatic sulfur compounds of H/C less than 1.3 with relatively low sulfur-to-carbon ratio are more abundant in NIST2717a. On the other hand, sulfur compounds with H/C > 1.5 are

more abundant in Arab Heavy than in NIST2717a. This indicates that the sulfur components in NIST2717a are more aromatic than those in Arab Heavy.

Thus, QC plots can assist in visual inspection and quantitative determination of the differences of crude oils in compound type and carbon number distributions. It is therefore highly recommended to integrate traditional analysis approaches with statistical models for information retrieval. Volcano plots and QC plots in the section will be further discussed in detail [4.92].

Fig. 4.18 A DBE versus C# QC plot in S₁-R class indicated by colored dots – fold change (\log_2 FC) from the volcano plot (Fig. 4.17). Blue indicates where S₁-R class compounds in Arab Heavy oil are more abundant than in NIST2717a. In the yellow area, S₁-R class compounds in NIST2717a are more abundant than in Arab Heavy. For S₁-R class compounds in gray between the blue and yellow areas, there is not much difference between oil samples

Fig. 4.19 A van Krevelen diagram QC plots in S₁-R class indicated by colored dots – fold change (\log_2 FC) from the volcano plot (Fig. 4.17). S₁-R class compounds in yellow represent higher fold change values for Arab Heavy oil. Conversely, S₁-R class compounds in blue reflect the higher fold change values for NIST2717a

4.2.3 Development of Tools with Enhanced Visual Discrimination

In crude oil analysis, investigators have been concentrating on using conventional methods combined with visual inspection/discrimination to extract significant features from analytical results. For large amounts of data and a large number of samples, statistical methods

have gradually been adopted. However, the development of tools with statistical methods requires visual discrimination, or color coding for heteroatom classes. Visual discrimination facilitates inspection of all the results from various analytical instruments. For example, when authors introduced the PCA technique [4.54] to analyze crude oil FT-ICR MS data, the PCA loading plot provides no significance, as shown in Fig. 4.20a.

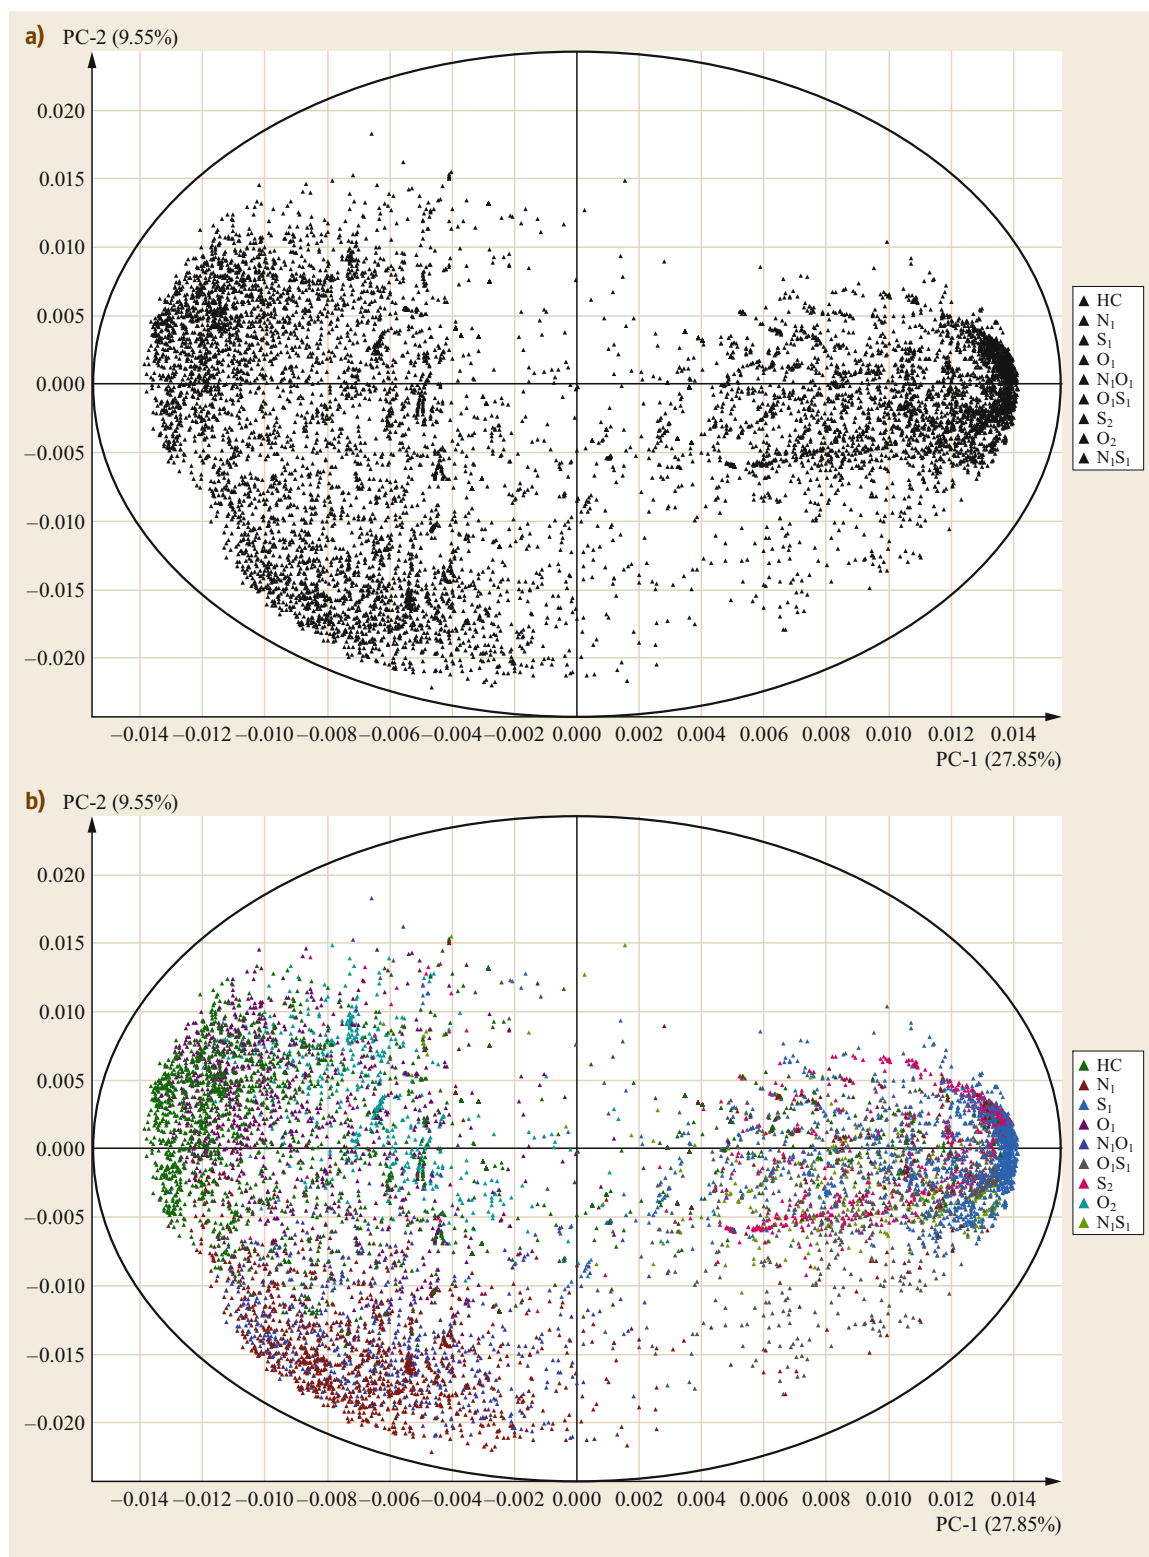

Fig. 4.20a,b Principal component analysis (PCA) plots – loading plot without a colored code (a) and loading plot with a colored code (b). Reprinted with permission from [4.55]. Copyright (2010) American Chemical Society

However, applying color coding to the loading plot for heteroatom classes reveals useful information, as shown in Fig. 4.20b. Therefore, when developing visualization tools for statistical methods, visual discrimination using colored codes should be actively adopted to enhance data interpretation information retrieval.

The tools for crude oil research should include dynamic data handling and visualization techniques to help researchers select areas of interest on the plots. A crude oil dataset could be much larger than the petroleomics dataset and others. Current petroleomics

has a lot of different visual diagnostic tools, which have played a significant role in petroleum research. However, the current tools for analyzing the data only generates static images. Researchers are hardly able to select data from the static images for comparing specific areas among oil samples. Also, it has been difficult to link the data on the conventional visualization with statistical results. Although tools are commercially available, researchers are not able to handle data freely across the existing data visualization programs. Such dynamic features are needed to be implemented for handling large datasets in crude oil studies.

4.3 Summary

Petroinformatics was defined at the beginning of this chapter and its components to be developed were discussed. Development of data interpretation methods, especially statistical approaches, is important for future petroinformatics development. In this regard, recent development and commercialization of PetroOrg [4.93] software, and highly interactive mzCruiser [4.87] software look very promising.

A software platform that can integrate data obtained from different analytical instruments among many samples is a very important step to achieve a more comprehensive understanding of crude oil, but quantitative analysis tools should also be combined with the software platform.

The next important step for *petroinformatics* is standardization of data and information. To achieve

this goal, we can learn from studies in other research fields. For example, there has been a lot of work devoted to the standardization of data and information in metabolomics [4.94–103], genomics [4.104], and proteomics [4.105–107]. Similar standardization is required in this field. Standardization helps to build a unified platform for a variety of devices and various researchers. It is also important to check reproducibility between data obtained from different laboratories. In addition, petroinformatics should have publicly available resources through cloud technology as a service (PaaS) [4.108]. The public resources should contain data from analytical instruments and metadata, including properties of a large number of crude oils in a wide variety of categories.

5. Separations in the Sample Preparation for Sulfur Compound Analysis

Jan T. Andersson

Analytical chemists have been interested in the sulfur compounds found in petroleum for over 100 years. They have developed an impressive array of methods for separating the sulfur compounds from the matrix and for separating the several functional groups from each other. These separations greatly aid in molecular characterization of these materials, which is of fundamental importance in areas such as desulfurization, catalyst development, geochemical studies, etc. Here, such methods are reviewed from the methodological perspective. Chemical transformations have a prominent place in this area and can reversibly or irreversibly change the compounds. Chromatographic separations are shown to have contributed greatly to our knowledge of the composition of

petroleum. Areas where current methods fail are also pointed out.

5.1 The Necessity of Sample Preparation

Crude oils are exceedingly complex mixtures of hydrocarbons and heteroatom-containing compounds and are the basis for a large number of commercial products made from them in refineries and the petrochemical industry. The majority of hydrocarbons do not cause any problems during refining or storage, with the possible exception of the most polar compounds, the so-called asphaltenes, and nonaromatic unsaturated hydrocarbons (olefins). The asphaltenes have low solubility because of their chemical structure and sometimes precipitate in boreholes or pipelines. Olefins are rarely present in crudes but are formed in cracking processes and show enhanced reactivity because of the double bond. On the other hand, compounds containing heteroatoms are frequently found to be involved in deleterious processes such as corrosion, fouling, and catalyst deactivation, and this forms the background to many studies into the heteroatom-containing compounds in petroleum with a view to gaining information on their identity, distribution into different fractions, ease of removal, etc. Especially the sulfur compounds have been

studied also by organic geochemists to obtain information about the sources of a crude [5.1], its source rocks, depositional environment, maturity [5.2], oil migration distances [5.3], etc. In environmental chemistry, sulfur aromatic compounds can be used as sources of information for different kinds of problems [5.4], including source apportionment of air pollution (e.g., gasoline versus diesel) [5.5]. Forensic analytical chemists use heterocyclic compounds to provide evidence on questions such as the source of an oil spill [5.6, 7].

Studies of heteroatom-containing petroleum components can involve group-type analysis, which allows a whole group of compounds to be lumped together, e.g., acids as characterized by the total acid number (TAN). A more detailed investigation is molecular characterization, which attempts to obtain information on selected subgroups of compounds, for instance how the alkyl carbon substituents in an aromatic nucleus are distributed in a particular aromatic compound or how, starting with a given ring structure, more complex molecules can be constructed through annealing

more rings to it. Finally, the most informative but at the same time most difficult characterization is that of identification of individual compounds. According to IUPAC, speciation analysis is *the analytical activities of identifying and/or measuring the quantities of one or more individual chemical species in a sample*. Here, we limit use of the term *speciation* to identification of individual compounds, i.e., their qualitative analysis. With respect to quantification, suffice it to say that the quantity of individual compounds is rarely sought in the petroleum area. Frequently, determining the sum of all compounds sharing a certain property such as acidity, nitrogen content, unsaturation, etc., independent of the exact chemical structure, is attempted.

The ultimate goal when trying to understand the composition of fossil material cannot be complete speciation – such an undertaking would be illusory. Even putting a number on how many compounds can be found in petroleum is pure guesswork, but for a distilled fraction (a middle distillate, boiling range 150–370 °C) this number has been estimated to be far above one million [5.8]. As the number of carbon atoms increases, the number of isomers increases exponentially: There are only 75 isomers of decane ($C_{10}H_{22}$), but no fewer than 366 319 are found for eicosane ($C_{20}H_{42}$), and 4 111 846 763 for triacontane ($C_{30}H_{62}$), compounds found in any crude oil [5.9]. It is doubtful whether any useful information would be gained by such complete speciation, even if it were possible. Certainly, one would not expect every single one of all these isomers to occur in petroleum (although many of them would). The complexity is so high that petroleum has been described as a *supercomplex mixture* [5.10], meaning that it cannot be entirely separated (down to the detection limit) using any one technique or combination of techniques. Despite this, separation science and, above all, mass spectrometry (which basically is a separation technique) have made tremendous progress in the last decades, so that even for supercomplex mixtures, a considerable amount of information on groups of compounds can be obtained.

It is tempting to imagine that sample preparation should play less of a role with the advent of high-resolution techniques such as Fourier-transform mass spectrometry and comprehensive GCxGC/MS. However, experience tells a different story, and proper sample preparation pays off handsomely also for such techniques, despite the extra work involved. Matrix effects leading to ion suppression [5.11] can be so severe that ions known to be present are not recorded [5.12]. The benefit of some sample preparation is nicely illustrated by a North American crude oil that displayed 7884 exact masses when analyzed without sample preparation

with atmospheric-pressure laser ionization and Fourier-transform ion cyclotron resonance mass spectrometry (FT-ICR MS) in positive mode [5.13]. After a simple fractionation on alumina into four fractions, namely saturates, aromatics, resins, and asphaltenes (see below), a total of 29 180 exact masses were counted, 3.7 times as many as before fractionation.

A similar experience was reported for the sulfur compounds in an analysis of a heavy gas oil [5.14]. A two-dimensional gas chromatographic system was used with a time-of-flight mass-selective detector. When the heavy oil was injected directly, without pretreatment, 9 sulfur compounds were recorded among the 7590 peaks detected. After isolation of the aromatic fraction on an alumina column, 135 peaks out of 8497 were assigned to sulfur compounds. Finally, after separation of the sulfur aromatic compounds from the hydrocarbons on a stationary phase containing Pd(II) ions (see below), the number of peaks for sulfur compounds increased to 317.

These results clearly show that, if detailed characterization of a petroleum sample is the goal, sample preparation that may involve several steps leads to much more information being obtainable. This is the perhaps surprising truth even today with the superior instruments available, as compared with the situation only 20 years ago, but it also shows that the analytical chemist with an intimate knowledge of both the instrumentation and the chemistry involved is not replaceable by expensive instruments.

Sample preparation for determination of the total amount of a hetero element in a petroleum is not covered here; a recent review gives information on this topic [5.15]. Rather, we deal with how to isolate sulfur compounds from the matrix of a petroleum sample and, in many instances, how to separate the sulfur compounds according to their functional groups. This step may turn out to be necessary because there are isomers also among the different classes of compounds. For instance, a sulfide containing three saturated rings is isomeric with alkylated thiophenes, etc. Mass spectrometry alone would thus not be able to tell the difference between the two compounds. With the sample preparations described in this chapter, detailed analysis of the sulfur compounds should be greatly facilitated.

5.1.1 Sulfur

The heteroatoms most prominently found in crude oil are sulfur, nitrogen, and oxygen, although many others occur in smaller amounts, including metals (present as salts or in complexes, not as *organometallic* com-

pounds – compounds that have a direct bond between the metal and a carbon atom – despite the frequent but erroneous use of this term in petroleum chemistry). Because of the noxious products formed on combustion of sulfur compounds, ultimately sulfuric acid, legislative efforts have mandated quite low sulfur limits in fuels today, in many countries 10 or 50 ppm ($\mu\text{g/g}$). This means that the sulfur content has to be lowered in the refinery from ca. 1–5% in most commercially important crudes, a factor of 1000. Another incentive to remove the element as far as possible is its affinity to many metals that are used as catalysts in refinery processes. Mainly noble metals are affected, leading to catalyst poisoning. For fuel cell applications, even lower sulfur limits are required [5.16]. This of course provides a strong incentive to reduce the concentration of the element as far as possible. Although a very large number of processes have been presented for removal of sulfur, hydrodesulfurization (HDS) dominates by far in industry. In a high-pressure hydrogen atmosphere, catalytic hydrogenation of the sulfur compounds takes place at a temperature around 350 °C, reducing the sulfur to hydrogen sulfide (as well as reducing many other functional groups in the crude, such as aromatic rings, ketones, phenols, etc.).

In petroleum, several kinds of sulfur functional group can be found, with quite different chemical and physical properties. The accepted view on the incorporation of sulfur in anoxic sediments into the organic precursors of petroleum invokes reduction of sulfate ions, originating in sea water, to reduced inorganic sulfur species that over time react with organic compounds [5.17]. Thiols can be formed, and in an intramolecular reaction these can form cyclic sulfides. If five-membered cyclic sulfides are dehydrogenated, a reaction that takes place during the maturation of the kerogen, a thiophene molecule arises. This may be subject to aromatic substitution, with the result that the

size of the aromatic system ultimately grows into polycyclic aromatic sulfur heterocycles (PASHs). Thus, the main sulfur species expected in petroleum are sulfides and thiophenes, accompanied by thiols, disulfides, and sulfoxides. Extensive alkylation of all these groups of compounds makes the total mixture of sulfur species extremely complex.

Different sulfur compounds show very different rates of hydrogenation. Thus thiols, disulfides, and sulfides are quite easily removed, but the aromatic sulfur compounds demand more severe conditions. Thiophenes and benzothiophenes (Fig. 5.1) are fairly easily hydrogenated, followed by ring systems containing four or more aromatic rings. The most difficult ones to desulfurize are the dibenzothiophenes (DBTs). Many studies on those DBTs that are particularly recalcitrant to HDS have shown that they possess alkyl groups in the positions closest to the sulfur atom, numbered 4 and 6. Speciation studies have revealed the identities of those DBTs that survive deep HDS [5.18].

Sample preparation involves all steps from sampling to ultimate analysis. In petroleum samples, most nitrogen compounds can be fairly easily separated from the matrix hydrocarbons based on their higher polarity. However, the carbon–sulfur bond is not polarized because the two elements have the same electronegativity, so that separation of sulfur compounds from hydrocarbons can be troublesome. Many efforts have been undertaken both to devise methods for separation of sulfur compounds from hydrocarbons (and other matrix components) as well as to separate sulfur compounds from each other based on their functional groups. It should be kept in mind that many compounds, especially in the heavier fractions of petroleum, can possess more than one heteroatom, such as two or three sulfur atoms. Furthermore, compounds with mixed heteroatoms such as N_1S_1 and N_1S_2 , are also well known. This contributes considerably to the difficulty of speciation.

5.2 Separation

Separation is needed to remove matrix components that interfere with qualitative and quantitative analysis of the compounds of interest. It is important to ensure that the ensemble of analytes is separated from the matrix as a group without losses; the selectivity in the separation step should be high versus matrix components but zero within the group of analytes. An early review discusses the techniques used in the 1980s [5.19], and a later one investigated separation methods for analysis of PASHs, especially in environmental samples that often are polluted by petroleum-derived material [5.20]. It should

not be overlooked that many reviews on petroleum analysis may be relevant to sulfur compound analysis even though they deal with general principles and not sulfur in particular [5.21, 22].

Many different approaches are reviewed here to show how analytical chemists have tried to use the chemical properties of their analytes for separation purposes. Although quite powerful techniques have resulted and are available today for routine use, it is still not possible to obtain clean class separations of all sulfur functional groups; For instance, disulfides remain

an unsolved problem, and no reliable separation principle exists for their analysis in fossil materials. This review also includes some methods described in fairly early works with the intention of illustrating that such approaches may stimulate thinking in new directions today when developing new sample preparation schemes. Some of these past attempts may be useful as a basis for continued method development in combination with modern analytical instrumentation – the field of sample preparation for heterocompounds in fossil materials is of basic importance and still a very fertile field for new work.

5.2.1 Chemical Methods

Chemical methods change an analyte through a – reversible or irreversible – reaction into a product that has more favorable properties for matrix separation than the analytes themselves do, thus enabling or at least facilitating sample preparation. Often this means making the analyte more polar so that it can be separated by chromatographic means from the unchanged matrix. Obviously, the chemistry should be as selective for, in this case, sulfur compounds as possible. The transformation leads to a product with quite different properties than the compounds had before; the matrix components retain their properties, enabling separation of the analytes from the matrix components in a subsequent step.

Oxidation

The sulfur atom is an obvious target for chemical transformations, since it is the chemical unit that distinguishes the analytes from the matrix components. Its reactivity allows for much chemistry to be carried out, and this has been used extensively in analytical chemistry. A scheme has been worked out for a visbroken naphtha that relies on selective oxidations of different sulfur-containing classes of compounds, namely thiols, sulfides, and thiophenes [5.23]. The thiols were oxidized to disulfides with iodine, and this increased their boiling point so much that in the gas chromatogram they appeared after the other sulfur species in the naphtha. The mercaptans and sulfides were oxidized with hydrogen peroxide in acetic acid to yield sulfonic acids and sulfones, respectively, which were removed by phase separation. The thiophenes were unreactive under these conditions and were easily analyzed by GC. The scheme was also applied to a jet fuel, and it was found that benzothiophene was lost to the extent of 16% [5.24]. It is well known that peracids (as formed by hydrogen peroxide in a carboxylic acid) oxidize condensed thiophenes to sulfones (see below), and although losses were ascribed to processing of

the solutions and considered to be of a physical nature, this oxidation requires more detailed investigation. The naphtha used was fairly low-boiling, meaning that the sulfur compounds are not too complex and reasonably soluble in the phase separation step. Higher-boiling materials are not likely to be amenable to this scheme.

Both sulfides and thiophenes can be selectively oxidized to either sulfoxides or sulfones (Fig. 5.2), but the course of the reaction is highly dependent on the oxidant and often on the reaction conditions to some extent. These products are considerably more polar than the original sulfur compounds, the sulfoxides more so than the sulfones, so that separation from nonoxidized compounds is easily carried out by using adsorption chromatography. The R_f values in thin-layer chromatography on silica were determined (unpublished) to be 0.71, 0.47, and 0.17 for dibenzothiophene, its sulfone, and its sulfoxide (benzene/acetone 9 : 1). In principle, the oxides should be analyzable without reduction to the starting compounds, e.g., by gas chromatography. However, the thermal stability differs appreciably between the two classes of compounds. Sulfones are stable and can easily be analyzed by GC, despite their polarity and often with better resolution than the nonoxidized compounds [5.25], but aromatic sulfoxides are commonly thermally degraded in the GC injector [5.26], although a scrupulously clean injection port liner can diminish this effect [5.27]. In an early work on identification of sulfur compounds in shale oils, the benzothiophenes were oxidized to the sulfones and the corresponding C_1 - and C_2 -isomers separated into individual compounds by either paper chromatography or preparative gas chromatography [5.28].

The two functional groups also differ in their ease of reduction. Sulfoxides are easily reduced back to the parent compounds, but the S=O bond in sulfones is much more stable and often resists reduction [5.29, 30]; other bonds in the molecule may be more reactive and be reduced, with the consequence that the identity of the analyte is lost. Unless the analytes can be analyzed as sulfones, this is a serious objection to

Fig. 5.2 Oxidation of organic sulfur compounds to sulfoxides and/or sulfones

use of oxidation to sulfones followed by reduction, as originally suggested for separation of condensed thiophenes [5.31].

Peracids. Peracids are well-known strong oxidants and form sulfones from sulfides and thiophenes when reacting in excess (as is done for an analytical sample). They can be produced in situ in an acid-catalyzed reaction from a carboxylic acid and hydrogen peroxide. In a work on the PASHs in shale oils and solvent-refined coals, the aliphatic sulfur compounds were first removed through liquid–liquid distribution between cyclohexane and dimethyl sulfoxide. Peracetic acid was then employed to oxidize the aromatic sulfur compounds to the corresponding sulfones [5.31]. The sample was boiled for 16 h in benzene solution with acetic acid and hydrogen peroxide. The sulfones were then separated by chromatography on silica gel, and the oxidized material reduced with LiAlH_4 . Criticism of this scheme centered on the oxidative changes to the matrix, which raised the suspicion that the analytes may also be changed (apart from sulfur oxidation), that the reduction back to the thiophenes is not clean, and that Diels–Alder condensation of the thiophene sulfones formed can take place, e.g., to yield benzonaphthothiophenes from benzothiophenes (Fig. 5.3) [5.30, 32]. The gas chromatogram of a test mixture of nine standard compounds showed little resemblance to that of the products from this procedure, so this procedure now seems obsolete.

A kinetic investigation showed that dibenzothiophene was completely converted to the sulfone after 65 min at 65 °C [5.33]. Despite some oxidation of dimethylphenanthrene, this reaction was judged more convenient than that involving *m*-chloroperbenzoic acid. The PASHs in a diesel (b.p. 190–360 °C) could be oxidized with or without preisolation of the aromatic fraction, and the products were analyzed qualitatively by reversed-phase LC with UV detection at 241 nm. The higher polarity of the sulfones than that of the unreacted hydrocarbons allowed them to elute so much earlier in the chromatogram that there was hardly any

Fig. 5.3 Formation of benzonaphtho[1,2-*b*]thiophene on oxidation of benzothiophene with hydrogen peroxide in acetic acid

overlap between the two classes of compound. It would seem that this procedure is amenable only to distilled materials; in a whole crude oil or in material with a larger boiling range, the smaller and more hydrophilic polycyclic aromatic hydrocarbons (PAHs) will elute together with the larger, more hydrophobic sulfones. The low resolution of traditional high-performance liquid chromatography (HPLC) will also not resolve all the compounds present, although it would be interesting to investigate such separation on modern sub-2 μm particles.

A milder reagent that avoids the harsh oxidation conditions and the byproducts and allows for a faster reaction is *m*-chloroperbenzoic acid (MCPBA). It has been said that the recovery of PAHs was somewhat lower than with peracetic acid while the removal of recovered MCPBA and the product *m*-chlorobenzoic acid made an additional step necessary [5.33]. This oxidation was also performed on crude oils to obtain the sulfones [5.34]. On collision-activated dissociation in a triple quadrupole mass spectrometer, sulfones from PASHs but not from aliphatic sulfones lost sulfur dioxide as a fragment of 64 Da, and recording ions showing this difference produced a mass spectrum of the condensed thiophenes in the crude.

Periodate. A selective reagent that oxidizes sulfides quite cleanly to sulfoxides is tetrabutylammonium periodate ($\text{Bu}_4\text{N}^+\text{IO}_4^-$), dissolved in a toluene/methanol mixture [5.35]. The method has been used for sulfides in asphalt; the sulfoxides were determined by IR spectroscopy [5.36]. The oxides of the sulfides produced in this way from heavy oils and bitumens from Alberta, Canada were removed on silica gel from the nonoxidized material that contained the condensed thiophenes. The sulfur aromatics in the latter fraction were separated from the hydrocarbons through oxidation with *m*-chloroperbenzoic acid to produce sulfones. Finally, after chromatographic removal of nonpolar material, the sulfones were reduced with lithium aluminum hydride to the thiophenes. It was noted that not all thiophenes were cleanly regenerated in this step [5.35]. It was not clarified how disulfides react in this scheme. A similar scheme was used for analyzing sulfur compounds in a high-sulfur Boscan aromatic immature asphaltene. This macromolecular material was pyrolyzed to obtain smaller fragments that could be analyzed by GC [5.37]. The sulfides were oxidized to sulfoxides by periodate, separated from the remaining material, and regenerated by treatment with LiAlH_4 . Then, the thiophenes were oxidized with MCPBA, separated, and reduced with LiAlH_4 . This process gave low recovery of sulfur compounds, no doubt to a great extent because of the reduction steps not being clean. A large signal for

1-methyldibenzothiophene indicated a low maturity of the asphaltene.

If the analysis step involves liquid introduction of the sample into a mass spectrometer, reduction of the sulfoxides is not necessary, as these are easily ionized in an electrospray ionization chamber to yield positive ions through proton [5.38] or, advantageously, lithium ion adduction [5.39]. It should be ensured that the material does not contain sulfoxides to start with, since the analysis would then not discriminate between sulfides and sulfoxides. MS reveals that the oxidation is not complete even after 72 h [5.38]. The most abundant sulfides in the saturates fraction of an Athabasca oilsand bitumen contained two or three rings.

Singlet Oxygen. Photochemically generated singlet oxygen has been shown to oxidize sulfides to the exclusion of the thiophenes in high yield [5.40], and this reaction was employed to petroleum sulfides [5.41]. Methanol was essential as solvent. The drawbacks are that the reaction required 4–5 days, some dark sticky material was formed, and the oxidation of the sulfides went to ca. 90% completion only. The sulfoxide fraction was separated on silica gel and subsequently reduced with lithium aluminum hydride, and the recovered sulfides analyzed by gas chromatography.

Oxone (Potassium Hydrogen Persulfate). Oxone is a powerful but not frequently used commercial oxidant for sulfur, consisting of KHSO_5 admixed with KHSO_4 and K_2SO_4 from the production process. It was used in isolation of terpenoid derivatives, hexahydrodibenzothiophenes, from a deeply desulfurized diesel [5.42]. Sulfones were formed from the sulfides as well as the PASHs, necessitating both normal- and reversed-phase liquid chromatographic steps for isolation. The thermal stability of the sulfones produced was utilized in GC-MS analysis that helped assign structures to the sulfur compounds. The same terpenoids were later isolated in a simpler procedure using ligand-exchange chromatography on Pd(II) (see Sect. 5.3.2, *Palladium Ions*).

Since new reagents for oxidation to sulfoxides are constantly being developed [5.43], it may make sense to investigate more recently developed reagents for the selective oxidations needed here.

Methylation

Because of the nucleophilicity of the sulfur atom, it can quite easily be methylated to give a methyl sulfonium (methyl thiophenium) ion. Such ions are frequently found in biochemical systems, and they are more stable than may appear at first sight. They are eas-

Fig. 5.4 Methylation of a sulfur compound with methyl iodide

ily formed on methylation with methyl iodide, aided by the presence of silver tetrafluoroborate. Silver iodide precipitates, facilitating the reaction (Fig. 5.4). Both sulfides and thiophenes react in this reaction, which is also used to ionize sulfur compounds for nuclear magnetic resonance (NMR) analysis [5.44], mass spectrometry, especially with electrospray ionization [5.45], and to impart electrophoretic mobility to PASHs for capillary electrophoretic analysis [5.46, 47]. The reaction is instantaneous, and there is no need to use an overnight [5.44] or 48 h reaction time as initially reported [5.45]. Although disulfides have been said to form similar ions with trimethyloxonium 2,4,6-trinitrobenzenesulfonate [5.48], experiments in the author's laboratory with commercial trimethyloxonium tetrafluoroborate failed to reproduce these results, and all disulfides were consistently recovered.

Methyl sulfonium ions are highly polar and precipitate in not too polar solvents such as dichloromethane, thus they can easily be separated from nonderivatized compounds by decantation. They are readily soluble in more polar solvents such as acetonitrile. After this separation, the sulfides and thiophenes can be recovered through demethylation with different nitrogen bases: 7-azaindole for the thiophenes, and 4-dimethylaminopyridine for the sulfides. This procedure was applied to a diesel and a vacuum gas oil [5.49] and crude oils [5.50]. Analysis of the separated sulfur compounds was done using both gas chromatography and mass spectrometry.

Reduction of Sulfides (Desulfurization)

The most drastic chemical procedure is surely complete removal of the sulfur atom. Sulfides can be desulfurized by treatment with nickel boride [5.50, 51], or Raney nickel [5.52] (Ra-Ni) in ethanol, and this reaction has been employed in studies of geochemical significance both to decompose large molecules into smaller ones that are amenable to GC analysis and to distinguish between different sulfide environments. The sulfides are recovered as hydrocarbons; naturally, it must be ensured that the hydrocarbons from the matrix do not interfere with the analysis of the hydrocarbons from this Ra-Ni reduction. The resins fraction of five crude

Fig. 5.5 Reduction with Ra-Ni of two sulfides

oils was treated in this manner, and the products analyzed by gas chromatography with flame ionization detection (GC-FID) [5.53]. *n*-Alkanes were the dominant products, mainly arising from reduction of cyclic sulfides (Fig. 5.5). They showed carbon numbers from 15 to ca. 44. Other important products were isoprenoid alkanes such as phytane, pristane, and norpristane, as well as tricyclic terpanes. Less dominant were *n*-alkylcyclohexanes, mid-chain methylalkanes, bicyclic terpanes, steranes, and hopanes.

Detailed information on cyclic terpenoid sulfides was obtained through desulfurization [5.41]. It turned out that the bicyclic and tetracyclic sulfides were reduced as expected, but that the tricyclic terpenoid sulfides resisted reduction unless forcing conditions were used. From these and other data, it was concluded that those tricyclic sulfides had the general structure shown in Fig. 5.6. This method has also been used to identify individual compounds in the hopane series [5.54] and of thiaindans (dihydrobenzothiophenes) in crude [5.55], showing how this sample preparation technique aids in speciation studies.

Thiols (mercaptans) are difficult to analyze due to the ease of their oxidation to disulfides. They can be added to electron-deficient olefins in a Michael addition, as is often done in bioanalytical work. Phenyl vinyl sulfone was recently introduced for thiols in crude oils and distilled fractions. Subsequent analysis of the resulting sulfones as sodium ion adducts was carried out by ESI FT-ICR MS [5.56].

5.2.2 Liquid-Liquid Extraction

Liquid-liquid extraction to separate sulfur compounds from hydrocarbons is not possible without using agents that selectively interact with the sulfur compounds. Sev-

Fig. 5.6 General structure of tricyclic terpenoid sulfides that are difficult to reduce with Ra-Ni (after [5.41])

eral kinds of Lewis acid have been used as such agents that can form a complex with the Lewis base sulfur (Fig. 5.7). This complex and the (noncomplexed) matrix should have very different distribution coefficients for the two phases, enabling their separation. It is important that the complex formation is reversible so that the sulfur compounds can be released for further analysis.

Protons

Protons from Brønsted acids can attach themselves onto the lone electron pairs of the sulfur atom in sulfides ($A^{n+} = H^+$ in Fig. 5.7). Dimethylsulfide has proton affinity similar to that of ketones such as acetone and esters such as methyl acetate [5.57]. This methodology has been used to separate both open-chain and cyclic sulfides from hydrocarbons in petroleum for nearly 100 years [5.58]. Shaking petroleum with strong sulfuric acid will protonate the sulfides, which then become soluble in the acid. In this way, they can be separated from the nonprotonated hydrocarbons. In a second step, the sulfuric acid is diluted with water, which reverses the protonation so that the sulfides can be extracted from the aqueous solution into an organic solvent. The final separation of individual low-molecular-weight sulfides has been done by repeated fractional distillation or through fractional crystallization of the sulfide complexes with mercuric chloride [5.59], which of course is possible only with a large sample. It is not clear whether higher-molecular-weight sulfides would be extractable in this way, since the hydrocarbon part of these molecules would tend to increase the solubility of the ion in the organic phase and thus prevent extraction into the sulfuric acid. This method has recently been used for extraction of 234 sulfides in jet A-1 fuel, which were analyzed by GC-MS; some thiophenes were likewise extracted [5.60]. The sulfides were cyclic in nature with carbon number between 6 and 14.

Fig. 5.7 Complexation/decomplexation of a sulfide with a Lewis acid (A^{n+})

Gasoline from fluid catalytic crackings was extracted with sulfuric acid with extraction efficiencies close to 100% for sulfides up to dipentylsulfide but very low efficiencies for mercaptans and thiophene [5.61]. However, thiophenes bearing several alkyl carbon atoms were efficiently extracted.

Hydroiodic acid dissolved in butane at -78°C has been used for the same purpose in crude oil analysis [5.55, 62].

Mercuric Ions

Lewis acids other than protons that have been employed for separation purposes are metal ions. It is expected that soft Lewis acids would interact better with the soft Lewis base sulfur, and indeed this seems to be the case. A set of metal ions of varying hardness was used in an attempt to extract sulfur compounds into complexing organic solvents, and the hard ones were shown to be less effective [5.63]. This was confirmed for the hard Lewis acid aluminum ion, which did not extract dibutyl sulfide to an appreciable extent [5.64]. The soft mercuric ions ($A^{n+} = \text{Hg}^{2+}$ in Fig. 5.7) were used to separate cyclic from dialkyl sulfides, the former complexes being more easily extractable into aqueous solution [5.65]. The sulfides were released through the action of hydrochloric acid on the mercuric complexes. Larger sulfides such as di-*n*-hexyl sulfide were not extractable. Mercuric acetate as complexing agent instead of the chloride led to complexes with higher aqueous solubility, so that also some larger sulfides were extractable [5.64]. A more detailed investigation of the influence of the counterions, cosolvents, release agent, time of extraction, etc. revealed that Na_2HgCl_4 worked well for the complexation with KCN and subsequent release of the sulfides from the complexes [5.66]. A peculiarity of the mercury(II) ion is its ability to form a direct C–Hg bond with aromatic compounds, particularly easily with thiophenes and benzothiophenes [5.67]. A serious objection to this scheme is the highly toxic nature of the salts of mercury,

which would seem to prevent this metal from being used in routine work.

In an early work, the $165\text{--}280^{\circ}\text{C}$ cut of a West Texas crude was treated with sulfuric acid to extract the sulfur compounds. When the extract was treated with aqueous mercuric chloride, the sulfides formed a paste-like complex, while the disulfides were found in the material that failed to form a complex [5.68]. This seems to be a rare example of separation between sulfides and disulfides, unfortunately involving toxic mercury salts.

Silver Ions

The silver ion looks like a good candidate for complexing sulfur atoms ($A^{n+} = \text{Ag}^+$ in Fig. 5.7), and its suitability for liquid–liquid extraction of sulfides has been investigated for standard substances [5.69]. Aliphatic and aromatic sulfides could be separated, albeit using a fairly elaborate extraction scheme, from unsaturated and aromatic hydrocarbons as well as from thiophenes and benzothiophenes. Silver nitrate extraction was employed to separate the sulfides in a shale oil, and they were found by gas chromatography to be alkylpentamethylene sulfides [5.70]. The sulfides were released from the complexes with ammonia. In view of the chromatographic separation of aromatic sulfur compounds on Ag^+ -modified phases (below), it is important to note that silver ions obviously do not interact with the sulfur atom in thiophenes, which is known to show lower Lewis basicity than the sulfur atom in sulfides. It has been found that many transition metals rather interact with the π -electrons of the benzo rings, e.g., in benzothiophenes, forming (η^6)-coordinated compounds [5.71].

A procedure in which sulfides and thiols in a naphtha were precipitated through treatment with a silver nitrate solution has been published [5.61]. The aromatic sulfur compounds were unaffected and could be analyzed by GC, free of interference from other classes of sulfur compound.

5.3 Chromatographic Methods

Chromatography is certainly the most important separation method used in analysis of petroleum, being used, in many variants, for both sample preparation and detailed analysis, including speciation. Here, we only consider chromatography in sample preparation. The stationary phases that have found use can be divided into those that separate the sample components with selectivity for sulfur and those that do not show this property. Both of these varieties are in very widespread

use and are treated here separately, beginning with such phases that are nonselective for sulfur.

5.3.1 Phases Nonselective for Sulfur

Silica and Alumina

The initial step in the sample preparation of crude oil and materials derived from it is very often a chromatographic separation of the components on a polar

stationary phase (silica, aluminum oxide) based on the ill-defined property known as polarity. SARA fractionation is widely used, leading to four fractions in order of ascending polarity:

- Saturates
- Aromatics
- Resins
- Asphaltenes.

The fractions are eluted using mobile phases of increasing solvent strength. It is important to realize that, in such systems, the compounds are not separated according to their functional groups but only based on the adsorptive strength of the whole molecule onto the stationary phase in the particular solvent used. Therefore, this fractionation does not deliver purified compound classes but mixtures of several compound classes of similar polarity. Aromatic sulfur compounds behave much like aromatic hydrocarbons and elute in the corresponding fractions, while sulfoxides are very polar and collect in the resins/asphaltenes fractions [5.72]. However, monoaromatic compounds can easily elute in the saturates fraction, especially if they are heavily substituted with alkyl groups. Thus, a series of terpenoid thiophenes were found in the saturates fraction from sulfur-rich Chinese oil samples [5.73].

Sulfides exhibit a more complex behavior. Experience shows that, although the C–S bond is not polarized (the electronegativity for carbon is 2.55 and for sulfur 2.58), sulfides do not as a class elute preferentially with the alkanes in the SARA fractionation, as might be expected, but are rather partially or fully distributed into the more polar aromatics and resins fractions [5.28, 41]. This occurs because of interactions of the free electron pairs on sulfur with the hydroxyl groups on the silica surface, as has been shown by IR spectrometry [5.74]. Such interactions between the analyte and the surface have been discussed for both silica and alumina [5.75]. Disulfides show smaller adsorption energies than sulfides [5.75]. This was shown in the separation of sulfur compounds in a fairly simple matrix, straight-run naphtha, on silica – the disulfides and most thiols were more weakly retained than the sulfides; both groups eluted with hexane:benzene, but with narrow cuts within the fraction, and the disulfides/thiols and sulfides could be separated [5.76].

The order of elution from silica gel has been given as [5.77]: aromatic hydrocarbons < thiophenes < alkanethiols < alkane disulfides < aromatic and cycloalkane thiols < alkane sulfides < cyclic sulfides.

Since nonaromatic sulfur compounds have been detected by mass spectrometry in the saturates, aromatics, and resins fractions of a heavy crude oil [5.78], a very basic question that arises is whether SARA fractiona-

tion is at all suitable for analysis of sulfur compounds or whether it would be more appropriate to develop a new separation scheme that is designed toward separating fossil material according to its sulfur functional groups.

Gel Permeation Chromatography

Gel permeation chromatography (GPC) is a technique in which the separation of the analytes depends on their hydrodynamic radius, with the consequence that larger molecules elute earlier than smaller ones. In the ideal case, the gel should not show any chemical interactions with the analytes, although in practice this is hard to avoid. In many cases, the gel is based on a mixed polymer of styrene and divinylbenzene and the aromatic groups can interact with aromatic rings in the analytes. It is desirable that the only role the gel should play is to provide pores that are used to sieve the molecules according to their size. Because of its low resolution, gel permeation (also called size-exclusion chromatography) has not been extensively used in sample preparation of materials derived from petroleum. Its main application has been for estimation of molecular weight distributions [5.79], but there is much debate about the accuracy of such data.

An early analysis involved GPC of an Alaska crude oil with detailed mass-spectrometric characterization [5.80]. A distilled fraction was subjected to a sample preparation scheme that started with an anion resin (removal of acids), a cation resin (removal of bases), treatment with ferric chloride (removal of neutral nitrogen compounds), and chromatography on silica + alumina to obtain the saturates, monoaromatics, diaromatics, and polyaromatics + polars fractions (with total consumption of 10 L of solvent in this latter step only). The final step was GPC (on a column with dimensions of 2.54 × 455 cm!) of the aromatic fractions, i. e., hydrocarbons and sulfur heterocycles, obtained from the normal-phase chromatography. A series of fractions were taken for offline MS analysis, and a large number of PASHs were detected with up to six aromatic rings. Benzothiophenes with 0–6 naphthene rings were detected in the diaromatic fraction. An alkyl chain carbon atom was found to contribute twice as much to the retention time in GPC as a carbon atom in a naphthene ring did, so that compounds of the same carbon number were separated to some degree.

The preisolated PASH fraction of a vacuum residue before and after hydrodesulfurization was separated by GPC followed by matrix-assisted laser desorption/ionization (MALDI) MS analysis [5.81]. It was verified that compounds of equal molecular weight but different degree of aromaticity showed strongly different retention times, depending on the mobile phase, as a result

of interactions with the polystyrene gel (Fig. 5.8). In the weaker solvent cyclohexane, the interactions were considerably stronger. Although narrow cuts were taken from the vacuum residue, the molecular weights within one cut differed by several 100 Da.

Although GPC has not been favored in sample preparation of fossil materials, modern phases allow sharper resolution than those used in earlier work. With careful attention to suppressing interactions between analytes and the gel and keeping in mind the possibility of association of analytes with each other (aggregation), the technique may find new uses in future work [5.82].

5.3.2 Phases Selective for Sulfur: Ligand-Exchange Chromatography

Some of the metal ions used in liquid-liquid extraction of sulfur compounds (Sect. 5.2.2) have also been deposited on a support material and used as stationary phases in liquid chromatography. A large range of metals have been evaluated for their interactions with different forms of sulfur compounds. Many of them have been studied with a view to complexing sulfur compounds and thus removing these from fossil fuels, as an alternative to hydrodesulfurization on a commercial scale. However, frequently only one or two sulfur compounds are used in such studies, so not enough data are available for estimating the usefulness of these methods for a general complexation scheme for analytical purposes. There are some metal ion systems that show selective properties for analytical separations and that can differentiate between sulfur and nonsulfur compounds, while others are useful for separating different kinds of sulfur functionalities. Since they all contain a metal ion of some kind, they are treated here according to the metal ion employed.

This form of chromatography is called ligand-exchange chromatography (LEC). A metal ion is incorporated into the stationary phase in liquid chromatography and used to form (reversible) complexes with sulfur compounds. The most frequent use involves such ions that allow the analytes to be eluted as groups of compounds that share some chemical feature. These groups are usually displaced by adding a component to the eluent that is strong enough to displace one group of compounds but weak enough to let other groups stay bonded. LEC has been called a *vital dimension for the reliable characterization of heterocycles in crude oils and refined products* [5.83].

In addition to sulfur compounds, nitrogen compounds also show strong interactions with these metal ions, and it would thus seem advisable to remove nitrogen compounds before separating the sulfur compounds. The nitrogen compounds will otherwise bind

to the metal and reduce its capacity for sulfur. Reconditioning of an LEC phase can be carried out by pumping a mobile phase with a strongly displacing eluent that does not elute the metal ions or by pumping a solution of the metal ion through the column [5.84].

LEC phases have received much attention also outside the petroleum area. Silver ions complex double bonds and thus can separate unsaturated from saturated compounds, e.g., fatty acids [5.85], and nickel ions are used in biochemical separations to separate proteins that have been tagged with the amino acid histidine, the so-called his-tag [5.86].

Mercuric Ions

Mercuric acetate deposited on silica gel is one of the very few systems that seem to allow a certain separation of sulfides and disulfides [5.87]. In thin-layer mode (TLC), a disulfide was more mobile than sulfides (and mercaptans) but exhibited considerable tailing. Dibenzothiophene and anthracene coeluted, indicating no particular interaction with a sulfur atom in a thiophene ring. By using two-dimensional TLC and scratching off the aromatic and sulfidic spots followed by extraction and GC-MS, series of alkyl thiophenols, alkyl hexahydrothiaindans, alkyl tetrahydrothiapyrans, and alkyl thiophenes were detected in a Kuwait crude oil.

A stationary phase containing 20% mercury(II) acetate deposited on silica was used to separate *n*-aliphatic sulfides [5.88]. They were not collected as a group but individually separated. Sulfides with carbon number up to ca. 18 could be efficiently separated from hydrocarbons; larger sulfides eluted with the hydrocarbons, as did the thiophenes. On the other hand, sulfides with carbon number below 10 were strongly adsorbed and could only be displaced as a group.

The ease of introducing Hg(II) into aromatic rings was the basis for the synthesis of a stationary phase containing mercuric ions bonded onto a phenyl group [5.89]. It was investigated for its selectivity towards sulfur aromatic compounds, but no such effect was seen [5.90]. However, it separated methyl-substituted aromatic compounds in the normal-phase mode very efficiently according to the number of methyl groups. Other sulfur compounds were not investigated.

Zinc Ions

Zinc(II) is a harder Lewis acid than mercury(II) and should therefore show weaker interactions with sulfur. Indeed, with a phase consisting of zinc chloride on silica, sulfides containing between two and six carbon atoms could be resolved while cyclic sulfides, being more nucleophilic than open-chain sulfides, were retained as strongly as a linear sulfide with two carbon atoms fewer [5.91].

Fig. 5.8 Two PASHs of nearly identical size but quite different retention time in gel permeation chromatography in dependence on the eluent in a cyclohexane-tetrahydrofuran system. Reprinted from [5.81] with permission from Taylor & Francis, LLC

Nickel Ions

In many Russian papers, chromatographic separation on silica containing 5% nickel chloride has been used to obtain separation of sulfur species [5.92, 93]. In the three fractions eluted with hexane, benzene, and ethanol-chloroform (1 : 1), most sulfur compounds were detected in the benzene fraction, but the separation was not clean. Longer-chain sulfides were recovered in the hexane fraction, probably because of their stronger interaction with the mobile phase.

Copper(II) Ions

Copper ions have been employed in LEC in various configurations. The simplest way is to deposit CuCl_2 on silica gel for column chromatography [5.94]. With hexane, a first fraction was obtained from a crude oil that contained hydrocarbons, but also a large proportion of disulfides that were weakly retained. Sulfides were eluted in a second fraction with chloroform-ethyl ether (9 : 1), but the recovery was not quantitative for a set of standard sulfides. Isomeric butyl sulfides showed different strengths of interactions with Cu(II) : the *t*-butyl isomer was most strongly retained, and the *n*-butyl isomer the least. It should be noticed that ketones also eluted in this fraction. Alkyl phenyl disulfides were found to be major aromatic sulfur compounds (apart from PASHs) in Wilmington crude.

An ion exchange resin, loaded with Cu(II) , showed excellent separation properties for sulfides in a model mixture [5.95]. Sulfides that are crowded around the sulfur atom exhibited weaker bonding to the phase. The phase was applied to the fractions obtained from a Wilmington crude oil (370–535 °C) on silica/alumina with pentane as mobile phase for the hydrocar-

Fig. 5.9a–d Ligands bonded onto a silica surface for complexation with Cu^{2+} . (a) N1, (b) N2, (c) X = OH: 8-quinolinol-silica, X = SH: 8-quinolinethiol-silica, (d) $n = 0$: N1-ACDA, $n = 1$: N2-ACDA, ACDA = amino-1-cyclopentene-1-dithiocarboxylic acid

bons and backwashing with pentane–ethyl ether for the sulfides. The monoaromatic fraction from the Cu(II) column showed no sulfides in the hydrocarbon fraction by MS; the sulfides were abundant in the sulfide fraction, dominated by three-ring cyclic sulfides. The diaromatic fraction was more complex, and an intermediate fraction between hydrocarbons and sulfides contained large amounts of diphenyldisulfides. The final sulfide fraction was a mixture of one- to six-ring cyclic sulfides, diphenyl disulfides, and some oxygenated species.

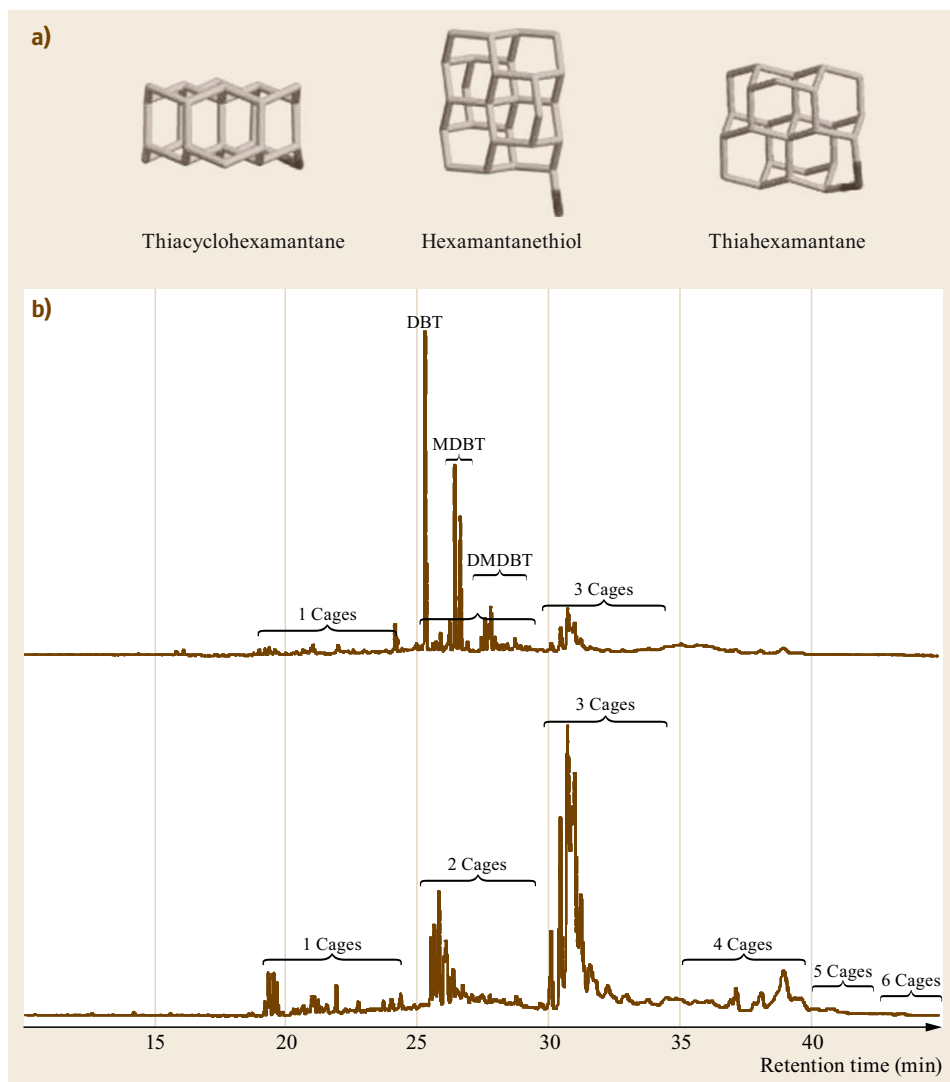

Fig. 5.10a,b GC trace with sulfur-selective detection of the (a) concentrated condensate, and (b) the third fraction from the chromatography on $\text{AgNO}_3/\text{silica}$. DBT: dibenzothiophene, MDBT: methyl dibenzothiophenes, DMDBT: C_2 -substituted dibenzothiophenes. One cage: thiaadamantanes and adamantane thiols; two cages: thiadamantanes and diamantane thiols; three cages: thiatriamantanes and triamantane thiols; four cages: thiatetramantanes and tetramantane thiols; five cages: thiapentamantanes and pentamantane thiols; six cages: thiahexamantanes, thiacyclohexamantane, and hexamantane thiols. The *black spots* in the structures indicate the sulfur atom (after [5.96], with permission from Elsevier)

A drawback with phases based on ion exchange is that their capacity is often fairly low, and thus the separation may not be optimal. A solution to this is to bind a ligand to a silica surface and form metal complexes with it, allowing considerably higher metal ion loading. A comparison of seven such ligands (Fig. 5.9) with Cu^{2+} as the metal ion showed that the N1-ACDA complex was superior to the others and that individual

sulfides could be separated in the normal-phase mode, with the smaller sulfides more strongly retained and the hydrocarbons much less strongly retained [5.97]. However, no petroleum sample was applied to these phases. Thiophenes were retained to the same extent as hydrocarbons, both on CuSO_4 deposited on silica in open column chromatography [5.98] and on CuCl_2 -impregnated silica in thin-layer chromatography [5.99];

Fig. 5.11 Silver ions bonded onto silica through a mercapto group

in the latter case, sulfides displayed considerably lower R_f values on the impregnated than on the bare silica phase.

Silver Ions

Silver is also considered to be a soft Lewis acid, but there seems to be no selective interaction between the sulfur atom in aromatic compounds and silver metal in nanoclusters [5.100] or silver ions in the form of silver nitrate deposited on silica [5.101]. The retention coefficients in liquid chromatography were very similar for PAHs and PASHs. Thus, phenanthrene had a k value of 5.9 and dibenzothiophene 6.7. Sulfides in crude oils from a carbonate reservoir, however, interacted more strongly with AgNO_3 deposited on silica [5.102]. Hydrocarbons eluted with ethyl acetate, and the sulfides were displaced with diethyl sulfide in chloroform. A high abundance of polycyclic sulfides was indicated by GC-MS. Similar results were obtained with a middle distillate; here, the sulfide fraction could be collected using methanol/diethyl ether (1 : 1) from AgNO_3 deposited on alumina [5.103].

A similar system was used for isolating the thia-diamondoids from a gas condensate produced from a deep reservoir in the Gulf of Mexico [5.96]. The column was eluted with hexane (saturates fraction), dichloromethane (aromatics including PASHs), and acetone (organic sulfur compounds except the PASHs). Subsequent analysis by GC and sulfur-selective detection gave the chromatograms illustrated in Fig. 5.10. The top trace shows the fraction before the chromatography on the AgNO_3 column, the bottom one after, with the PASHs removed. Sulfides with up to six cages were indicated ($\text{C}_{25}\text{H}_{28}\text{S}$).

However, silver ions can also be bonded onto silica through a spacer containing a thiol group, in the simplest case mercaptopropyl (Fig. 5.11).

Ag^+ in this form shows quite useful interactions with the π electron cloud in aromatic compounds, which is considered to be a soft Lewis base. Indeed, many complexes of transition metals with benzothiophene have been described that contain an η^6 -BT ligand in which the heterocycle is bonded through the benzene π electron system to the metal ion [5.104]. This was utilized to separate the PASHs in Wilmington crude oil according to the size of the aromatic

system [5.105]. Compounds containing one, two, and three benzo rings (in addition to the thiophene ring) were very well separated, including the alkylated and naphtheno ring substituted aromatics (Fig. 5.12). It was shown mass spectrometrically that the PASH systems benzothiophene and dibenzothiophene are accompanied by derivatives containing up to five naphtheno rings.

Contrary results have been reported for the same silver system as in Fig. 5.11 [5.106]. Polycyclic aromatic sulfur heterocycles in a heavy gas oil could be separated from the PAHs, using a more polar solvent for the former, and then analyzed by GC \times GC-TOF MS.

Palladium Ions

A commonly used way to separate PASHs from PAHs and sulfides is LEC on a phase containing Pd(II) ions. Hydrocarbons do not interact with the metal ions and are eluted with cyclohexane, the PASHs show a medium bond strength, so that they can be easily eluted with a moderately strong eluent such as dichloromethane, and sulfides bind quite strongly and must be displaced with an agent that binds more tightly than the analytes. This technique has been widely applied to samples of varying origin and composition.

The simplest system involves depositing 5% PdCl_2 on silica [5.99], and this was used for isolating the PASHs from the preisolated aromatic fraction of a catalytically cracked petroleum bottom [5.107] and a catalytically cracked vacuum residue [5.108]. The PASHs eluted as a complex with PdCl_2 , and this complex needed to be destroyed in a separate step, e.g., with diethylamine. A closer study showed that many benzothiophenes as well as PASHs with a terminal thiophene ring are lost because they elute together with the hydrocarbons due to weak interactions with the Pd(II) [5.101, 109]. The decomplexation could be conveniently carried out online by incorporating some aminopropyl silica in the column [5.101, 109]. The procedure has been used for analysis of PASHs in samples such as a vacuum gas oil [5.110], a shale oil [5.111], and a diesel [5.112]. Sulfur compounds other than PASHs were isolated with this system, and three fractions were taken from a crude oil, a coal extract, and a hydrogenated coal liquid [5.113]. One PAH and one PASH fraction were collected, and a sulfur-containing polycyclic aromatic compound (S-PAC) fraction that contained sulfides. However, several compounds in a solution of standards were partially lost, and some compounds eluted in two fractions. A correlation between the elution behavior and the Hückel π electron densities of several thiophene benzologs was demonstrated.

To prevent elution of the palladium complex with the analytes, the Pd(II) ions can be incorporated into

Fig. 5.12 Separation of a standard PASH mixture and a PASH fraction of Wilmington crude on a silver(I)-mercaptopropano silica gel stationary phase (250 × 4.6 mm). Conditions: mobile phase cyclohexane/isopropanol step gradient elution, 2.5 mL/min, room temperature, UV detection at 254 nm (after [5.105], with permission from Elsevier)

a complex that is bonded onto the silica surface. First successful attempts for isolation of PASHs [5.114] from middle distillates [5.115] and vacuum residues [5.45] were recorded for ACDA complexes (Fig. 5.9d, $n = 0$). With this isolation and through comparison with synthesized reference compounds, it was possible to identify the structures of 11 alkylidibenzothiophenes that were recalcitrant to deep hydrodesulfurization [5.18]. However, this ligand must be synthesized in the analytical laboratory, and thus there is some resistance to its use. A convenient alternative is offered by the simpler mercaptopropyl ligands that are bonded to the silica (MPSG, mercaptopropyl silica gel, Fig. 5.11 with Pd^{2+} instead of Ag^+); such phases are commercially available and need only to be treated with a solution of a palladium salt. As a stationary phase, it seems to have essentially the same separation properties as the Pd-ACDA complex and has been used extensively to isolate both a PASH fraction and, less commonly, a sulfide fraction. Although simple thiophenes are not retained and elute with the hydrocarbons [5.83, 114], this is not of great importance in many applications because such thiophenes are not present in relevant amounts.

Sample preparation using Pd-MPSG has been shown to greatly facilitate analysis of sulfur compounds in petroleum-related samples. In a comprehensive two-dimensional gas chromatographic study of heavy gas oils, 317 sulfur compounds were detected following this separation, but only 135 without it [5.14]. PASHs with two to five aromatic rings were recorded, as well as some hydrogenated PASHs.

A high-boiling Iranian vacuum gas oil (390–460 °C) was analyzed by atmospheric-pressure laser ionization (APLI) FT-ICR MS following separation of the PASHs on Pd-MPSG [5.117]. With atmospheric-pressure photoionization, a large number of OS and O_2S species were detected that were not found with APLI or electrospray ionization. Proper sample preparation removes sulfones and sulfoxides, so that the presence of such compounds in the mass spectrum is not necessarily an indication of their presence in the sample but probably of oxygenation in the instrument. However, it has been found that sulfides can oxidize to their sulfoxides also during sample separation [5.118]. On the whole, sample preparation should help avoid false assignments based only on mass-spectral data.

An example for the collection of a sulfide fraction from chromatography on a Pd complex is the elucidation of the structures of sulfides in a heating oil that are recalcitrant to deep hydrodesulfurization to 16 ppm S [5.116]. These compounds had the structures shown in the gas chromatogram in Fig. 5.13. The fraction shown was collected after removal of the hydrocarbons (fraction 1) and PASHs (fraction 2) with an eluent containing a 2 : 1 mixture of cyclohexane:dichloromethane with 1.5% ammonia-saturated isopropanol. The ammonia was needed to displace the strongly bonded sulfides from the complex with Pd^{2+} . The same separation technique was used to separate the sulfides from a crude oil. FT-ICR MS indicated double bond equivalents from 1 to 12. Obviously, this procedure is more convenient than the oxidation followed by several chro-

Fig. 5.13 Gas chromatogram with sulfur-selective atomic emission detection (AED) of the recalcitrant sulfides in a deeply hydrodesulfurized heating oil. This fraction was collected as fraction 3 from a Pd–MPSG column (after [5.116], Copyright 2009 American Chemical Society)

matographic steps as described above for the same compounds (Sect. 5.2.1, *Oxone (Potassium Hydrogen Persulfate)*) [5.42].

Quite a number of publications on various materials have now reported use of Pd(II) for separation. Heavy

oil [5.119], straight run diesel [5.120], Saudi Arabian heavy crude oil and its distilled fractions [5.83], residue fluid catalytic cracking diesel [5.121], coal tar [5.122], and vacuum gas oils [5.10, 123] are among the high-lights.

5.4 Conclusion

A large variety of separation methods have been presented here as applied to sulfur-containing compounds in fossil materials. Despite the very many approaches, it becomes clear that there is still much work left before sample preparation for molecular characterization of such compounds can be considered sophisticated enough to allow isolation of any desired functional group. Not even the first step in sample preparation, i. e., SARA fractionation, allows one functional group to elute cleanly in one fraction; such a result should be the goal of any initial separation. Here lies a vast land of useful discoveries to be made.

The next step in an analysis would often be separation of hydrocarbons from the sulfur compounds in such a fraction. Many of the techniques described

here approach this topic, but none are fully satisfactory. The oxidation/reduction schemes are laborious and not easy to automate, and the ligand-exchange chromatography methods suffer from some loss of analytes by too early breakthrough, as well as from binding some compounds so strongly that their removal presents problems. A displacer may be necessary for such compounds, which in turn binds so strongly that it may be impossible to regenerate the phase for another separation, necessitating the use of a fresh column for each application. Stationary phases based on noble metals such as palladium can be an expensive drawback for routine work.

One extension of any separation method would be to compounds containing mixed heteroatoms, presenting its own problems. Even if only heterocyclic compounds

are considered, this will be a challenge of its own. In all schemes, the mixed heterocycles would be expected to be distributed into the fraction of the *strongest* heteroatom, for instance OS compounds into the S fraction and NS compounds into the N fraction. To characterize these compounds in further depth than is possible by recording the molecular mass in MS, further separa-

tions would be needed that build on the presence of the other heteroatoms.

Despite these lacunae, it is impressive to see how far separations have come. The improvement in the analytical data with proper sample preparation provides strong motivation to continue such work and improve on current methods.

Asphaltenes

6. Asphaltenes

Oliver C. Mullins, Andrew E. Pomerantz, A. Ballard Andrews, Rudraksha Dutta Majumdar, Paul Hazendonk, Yosadara Ruiz-Morales, Lamia Goual, Richard N. Zare

Asphaltenes are the most enigmatic component of crude oil, and resolution of fundamentals such as asphaltene molecular weight and predominant molecular architecture has been required for the field to advance. Application of many sophisticated analytical methods to asphaltenes has recently given rise to a broad understanding. This chapter reviews many of the most important and recent studies of asphaltene molecular and nanocolloidal structures that have been codified in the Yen–Mullins model. Broad consistency across wide-ranging disciplines has been achieved, yielding robust interpretations. The result that a simple nanoscience model applies to chemically diverse asphaltenes is placed within the context of related similar findings of the gas and liquid components of crude oil. Implications are discussed for thermodynamic modeling of asphaltenes that are specifically treated in the next chapter. In addition to describing measurements of average molecular parameters, this chapter deals with the characterization of the width of certain asphaltene distributions, including molecular weight and the range of asphaltene polycyclic aromatic hydrocarbons (PAHs). The unique role of the asphaltene PAHs in intermolecular interaction is discussed within the context of structure–function relations, for example, for interfacial properties. With these advances, the concept of petroleomics, predictive petroleum science, is realized, even for the most complex fraction of petroleum.

6.1 Overview of Asphaltenes

Asphaltenes have long been the most enigmatic component of crude oil [6.1–3]. Almost every chemical and physical property of asphaltenes has been the subject of debate, spanning at least one order of magnitude except, mercifully, their elemental composition. For example, the debate regarding asphaltene molecular weight persisted for decades with published reports varying by two or more orders of magnitude [6.4]. Fortunately, this particular debate is settled. There is seemingly a paradox in asphaltene science; asphaltenes constitute a class of compounds with very broad ranges in molecular attributes such as molecular weight, size of polycyclic aromatic hydrocarbon (PAH), variability in heteroatom content, variable alkane type, etc. Nevertheless, there is substantial convergence of diverse studies resolving a wide variety of asphaltene molecular and colloidal properties. A very simple model of asphaltenes has emerged, the Yen–Mullins model, which accounts for the predominant molecular and colloidal structures of asphaltenes. The chemical polydispersity of asphaltenes is expected; the adherence of asphaltenes to a simple model is a positive surprise. Indeed, the overall uniformity of character for virgin (or chemically unaltered) crude oil asphaltenes is shown within this overarching construct. The current risk of misunderstanding asphaltenes is to overlook and underappreciate the overall simplicity of asphaltenes when investigating wide ranging attributes within this class of compounds.

To understand this paradox of tremendous polydispersity yet simplicity of asphaltenes, it is very instructive to consider the gas and liquid components of crude oil. With these compounds, there also exists huge chemical polydispersity. Advanced analytical methods such as two-dimensional gas chromatography (GC×GC) elucidate the complexity of the liquid phase of crude oils very clearly [6.5–7]. Nevertheless, many thermodynamic properties of live crude oil (containing the associated gas phase as in oil reservoirs) are very amenable to cubic equations of state, the simplest cubic equation of state (EoS) being the van der Waals EoS. The primary reason that a simple theoretical formalism is effective for a polydisperse chemical mixture, such as live crude oils, is that the corresponding dominant components, hydrocarbons, are nearly ideal. Moreover, there is largely a continuum of the chemical composition that obviates concerns of idiosyncratic behavior of specific components. The intermolecular interactions of alkanes are weak (per unit carbon) and the chemical population is a continuum; thus, simple mixing rules and *lumping* approaches work in the application of theory for this complex mixture.

For asphaltenes, the strength of interaction is certainly greater than that for alkanes. Nevertheless, the predominant intermolecular interaction for bulk asphaltenes is via dispersion forces, not hydrogen bonding and not polarity. Thus, although asphaltenes are not ideal (they do form nanocolloidal structures in oil), this intermediate strength of interaction does not preclude simple formalisms on its own. The important consideration is not whether asphaltenes are close to ideal, but whether they have moderate, simple intermolecular interactions on average, and whether they exhibit systematic behavior. In addition, asphaltenes also contain a chemical continuum similar to the alkanes. Moreover, for important applications such as understanding asphaltene gradients in reservoir fluids, simple polymer theory modified with a gravity term can be very useful. Naturally, the gravity term requires a (colloidal) size of the asphaltene particle. The asphaltenes have a predominant molecular architecture, which gives rise to a relatively well-defined nanoaggregate. In turn, with an increase in asphaltene concentration, these nanoaggregates can form clusters, again of relatively well-defined size. Consequently, asphaltenes are amenable to a simple molecular and colloidal construct, the Yen–Mullins model [6.8,9] which can then be used in a modified polymer theory, the Flory–Huggins–Zuo (FHZ) EoS [6.10–12] to treat asphaltene concentration gradients in reservoir crude oils. In addition, the Yen–Mullins model coupled with the Langmuir EoS has found significant utility associated with oil–water interfacial characterization [6.13–15]. This capability in the more demanding arena of interfacial science lends credence to the related formalisms applied to bulk crude oil.

In this chapter, simple, yet accurate descriptions of asphaltenes are emphasized, with congruence from diverse investigative studies. Consideration is given to the strength of intermolecular interactions of asphaltenes. A variety of bulk measurements associated with molecular and colloidal structures are discussed. Emphasis is placed on a variety of nuclear magnetic resonance (NMR) measurements. Laser mass spectrometry especially with unimolecular decomposition studies of asphaltenes is also considered and contrasted with bulk decomposition. A variety of other approaches from x-ray and neutron scattering to high-Q ultrasonics and direct current (DC) conductivity are also considered. Results for petroleum asphaltenes are compared with coal-derived asphaltenes as a means to understand structure–function relations in both types of asphaltenes. Important thermodynamic implications

associated with these simplifying ideas of asphaltenes are reviewed especially within the context of novel

applications associated with oilfield reservoir evaluation.

6.2 Reservoir Crude Oils

Reservoir crude oils consist of dissolved gases, liquids and dissolved solids, called as asphaltenes (Fig. 6.1). Although many carbonaceous materials contain an asphaltene fraction, it is for crude oils that asphaltenes are fundamental and key. Asphaltenes are defined by a chemical operational definition because (1) there had been such confusion about their chemical properties and (2) they remain a polydisperse class with many constituents. Consequently, any definition of asphaltenes delineating a chemical identity was precluded. Asphaltenes are defined by their solubility characteristics; typically, they are defined as the fraction of crude oil (or carbonaceous material) that is toluene soluble and *n*-heptane insoluble. This definition might seem arbitrary but it is not; this solubility fraction captures the heaviest, aromatic component of crude oil and largely captures the fraction of crude oil that is self-assembled in nanocolloidal particles under both reservoir and laboratory conditions. Also, this definition largely captures the fraction of crude oil that is (nonwax) solid.

It is instructive to consider the liquid and gas fractions of crude oil in order to guide thinking about asphaltenes. Analytic methods for gas analysis are well developed and accurate. For most gas phase components, gas chromatography (GC) yields reliable and unambiguous analyses [6.5, 16]. For reactive gases such as H₂S, Hg, and, to a lesser extent, CO₂, preservation of the sample from acquisition in the borehole to well site or laboratory represents a major challenge. In situ downhole fluid analysis in oil wells is a well-developed discipline [6.17] and is being extended to include labile crude oil components. The gas phase components of crude oils can consist of both hydrocarbon gases and nonhydrocarbon gases, including CO₂, H₂S, N₂ and to

a much lesser extent, Hg, and He (predominantly from α decay). The ratio of methane to other hydrocarbon gases depends explicitly on the origin of these gases, whether thermogenic or biogenic.

The liquid fraction of crude oils typically contains a very large number of components. Although methods such as gas chromatography-mass spectrometry (GC-MS), in principle, can be used to identify specific components unambiguously [6.6], the very large number of liquid components in crude oils precludes indiscriminant GC-MS application. For specific purposes, such as biomarker analysis, GC-MS has been very useful [6.18–20]. Comprehensive two-dimensional gas chromatography (GC×GC) is a powerful analytical tool for crude oil analysis [6.7]. In this method, two GC columns are used sequentially that perform separation based on different chemical attributes, such as volatility for the first column and polarizability for the second column. Each analyte in the sample is then characterized by two retention times, thereby, greatly expanding resolution. Although there are still many overlapping peaks in GC×GC, different chemical classes are much better resolved than in traditional GC and, in many cases, GC×GC achieves individual chemical resolution. Use of GC×GC-MS enables molecular structural characterization of many of the peaks in the GC×GC chromatogram. Figure 6.2 shows a typical GC×GC for a complex crude oil [6.21]. GC×GC provides much chemical specificity for crude oil composition of the liquid fraction of crude oil. The vision of petroleomics is to establish predictive petroleum science based on the composition of crude oil [6.1, 22]. This goal requires chemical resolution of the dominant components of any crude oil; GC×GC is an integral step in this process. As asphaltenes do not traverse GC columns, they cannot be analyzed by this method.

Figure 6.2 has been used to analyze the complex processes that have acted to give rise to this Colombian crude oil. The Llanos basin, east of the Andes Cordillera in Colombia, is known to have one of the more active aquifers on the planet. For certain fields in the Llanos basin, the putative claim is made that *production goes up when it rains*. The same conditions that form the Amazon river, the largest on Earth in terms of volumetric flow, also produce a large flux of water through aquifers adjacent to oil reservoirs in

Fig. 6.1 Reservoir crude oils generally consist of dissolved gases, liquids, and dissolved (or nanocolloidally suspended) solids, called asphaltenes

Fig. 6.2 GC×GC chromatogram of a Colombia crude oil. This chemical specificity enables identification of the complex processes that have acted on this reservoir crude oil including water washing (the lack of naphthalene), biodegradation (dominance of 25-norhopanes in the biomarker region), and multiple charging (presence of *n*-alkanes along with 25-norhopanes). Reprinted with permission from [6.21]. Copyright 2015 American Chemical Society

the Llanos basin. Figure 6.2 shows depletion of naphthalene as well as other water soluble components from this oil, which has been ascribed to water washing [6.21]. In addition, the dominance of 25-norhopanes over the hopanes in this oil shows that the oil has undergone extensive biodegradation, a level of 6 on the Peters–Moldowan scale [6.19, 20]. Moreover, the strong presence of *n*-alkanes in Fig. 6.2 shows that a large fraction of this oil is not biodegraded and is attributed to a process of reservoir paleopasteurization in the upper Miocene epoch, with a subsequent second crude oil charge into the reservoir. Moreover, a petroleum system analysis of the Llanos basin has confirmed all essential elements of the GC×GC analysis. Indeed, the vision of petroleomics is being realized in the analysis relying on GC×GC with specific geochemical processes being related to specific chemical composition of the crude oil.

Another significant advancement in petroleum science has been the application of high-resolution Fourier transform, ion cyclotron resonance mass spectrometry (FT-ICR MS) for its ability to resolve tens of thousands of components of unique elemental composition in typical crude oils [6.22, 23]. For example, long standing uncertainties about porphyrins in crude oils have been addressed in a very direct manner using these methods [6.24, 25]. In addition, examination of interfacially active components in complex carbonaceous materials can be isolated and characterized by FT-ICR MS [6.26]. Organic acids are particularly well suited to such analysis [6.27]. The combination of GC×GC with FT-ICR MS and downhole fluid analysis has proved very valuable in unraveling complexities of multiple charging, biodegradation, and reservoir connectivity [6.28].

It is also very important to perform thermodynamic analysis of reservoir crude oils for many fundamental purposes. It is necessary to maintain the pressure in the oil reservoir above the saturation pressure. If gas breakout occurs during oil production from the subsurface formation, then gas flows preferentially leaving the valuable liquids behind. The loss of gas removes a primary mechanism of pressure support in oil production. In addition, interfacial energy impedes a two-phase flow in porous media, thereby, reducing fluid mobilities. Thermodynamic modeling of the saturation pressure is required to understand pressure reduction limits, and thus oil (and cash) flow limits. In addition, understanding spatial variations of the gas–oil ratio (GOR) determines corresponding temporal GOR variations in production. There are major differences, particularly in cost, for gas versus liquid handling in oilfield facilities, hence accurate GOR analyses are required. There are many more issues that are addressed by thermodynamic modeling of crude oil [6.29].

Modified van der Waals EoS, the so-called cubic EoSs, have been very effective for modeling crude oils [6.29, 30] and are used in virtually every reservoir simulator that employs compositional analysis [6.31]. The Peng–Robinson EoS remains one of the most popular cubic EoSs to be used for crude oils. Requisite pseudo-critical constants can be obtained by simple mixing rules based on even a rough compositional analysis for crude oils. The long-term application of the cubic EoS to petroleum has led to acceptance of the seemingly implausible result that such a simple formalism works so well for gas–liquid equilibria of crude oils with their tens of thousands of components (or more).

For example, the cubic EoS is not well suited to handle simple mixtures of H_2O , CO_2 , and H_2S , yet can handle crude oil. Why? A significant part of the explanation is that saturated hydrocarbons and to a lesser extent aromatic hydrocarbons are nearly ideal, with very low energies of intermolecular interactions. Ideal solutions where simple mixing rules can apply are considered to consist of noninteracting components. Of course, to be a liquid, molecules must interact, but this minor discrepancy is overlooked.

The key point is that there is utility performing both the detailed compositional analysis of the gas and liquid components of crude oil and the simple thermodynamic modeling of these same components. The large number of chemical constituents does not preclude utility of either approach. The fact that both investigative di-

rections are successful makes petroleomics a reality. Nevertheless, for crude oil, it is required to incorporate asphaltenes into both types of analyses as best as possible. To treat asphaltenes in reservoir crude oils within a thermodynamic context, gravity is the key. Thus, a simple molecular and nanocolloidal description for asphaltenes is required. Projection of such a model to interfacial science is of interest. In addition, for a variety of purposes, it is important to characterize the specifics of asphaltene chemistry in a detailed manner. Phenomenological measurements such as surface tension might have chemical dependencies that are difficult to elucidate by the phenomenological method alone. Combining surface tension measurements with a detailed chemical characterization may lead to deep understanding.

6.3 Asphaltenes and the Yen–Mullins Model

Many characterization techniques have been applied to asphaltenes, and a clear picture of predominant structures has evolved. The predominant molecular and stable nanocolloidal structures of asphaltenes have been codified in the Yen–Mullins model and are shown in Fig. 6.3. In essence, this model is meant to represent the centroid of different species. Nevertheless, for some applications, the width to the distributions of these species is also very important. This model has been subjected to increasingly stringent tests in an expanding variety of ways, and the utility of the model has been established. Herein, we will review both key and recent results associated with this model of Fig. 6.3. In particular, a series of laser desorption, laser ionization mass spectral (L^2MS) studies have tested fundamental aspects of this model with strongly

supportive results [6.32–35]. In addition, recent NMR studies strongly support this model as well [6.36–39]. Combined studies of neutron and x-ray scattering also confirm this model [6.40–42]. Molecular orbital calculations combined with optical spectroscopy provide a clear picture of a range of sizes of asphaltene PAHs [6.43, 44]. Various other results such as combined TRFD, IR and NMR studies [6.45] and combined DC conductivity and centrifugation studies corroborate the Yen–Mullins model [6.46].

Each of these structures in Fig. 6.3 has been observed in reservoir crude oils; thus, each is stable for geologic time [6.12]. These structures have been employed with the Flory–Huggins–Zuo (FHZ) EoS to model asphaltene gradients in reservoirs. This novel approach of exploring the extent of thermodynamic

Fig. 6.3 The Yen–Mullins model depicts the dominant molecular and stable nanocolloidal species of asphaltenes [6.8, 9]. A molecule (*left*) with a single PAH with seven fused aromatic rings is shown. The nanoaggregate (*center*) consists of a disordered stack of approximately six molecules. The cluster (*right*) consists of approximately eight nanoaggregates

equilibrium of asphaltenes in reservoir fluids has been used to address many issues in production such as flow connectivity. In addition, the molecular and nanocolloidal species of asphaltenes are consistent with application of the Langmuir EoS applied to oil–water interfacial measurements, which will also be discussed below. The energetics of asphaltene intermolecular interactions is of considerable interest. This topic will also be addressed from several viewpoints. The importance of PAH polarizability is evident in many ways and plays a significant role in the applicability of the FHZ EoS.

In addition to bulk measurements and to centroid structures, there is great interest in specific molec-

ular structures that comprise asphaltenes. Unlike the liquid phase components, asphaltenes are not readily amenable to separation of individual molecular components, which of course precludes characterization of individual molecular structures. For example, ultrahigh resolution mass spectrometry applied to asphaltenes has been limited by the inability to break up asphaltene nanoaggregates in these studies [6.47]. In contrast, other mass spectral techniques such as L^2MS are readily able to disaggregate asphaltenes [6.35] but have only been employed in low resolution modes to date. Further improvement of various methods will be required to probe the very large number of individual chemical species of asphaltenes.

6.4 Asphaltene Molecules

The Yen–Mullins model starts with the predominant molecular structure. For many years, there had been no consensus regarding many fundamental properties of asphaltene molecular structure. For example, even such a basic property such as asphaltene molecular weight was unresolved, with disparities spanning several orders of magnitude [6.4]. The tendency of asphaltenes to aggregate negatively impacts a variety of experiments including mass spectrometry and colligative techniques such as vapor pressure osmometry (VPO). Today, these issues are understood and are addressed in the section below treating asphaltene nanoaggregates.

6.4.1 Time-Resolved Fluorescence Depolarization

Crucial early experiments that set the stage for resolution of many asphaltene molecular properties including molecular weight were the first experiments to determine asphaltene molecular diffusion constants, here, rotational diffusion, using time-resolved fluorescence depolarization (TRFD) [6.48–51]. Figure 6.4 shows the TRFD results on various asphaltene samples.

TRFD measurements determine the rotational correlation time of molecular species in dilute solution by measuring the rate of rotational depolarization. This is accomplished with an initial exciting laser pulse with laboratory z -polarization. The extent of polarization of fluorescence emission is measured versus time giving the rate of ensemble depolarization. The rotational correlation time is proportional to molecular volume, and thus molecular weight.

TRFD results show that virgin petroleum asphaltenes diffuse rapidly; thus, the molecules are fairly small. Comparison with known model compounds

shows that asphaltenes have a mean molecular weight of ≈ 750 Da. Asphaltenes extracted from vacuum distillation resid are smaller, as expected, in that their alkanes are cracked off reducing molecular weight. The larger PAHs that are formed in the refining process are part of the coke fraction, not the soluble asphaltenes. Coal asphaltenes are far smaller and are at the limit of TRFD correlation time measurements. Coal-derived asphaltenes have a very small alkane fraction and slightly smaller PAHs, so are roughly half-size compared to virgin crude oil asphaltenes [6.33, 48].

We use the term asphaltene to refer to virgin crude oil asphaltenes unless otherwise specified. The large range ($\approx 10\times$) of asphaltene correlation times reflects the expected large range of asphaltene molecular weight. However, the strong dependence of rotational correlation time on fluorescence emission wavelength is most instructive regarding asphaltene molecular architecture. The size of a PAH (i.e., the number of fused aromatic rings (FAR)) is related to its emission wavelength. This well-known result follows from the simple quantum description of a *particle-in-a-box*. Larger PAHs have longer wavelength π -electron orbitals, and thus lower energy transitions. For example, benzene is colorless with π -transitions only in the UV region, whereas graphite is black with π -transitions extending into the near-infrared (NIR) region [6.43, 44, 52]. Thus, the strong dependence of rotational correlation time versus fluorescence emission wavelength indicates that small asphaltene PAHs rotate $10\times$ faster than large asphaltene PAHs. This means they are not cross-linked. Thus, there is predominantly one asphaltene PAH per molecule. Exhaustive molecular orbital calculations were performed to check this logic [6.44].

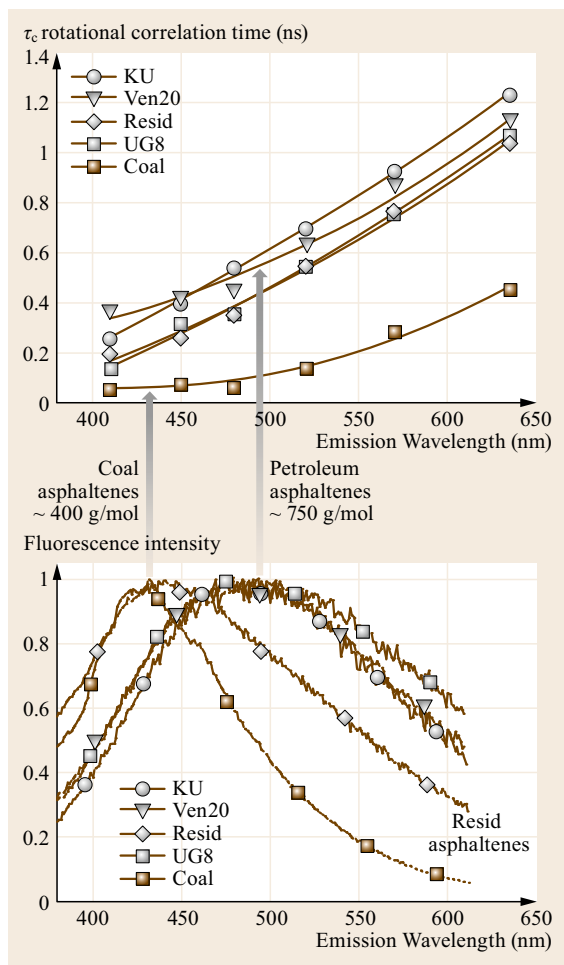

Fig. 6.4 Molecular diffusion measurements of asphaltenes by TRFD (after [6.48]). The rapid rotational diffusion indicates that petroleum asphaltenes are relatively small molecules (\leq kDa). The $10\times$ faster rotation of smaller, blue fluorescing PAHs versus larger, red fluorescing fluorophores indicates that different PAHs are not cross-linked; there is predominantly one PAH per asphaltene molecule. Centroids of the distributions of coal-derived asphaltenes and petroleum asphaltenes are indicated in the figure corresponding to the maxima in fluorescence emission spectra

6.4.2 Molecular Orbital Calculations and Optical Spectroscopy

In addition to size, PAH π -transitions are also dependent on the extent of aromatic sextet carbon versus isolated double bond carbon. Carbon x-ray Raman studies of asphaltenes show that they have more of the more stable sextet carbon in their PAHs [6.53]. Exhaustive molecular orbital calculations of PAHs confirm

Table 6.1 Number of compounds with differing numbers of FAR (fused aromatic rings) used in the absorption spectrum of Fig. 6.5. The weighting used for each FAR class is also given

FARs in PAH	Number of compounds used	Weighting in distribution
3FAR	2	0.20
4FAR	5	0.40
5FAR	28	0.60
6FAR	27	0.80
7FAR	41	1.00
8FAR	39	0.80
9FAR	71	0.60
10FAR	46	0.40
11FAR	41	0.20
12FAR	34	0.18
13FAR	61	0.16
14FAR	64	0.14
15FAR	64	0.12

that a distribution of PAHs spanning 3–15 fused rings with 7 fused rings most probable, largely reproduces the measured optical spectrum of asphaltenes as shown in Fig. 6.5. All π -electrons have unit oscillator strength, hence all PAHs appear in the absorption spectrum. For example, the proposed PAH distributions that have a preponderance of small ring systems would have too much absorption in the UV and not enough in the visible and NIR. Table 6.1 shows the PAH profile for the 523 PAHs used for the theoretical prediction in Fig. 6.5 [6.44]. The use of 523 PAHs acknowledges that there is significant chemical polydispersity in asphaltenes; nevertheless, it remains useful to identify centroids of distributions as shown in the Yen–Mullins model of Fig. 6.3. Interestingly, Table 6.1 shows that rather large PAHs had to be used to account for the significant NIR absorption of asphaltenes.

The first measurements of triplet state spectroscopy of asphaltenes in pump-probe experiments are consistent with the singlet state spectroscopy [6.54]. The chromophore population of asphaltenes obtained from spectral analysis indicates that asphaltenes have a preponderance of large PAHs.

There is a stringent consistency check with the TRFD predictions as confirmed by molecular orbital calculations. The TRFD results indicate that the mean molecular weight is 750 Da, and the PAH centroid has 7 fused rings. Knowing that asphaltenes are 50% aromatic carbon and 50% alkane carbon, the question arises whether these numbers are consistent. Coronene, a 7 fused ring PAH, has 24 carbons. This gives 48 carbons in total for the proposed molecule. Add \approx 58 hydrogens and 1 sulfur atom and obtains a molecular weight of 666 Da. A less symmetric distribution of 7

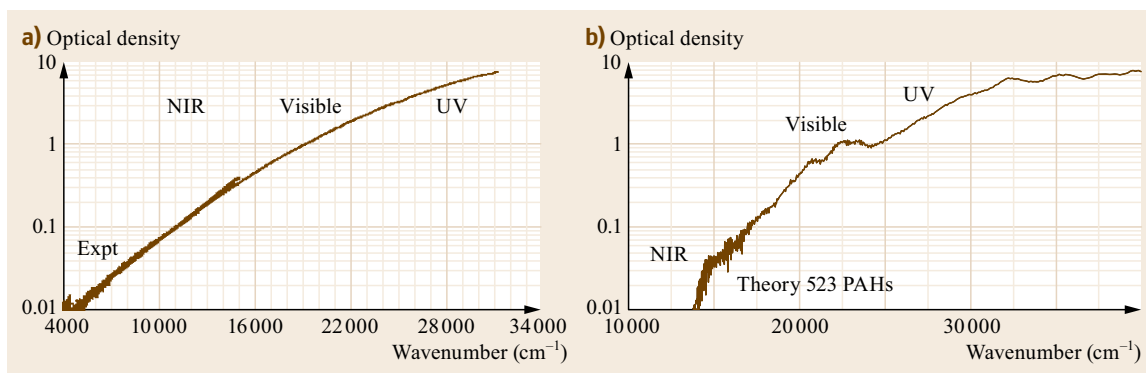

Fig. 6.5a,b Comparison of the measured and predicted absorption spectra of asphaltenes. The theoretical curve (right) utilized the sum of calculated spectra for 523 PAHs with a distribution shown in Table 6.1. A large distribution of PAHs including large PAHs is required to account for the absorption spectrum of asphaltenes. Reprinted (adapted) with permission from [6.44]. Copyright 2009 American Chemical Society

fused rings gives a larger number of carbon atoms. This is close to the measured mean of 750 Da, hence the TRFD results are internally self-consistent.

6.4.3 Nuclear Magnetic Resonance (NMR) Spectroscopy

Recent NMR experiments exploit both ^1H -NMR relaxometry as well as sophisticated 2D-HSQC (heteroatom single quantum coherence) NMR spectroscopy [6.38]. This work extends the previous NMR findings that are consistent with 6 fused ring PAHs as the mean for asphaltenes [6.36, 37, 55]. The latest NMR work provides a wealth of information about asphaltenes, not just on molecular architecture, but also regarding aggregate structures as well [6.38, 39]. A proposed molecule from this NMR work is shown that is consistent with the molecule shown in Fig. 6.3.

In Fig. 6.6, several fused alicyclic rings are shown in order to account for the measured large aromatic-aliphatic heteronuclear correlations [6.38]. Fused alicyclic groups were initially proposed for asphaltenes based on active asphaltene hydrogen similar to that to tetralin [6.56]. Again, similar conclusions from very different methods arrive at similar conclusions and reinforce each other. Unlike TRFD measurements, all of the asphaltene sample is interrogated in NMR studies.

6.4.4 Pendant Drop Interfacial Studies

Studies of the interface between asphaltene containing solutions and water have recently shown that a universal curve is obtained for surface tension versus (relative) asphaltene coverage at the interface, and is independent of surface aging time (between 0.5

Fig. 6.6 A proposed *average* asphaltene molecule that satisfies many results from ^1H and ^{13}C NMR (after [6.38]). This structure is very similar to that in Fig. 6.3 showing consistency across many methods

and 12 h), asphaltene solution concentration, and viscosity (Fig. 6.7) [6.13, 14]. In addition, the elastic and loss moduli curves of the interface also exhibit universal curves dependent only on asphaltene surface coverage [6.13, 14]. The existence of universal curves lends credence to the analysis.

The Langmuir EoS (6.1) gives the surface tension $\gamma(\Gamma)$ at a particular surface coverage of asphaltenes Γ in terms of the clean surface interfacial tension γ_0 , kT (Boltzmann's constant k and temperature T), and the maximum surface coverage of asphaltenes Γ_∞ (in molecules per unit area)

$$\gamma(\Gamma) = \gamma_0 + kT\Gamma_\infty \ln \left(1 - \frac{\Gamma}{\Gamma_\infty} \right). \quad (6.1)$$

Fig. 6.7 Interfacial tension of oil–water versus (relative) coverage of the surface by asphaltenes (after [6.13, 14]). A universal curve is obtained that is given by the Langmuir EoS

Analysis of the universal curve in Fig. 6.7 with the Langmuir EoS gives an asphaltene molecular contact area of 6.2 ring PAH [6.13, 14]. This presumes an orientation of the asphaltene PAH in-plane and the alkanes out-of-plane; exactly this asphaltene molecular orientation was shown by sum frequency generation

experiments on Langmuir–Blodgett films [6.58]. In addition, recent pendant drop experiments on coal-derived asphaltenes, petroleum asphaltenes, and alkylhexabenzocoronene gave expected molecular contact areas over a range of a factor of 3, strongly validating these analyses [6.59]. These results are in excellent agreement with the molecular structures shown in Figs. 6.3 and 6.6. Moreover, these experiments show that the asphaltene nanoaggregate does not load onto the surface as expected due to its peripheral alkanes [6.13, 14].

6.4.5 Laser Desorption, Laser Ionization Mass Spectrometry (L^2MS)

A significant concern is that the TRFD studies are sensitive only to fluorescent asphaltene molecules. It is possible that fluorescent asphaltene molecules differ in molecular weight or architecture from nonfluorescent asphaltene molecules. What is needed is a method that can analyze molecular weight and molecular architecture and that is sensitive to the entire asphaltene sample. The method laser desorption, laser ionization mass spectrometry (L^2MS) satisfies all of these demanding constraints.

In L^2MS , an IR laser pulse desorbs asphaltenes from a surface with heating rates of 10^8 deg/s, creating a neutral plume of asphaltene molecules in the vacuum. A UV laser pulse then ionizes asphaltene molecules in this plume. An electric field is used to determine mass by time of flight. Figure 6.8 shows

Fig. 6.8 L^2MS molecular weight determination for UG8 asphaltene (after [6.57]). The L^2MS results for asphaltenes are independent of UV laser power, IR laser power, surface concentration of asphaltene, and time delay for the ionization pulse, proving accuracy of this method. L^2MS and TRFD find comparable asphaltene molecular weights. Reprinted with permission from [6.57]. Copyright 2009 American Chemical Society

that L²MS molecular weight determination is independent of key experimental parameters, such as laser power, surface concentration of asphaltenes, and time delay of the ionization pulse [6.57]. Other methods such as laser desorption ionization (LDI) have shown acute sensitivity of molecular weight determination on laser power and surface concentration of asphaltenes in part associated with aggregation in the charged plume of asphaltenes. Carefully controlling for these factors does allow accurate asphaltene molecular weight determination with LDI [6.60]. The insensitivity of L²MS results to these experimental parameters establishes the accuracy of this method for molecular weight determination [6.35, 61].

In addition to molecular weight determination, L²MS has been crucial for the characterization of asphaltene molecular architecture [6.32]. There has been considerable debate regarding the number of isolated PAHs (not conjugated) in asphaltenes. When very high molecular weights were proposed for asphaltenes, the proposed number of PAHs was large [6.62]. Such a molecule has been termed the archipelago model. TRFD studies indicate that the predominant asphaltene molecular architecture has only one (maybe two) PAHs; this has been termed the island model [6.45, 48–50]. As the molecular weight of asphaltenes is now known to be rather small, the term archipelago is still even used for molecules containing two PAHs. Indeed, as noted in the original TRFD papers, a lesser fraction of molecules with two PAHs along with a dominant fraction of molecules with a single PAH is consistent with the TRFD data [6.48]. Some bulk decomposition studies have supported the presence of archipelago

molecules (possibly with two PAHs) [6.63]. Nevertheless, caution is advised as these decomposition methods are known to produce archipelago compounds [6.64].

Other mass spectral methods have yielded similar conclusion regarding asphaltene molecular weight and architecture. Molecular weights on a broad range of samples have been obtained by laser-induced acoustic desorption mass spectrometry (LIAD-MS) [6.65]. Fragmentation studies of asphaltenes from electron impact and collisional activated dissociation (CAD) indicated that island architecture was consistent with the results [6.66, 67].

The L²MS results in Fig. 6.9 indicate that, by comparing molecular stability of asphaltenes and model compounds, island molecular architecture dominates asphaltenes. This is consistent with the nondestructive TRFD studies. Of course, some smaller fraction of molecules with two PAHs is not inconsistent with this data. The L²MS decomposition study differs from bulk decomposition; the L²MS decomposition must be unimolecular, precluding the possibility of bimolecular reaction forming archipelago compounds. The L²MS results are particularly compelling in that the L²MS methods analyze all of the asphaltene sample with relatively uniform sensitivity for different molecular types [6.35].

Figure 6.10 shows that all of the asphaltene sample is placed in the vapor phase. No asphaltene remains on the sample plate where the IR laser has desorbed the sample (a line running from upper left to lower right in the figure) [6.35]. In addition, in the L²MS experiments, single photon ionization (SPI) with a single high energy UV photon accesses all molecules with a lower ioniza-

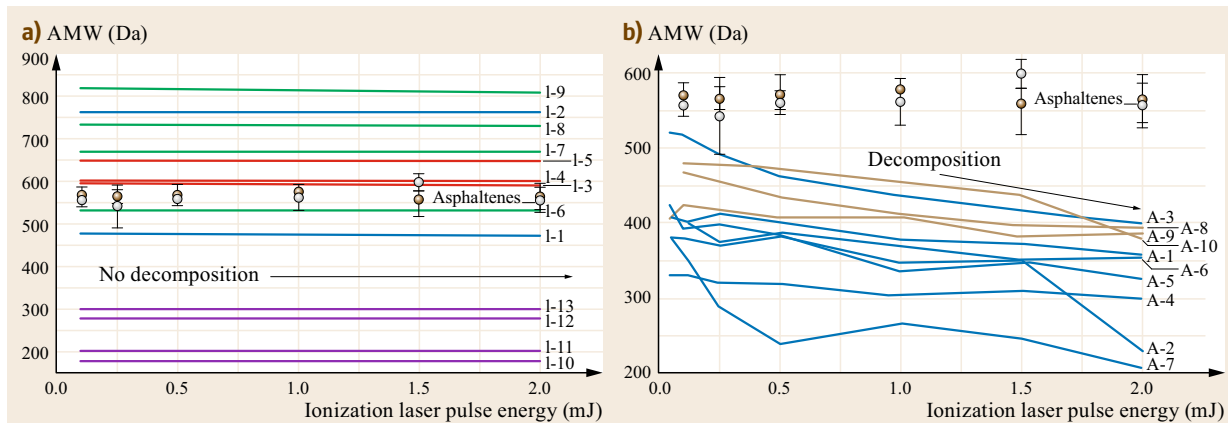

Fig. 6.9a,b L²MS average molecular weight (AMW) versus ionization laser pulse energy (after [6.32]). Fragmentation corresponds to a reduction of AMW. (a) All island model compounds measured and asphaltenes are resistant to decomposition at these laser energies. (b) All archipelago model compounds measured are labile and undergo decomposition at higher laser energies (AMW decreases with laser pulse energy). This indicates asphaltenes are predominantly island architecture. Tables 6.2 and 6.3 show the model compound structures (after [6.32])

Table 6.2 The model compounds for island and archipelago structures used for L²MS decomposition studies (after [6.68]). The greater stability of the island compounds and asphaltenes in L²MS indicates that asphaltenes are predominantly island structures. The asphaltene stability is consistent with these molecules being in oil reservoirs for geologic time

tion potential than the photon energy. In the case of the L²MS SPI experiments, this includes all PAHs with two or more rings, thus, including virtually all the asphaltene fraction (Fig. 6.5 and Table 6.1). L²MS with SPI was shown to be relatively uniform in ionization and detection cross section using mixtures of model compounds [6.35]. These results compared favorably with L²MS results using resonance enhanced, multiphoton ionization (REMPI) [6.35].

Another concern is asphaltene aggregation. As mentioned previously, aggregation of asphaltenes greatly hinders application of specific molecular weight mea-

Fig. 6.11 Mass spectra of caffeic acid using several laser based techniques (after [6.61]). All techniques show the parent ion peak associated with caffeic acid. SALDI shows considerable aggregation. REMPI-L²MS shows no aggregation, but does show some fragmentation. SPI-L²MS shows no aggregation and almost no fragmentation (after [6.61])

surements such as VPO and LDI (unless care was taken to use low plasma concentrations) [6.4, 60]. A recent report noted that some mass spectra techniques are not able to disaggregate the asphaltene nanoaggregates, thereby limiting corresponding applicability to a smaller mass fraction of asphaltenes [6.47]. This might be considering a bit surprising because the strength of binding in the asphaltene nanoaggregate is only moderate (as discussed below). For example, asphaltene nanoaggregates fall apart in toluene at 10⁻⁴

Fig. 6.12 (a) SALDI (3000 nJ/pulse) applied to coronene showing extensive aggregation with aggregates up to 12 monomers (M) (top) (after [6.34]) and L²MS applied to coronene showing a single peak without any aggregation (bottom). (b) SALDI applied to asphaltene with varying laser pulse energies (after [6.33]). At moderate laser power a peak corresponding to aggregation number of eight is observed. This corresponds to the asphaltene nanoaggregate. At increasing laser power, the nanoaggregate is broken up into decreasingly smaller multimers. Reprinted (adapted) with permission from [6.33, 34]. Copyright 2014 American Chemical Society

mass fraction as discussed below [6.69, 70]. Nevertheless, it is important to establish that laser-based mass spectral methods, especially L²MS, are able to disaggregate any asphaltene aggregates. First, model compound analysis is instructive. Figure 6.11 shows mass spectra of caffeic acid, a compound that has strong intermolecular interactions via the carboxylic acid and two hydroxyl groups (and is a matrix material for matrix-assisted LDI) [6.61].

Figure 6.11 shows that L²MS does not detect aggregates of caffeic acid with either REMPI or SPI. In contrast, this figure shows the surface-assisted laser desorption ionization (SALDI) exhibits considerable aggregation. REMPI-L²MS does show some fragmentation. This data shows that L²MS is much more efficient at breaking up aggregates than SALDI [6.61].

Figure 6.12a compares SALDI versus L²MS applied to coronene [6.34]. SALDI shows extensive aggregation, whereas L²MS detects a single peak corresponding to the parent ion. Figure 6.12b shows that SALDI applied to asphaltene detects aggregates. At

moderate laser power (3500 nJ/pulse), the asphaltene nanoaggregate is detected with an aggregation number of ≈ 8 . With increasing laser power, there is a reduction of the aggregation number [6.33, 34]. At 5500 nJ/pulse, the primary aggregate is the dimer. These data clearly show that even in SALDI where aggregates are easily detected, higher laser power can disaggregate asphaltene. L²MS, which is far more efficient at removing all vestiges of aggregates than SALDI, for example, with coronene, can clearly disaggregate asphaltene. For laser mass spectrometry, it is the preservation of the nanoaggregates that is difficult, not their disaggregation. Moreover, L²MS also has a relatively flat cross section for all types of asphaltene molecular structures [6.61]. Consequently, the fact that L²MS is sensitive to all fractions of asphaltene without problems of aggregation reinforces the validity of all L²MS results: Asphaltene molecular weight is ≈ 750 Da, the island molecular structure dominates and the aggregation of nanoaggregates is ≈ 8 (close to 6 depicted in Fig. 6.3).

6.5 Asphaltene Nanoaggregates

6.5.1 Surface-Assisted Laser Desorption Ionization Mass Spectrometry

SALDI in Fig. 6.12b shows a nanoaggregate aggregation number of ≈ 8 . Additional SALDI data on the aggregation number is shown in Fig. 6.13 where the baseline is subtracted. The petroleum asphaltenes all exhibit about the same aggregation number of ≈ 8 . The coal-derived asphaltene, with its very different character, has only a slightly different aggregation number of 6. The large difference in coal-derived asphaltenes with their very large aromatic carbon fraction ($\approx 85\%$) yields only a small difference in aggregation number. This is consistent with the same solubility of both types of asphaltenes. This also indicates that variation of aggregation numbers of virgin petroleum asphaltenes is minor. That is, the aggregation of coal-derived asphaltenes is similar to that of virgin petroleum asphaltenes. And all virgin petroleum asphaltenes are far more similar in chemical nature compared to coal-derived asphaltenes. Thus, the conclusion is that the aggregation properties of all virgin petroleum asphaltenes are similar, and thus dictated by their identical solubility constraints imposed by the definition of asphaltenes.

Fig. 6.13 SALDI measurements of aggregation numbers of asphaltene nanoaggregates for three petroleum asphaltenes, CAL, BG5, and UG8, and for a coal-derived asphaltene, TH Coal. The aggregation numbers for the petroleum asphaltenes are about 6–8 in agreement with Fig. 6.3 (after [6.33])

6.5.2 Small Angle X-ray Scattering (SAXS) and Small Angle Neutron Scattering (SANS)

SAXS and SANS have both been very informative with regard to asphaltenes. When combined into a single framework, they are most illuminating [6.40–42]. In asphaltenes, x-rays scatter preferentially from carbon, which is enriched in PAHs, whereas neutrons scatter preferentially from hydrogen, which is predominantly in alkane groups. The divergence of the SAXS versus SANS cross sections shown in Fig. 6.14 demonstrates that aromatic and saturate carbon groups are separately distributed in asphaltenes at the 1.4 nm length scale, the nanoaggregate. Analysis of this data shows that there is an aromatic carbon core and a periphery of

Fig. 6.14 Comparison of absolute cross sections of SAXS and SANS versus scattering vector q . The divergence at 14 \AA^{-1} (and smaller) shows that nanoaggregates have a core of aromatic carbon and a periphery of saturate carbon (Fig. 6.3) (after [6.40–42])

Table 6.4 Chemical shift assignments $\delta\{^1\text{H}\}$, line widths ($\Delta\vartheta_{1/2}$), and transverse (T_2) relaxation constants for the fitted peaks of solid-state ^1H -NMR spectrum at 8 kHz MAS, obtained with the 414 μs dipolar filter and variable delay spin-echo filter^a, corresponding to the spectrum in Fig. 6.15 (after [6.39])

alkane carbon for asphaltene nanoaggregates. As noted by the authors, this geometry of the nanoaggregate is strongly supportive of the molecular architecture shown in Fig. 6.3 [6.40–42]. The length scale of the nanoaggregate in these combined SAXS and SANS studies led the authors to predict an aggregation number of 12, whereas an aggregation number of 6 is listed in Fig. 6.3. For such nanoscience determinations, this is largely considered agreement. For example, micelles and related structures often have aggregation numbers of 60 or 100. The central point is that asphaltene nanoaggregates have roughly an aggregation number of 10, with some spread in determination of the exact number. In any event, the structure and size of the nanoaggregate found in the combined SAXS and SANS study are in close agreement with the nanoaggregate shown in Fig. 6.3 and was predicted long before this observation based on simple steric repulsion arguments [6.69, 70]. The attractive central PAHs tend to form a stack, whereas peripheral alkanes interrupt stacking via steric hindrance [6.69, 70]. This simple argument predicts both a central PAH core with peripheral alkanes and small aggregation numbers as observed by SALDI [6.33, 34] and other methods.

6.5.3 NMR

The proposed disordered PAH stack of the nanoaggregate would yield some highly shielded alkane groups attached to these PAHs due to the familiar aromatic ring currents. The upfield peak at −0.18 ppm and other up-

Fig. 6.15 ^1H -NMR spectrum of Athabasca bitumen asphaltene. The solid-state spectrum is shown at 8 kHz magic angle spinning after 414 μs dipolar filter and 125 μs Hahn-echo or T_2 relaxation filter showing the deconvolved peaks. The aromatic signals have been filtered out. The peak assignments are given in Table 6.4. The upfield peak (#1) corresponding to a −CH₃ group intercalated in a PAH stack is shown for the first time (after [6.39])

field peaks have been measured using solid-state magic angle spinning methods and, as the authors note, are consistent with the nanoaggregate and cluster structures shown in Fig. 6.3. This study also utilizes relaxation rates (Table 6.4) to discern inflexible alkane and aromatic groups, again lending support to fused alicyclic rings to the PAH as shown in Figs. 6.3 and 6.6 [6.39].

6.5.4 High-Q Ultrasonics, DC Conductivity, and Centrifugation

Other methods have shown the asphaltene nanoaggregate aggregation numbers to be quite small. These methods rely on measurement of properties above and below the critical nanoaggregate concentration (CNAC). The first determination of the CNAC where aggregate growth ceases was performed by high-Q ultrasonic studies [6.69, 70]. At that time, there was confusion about the value of the CNAC in part because it was not then recognized that there are two, not one aggregation thresholds for asphaltenes. Some studies were evidently sensitive to clustering, not nanoaggregate formation. For determination of asphaltene CNAC

in toluene, the high-Q ultrasonic results match with those of DC conductivity as shown in Fig. 6.16 [6.71]. The value of the CNAC, 10^{-4} mass fraction, is slightly larger than the onset of aggregation as determined by fluorescence measurements, as expected [6.72]. DC-conductivity measurements also confirmed that resins are unlikely to coat asphaltene nanoaggregates. Thus, the long-time-standing Nellensteyn hypothetical model, where resins adsorb on asphaltenes to provide a steric stabilizing layer, is not valid [6.73].

High-Q ultrasonics is sensitive to all asphaltenes in the corresponding solutions. The high precision in speed-of-sound determination allows the slight change of solution compressibility at CNAC to be detected. The speed of sound u is given by $u = \sqrt{1/(\beta\rho)}$, where β is

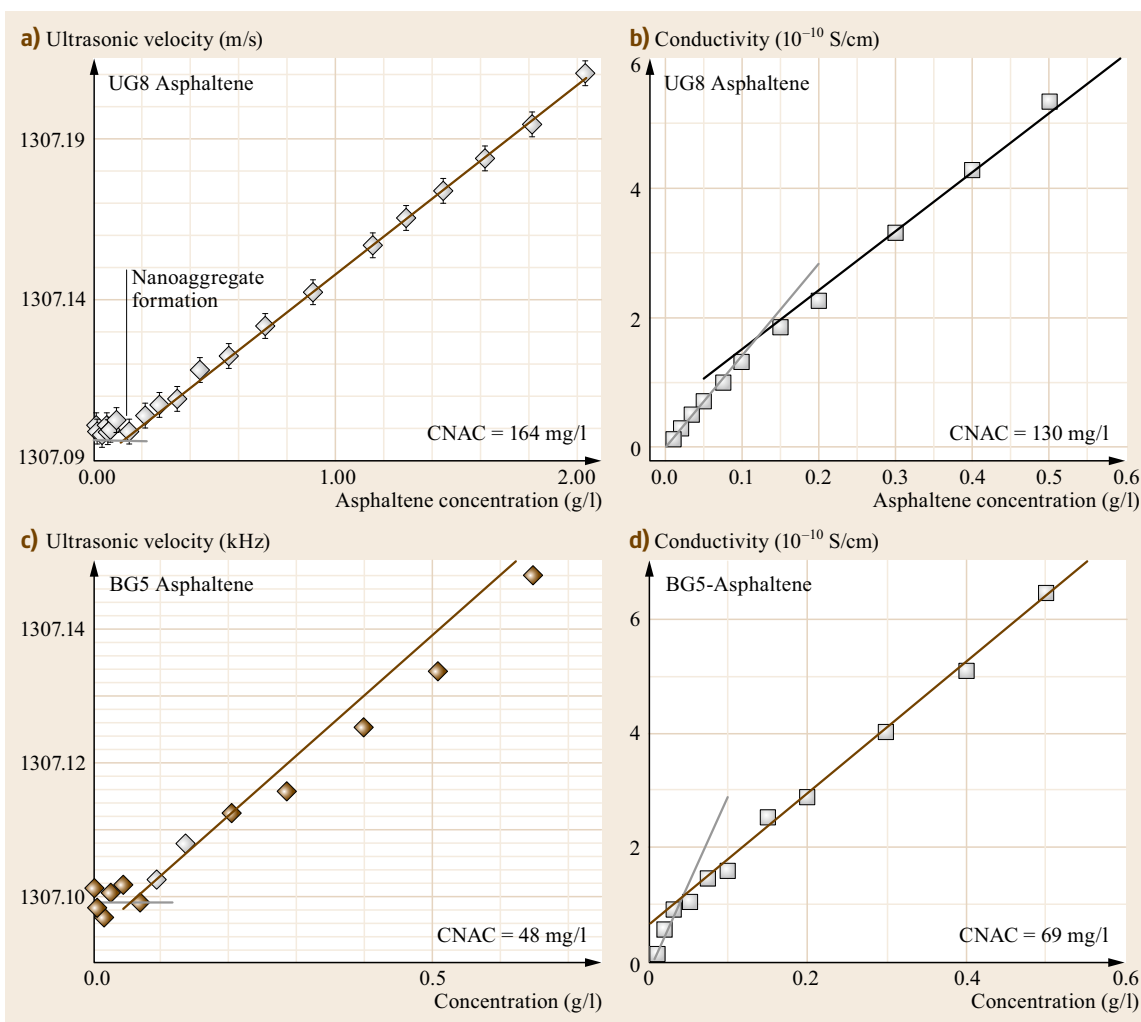

Fig. 6.16a–d Measurement of CNAC in toluene by (a,c) high-Q ultrasonics (after [6.69, 70]) and by (b,d) DC conductivity (after [6.71]) are in accord. The small increase in stokes drag at CNAC for DC conductivity indicates the aggregation number is small

compressibility and ρ is density. With the very small aggregation numbers, there is a range of concentrations corresponding to the CNAC; there is not one sharp, single CNAC [6.74]. These small variations require a very high quality factor Q of the resonator ($Q \approx 10\,000$), enabling speed of sound to be measured to a few parts per million (ppm). The DC conductivity depends on very different physics. In toluene, approximately one part in 10^5 of the asphaltene is ionized [6.71]. Thus, DC conductivity examines a small fraction of the sample. At CNAC, neutral molecules pack around the ion forming a nanoaggregate, thereby increasing the ion Stokes drag, which is linear in radius, yielding decreasing DC conductivity. The agreement between high- Q ultrasonics and DC conductivity validates the results. The change in Stokes drag at CNAC provides an estimate of the aggregation number. The obtained values for the aggregation number of the asphaltene nanoaggregate are always less than 10 by DC conductivity [6.71, 75, 76].

When homogeneous solutions of asphaltene nanoaggregates are centrifuged at a given speed, the nanoaggregates reach terminal velocities and, given time, will accumulate at the base of the centrifuge tube. By selecting centrifuge times that collect nanoaggregates, but not molecules, the CNAC can be determined. The centrifuge times are also dependent on nanoaggregate size as well. The sedimentation equation given below is applicable to these experiments

$$v_e = \frac{d^2 \Delta \rho g}{18 \eta}, \quad (6.2)$$

where v_e is the velocity of the colloidal particle in a gravitational or acceleration field of strength g , d is the particle diameter, $\Delta \rho$ is the discrete to continuous phase density difference, and η is the solvent viscosity. The sedimentation equation was previously shown to

Table 6.5 Calculated spin times for collection of corresponding asphaltene particles with diameter d . Time based on settling velocity from (6.2) (after [6.77])

Particle diameter (nm)	Settling velocity (m/s)	Spin duration
1.5	1.71×10^{-8}	21.8 days
2.5	4.75×10^{-8}	7.86 days
5	1.90×10^{-7}	1.96 days
10	7.59×10^{-7}	11.74 h
20	3.04×10^{-6}	2.93 h
50	1.90×10^{-5}	0.47 h

be applicable to asphaltene flocs of various sizes (in the order of $1 \mu\text{m}$), and these results were consistent with particle size determination from wavelength-dependent light scattering measurements [6.78]. Table 6.5 gives the spin times for the particular experimental configuration used versus asphaltene particle diameter in the toluene solutions.

In these asphaltene sedimentation experiments for nanoaggregates, centrifugation was carried out at fixed rotational frequency and temperature, 18 000 rpm and 298 K, respectively [6.77]. The settling field varied from 13 000 g near the top of the liquid surface to 37 600 g near the bottom so that the average settling field near the midpoint of the major axis of the tube was about 25 000 g. In these experiments, samples were spun for 7.86 days, corresponding to a particle size of 2.5 nm diameter. There is a variable collection efficiency dependent on where in the tube (vertically and laterally) the volume element is. Thus, centrifugation results are not precise in particle size, but the results are very robust, collecting asphaltene at the base of the tube.

Figure 6.17 shows that DC conductivity and centrifugation are in accord. DC-conductivity measurements rely on the increase of Stokes drag at CNAC. Centrifugation relies on the increased settling veloci-

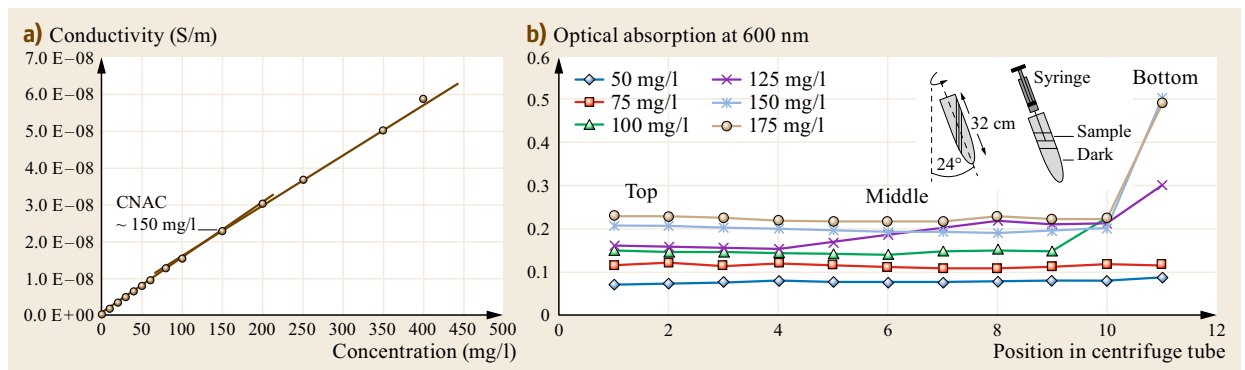

Fig. 6.17a,b Agreement of GOM asphaltene CNAC determination by (a) DC conductivity and (b) centrifugation (after [6.76, 77])

ties at CNAC. The CNAC determined by both methods are similar. The aggregation number determined by DC conductivity is less than 10. The nanoaggregate size determined by centrifugation is ≈ 2.5 nm, consistent with a small aggregation number. The temperature dependence of the CNAC is rather small [6.76, 79]; thus, the formation of the nanoaggregate has a significant entropic component. Nevertheless, the PAH stack in the nanoaggregate corresponds to the most stable energetics.

6.6 Clusters

6.6.1 SAXS and SANS

A second asphaltene nanocolloidal species can form: the asphaltene cluster. The combined SAXS and SANS studies show a fractal cluster with an aggregation number of 12 nanoaggregates [6.40–42]. This method is sensitive to nanoaggregate formation as discussed earlier, hence, the second level of aggregation found is robust and not due to confusion with nanoaggregate formation.

6.6.2 Light Scattering and Flocculation Kinetics

The critical clustering concentration (CCC) was first determined by examination of the kinetics of floc formation from different toluene solutions of asphaltenes upon *n*-heptane addition. Values of 2–5 g/l were obtained [6.80, 81]. Again, as with the CNAC, because the aggregation number of the cluster is small, there is a range of concentrations that corresponds to the CCC [6.74]. Below the CCC, the flocs are formed by diffusion limited aggregation (DLA); there is no barrier to floc formation from nanoaggregates. In contrast, above the CCC, the flocs are formed via reaction limited aggregation (RLA); clusters do not necessarily stick when colliding. A morphological change of the fractal cluster is required in order to stick, thus, RLA kinetics [6.81].

6.6.3 DC Conductivity and Centrifugation

Cluster formation has been probed by DC conductivity [6.46, 71] and centrifugation [6.46]. In DC conductivity, the increase in Stokes drag associated with cluster formation is recorded. In centrifugation, the settling velocity changes upon cluster formation essentially related to the change in Stokes drag and gravitational or cen-

trifugal force. Mass spectrometry has been used to measure CNAC; in a related solvent system [6.47], a CNAC of a little less than 10^{-4} mass fraction was obtained. NMR has also been used to obtain CNAC in toluene [6.79] and in a related solvent [6.13]. A somewhat lower CNAC was obtained in the less good solvent. The aggregation number of the mass spectral study was somewhat larger than 10 [6.47]; perhaps the different solvent system with a large methanol fraction accounts for this higher aggregation number.

The slight decrease in conductivity with cluster formation indicates that the aggregation number is less than 10. Likewise, the centrifugation spin conditions were set to detect a cluster size of 4 nm, corresponding to a spin time of about 3 days at 18 000 rpm (Table 6.5). This represents a lower limit for the clusters. If the particles are grown to 5 nm particle size, then the centrifugation experiments performed here (with longer spin times for smaller particles) would underestimate the CCC. The relevant spin parameters are the centrifugation speed and the time of spin. With these parameters fixed, and with changing concentration, Stokes drag determines whether asphaltenes can accumulate at the bottom of the centrifuge tube. As can be seen in Fig. 6.18, there is a large collection of asphaltenes in 1.5 g/l and above. Thus, the CCC is about 1.5 g/l.

In a related centrifugation study, a fixed asphaltene concentration of 3 g/l was used; this is above the CCC shown in Fig. 6.19. A large increase in asphaltene accumulation is observed at a spin time of 1.96 days, corresponding to 5 nm as shown in Table 6.5.

Figure 6.19 shows the spin time that corresponds to the accumulation of clusters toward the base of the centrifuge tube for this 18 000 rpm spin (Table 6.5). Most of the asphaltene gets accumulated at the base for a spin, corresponding to 5 nm particles for both the LC and HO asphaltenes [6.46].

The centrifugation experiments are robust in showing a change in aggregation occurring at the CCC and for showing the colloidal size. However, the centrifugation experiments are not as precise for showing CCC or particle size because there is variable centrifugation collection efficiency versus position in the centrifuge tube. The DC-conductivity measurements are perhaps more robust in determining the CCC. There is agreement in many studies that clusters are approximately 5 nm in diameter with an aggregation number of ≈ 8 nanoaggregates.

Fig. 6.18a,b Critical cluster concentration (CCC) measured by (a) DC conductivity and (b) centrifugation is in agreement, ≈ 1.4 g/l for this HO asphaltene. The small change in Stokes drag in both measurements indicates a cluster aggregation number less than 10 (after [6.46])

Fig. 6.19 Accumulation of asphaltene clusters versus spin time. Comparison with Table 6.5 and (6.2) shows that clusters are ≈ 5 nm in size (after [6.46]). Data for the asphaltenes, HO, and LC are shown

6.6.4 NMR Spectroscopy and Relaxometry

NMR measurements give a comparable cluster size by examining the diffusional motion of the peripheral alkane chains of asphaltenes. Figure 6.20 shows a schematic how T_1 and T_2 measurements of asphaltene alkanes at high concentration are used to evaluate

Table 6.6 Transverse (T_2) and longitudinal (T_1) relaxation times for the ^1H -NMR peaks in the solution state. The values in parentheses represent the percentage of protons having the corresponding T_2 (after [6.38])

$\delta \{^1\text{H}\}$ (ppm)	Assignment	T_2 (ms)	T_1 (s)
0.9	CH ₃ not attached to aromatic rings	33.3 (11.6%), 84.7 (88.4%)	0.73, 2.50
1.3	Aliphatic chain CH ₂	31.8 (9.7%), 59.5 (90.3%)	0.59, 1.50
1.6	Alicyclic CH ₂	24.9 (21.5%), 86.9 (78.5%)	0.35, 5.00
2.5	CH ₃ attached to aromatic rings	64.9	0.55, 7.10
2.8	Aliphatic chain/cyclic CH ₂ α or β to aromatics	24.4	0.42, 7.70
7.5	Aromatic CH	30.9 (15.6%), 75.2 (84.4%)	0.69, 2.90

cluster size. Estimates of the relative percentages of the rigid and mobile components of each signal were made by using the bi-exponential behavior of T_2 decay curves and are listed within parentheses in Table 6.6.

These percentages are indicative of the geometry and size of the nanoaggregates and their clusters. The low percentage of rigid aliphatic methyl and methylene groups (11.6 and 9.7%, respectively) indicates that the majority of the aliphatic chains remains on the periphery of the clusters [6.38]. This in turn implies that the clusters are made up of a small number of nanoaggregates. Moreover, the aromatic protons on the interior of

Fig. 6.20 (Not-to-scale) graphic showing that ^1H (T_1/T_2) ratios increase with rigidity of molecules (or their aggregates). Each oval with its side chains represents an asphaltene nanoaggregate. Higher correlation time (τ_c , x -axis) is an indicator of greater rigidity; all τ_c 's observed for Athabasca bitumen asphaltene protons at concentrations above the CCC lie beyond the T_1 -curve inflection point which is inversely proportional to the ^1H Larmor frequency. The aromatic protons on the interior of the clusters are significantly more rigid ($T_1/T_2 \approx 100$) than those on the periphery ($T_1/T_2 \approx 10$) and constitute $\approx 15.6\%$ of the total number of aromatic protons in the cluster, accounting for ≈ 1 in 6 or 7 nanoaggregates (after [6.38])

the clusters are significantly more rigid ($T_1/T_2 \approx 100$) than those on the periphery ($T_1/T_2 \approx 10$) and constitute $\approx 15.6\%$ of the total number of aromatic protons in the cluster. This fraction of highly rigid aromatic protons agrees with the cluster size of 6 or 7 nanoaggregates reported via other independent techniques (see above), where 15.6% would account for ≈ 1 rigid nanoaggregate at the center of the cluster. A cluster size larger than 6 or 7 would imply a larger fraction of these *interior* rigid protons. Therefore, the number of nanoaggregates per cluster can be predicted as 6–7, where the peripheral nanoaggregates have a higher mobility than the internal ones. This is in close agreement with the cluster aggregation number of 8 in the Yen–Mullins model (Fig. 6.3).

The 5 nm cluster of asphaltenes is stable for geologic time [6.82]. Many studies have been performed on asphaltene instability, and frequently, asphaltene flocs of greater than 1 μm are detected optically [6.78, 83]. As the instability is reduced, the rate of floc formation slows down essentially exponentially [6.84–86]. These slowly growing unstable asphaltene species have been shown to be in the range of 10 nm, which is close to the

Fig. 6.21 HRTEM micrograph of asphaltene flocculate in 70/30 toluene/heptane. The building blocks are clusters with an average size of 5 nm. Reprinted with permission from [6.87]. Copyright 2014 American Chemical Society ▶

size of the stable species, that is, the 5 nm asphaltene clusters.

6.6.5 High-Resolution Transmission Electron Microscopy (HRTEM)

Recent HRTEM studies on asphaltene aggregation in toluene/heptane solutions revealed that the onset of asphaltene flocculation was near 70/30 toluene/heptane.

At this ratio, clusters of clusters were no longer in colloidal stability and flocculated out of the solution. In these HRTEM images, small flocculates are globular in shape with an average diameter of 100 nm. Figure 6.21

presents a micrograph of small flocculates interacting with each other to form a larger one. The building blocks in this figure are clusters with an average size of 5 nm [6.87].

6.7 Intermolecular Interaction of Asphaltenes

In order to assess the range of applicability of any simple *universal* model of asphaltenes, it is important to understand their chemical interactions at the molecular level. Similar to the alkanes, weaker, simpler bonding is compatible with simpler asphaltene descriptions which may have broad applicability. Asphaltenes have been considered to be *strongly interacting*. However, the point of comparison to gauge asphaltene interaction is largely the other components of crude oil, the alkanes, which are very weakly interacting such that ideal solution formalisms are applicable. Moreover, intermolecular interaction yields aggregates of asphaltenes that are known to disrupt many molecular weight measurements such as laser desorption ionization mass spectrometry (LDI MS), atmospheric pressure chemical ionization mass spectrometry (APCI MS), and VPO [6.4, 35, 60]. However, mass spectrometry requires molecules to be in the vapor phase, and VPO necessitates the use of high concentrations; thus, these techniques accentuate issues related to intermolecular interactions. Nevertheless, asphaltenes are known to be predominantly molecularly dispersed in laboratory solvents at fairly high concentrations, 10^{-4} mass fraction, in toluene [6.69, 70], indicating that intermolecular interaction of asphaltenes is not that strong in comparison to a covalent bond.

The equilibrium constant K for aggregation depends on standard Gibbs free energy of nanoaggregate formation ΔG° as $K = \exp\{-\Delta G^\circ/kT\}$, where $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$, ΔH° is the standard enthalpy of formation, and ΔS° is the standard entropy of formation. The temperature variation of the CNAC (in toluene) was determined to be smaller than error over a limited range of over the range 298–324 K [6.76]. Consequently, to zeroth order, the lack of temperature dependence of the CNAC means that the enthalpy of aggregate formation is zero as shown by van't Hoff equation

$$\frac{\partial \ln K}{\partial T} = \frac{\Delta H^\circ}{kT^2}, \quad (6.3)$$

where k is Boltzmann's constant and T is temperature. The important point is that the binding energy (enthalpy) of asphaltenes in solution is not high.

One should not confuse the role of minimum energy; the molecular configuration of the nanoaggregate

certainly minimizes the energy. An unfavorable configuration would require energy to form. With $\Delta H \approx 0$, ΔS° can be approximated. One can presume that the nanoaggregate forms in a process forming dimers, trimers, etc., and that the equilibrium constants of dimer formation, trimer formation, etc. are all presumed to be the same. At CNAC, the concentration of the monomer equals the dimer which equals the trimer . . . , and equals the CNAC, then $K = 1/[\text{CNAC}]$ and (6.4) follows

$$\Delta G_{\text{CNAC}}^\circ = -T\Delta S_{\text{CNAC}}^\circ = RT \ln(\text{CNAC}), \quad (6.4)$$

with the $\text{CNAC} = 150 \text{ mg/l} = 2 \times 10^{-4} \text{ mole/l}$, $\Delta S^\circ \approx 17 \text{ cal}/(\text{deg mol})$. This entropy is positive (intuition would naively suggest it should be negative). Evidently, the solvent positive change in solvent entropy more than compensates the negative change in asphaltene entropy upon aggregate formation. The magnitude of this entropy change at CNAC is comparable to the corresponding entropy change of critical micelle concentration for some aqueous surfactants when the enthalpy of formation is also zero [6.88]. This positive entropy of formation is larger than a previous determination for asphaltenes (8.3 cal/(deg mol)); this previous work also found a small negative enthalpy of formation (-3.6 kcal/mol) [6.79].

The Hildebrand solubility parameter, δ , is defined as the square root of the cohesive energy density, and provides a way to quantify intermolecular interaction. δ is very low for saturated hydrocarbons. For example, $\delta = 14.9 \text{ MPa}^{1/2}$ for *n*-hexane and $\delta = 16.0 \text{ MPa}^{1/2}$ for *n*-dodecane, whereas $\delta = 48 \text{ MPa}^{1/2}$ for water (Table 6.7). Alkanes are nearly ideal, whereas water is not. At room temperature, water, with one heavy atom, is a liquid, whereas for *n*-alkanes, it takes five heavy atoms to form a liquid (*n*-pentane). Regular solution theory such as Flory–Huggins theory accounts for some deviation from ideal solution theory, accounting for some limited intermolecular interaction. In particular, the applicability of simple regular solution theory depends on the types of intermolecular interactions. Projecting the Hildebrand solubility parameter, δ , into the composite Hansen solubility parameters of the three predominant intermolecular interactions, such as dispersion (or polarizability) δ_D , polarity δ_P , and hydrogen

Table 6.7 Hildebrand solubility parameters and the Hansen solubility parameters for asphaltenes and selected compounds

Compound	Hildebrand δ (MPa ^{1/2})	Hansen parameters

bonding, δ_{H} , helps to clarify essential interactions and guide thinking on application of different solution theories.

The dependence of solubility on a comparison of the Hansen solubility parameters of the species in question is simply the manifestation of the well-known chemical axiom, *like dissolves like*. Table 6.7 provides a list of different classes of compounds (and asphaltenes) and the Hildebrand and Hansen solubility parameters

$$\delta = (\delta_{\text{D}}^2 + \delta_{\text{P}}^2 + \delta_{\text{H}}^2)^{1/2} \quad (6.5)$$

Small differences in the solubility parameters of two compounds indicate mutual solubility; large differences preclude solubility. If the two compounds are dominated by dispersion forces, then comparison of

Hildebrand parameters is sufficient. If the intermolecular interactions are complex including polarity and H-bonding, then the comparison must be made considering Hansen solubility parameters, with the root mean square of the distance in the Hansen space being the metric, along with the factor of two increase of the dispersion term difference. The latter point is that for compounds dominated by dispersion forces, subtler differences in δ_{D} can preclude solubility.

As noted earlier, alkanes are weakly interacting and water is strongly interacting. Table 6.7 quantifies these strengths. (The numerical value of the solubility parameter in MPa^{1/2} is 2.0455 times the value in (cal/cm³)^{1/2}). Alkanes are characterized by relatively small Hildebrand interaction parameters with the Hansen dispersion term dominating. In contrast,

water, alcohols, acids, and sulfoxides all have much larger Hildebrand parameters which have large contribution from the H-bonding parameter and from the polar term. Asphaltenes are intermediate in terms of their Hildebrand parameter, which, as with alkanes and aromatics, is dominated by the polarizability term. From the vantage of strongly interacting compounds listed in Table 6.7, asphaltenes are somewhat weak in their interaction. The relatively small heteroatom content of asphaltenes is also predominantly dominated by polarizability such as sulfide, thiophene, and aromatic nitrogen. This heteroatom content of asphaltenes does give rise to some dipolar charge separation; nevertheless, the dominant interaction is via polarizability. Solvents that dissolve asphaltenes likewise have comparable interaction parameters that are also dominated by polarizability, such as toluene and chlorinated solvents.

The fact that polarizability dominates the asphaltene solubility parameter [6.89] indicates that the central, large PAH of asphaltene molecules is the primary site of intermolecular attraction. The determination of molecular orientation at the oil–water interface in Langmuir–Blodgett films supports this conclusion. Sum frequency generation (SFG) experiments showed that asphaltenes orient with their PAH in-plane and their alkanes out-of-plane at the oil–water interface [6.58]. In contrast, PAHs with oxygen containing moieties along one side of the molecule or in pendant groups were shown to orient edge-on in the oil–water interface [6.58]. Evidently, asphaltene intermolecular attractive interactions are mediated by their PAH, not by heteroatom containing pendant groups. These results are also consistent with pendant drop experiments which obtain that the asphaltene contact area with the oil–water interface equals approximately 6 fused rings [6.13, 14]. These pendant drop experiments obtained three universal curves, lending credence to the results. One of the universal curves is the surface tension variation with relative asphaltene coverage. The Langmuir EoS was used to fit this curve, and one of two fitting parameters is the molecular contact area. The result of a 6-ring PAH for asphaltenes is consistent with the SFG results of direct determination of this same molecular orientation. Both the SFG and pendant drop experiments reinforce the idea that the asphaltene PAH dominates asphaltene intermolecular attraction.

Fig. 6.22 Molecular dynamics simulation showing π -stacking of PAH-containing alkyl aromatic (with oxygen functions as well). Reprinted with permission from [6.90]. Copyright 2013 American Chemical Society

Molecular dynamics (MD) simulations have been performed on various model systems and frequently exhibit π -stacking, reinforcing the idea that the asphaltene PAH dominates intermolecular attraction (Fig. 6.22). In addition, the steric repulsion of long alkane chains was observed on the π -stacking as expected [6.90]. Asphaltenes have significant polydispersity that leads to some disorder in the π -stacking. In other MD studies, the interactions between aromatic cores of asphaltene molecules were the major driving force for association as the energy of association increased substantially with the number of aromatic rings. Moreover, heteroatoms attached to the aromatic cores had much more influence on the association free energy than to ones attached to the aliphatic chains. The length and number of aliphatic chains did not have a noticeable effect on asphaltene dimerization; however, they had a profound effect on asphaltene aggregation size since steric repulsion could prevent asphaltenes from forming T-shape configurations and therefore decrease the aggregation size of asphaltenes significantly [6.91].

6.8 The Flory–Huggins–Zuo Equation of State

Modeling reservoir crude oils necessitates knowing the effect of gravity. Prior to the Yen–Mullins model, the size of asphaltene particles and even molecules in crude oils or laboratory solvents was unknown. This precluded any modeling of asphaltene gradients in reservoirs. With the Yen–Mullins model, this size is resolved. Knowing the size of asphaltene particles in crude oil enables evaluation of the gravity term, an essential component of modeling reservoir fluids. The first theory introduced for asphaltene gradients is the FHZ EoS, which, of course, incorporates the effects of gravity. The gravity term is given by Archimedes buoyancy ($V\Delta\rho g$) of the asphaltenes in the Boltzmann distribution, where V is the size of the asphaltene particle, $\Delta\rho$ is the density contrast between the asphaltene particle and the oil phase, and g is Earth's gravitational acceleration. OD_i is optical density at height i in the reservoir, k is Boltzmann's constant and T is temperature

$$\frac{OD_h}{OD_o} = \exp\left(\frac{-V\Delta\rho gh}{kT}\right). \quad (6.6)$$

Replacing $V\Delta\rho$ with the weighted mass of nitrogen and oxygen molecules yields the barometric equation, which gives the atmospheric pressure gradient of planet Earth from the sea level to Mt. Everest and beyond. The weighted sum of atmospheric gases is used because compositional mixing from weather systems is far more rapid than the diffusive process that would lead to separate density gradients of the different gases. The Boltzmann distribution describes the counterbalance between excitation energy and temperature; gravity pulls objects with mass to lower elevation while thermal energy lifts objects to heights. For low GOR crude oils, the FHZ EoS largely reduces to this gravity term (6.6). The full FHZ EoS is listed below and applies to heavy ends in all crude oils [6.10–12].

By adding the gravity term to the Flory–Huggins polymer solution theory, the FHZ EoS is obtained. This theory combines simple regular solution theory of solubility with the effects of gravity to describe the distribution of dissolved (or nanocolloidally suspended) asphaltenes in reservoir fluid. The FHZ EoS is the first EoS for predicting asphaltene concentration gradients with depth in oil reservoirs [6.10–12]. It is the only proven EoS to describe asphaltene gradients in oil reservoirs for crude oils ranging from condensates to heavy oils [6.12]. Because of the simple form of the FHZ

EoS, it can use various measurements of reservoir fluid properties, in particular, by employing asphaltene concentration ratios or optical density ratios at two different depths in the reservoir. The FHZ EOS is given as

$$\begin{aligned} \frac{OD(h_2)}{OD(h_1)} &= \frac{\varphi_a(h_2)}{\varphi_a(h_1)} \\ &= \exp\left(\frac{v_a g (\rho - \rho_a)(h_2 - h_1)}{kT} \right. \\ &\quad \left. + \frac{v_a}{kT} [(\delta_a - \delta)_{h_1}^2 - (\delta_a - \delta)_{h_2}^2] \right. \\ &\quad \left. + \left[\left(\frac{v_a}{v}\right)_{h_2} - \left(\frac{v_a}{v}\right)_{h_1} \right] \right), \quad (6.7) \end{aligned}$$

where OD , k , ϕ , v , δ , T , g , ρ , and h are the optical density, Boltzmann's constant, volume fraction, molar volume, solubility parameter, temperature, gravitational acceleration, density, and depth (or height), respectively. Subscript a denotes the properties of asphaltenes; subscripts h_1 and h_2 stand for the properties at depths h_1 and h_2 , respectively. It should be pointed out that the crude oil solubility parameter, molar volume, and density of bulk fluids, temperature, pressure, and compositions are all dependent on depth.

In addition to the gravity term (the leading term in the argument of the exponential), the second term in the exponential is the solubility term. This term is the specific manifestation of the chemical axiom *like dissolves like*. If the solubility parameters of the asphaltene and the crude oil are not too dissimilar, then the energetics allow dissolution. Gaseous hydrocarbons are, well, gaseous and colorless. Hydrocarbon gases are colorless because asphaltenes do not partition (or dissolve) in this phase. Gaseous hydrocarbons are not *like* the dark brown solid, the asphaltenes. Consequently, high GOR crude oils have very limited capacity to dissolve asphaltenes, whereas low GOR fluids can dissolve asphaltenes. The variation of the solubility term in reservoir crude oils is dominated by GOR variations. For low GOR crude oils, the oils are incompressible; thus, there is very little GOR variation with depth. Consequently, the solubility term is constant, and the asphaltene variation is dominated by the gravity term.

The last term in the argument of the exponential in (6.7) is the entropy term. This term tends to be small and acts to yield distributions that are macroscopically homogeneous, that is, randomly distributed.

6.9 Conclusions

The confluence of results from very diverse, detailed studies on asphaltenes has led to the Yen–Mullins model to characterize the dominant molecular and nanocolloidal structures of asphaltenes. Original studies that gave rise to this model as well as recent studies that tested this model have been discussed herein and provide strong support for this model. The simplicities of the nanocolloidal structures of asphaltenes traces back in part to molecular architecture, with the single, attractive PAH in the molecular core and with peripheral alkanes involving steric hindrance. The dominant intermolecular interaction of polarizability also helps explain why simple concepts account for many obser-

vations associated with asphaltenes. The Yen–Mullins model provides a framework for understanding many asphaltene properties. It also serves as the foundation of the Flory–Huggins–Zuo EoS (discussed in the next chapter), which is now ubiquitously used for reservoir evaluation. It has long been known that the simplicity of crude oil gas and liquid components allows for broad applicability of the cubic EoS and simple mixing rules to account for many diverse properties of the gas and liquid phase equilibria of crude oils. The Yen–Mullins model coupled with the Flory–Huggins–Zuo EoS now extends these overarching concepts to solution and (dissolved) solid equilibria of crude oils.

7. Reservoir Evaluation by DFA Measurements and Thermodynamic Analysis

Go Fujisawa, Oliver C. Mullins

Downhole fluid analysis (DFA) has enabled the cost-effective measurement in oil wells of a variety of chemical properties of reservoir crude oils. An immediate benefit of DFA is the improvement of the sample quality of the reservoir fluid in the subsurface environment. In addition, this early feedback on the nature of the reservoir fluid aids in understanding key reservoir challenges. DFA also enables the accurate determination of fluid gradients in the reservoir in both vertical and lateral directions. These gradients can then be analyzed in a thermodynamic equation of state (EoS) context; the gas-liquid properties can be modeled with the cubic EoS and the asphaltene gradients equilibrium can be modeled with the Flory-Huggins-Zuo (FHZ) EoS with its reliance on the Yen-Mullins model of asphaltenes. Time-dependent processes in geologic time can be modeled by adding appropriate dynamic terms to the EoS. Simple thermodynamic models can then be used to understand distributions of key fluid properties for reservoir crude oils and aid in simulating production. This thermodynamic analysis of the geodynamics of reservoir fluids fills a gap in the industry's modeling of reservoir fluids. Traditional basin modeling predicts what fluids enter

the reservoir. This new geodynamic modeling coupled with DFA measurements determines what transpired in geologic time in regards to fluid distributions within the reservoir. The output of this fluid geodynamic modeling can then be used as input for traditional reservoir simulation for production. This new understanding of reservoir fluid geodynamics is made possible by new DFA measurements coupled with new FHZ EoS with the Yen-Mullins model.

The volume and properties of hydrocarbon fluids (oil and/or gas) play a central role in establishing economic value of reservoirs and in developing production plans for those reserves [7.1]. For example, the gas-to-oil ratio (GOR) determines the fundamentally different requirements for handling high pressure gas versus oil. The asphaltene content has an enormous impact on viscosity, which impacts rates of fluid flow as well as economic value. The properties of the reservoir crude oil determine whether a deleterious phase transition will occur during production; transitions include asphaltene deposition, wax deposition, and organic scale, which can impede production and mandate costly solutions. Moreover, important fluid properties can vary dramatically vertically and laterally in reservoirs. Along the

lines of the ergodic theorem, spatial variation of fluid properties translates to temporal variation of fluid properties in production, and these variations need to be understood for production optimization.

In addition, the analysis of fluid gradients in the reservoir can address a variety of important issues. For example, the observations of thermodynamic equilibration of reservoir fluids is a strong indicator of reservoir connectivity, at least at some point in geologic time if not at the current time [7.2]. Disequilibrium of reservoir fluids often implies existence of a transient process in geologic time occurring in the reservoir. In turn, this aids in understanding complex reservoirs with simple formalisms enabling improved risk assessment of field development planning [7.3].

This analysis of reservoir fluids is best accomplished prior to production as production facilities, which represent significant capital expenditure and are designed to accommodate the specific reservoir fluid. Consequently, wireline logging and drilling tools have been developed to acquire fluid samples in openhole (or even cased hole) shortly after the well is drilled and long before production commences [7.4]. Nevertheless, it is not economical to blindly acquire fluid samples at all possible depths in the well to carry out this critical objective of reservoir fluid analysis. It is very important to be able to assess hydrocarbon reservoir fluid inside a wellbore in real time by the sample acquisition tool, so that informed and optimum decisions can be made regarding whether a fluid sample is required from any particular section of the well and if the current quality of fluid sample is sufficient [7.2]. Today, this important role is performed by downhole fluid analysis (DFA) and mostly by visible and near-infrared (Vis/NIR) spectroscopy [7.2]. Vis/NIR spectroscopy is a very powerful analytic tool and is utilized in many industrial settings. Vis/NIR spectroscopy has been the most powerful DFA measurement to analyze reservoir fluid in situ in oil/gas wells for more than 20 years. Today, DFA by Vis/NIR spectroscopy is widely accepted by upstream oil and gas companies as a valuable and indispensable method to understand their hydrocarbon fluids and reservoirs.

The capabilities of DFA have recently greatly expanded due to the ability to employ proper thermodynamic modeling of DFA data. Reservoir crude oils consist of dissolved gases, liquids and dissolved (or nanocolloidally suspended) solids, known as asphaltenes (Chap. 6). For decades, the dissolved gas and liquid properties of reservoir fluids have been treated by various cubic EoSs [7.1]. The effectiveness of this approach is well known and powerful for gas–liquid equilibria [7.1]. However, cubic EoSs, including the original cubic EoS the Van der Waals EoS, were never designed to handle colloidal solids. Crude oils contain (nanocolloidal) asphaltenes, and modeling of asphaltene gradients in reservoir crude oils has resisted proper

thermodynamic foundations until now. The problem was that nobody knew the size of asphaltene particles in crude oil. Even the asphaltene molecular weight had been the subject of debate spanning orders of magnitude [7.5]. This uncertainty precluded any understanding of the nanocolloidal structures of asphaltenes in crude oils. With the asphaltene size unknown, the corresponding gravitational force was unknown, and asphaltene gradient modeling was precluded. Fortunately, in recent years, the dominant molecular and colloidal structures of asphaltenes have been resolved and codified in the Yen–Mullins model [7.6]. With the gravity term resolved, a variation of a polymer regular solution theory, the Flory–Huggins–Zuo EoS has been used to great effect to model asphaltene gradients [7.7, 8].

In this chapter, we first describe measurement principles behind Vis/NIR spectroscopy of hydrocarbon reservoir fluids. Next, we explain some of the engineering challenges for implementing DFA hardware. Then, we explain the basic form of DFA operations and applications in a setting of formation testing and sampling tools to give clear views on how DFA is utilized in typical exploration and appraisal wells. The leading tool for sample acquisition in wireline logging is known as the modular formation dynamics tester (MDT), and we will refer to the MDT as the sample acquisition tool of interest. DFA is performed with specific DFA tools that are part of the MDT tool string. DFA data acquired by the MDT can then be analyzed using a thermodynamic basis. The cubic EoS is used for gas–liquid equilibria. The FHZ EoS along with the Yen–Mullins model is used for interpretation of DFA-measured asphaltene fluid gradients in oilfield reservoirs. Several case studies are shown that illustrate the power and capability of DFA and thermodynamic analysis to evaluate major reservoir concerns. A myriad of reservoir concerns are addressed such as connectivity, gas charging into oil reservoirs, tar mat formation and biodegradation. The combination of new asphaltene science and new DFA technology is leading to an explosion of applications in the oilfield.

7.1 The Borehole Environment

The borehole environment of oil wells presents several challenges for the objective of measurement of properties of fluids contained in the subsurface (rock) formations. Hydrocarbons can survive for geologic time at temperatures as high as 175 °C and at times above 200 °C so these temperatures set the specification for DFA measurements. These temperatures are associated

with pressures of 20 000 psi or at times 30 000 psi given normal temperature and pressure gradients in earth formations; thus setting the pressure specification for DFA measurements. Wellbore diameters can vary; frequently bit sizes are used in the hydrocarbon zones of interest that have diameters not much larger than 6 inches. Consequently, the tool housing, which must support the

Fig. 7.1 A wellbore is depicted along with a formation sampling tool, the MDT. Oil wells are drilled with a drilling mud which can either be oil-based or water-based; the latter is depicted here. Some base fluid leaks into the formation giving an annulus of *mud filtrate* in an annular region in the formation. Clean sample acquisition of formation fluids requires good probe configurations and sufficient pumping times to drain the contaminating mud filtrate. DFA has the charter to monitor and quantify the filtrate contamination of the formation fluids (after [7.2])

large pressures just discussed, must not exceed 6 inches in order to be broadly used. The DFA measurement systems must be compact.

Oil wells are drilled with a drilling mud. The mud serves many purposes. The mud is pumped down the center of the drill string and flows back to surface along in the annular space between the drill string and borehole wall. This mud flow carries the rock cuttings out of the well. The mud is weighted with solids to maintain the fluid pressure in the borehole greater than that of the zones penetrated to prevent uncontrolled influx of formation fluids into the borehole. Such a blowout is extremely dangerous in all ways. The muds contain clays and bridging agents to build mud cakes on the borehole wall at permeable zones in order to prevent excessive fluid loss from the high pressure borehole to the lower pressure permeable zones. Excess fluid loss can lead to loss of well control due to loss of hydrostatic head pressure in the mud column. Excess fluid loss can also lead to formation damage hindering the eventual production of oil. The drilling muds can have either water or oil as the base fluid.

Figure 7.1 presents a clean view of the borehole, with an annulus of invaded mud filtrate that penetrates through the mud cake present on borehole wall at permeable zones. A sampling tool is depicted in the center of the borehole. The industry-leading fluid openhole sampling tool is the MDT, the modular formation dynamics tester tool [7.4]. Openhole refers to the condition of the wellbore prior to placement of casing, or cased hole. Thus, openhole sampling tools such as the MDT must establish hydraulic communication of the MDT probe with permeable formations in the presence of mud in the wellbore, and mud cake on the borehole wall of the permeable zone. A probe module with a strong tube is shown that contacts the borehole wall to make hydraulic communication with the formation fluids. Figure 7.1 correctly shows that the initial flow of fluid into the MDT will have significant contamination from the mud filtrate that has leaked into the permeable zones in the time between drilling the well and logging the well with the MDT [7.2]. Figure 7.1 depicts an oil-bearing formation with a water-based mud (WBM). Often oil bearing formations are drilled with oil-based

mud (OBM). One of the DFA objectives is to differentiate between the contamination mud filtrate versus formation fluids. This requires differentiating between oil and water for cases such as shown in Fig. 7.1. In addition, it is necessary to differentiate between OBM filtrate and crude oil. The OBM filtrate has little dis-

solved gas and no asphaltenes. Finally, there is interest in differentiating between WBM filtrate and formation water or connate water. Typically the WBMs are quite basic, thus pH measurements downhole using optical spectroscopy with litmus paper dyes become quite useful [7.9].

7.2 VIS/NIR Spectroscopy of Hydrocarbon Reservoir Fluids

Vis/NIR spectroscopy investigates molecules by spectral (electromagnetic) interrogation of various molecular modes. Typically, UV/Vis spectroscopy corresponds to valence electronic state transitions, infrared spectroscopy corresponds to vibrational modes and microwave spectroscopy to rotational modes. For downhole analysis in situ in oil wells, visible (Vis) and even near-infrared (NIR) spectral ranges are used to evaluate the electronic absorption edge of crude oils, specifically the asphaltenes and heavy resins of the oils. It is the large polycyclic aromatic hydrocarbons (PAHs) of asphaltenes that give rise to long wavelength absorption [7.5]. NIR is also used to examine the vibrational overtones of molecules. Mid-infrared spec-

troscopy (MIR) is of limited utility downhole because the large absorption strengths ensure nonlinear spectral response, thus it is error prone, and the requisite low photon energy sensitivity of MIR detectors yields large thermal noise at the elevated temperatures encountered downhole. In contrast, NIR spectroscopy is linear at pathlengths (2 mm) convenient for downhole flowlines, and the relatively high energy cutoff of NIR detectors minimizes thermal noise.

Figure 7.2 shows typical crude oil spectra in the Vis/NIR wavelength range for a 2 mm pathlength, which is operationally convenient downhole. OD is *optical density*, which accounts for attenuation from optical absorption and light scattering. There is no light

Fig. 7.2 Vis/NIR spectra of typical crude oils. The vibrational peaks can be used to differentiate oil versus water, while the differing, sloping electronic absorption edges can be used to differentiate amongst different oils (after [7.2])

scattering for the single phase fluids shown in Fig. 7.2. OD is defined as

$$OD = -\log_{10} \left(\frac{I}{I_0} \right), \quad (7.1)$$

where I_0 is the incident light intensity and I is the transmitted light intensity. OD is linear in the molecular extinction coefficient, concentration and pathlength. Both water and oil exhibit peaks associated with vibrational overtone and combination bands. The bands are (formally) forbidden, thus accounting for their small cross-section in comparison to the allowed fundamental vibrational bands in the MIR, which are roughly a thousand times larger in OD. The higher energy peaks (shorter wavelength) in Fig. 7.2 correspond to higher overtones and combination bands and are *more forbidden* accounting for their smaller size. These peaks offer the capability to differentiate water and oil in a robust manner. In addition, the oil spectra have differing electronic absorption spectra that are characterized by increasing absorption at shorter wavelengths. This variable, sloping absorption corresponds to the

electronic absorption edge of crude oils. Overall, the electronic spectrum of a crude oil is an incoherent sum of many contributing spectra from the numerous chemical constituents in crude oil. This valence shell electronic absorption increases continuously towards shorter wavelengths; towards the vacuum ultraviolet range (Chap. 6).

Identification of oil versus water is always key in oil well logging. Water has very distinctive absorption peaks around 1440 and 1940 nm. The peak at 1440 nm corresponds to the vibrational overtone of the O–H stretch mode (symmetrical and/or asymmetrical) of water, and the peak at 1940 nm corresponds to the combination of stretch plus bend mode of water. Oil has a group of absorption peaks around 1725 and 2350 nm. The peak at 1725 nm corresponds to the overtone of the stretch mode of the C–H bond (predominantly in methylene groups), and the peak at 2350 nm corresponds to the combination mode of the stretch plus bend of the C–H bond (again predominantly in methylene groups). The clear separation of water and oil peaks allows easy identification and quantification of water and oil in flowing fluid sample [7.10, 11].

Fig. 7.3 The two-stretch overtone NIR spectra of methane, *n*-heptane, and a mixture of methane and *n*-heptane. The CH_4 two-stretch overtone is shifted to higher energy (1670 nm). The $-\text{CH}_3$ overtones appear as a doublet at 1690 and 1700 nm. The dominant $-\text{CH}_2-$ overtone is at 1725 nm; the so-called oil peak (after [7.10])

Fig. 7.4 The cleanup process for acquisition of crude oil in a well drilled with OBM. As MDT pumping time advances, the contamination of the flowline fluid is reduced enabling acquisition of clean formation crude oil. The OCM algorithm allows quantification of the time dependence of the color measurement or GOR (not shown) in real time during sample acquisition and is in agreement with subsequent lab contamination analyses (after [7.2])

Differentiation of different CH groups, CH_4 – CH_3 and $-\text{CH}_2-$ can be obtained by analysis of the two-stretch overtone at ≈ 1725 nm. (In crude oil, the methine contribution is very small and not useful.) Although all hydrocarbon molecules show absorption around 1725 nm, the exact absorption spectrum depends on the resonance frequency of each vibration mode. Since resonance frequency of carbon-hydrogen vibration is slightly different in methane (CH_4), methyl ($-\text{CH}_3$), or in methylene groups ($-\text{CH}_2-$), then some hydrocarbon compositional information can be obtained from the CH two-stretch overtone. Figure 7.3 shows relevant spectra and furthermore helps establish that the spectra are linear in composition [7.2].

For gaseous alkanes there are some further energy differences in the overtones enabling further spectral characterization of composition. This similarity of spectra among hydrocarbon molecules effectively sets a practical limit to a number of independently extractable compositional groups. We use a chemometric approach, principal components regression (PCR) [7.10] and partial least squares regression (PLS), to build interpretation models that map the measured spectrum into composition. The latest DFA spectrometer can determine methane (C_1), ethane (C_2), the C_3 – C_5 group, and C_{6+} groups in crude oil with reasonable accuracy [7.10]. In additions to these grouped hydrocarbon compositions, the CO_2 measurement is

also possible by measuring its peak around 2000 nm under some situations. These compositional analyses are useful by themselves, and furthermore, they also allow calculation of the GOR, which is one of the most important parameters for characterizing reservoir hydrocarbons [7.1].

In addition, differentiating between or among different oils is also essential downhole. In particular, oil wells are often drilled with oil-based muds (OBM) as discussed above (Fig. 7.1). Some of the OBM filtrate leaks into permeable zones. Differentiation of the OBM filtrate versus crude oil is essential. The OBM filtrates do not possess dissolved gas or asphaltenes. Thus, Vis-NIR spectroscopy can be used to differentiate drilling fluid versus subsurface formation crude oil. In particular, almost all reservoir crude oils contain dissolved gas, dissolved asphaltenes, or both. Using the NIR spectral analysis, the GOR of the flowline fluid is determined. Using the Vis-NIR measurement, the color of the flowline fluid is measured. Both GOR and color are measured as a function of pumping time. Using various algorithms such as the OCM algorithm [7.2], the measurement of color and GOR versus pumping time can be quantified as a percent contamination as shown in Fig. 7.4 [7.2].

In addition, to obtaining clean formation fluids, DFA is critical for understanding the spatial variation of formation fluid properties. Understanding the nature of crude oil variation throughout reservoirs is essen-

Fig. 7.5 Dead crude oils (at one atmosphere thus without their gas fraction) from a single oil reservoir, deepwater Gulf of Mexico. These oils have a huge, monotonic range of asphaltene content (courtesy of Hani Elshahawi, Shell)

tial for optimizing production. Figure 7.5 shows the type of variation of crude oil that can naturally occur in oil reservoirs. Some origins of these variations are discussed in case studies below.

Those working in the oil industry know that heavy oils have a black color and light condensates have a light brown to yellow color. Figure 7.3 shows a huge change in (dead) oil color in a single reservoir associated with dramatically differing asphaltene concentrations. The right side of Fig. 7.3 corresponds to the top of the reservoir and the left side corresponds to the base of the oil reservoir.

This color variation is caused by the variation in concentration of asphaltenes. Asphaltenes with their significant fraction of large PAHs absorb light in $\pi-\pi^*$ electronic transition of polycyclic aromatic hydrocarbons (PAHs). Larger fused ring systems of PAHs have greater π -orbital delocalization, thus lower energy transitions. Two extreme examples of π -electron excitation

are benzene and graphite. Benzene has just one aromatic ring with minimal π -electron delocalization, and requires relatively large energy (≈ 250 nm) to excite $\pi-\pi^*$ transitions. Graphite (or graphene), on the other hand, has essentially an infinitely large fused aromatic ring system with π -electrons that are completely delocalized; graphite is a two-dimensional electrical conductor and a zero bandgap semiconductor, thus readily absorbs across the Vis/NIR range. The number of fused rings in asphaltene PAHs can exceed 15 rings (Chap. 6) giving rise to red-shifted $\pi-\pi^*$ transitions. This explains why heavy oil, rich in large PAHs of asphaltene molecules, have very dark color. Crude oil color can be used as an indicator of oil weight (density). While this analysis has been mostly qualitative in nature in the past, recent developments provide a strong foundation in chemical physics and thermodynamics for quantitative interpretation of DFA data as will be discussed herein.

7.3 Implementation of DFA Hardware

While Vis/NIR spectroscopy is a common analytic method in laboratory settings, implementation of DFA hardware (downhole) has always been a challenging scientific and engineering task. This challenge can be understood by contrasting the environmental requirements of oil and gas wellbores versus laboratories. Figure 7.6 shows a range of pressure and temperature conditions encountered in hydrocarbon-bearing formations, and thus provides specifications for DFA tools. The temperature inside oil and gas wells can be above 175°C (347°F) or even over 200°C (392°F). Moreover, the temperature might not even be stable during the DFA measurements. The pressure inside oil and gas wells can reach 140 MPa (approximately 20 000 psi) or may reach 200 MPa in very deep wells, for example, in the Gulf of Mexico. DFA instruments may experience severe and continuous shock and vibration during transportation to a well site and descent in wells to the designated depths. The latter is particularly demanding if the DFA spectrometer is a part of a drill string. Other important hardware design considerations for

DFA spectrometers include hardware footprint, maintainability and reliability. We will briefly explain these factors in this section.

The most obvious and probably the most demanding environmental requirement for engineering any scientific measurement instrument is high temperature, which can exceed 175 or even 200°C . High temperature can affect DFA optical train design in several different ways. First, it may destroy or significantly reduce the functionality and/or lifetime of typical optoelectronic and electronic components. It is known through years of experiences that failure rates of typical plastic packaged components increase dramatically above 150°C . For reliable operation at higher temperature, packaging of optoelectronic and electronic components requires exotic high-temperature plastic, metal or ceramic packages, which almost certainly requires customization and increase of manufacturing cost.

High temperature may not destroy components but it may still significantly alter the characteristics of

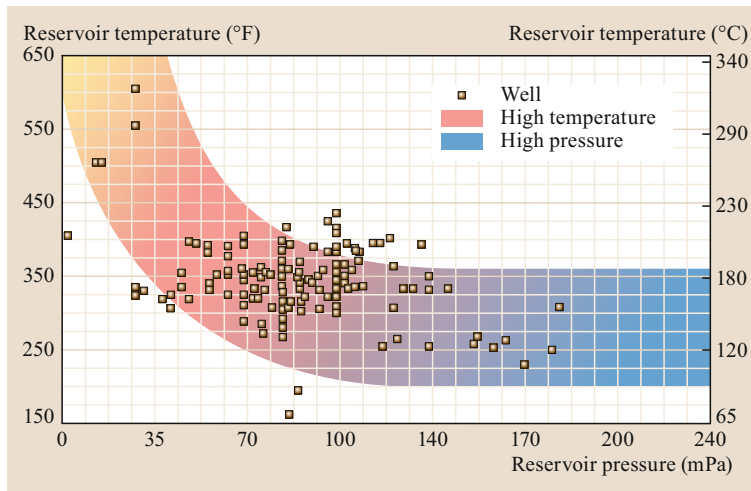

Fig. 7.6 Temperature and pressure conditions for selected wells (after [7.12]). The high temperatures are challenging for detectors and electronics. The high pressures mandate small devices

optoelectronic components. For example, lasers and light-emitting diodes (LEDs) may survive high temperature but their emission may be significantly altered, requiring significant compensation. For this reason, we have used a tungsten-halogen incandescent lamp operating around 3000 K for a light source for DFA spectrometers. A 3000 K black body radiator gives usable intensity in the entire Vis/NIR wavelength and tungsten-halogen lamps remain stable throughout a typical operating environmental range of room temperature to over 150 °C. Optical bandpass filters based on Fabry–Pérot interferometers may shift wavelength with temperature as high temperature causes thermal expansion and changing refractive index. High temperature can defocus and misalign optics by thermal expansion, particularly if the spectrometer is based on diffraction. These are some of the examples of engineering challenges for DFA spectrometer implementation.

Very high pressure, over 100 MPa (approximately 14 500 psi), is another common environmental requirement for measurement instruments used in oil/gas wellbores (Fig. 7.6). Realistically, the only way to design a DFA spectrometer in this setting is to seal the entire section of the spectrometer against pressure and only leave the optical window (or cell or probe) exposed to the high-pressure fluid. The optical window material needs to be strong enough to withstand high pressure, chemically stable against corrosive fluids, and transparent in the wavelength range used for spectroscopy. Sapphire is a perfect material satisfying all these requirements. For transmission geometry, we use a pair of sapphire windows separated by a flow channel enabling transmission spectroscopy.

Spectrometers generally are incompatible with mechanical shock and vibration, which is why most lab-

oratory spectroscopy often employs a shock absorbing table. Nevertheless, the DFA measurement setting requires that the DFA spectrometer will experience significant shock and vibration. Spectrometer hardware can achieve wavelength dispersion utilizing prisms and gratings, interferometry (e.g., FT-IR), or a set of (fixed wavelength) optical filters. Against mechanical shock and vibration, a spectrometer with fixed-wavelength optical filters (filter-array spectrometer) is the most robust design, although a high-resolution grating spectrometer is in use in a commercial DFA tool: the in situ fluid analyzer (IFA) [7.13].

A simplified schematic of a filter-array spectrometer is shown in Fig. 7.7. A 3000 K tungsten-halogen incandescent light source produces broadband radiation with a maximum output at roughly $\lambda = 1 \mu\text{m}$ and which covers the entire Vis/NIR wavelength range. A rotating chopper wheel selects the optical path and modulates the signal, reducing the noise floor. The modulated light source is selectively guided into a measurement cell or reference path via optical fiber bundles. The light transmitted out of a measurement cell and reference path are redistributed to individual photodetectors (PD) each coupled with a designated optical bandpass filter (only one of them is drawn in Fig. 7.7). The total number of optical bandpass filters (or channels) can be 10, 20, or any number decided by measurement requirements. With proper design customization, semiconductor-based PDs and optical filters can be reliable even over 150 °C.

Other important considerations for the DFA spectrometer design include the hardware size, maintainability and reliability. Space is a premium for downhole tools and the hardware needs to be designed to fit into a cylindrical tool string of typically 4 in or less in inner diameter. Once the DFA spectrometer is dispatched

Fig. 7.7 A schematic of a DFA filter spectrometer. This figure is drawn for only one wavelength channel for simplicity

Fig. 7.8 Comparison of compositions obtained from a DFA spectrometer (in situ fluid analyzer) and laboratory (gas chromatography) (after [7.10])

to a wellsite for measurement, there is no further opportunity for calibration. The spectrometer calibration needs to be stable and can only be performed at the tool shop on a very intermittent basis. Reliability is critically important in an oilfield business setting. Rig costs can exceed \$ 1 million per day; lost time due to instrumentation failure is prohibitively expensive. Finally, the DFA tools must be economically viable. The cost of the DFA tools and DFA data must be commensurate with corresponding value. All these factors add to make DFA requirements most demanding.

DFA spectrometers schematically depicted in Fig. 7.7 have been successfully engineered, manufactured, and deployed to oil/gas wells all over the world and routinely provide vital measurements inside wellbores under these demanding conditions. By exploiting spectral overtone analysis, DFA spectrometers can achieve compositional analysis displayed in Fig. 7.8, which shows excellent agreement of between hydrocarbon compositions measured by a DFA spectrometer (Schlumberger in situ fluid analyzer [7.13]) and by laboratory gas chromatography [7.10].

7.4 Basic DFA Operations and Applications

When a wellbore is drilled and a hydrocarbon reservoir is penetrated, several measurements are made to understand the subsurface formation properties. These measurements include formation density, porosity, basic lithology, resistivity, and rock stress. To understand fluid properties and fluid distributions, a formation fluid sampling tool or *formation tester* is required. The lead-

ing formation tester tool in the industry is the MDT tool [7.4].

A typical MDT tool sting consists of one or more probe modules, pump modules, DFA modules, and sample chamber modules. Figure 7.9 shows an example formation tester. The main role of the probe module is to create a sealing contact at the wellbore wall, thus allowing formation fluid to flow into the MDT. The actual shape of probe can be a simple small tube surrounded by a sealing rubber flange, or two concentric tubes with two layers of sealing rubber flanges for more efficient sampling, or two sets of packers isolating a section of wellbore. Pump modules generate a differential pressure to move fluid from the formation to the formation tester. Typically, because of mud filtrate invasion into the formation, a large amount of formation fluid needs to be pumped and expelled into the wellbore before the desirable quality fluid is obtained. DFA modules analyze and evaluate the flowing fluid inside the MDT flowline in real time so that the operators can make necessary decisions such as whether and when to take fluid samples. Sample chamber modules are used to capture the fluid flowing inside the MDT if it is judged as worthy of detailed analysis in a laboratory.

DFA has many uses. As noted above, DFA is used to analyze the sample cleanup during acquisition of formation samples as shown in Fig. 7.4. By analysis of the types of formation fluids in real time, the sample program can be optimized. Of course, hydrocarbon fluids are desired (versus water). DFA can be used to determine when a high-pressure bottle should be filled with the formation fluid for laboratory analysis. The sampling quality assurance is the procedure to obtain representative reservoir fluids in a sample bottle for further analysis in the laboratory. It is vitally important that the sample fluid is captured under a single phase condition otherwise the differential flow rate of two phases (gas and liquid) will not yield a representative sample. To achieve this goal, the DFA spectrometer module continuously measures and monitors flowline contents to detect any indication of phase segregation [7.2]. If different subsurface permeable zones contain different hydrocarbons, more sample bottles can be filled and brought to the surface. A new and powerful use of DFA is to perform reservoir evaluation to address major production concerns.

7.5 Reservoir Evaluation via DFA and Thermodynamics

DFA is the best method to measure fluid compositional gradients in oilfields. Figure 7.10 shows a schematic of the many uses of DFA measurement and thermodynamic analysis of reservoir fluid gradients. For measurements performed in single wells, many systematic errors cancel because DFA measurements at different points in the well have the same tool, almost the same time and temperature, the same calibration and same technologists. Thus, even subtle fluid gradients can be measured. With significant effort, tool-to-tool variation has been minimized in the latest generation of DFA tools such as the IFA; consequently, lateral variations of fluid properties can be measured accurately. In addition, the DFA data acquisition program can be matched to the complexity of the oil column. When large fluid differences are measured at two different depths in the well, DFA can be acquired at several intervening depths to clarify the type of fluid gradients.

In addition to the gravity term (the leading term in the argument of the exponential), the second term in the exponential is the solubility term. This term is the specific manifestation of the chemical axiom *like dissolves like*. If the solubility parameter of the asphaltene and the

crude oil are not too dissimilar, then the energetics allow dissolution. Gaseous hydrocarbons are gaseous and colorless. Hydrocarbon gases are colorless because asphaltenes do not partition (or dissolve) in this phase. Gaseous hydrocarbons are not *like* the dark brown solid, the asphaltenes. Consequently, high-GOR crude oils have very limited capacity to dissolve asphaltenes, while low-GOR fluids can dissolve asphaltenes. The variation of the solubility term in reservoir crude oils is dominated by GOR variations. For low-GOR crude oils, the oils are incompressible, thus there is very little GOR variation with depth. Consequently, the solubility term is constant, and the asphaltene variation is dominated by the gravity term (cf. Eq. (7.2)).

The last term in the argument of the exponential in (7.3) is the entropy term. This term tends to be small, and acts to yield distributions that are macroscopically homogeneous; that is randomly distributed.

Equation (7.3), mandates knowing the size of the asphaltene particle, explicitly the asphaltene size (or volume V). The inability to characterize asphaltene size previously precluded development of any EoS for asphaltene distributions. Without a known size, Newton's

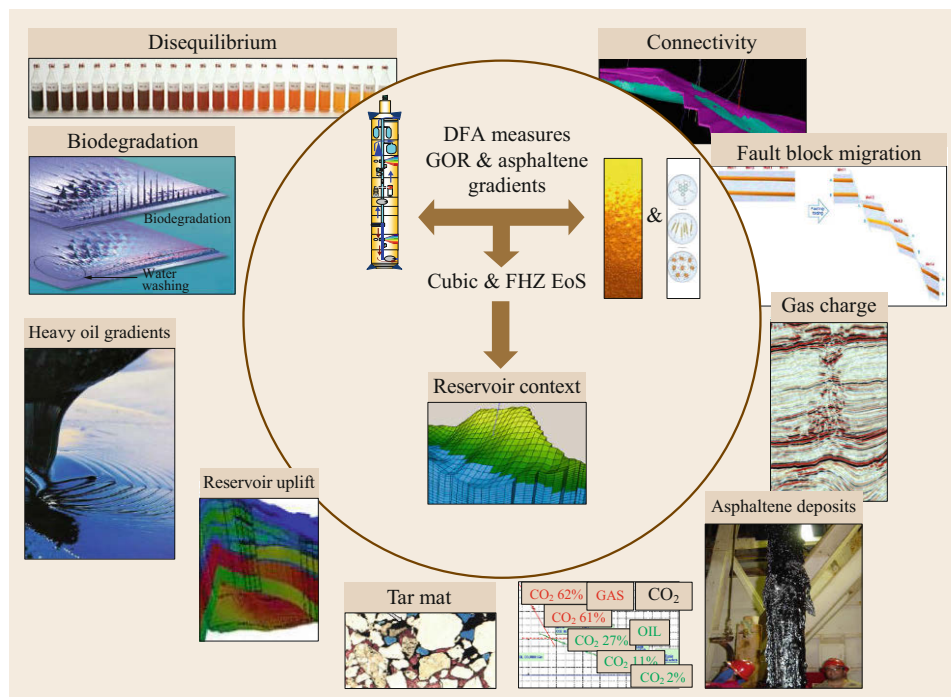

Fig. 7.10 The DFA workflow (after [7.3]). DFA measurements of fluid properties and gradients of fluid properties are made vertically and laterally in the reservoir. Thermodynamic analysis of the gas–liquid properties is performed with the cubic EoS. Asphaltene–fluid gradients are analyzed by the Flory–Huggins–Zuo equation of state (FHZ EoS) (after [7.8])

Fig. 7.11 The Yen–Mullins model depicting the predominant molecular and nanocolloidal structures of asphaltenes in crude oils and in laboratory solvents. At low concentrations such as in light oil, asphaltenes are dispersed as a true molecular solution (*left*). At higher concentrations such as in black oils, asphaltenes are dispersed as nanoaggregates (*center*). At yet higher concentrations such as in mobile heavy oils, asphaltenes are dispersed as clusters of nanoaggregates (*right*) (after [7.6]). All of these species are stable in the corresponding crude oils for geologic time

second law of motion, $F = ma$, remains undetermined for asphaltenes in a gravitational field. F is force, m is mass and a is acceleration; for a gravitational field $a =$

g . The size of asphaltenes has been resolved and codified in the Yen–Mullins model shown in Fig. 7.11 [7.6]. Chap. 6 treats this model in detail.

7.6 Reservoir Case Studies

The first reservoir to be studied linking the FHZ EoS and the Yen–Mullins model for reservoir evaluation was performed by Schlumberger and Chevron technologists for a reservoir in deepwater, Gulf of Mexico. Figure 7.12 depicts the upper and lower boundaries of the reservoir located at roughly 20 000 ft below sea level with a water depth of many thousand feet.

Fluid gradient data is essential in order to understand the thermodynamic context of the reservoir fluids. A single sample does not constrain the thermodynamic modeling. In contrast, fluid gradients provide a strin-

gent test for any thermodynamic modeling. The cubic equation of state (EoS) is used for modeling gas–liquid properties such as GOR and composition [7.1]. At this stage, this approach can be considered classic and is not reviewed here. In contrast, modeling asphaltene gradients is very new. Chapter 6 of this handbook describes the resolution of the molecular and colloidal structure of asphaltenes, which is now represented in the Yen–Mullins model. Knowing the size of asphaltene particles in crude oil enables evaluation of the gravity term, an essential component of modeling reservoir fluids. The first theory introduced for asphaltene gradients is the Flory–Huggins–Zuo EoS (FHZ EoS) which, of course, incorporates the effects of gravity. The gravity term is given by Archimedes buoyancy ($V\Delta\rho g$) of the asphaltenes in the Boltzmann distribution where V is the size of the asphaltene particle, $\Delta\rho$ is the density contrast between the asphaltene particle and the oil phase, and g is Earth’s gravitational acceleration. OD_i is optical density at height i in the reservoir, k is Boltzmann’s constant and T is temperature (cf. Eq. (7.2)).

Fig. 7.12 The upper and lower surfaces of a reservoir are depicted: deepwater, Gulf of Mexico (after [7.2]). The reservoir contains two stacked sands at different pressures thus not in flow communication. The reservoir is tilted and faulted due to basin distortion. The primary risk in reservoir development is the extent of flow connectivity in each reservoir sand ◀

$$\frac{OD_h}{OD_o} = \exp \left\{ \frac{-V\Delta\rho gh}{kT} \right\}. \quad (7.2)$$

Replacing $V\Delta\rho$ with the weighted mass of nitrogen and oxygen molecules yields the barometric equation, which gives the atmospheric pressure gradient of planet Earth from sea level to Mount Everest and beyond. The weighted sum of atmospheric gases is used because compositional mixing from weather systems is far more rapid than the diffusive process, which would lead to separate density gradients of the different gases. The Boltzmann distribution describes the counterbalance between energy; gravity pulling objects with mass to lower elevation versus thermal excitation – thermal energy lifting objects above the lowest point. For low-GOR crude oils, the FHZ EoS largely reduces to this gravity term (7.2). The full FHZ EoS is listed below and applies to heavy ends in all crude oils [7.7, 8].

By adding the gravity term to the Flory–Huggins polymer solution theory, the Flory–Huggins–Zuo EoS is obtained. This theory combines simple regular solution theory of solubility with the effects of gravity to describe the distribution of dissolved (or nanocolloidally suspended) asphaltenes in reservoir fluid. The Flory–Huggins–Zuo (FHZ) EoS is the first EoS for predicting asphaltene concentration gradients with depth in oil reservoirs [7.7, 8]. It is the only proven EoS to describe asphaltene gradients in oil reservoirs for crude oils ranging from condensates to heavy oils [7.8]. Be-

cause of the simple form of the FHZ EoS, it can use various measurements of reservoir fluid properties in particular by employing asphaltene concentration ratios or optical density ratios at two different depths in the reservoir. The FHZ EoS is

$$\begin{aligned} \frac{OD(h_2)}{OD(h_1)} = \frac{\phi_a(h_2)}{\phi_a(h_1)} = \exp \left\{ \frac{v_a g (\rho - \rho_a) (h_2 - h_1)}{kT} \right. \\ \left. + \frac{v_a}{kT} [(\delta_a - \delta)_{h_1}^2 - (\delta_a - \delta)_{h_2}^2] \right. \\ \left. + \left[\left(\frac{v_a}{v} \right)_{h_2} - \left(\frac{v_a}{v} \right)_{h_1} \right] \right\}, \quad (7.3) \end{aligned}$$

where OD, k , ϕ , v , δ , T , g , ρ , and h are the optical density, Boltzmann's constant, volume fraction, molar volume, solubility parameter, temperature, gravitational acceleration, density and depth (or height) respectively. Subscript a denotes the properties of asphaltenes; subscripts h_1 and h_2 stand for the properties at depths h_1 and h_2 respectively. It should be pointed out that the crude oil solubility parameter, molar volume, and density of bulk fluids, temperature, pressure and compositions are dependent on depth.

For this low-GOR reservoir of crude oil, the GOR is largely homogeneous, and for asphaltene gradients the gravity term dominates. The measured asphaltene gradients versus true vertical depth (TVD) are shown in Fig. 7.13. In the following figures, TVD is arbitrarily offset to avoid using the actual depth which is proprietary.

Fig. 7.13 Asphaltene (color) gradients versus true vertical depth. All three sands (grey, dark brown and light brown) are seen to fit (7.2) (lines) with a 1.6 nm asphaltene nanoaggregate size (after [7.2]). Thus, each sand individually shows equilibrated asphaltenes. Equilibrated asphaltenes indicate reservoir connectivity

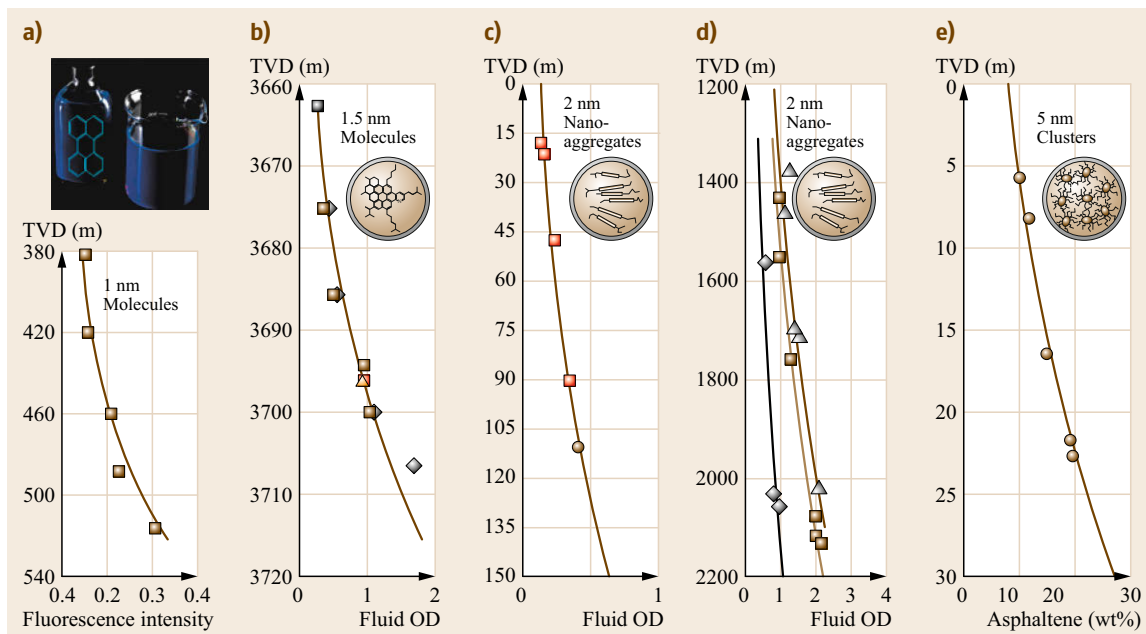

Fig. 7.14a–e The asphaltene (or heavy end) gradients in five reservoirs containing oil ranging from condensate (a) to heavy oil (e). (a) Condensate GOR = 600 m³/m³, (b) Volatile oil GOR = 350 m³/m³, (c) Black oil GOR = 180 m³/m³, (d) Black oil GOR = 90 m³/m³, (e) Heavy oil GOR = 12 m³/m³. In the light oil (a), the heavy ends are heavy resins such as perylene (inset), as this oil contains no asphaltenes (after [7.8]). For the other cases (b–e), the specific asphaltene structure from the Yen–Mullins model is shown (molecules, nanoaggregates and clusters). In all cases, the FHZ EoS fits the asphaltene gradients indicating equilibrated asphaltenes (or heavy ends). In all cases, the production established reservoir connectivity

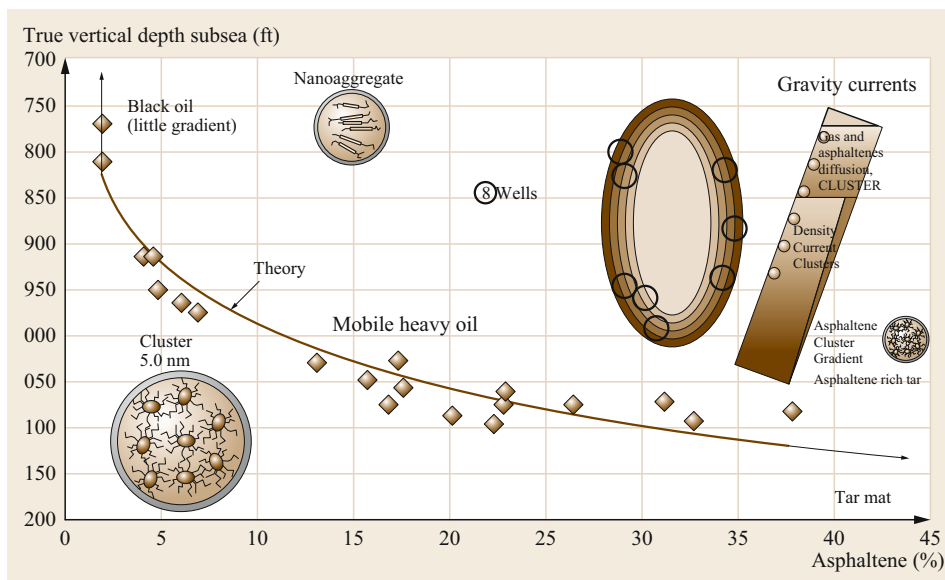

Fig. 7.15 A heavy oil rim of ≈ 100 km in length is accurately described by (7.2) using a 5.1 nm asphaltene cluster size, the only adjustable parameter, which is in excellent agreement with a nominal 5.0 nm cluster size (after [7.14]). The $10\times$ gradient of asphaltenes in ≈ 150 feet of height (≈ 50 m) over 100 km in length provides a very stringent test and positive result for fitting with (7.2). Reprinted with permission from [7.14]. Copyright 2013 American Chemical Society

For each of the two stacked sands, the grey sand and the dark brown sand, the asphaltene gradients are accurately fit by (7.2). The asphaltene particle size is the

only adjustable parameter in the fitting and the obtained size is 1.6 nm. The range of size of colloidal particles varies from 1 nm to 1 μ m. Any smaller and the system

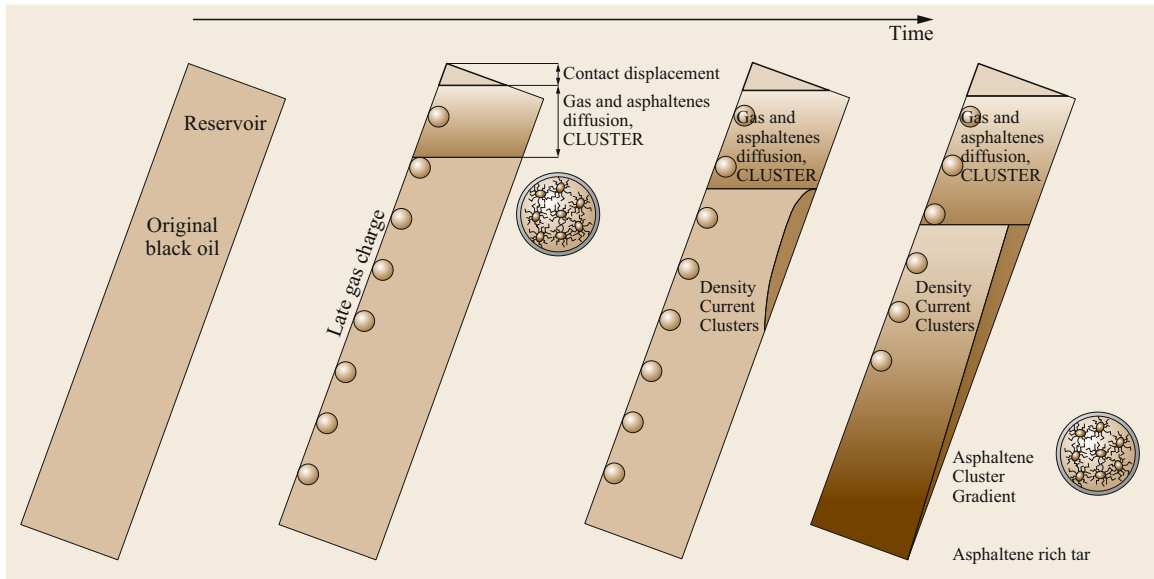

Fig. 7.16 The time sequence of a slow gas charge into an oil reservoir (after [7.3]). A diffusive front of gas entry into the oil column takes places thereby increasing solution gas at/near the GOC. Asphaltenes are expelled out of the high-GOR, upper regions of the oil column and diffuse in the form of asphaltene clusters ahead of the gas front. This causes a pileup of asphaltenes at the diffusive gas front, increasing the oil density there above the original oil. Convective currents follow and pump asphaltene-enriched oil to the base of the reservoir. This can cause formation of heavy oils at the base of the reservoir with large (asphaltene cluster) gravity gradients. With continued gas entry at the crest, asphaltene accumulation continues at the base causing formation of tar mats if sufficiently high concentrations of asphaltenes are attained

is molecular thus not colloidal, and any larger and the buoyancy forces cause rapid segregation. The nanoaggregate size obtained from Fig. 7.13 is within 20% of expected nanoaggregate size, thus is close to what is expected a priori.

The existence of equilibrated asphaltenes is a strong indicator of reservoir connectivity [7.15]. The separate equilibration curve shown in brown in Fig. 7.13 in the north of one of the sands indicates that this reservoir section is separate and not connected. One cannot have coffee color in one sand, tea color in another sand at the same depth and have all in equilibrium. All connectivity predictions made by DFA analysis here have been confirmed in production [7.2].

Figure 7.14 shows DFA data from five reservoirs with crude oils ranging from condensate to heavy oil. In all cases, the asphaltenes or heavy ends are equilibrated vertically and, in the cases with multiple wells, laterally, and in all cases in Fig. 7.14, connectivity has been established with production. In all cases, the FHZ EoS accurately accounted for the heavy end gradients [7.8].

The salient feature of Fig. 7.14 is the strong link between equilibrated asphaltenes (as determined by FHZ EoS analysis) and reservoir connectivity, established in production, a dynamic measurement. The lack of equilibration of asphaltenes does not mean there is no

connectivity; reservoir fluid geodynamics can preclude fluid equilibrium as shown below. In addition, there are cases where the asphaltenes equilibrated, then a subsequent geologic event sealed part of the reservoir. In such a case, asphaltene equilibration does not indicate connectivity. Nevertheless, the petroleum system is tightly constrained by the DFA data to have fluid equilibration followed by a sealing event.

In most cases in Fig. 7.14, the cubic EoS analysis of GOR gradients was not very instructive; thus the FHZ EoS analysis is key [7.8]. For low-GOR black oils (Fig. 7.14d) and heavy oils (Fig. 7.14e), the GORs are homogeneous, thus precluding effective connectivity analysis. The same fluid on both sides of a fault does not indicate the fault is hydraulically transmissive. Instead, it is a continuous gradient through a fault which indicates transmissivity (or connectivity). In addition, the error in GOR determination, lab or downhole, is often bigger than the corresponding gradient, thus giving an ambiguous connectivity analysis. This error problem generally applies to high-GOR black oils (Fig. 7.14c). In some cases, with late gas charge into the reservoir, the GOR can be in disequilibrium while the asphaltenes are equilibrated (Fig. 7.14b). As shown in production, the reservoir is connected proving the value of the FHZ EoS analysis. That is, fluid geodynamics in this

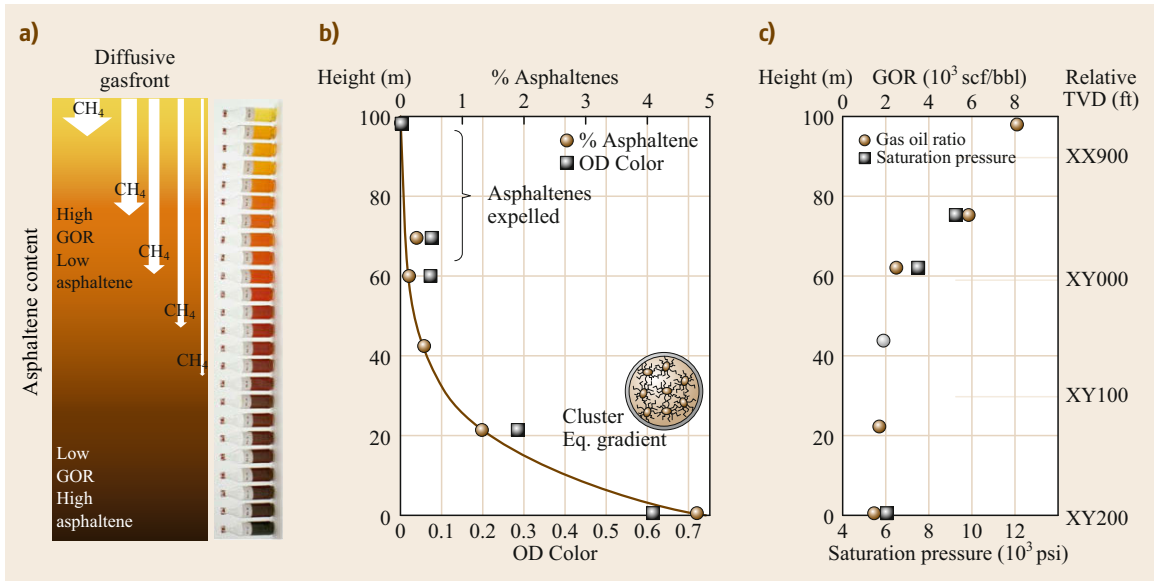

Fig. 7.17a–c A reservoir in the middle of a slow, late gas charge into oil (after [7.3]). **(a)** The color gradient of a series of dead oils from a single oil column (Fig. 7.5). Also shown is a cartoon of the process of diffusive methane entry into the oil column from the GOC. The solution gas gradient is diffusive as depicted in the cartoon. **(c)** Confirmation of a huge disequilibrium of solution gas in the top half of the oil column. XY is used to mark the leading numbers as the data shown is confidential. The GOR varies from 8000 to 2000 scf/bbl in 150 ft of height. The GOR in the bottom half of the oil column is equilibrated; the diffusion of methane has not had time to reach the bottom. **(b)** The asphaltenes have been expelled from the top of the oil column due to high GOR (the liquids possesses little color). Gravity currents of clusters pumped asphaltenes to the base of the reservoir yielding a gravitation gradient of asphaltene clusters. Copyright 2014, Society of Petroleum Engineers Inc. Reproduced with permission of SPE. Further reproduction prohibited without permission

reservoir precluded equilibration of the light ends but the perturbation was not sufficient to disturb the asphaltenes in this case [7.8].

Another reservoir, depicted in Fig. 7.15, in a four-way sealing anticline, has a fairly simple distribution of contained fluids. The crest of the field contains a black oil of low GOR and moderate asphaltene content. Around the 100 km rim of the field, there is ≈ 50 m height of heavy oil. This heavy oil is underlain by a tar mat of ≈ 10 m. As the GOR is low, the gravity term (7.2), dominates the distribution. The asphaltene particle in heavy oils is the asphaltene cluster. Figure 7.15 shows the data from seven of the eight wells that intersected this reservoir [7.14, 16]. A similar stacked reservoir in this field showed the same gradient.

The equilibration of the oil in Fig. 7.15 provides a strong indication of reservoir connectivity, as has been proven in production [7.16]. The only way to equilibrate fluids over such great distances is through convective currents, not diffusion. A diffusive process over a distance of 50 km would take a trillion years; while this reservoir is old, it is not 70 times the age of the universe! The origin of the convective currents is

associated asphaltene instability upon charging of a second light oil or gas into a black oil reservoir. Figure 7.16 shows a schematic of this process.

This same process occurs even if the second charge is not a slow gas charge, but instead is a slow, light liquid hydrocarbon charge. The light charge would migrate to the crest. The light components would diffuse into the oil column destabilizing asphaltenes, and the asphaltenes would diffuse down and away from oil enriched in light hydrocarbon components. For simplicity, we represent this second charge as a gas charge, but the same line of reasoning applies for a light hydrocarbon charge into an original column of black oil. Thus, a gas cap is not a prerequisite for the occurrence of this slow, late, light hydrocarbon charge into an oil column.

A key component in this process is the accumulation of asphaltenes at the base of the diffusive gas front. At greater times, expelled asphaltenes pile up ahead of the gas front similarly to the way snow piles up in front of a snow plow. Coupled diffusion equations between methane and asphaltenes in crude oil show this piling-up phenomenon [7.17].

The giant reservoir depicted in Fig. 7.15 shows the end result of this process. Figure 7.17 shows a reser-

Fig. 7.18 The upper and lower horizons of the Bhagyam field. The field is only 300 m below surface and has been undergoing biodegradation since reservoir charging, which commenced in the lower Eocene. The rate-limiting step in the biodegradation is diffusion of labile alkanes to the oil-water contact at the base of the oil column. Reprinted with permission from [7.18, 19]. Copyright 2015 American Chemical Society

voir that is in the middle of gas diffusion and asphaltene convective currents. This reservoir fluid, particularly the light ends, is far from equilibrium even in this connected reservoir. Recent and ongoing reservoir fluid geodynamics can preclude equilibration as seen in Fig. 7.17.

Figure 7.17 shows the dramatic effects on oil properties associated with a slow gas charge into an oil reservoir. Both DFA and lab data show this effect. The gas charge into the oil reservoir migrates quickly to the top of the oil column, the so-called Stainforth charge mechanism [7.2]. In this deepwater field, the reservoir pressure is sufficiently high that the gas dissolves in the oil. The newly charged gas then diffuses down into the oil column. The GORs and saturation pressures for the top half of the oil column are grossly out of equilibrium (Fig. 7.17c). Instead the solution gas in the top half of the oil column is determined by the diffusion of methane from the top. The lower half of the oil column has equilibrated GOR and saturation pressure; diffusion of methane from the top has not had sufficient time to reach the bottom half of the oil column. For diffusion,

it is not the height that determines the requisite time, rather it is the distance along the reservoir (measured depth).

Figure 7.17 also shows that the asphaltenes have been expelled from the top of the oil column in accordance with the high solution gas; the higher the GOR, the less the asphaltene concentration. The bottom half of the oil column has equilibrated with solution gas exhibiting little variation with depth. Consequently, there was no perturbation of the asphaltene concentration in the lower half of the oil column from variations in solution gas. Nevertheless, there is a large asphaltene gradient matching a gravitation gradient of clusters. The most likely explanation for this observation is that the expelled asphaltenes from the top half of the oil column flowed in gravity currents to the base of the reservoir in the form of asphaltene clusters.

The gravity currents occur when the light hydrocarbon diffuses into the black oil and expels asphaltene [7.3]. These convective currents pump asphaltene from the crest of the field to the base of the field, giving rise to heavy oil at the base. If the asphaltene instability

Fig. 7.19 The relative asphaltene content versus depth in the Bhagyam field, along with GC traces of selected samples. Approximately the top half of the oil column has GC traces exhibiting a full complement of alkanes (the tall regular *spikes*). The alkanes are seen to diminish with increasing depth (except the filtrate contamination). Reprinted (adapted) with permission from [7.18, 19]. Copyright 2015 American Chemical Society

process continues, enough asphaltene can be pumped to the base of the crude oil column to yield a tar mat [7.3]. The giant reservoir depicted in Fig. 7.15 had just this process. A cartoon showing the gas charging into the reservoir, gas diffusion into the oil column, along with an asphaltene-rich gravity current, is shown in the inset of Fig. 7.15 and in Fig. 7.16.

Other reservoir fluid processes can take place in geologic time that can preclude equilibration in addition to a late gas charge. An example of such a case is provided by the Bhagyam reservoir in the Rajasthan basin in India and shown in Fig. 7.18 [7.18]. There are five stacked sand reservoirs penetrated by four wells (in this study); all sands show identical fluid gradients.

The five-stacked sand reservoirs of the Bhagyam field commenced charging in the lower Eocene and ceased charging with uplift in the lower Miocene [7.20]. Figure 7.19 shows the DFA-measured fluid color (which gives the relative asphaltene content) versus depth in the field. In addition, the gas chromatograms (GCs) are shown for oils at various depths in the field. In addition, a GC of the OBM mud filtrate is also shown in Fig. 7.16 [7.18, 19].

The impact of biodegradation is readily observed in the GC traces in Fig. 7.19 towards the bottom of the oil column (the oil-water contact; OWC). The microbes live in the water and preferentially consume the alkanes. As the alkanes disappear, the asphaltenes become concentrated and the viscosity increases. The rate-limiting step is diffusion of alkanes higher in the oil column to the OWC; the biodegradation step is more rapid.

Fig. 7.20 Thermodynamic modeling and data from five-stacked sands (after [7.19]). The Bhagyam field is shown in Fig. 7.18, and the GC traces are shown in Fig. 7.19. Diffusion is the rate-limiting step; the analysis shows that the diffusive process initiated approximately 50 million years ago ◀

Fig. 7.21 Results from the Rajasthan basin modeling (1-D burial model) showing that the Bhagyam field commenced charging in the lower Eocene and terminated charging with uplift in the lower Miocene. Increasing thickness of the *dark and light green shaded areas* corresponds to source maturity and reservoir charging. The diffusion-biodegradation process has been taking place for ≈ 50 million years (after [7.20])

Figure 7.20 shows data from five separate sands; the DFA color (OD) all overlay. The top half of the oil column is well fit by the FHZ EoS using the 2 nm nanoaggregate from the Yen–Mullins model. The bottom half of the oil column increasingly diverges from the static FHZ EoS model with depth. Including a (time-dependent) diffusive term accounts for the gradient in asphaltenes and is also consistent with the GC traces in Fig. 7.19.

The data presented in Figs. 7.19 and 7.20 show that a diffusive gradient exists in the reservoir and accounts for the gross disequilibrium of the alkane distribution as well as the asphaltene distribution. The one-dimensional diffusion equation gives

$$2Dt = x^2, \quad (7.4)$$

where D is the diffusion constant, t is time, and x is the mean displacement. Using a reasonable value for the diffusion constant, $D = 4 \times 10^{-8} \text{ cm}^2/\text{s}$ (oil is $> 20 \text{ cP}$) and $\approx 100 \text{ m}$ for the vertical distance from the

OWC, a 13° reservoir dip angle, one obtains 40 million years as an approximate duration of this diffusion and biodegradation process [7.19].

The petroleum system analysis presented in Fig. 7.21 is consistent with the simple diffusion analysis of a ≈ 40 million year duration of the diffusion and biodegradation process. With a reduction of the alkane composition of the crude oil, the asphaltenes are concentrated. Biodegradation can consume approximately two thirds of the oil [7.21], thus the asphaltenes can concentrate by a factor of three, which is exactly the increase above FHZ EoS equilibration seen in Fig. 7.20. The asphaltenes tend not to diffuse up the column despite the high concentration of asphaltenes low in the column because the reduction of alkanes makes the remaining crude oil a better solvent for asphaltenes. Being able to model the asphaltene gradient, and thus the viscosity gradient, with a simple chemical physics model is important to optimize the field development plan.

7.7 Conclusions

Prior to DFA, there had been the presumption that reservoir crude oils are largely homogeneous at least for the purposes of field development planning. However, assumptions of reservoir fluid homogeneity often led to significant production inefficiencies. Moreover, DFA surveys of reservoirs have become increasingly popular in establishing that reservoir fluid complexities frequently prevail. Moreover, the cost structure of DFA is compatible with the routine evaluation of fluid complexities in order to manage risk in reservoir development. In addition, for the first time, the asphaltene gradients in reservoirs can be modeled from a first principles approach using the FHZ EoS and its reliance on asphaltene nanostructures described in

the Yen–Mullins model. The combination of new DFA technology and new petroleum asphaltene science has led to an explosion of applications for oilfield development. Many reservoirs are now being understood within simple chemical physics models. These models are being combined with petroleum system modeling to maximize reservoir evaluation. A new understanding of commonly misunderstood reservoir observations such as tar mats, heavy oil gradients, and GOR gradients are firmly within the purview of these new formalisms. Efficiencies in field development planning and production of crude oil follow from these growing insights. The enhanced role of science and technology continues unabated in the petroleum industry.

8. Phase Behavior and Properties of Heavy Oils

John M. Shaw, Marco A. Satyro[†], Harvey W. Yarranton

The phase behaviors and thermophysical and transport properties of heavy oils not only share numerous features with light oils and reservoir fluids, but also exhibit substantial differences because of their more complex chemistry and fluid physics associated with this chemistry. As a consequence, conventional understanding, experimental methods, and property/phase behavior computation tools are stretched to their limits. They often fail to provide needed data and insights for process development, design, and operation for production, transport, or refining applications. Heavy oils are inherently multiphase and exhibit time-dependent and polymorphic behaviors that depend not only on temperature and pressure, but also on thermal and shear history as well. Simple properties such as density at fixed temperature and pressure have irreducible uncertainty, and one must think in terms of rheological response rather than viscosity, particularly at low temperatures. Heavy oil characterization poses challenges as well because available analytical tools can provide composition information for less than 50 wt% of typical heavy oils and there is much guess work and correlation needed even to generate composition/property estimates with significant – and hard to quantify uncertainties. In this chapter, we draw upon our diverse experiences to survey the current state of the experimental and computational landscapes related to heavy oil thermophysical and transport properties and phase behavior. Differing and occasionally opposing approaches are presented. Limitations of experimental and computational methods and knowledge needs are discussed, and practical recommendations for specific calculations are noted, typically with caveats. There caveats arise because the landscape is changing rapidly and best practices are evolving continuously, even though we have been producing hydrocarbon resources, transporting, and refining them into diverse products at an industrial scale worldwide for more than a century.

8.1 Background

Crude oil has been produced, pipelined, and refined into transportation fuels and other products for more than a century on a global scale. Superficially, one would be excused for thinking that there is little new to report on the topic of oil characterization in what is increasingly perceived as a sunset industry. However, the nature of the resources now being produced, from shale oil to heavy oil and bitumen; the conditions under which they are produced, from mining to deep off-shore wells; the processes used for production and refining, from steam-assisted gravity drainage (SAGD) to solvent assisted processes; and the economic, environmental, and political constraints have changed radically during this period. The *newer* hydrocarbon resources are typically rich in undistillable fractions (500 °C+ equivalent atmospheric boiling fractions) that are difficult to characterize in detail. At the same time, environmental regulations and product specifications have become more stringent. Consequently, the need for accurate equilibrium phase behavior and phase composition data, transport property data, and models to support resource and product valuation, process design, process development and process optimization has intensified in an environment where conventional analytical tools and characterization schemes often fail. The knowledge demands arise at diverse length and relaxation time scales. Pertinent length scales range from the submolecular and molecular length scales to nano, micro, and larger length scales. Relaxation times in some heavy oil systems are so large that considerable care must be exercised before declaring that a physical property, as understood by classical thermodynamics, has been measured correctly.

This knowledge complexity is presented in the knowledge landscape, as shown in Table 8.1. Composition knowledge at the molecular and submolecular length scales is needed for resource valuation because the elements, functional groups, molecular sizes, and structures in the oil define the refining potential of a resource and the processes needed to transform it. Knowledge at this length scale also provides needed inputs for phase behavior modeling and operating condition selection for refining processes. At the supramolecular length scale, self-association and surface phenomena, arising from asphaltenes and waxes in particular, impact all stages of the production chain, including fluid extraction or production, transport, storage, and refining. At the micro scale, biphase liquid crystal domains have been identified in heavy hydrocarbon resources and resource fractions [8.1], and these materials have been shown to be inherently multiphase [8.2–4] over broad ranges of conditions. The supramolecular structures and microscopic and larger phase domains impact bulk fluid densities, transport properties (diffusivity, and Newtonian and non-Newtonian rheological behaviors), and the potential roles for solvents, for example, in production transport and refining operations. As many of these properties are irreversible to some extent within practical processing time scales, their values and impacts on production operations are affected by the actual thermal and shear histories of samples [8.1–5], and there are inherent limitations in property measurement reproducibility and repeatability that impose constraints on property certainty and consequently on property model development and the associated model quality.

Table 8.1 Heavy oil knowledge landscape

Length scale	Characterization	Motivations	Issues ^a
≈ 1 nm	Molecular and submolecular structures	Resource valuation, refining, phase behavior modeling	Molecular motif identification, species quantitation, tracking chemistry
≈ 10 nm	Self-associating and surface active species, <i>asphaltenes</i>	Avoid production and processing problems, source for refined products	(1) Dissonance regarding molecular structure and driving forces for assembly (2) Artifacts due to definitions (3) Disconnect between nanostructured materials studied in laboratories and those arising in situ.
≈ 20 μm	Liquid crystal domain	New category of materials, surface active	Composition, process and product implications
Bulk	Phase behavior, phase composition, transport properties, energy properties	Production and process models, new process development, transport models, roles of solvents, etc.	A priori prediction is infeasible. Correlation within narrow ranges of conditions is feasible, model breakdown, misuse and misconceptions are common.

^a Sampling and subsampling present challenges and create additional ambiguity at all length scales

Each of these length scales also presents challenges for measurement and theory. At the molecular and submolecular length scales, Fourier transform ion cyclotron resonance mass spectroscopy (FT-ICR MS) can provide a wealth of detail concerning the elemental composition and molar mass of molecules present in heavy oil samples [8.6, 7]. But this powerful technique has yet to yield quantitative composition information suitable for property prediction. This lack of quantification arises because, in spectroscopy, the relative sensitivities of the method to a specific molecular species are dependent on the chemical nature of constituents and mass fractions of all constituents present [8.8, 9]. So, the analysis of a sample as a whole, or as a series of subfractions prepared on the basis of a specific property such as polarity or boiling point range, can yield significantly different impressions as to the principal constituents of a sample from a mass or mole fraction perspective. The resolution of the issue of fluid composition quantitation based on FT-ICR MS analysis is a subject of intense research and the prize is significant. Alternate approaches targeting quantitative a hydrocarbon resource or resource fraction composition knowledge at this length scale based on combining various forms of spectroscopy such as ^{13}C and proton NMR, with elemental analysis, vapor pressure osmometry, and other more conventional techniques with subjective molecule construction algorithms are underconstrained mathematically and yield ambiguous outcomes at the molecular level [8.10, 11]. With additional constraints introduced from photo acoustic infrared and Raman analysis, this latter approach, offers the possibility of providing a limited number of characteristic molecular substructures, referred to here as molecular motifs, suitable for tracing the impact of chemical reaction on fluid composition and phase behavior and for providing practical inputs to production or refining process models based on a common characterization procedure. However, this potential is as yet unrealized. Consequently, conventional refinery characterization approaches continue to be extended to heavy oil composition assessment and modeling.

At the supramolecular length scale, there are divergent perspectives particularly regarding the properties and behaviors of the self-assembling *asphaltene* fraction. This divergence arises in part because of the structural ambiguity at the molecular and submolecular level. Diverse molecular prototypes are envisaged [8.12–15] and consequently diverse self-association mechanisms have been proposed [8.16–19]. These include the assembly of dense and open supramolecular or colloidal structures held together with noncovalent bonds of which acid–base interactions, hydrogen bonding, hydrophobic pockets, aro-

matic π – π stacking have all been proposed. Experimental validation of assembly mechanisms has so far proven to be elusive, and the assembly mechanisms and the nature of the resulting supramolecular structures continue to be subjects of ongoing research. Even defining the size range of aggregates poses numerous experimental challenges [8.20]. With further development, computational and experimental spectroscopy may provide both positive and negative controls [8.21, 22]. The second reason for divergence at this length scale arises because of the ambiguity of the definition of asphaltenes [8.23]. There are numerous pentane and heptane asphaltene definitions and variants to which differing mass fractions and presumably different chemical species of a crude oil report. Further, the link between the chemically separated asphaltene fractions, particularly any of the *heptane asphaltenes*, and the nanodispersed species in crude oils appears tenuous [8.24, 25]. With these caveats in mind, much of the research pursued at the nanometer length scale follows one of two radically different and incompatible paths. Along one path, asphaltene nanoaggregates are presumed to be soluble in toluene and in crude oils and to assemble/destabilize/precipitate from the solution by the addition of *n*-alkanes or systematic variation of intensive variables such as pressure. Pressure changes move solvent-like materials in or out of the oil phase and therefore significantly affect the oil stability and consequently the precipitation of asphaltenes. Along the other path, asphaltene nanoaggregates are presumed to be dispersed, rather than solubilized, in crude oils and even in toluene. Observed behaviors are then interpreted as a change in the nature or extent of aggregation. The difference between these perspectives is profound because the underlying physics and chemistry implied by them differ radically one from the other. As we will show, much of bitumen behavior can be explained with the former conventional approach, including phase behavior (via equations of state and regular solution theory) and physical properties (e.g., viscosity correlations based on Newtonian flow). However, there are instances where the conventional approach fails and these failures have begun to be probed systematically. For example, bitumen exhibits non-Newtonian behavior below approximately 300 K, indicating structure formation in the fluid [8.5]. Asphaltene + toluene + polystyrene mixtures have also been shown to exhibit fluid–fluid equilibrium, including a critical point [8.26]. This phase behavior is driven by a depletion flocculation mechanism that is only active if a significant fraction of asphaltenes are particulate in nature. Further, the application of conventional concepts of solubility such as regular solution theory to the behavior of asphaltene + solvent

mixtures has been challenged [8.27]. As asphaltene solubility concepts underlie deBoer plots [8.28] and so-called stability indices [8.29], this result may explain their high failure rate for predicting asphaltene deposition problems in industry. These examples demonstrate that the integration of the asphaltene self-assembly into phase behavior and property modeling is, at best, incomplete.

Bulk thermophysical and transport property measurement and prediction, and phase behavior measurement and prediction for heavy oil and bitumen, also present experimental and computational challenges, and many properties possess significant irreducible uncertainty. For example, normal boiling point, critical temperature and critical pressure, typical input parameters for phase behavior, and thermophysical property models are not accessible experimentally for heavy oils and along with mean molar mass become indirect fitting parameters for equation-of-state models. Thus, these fluids push the limits of traditional refinery-type fluid equilibria and property models. Alternative approaches based on group contributions from molecular pseudo-components selected to reflect the molecular structure and molar mass diversity of a sample that are identified using spectroscopic techniques and constrained by mass balance or carbon-type data are under development [8.30]. But for the moment these do not offer a significant advantage for property prediction over refinery models [8.31]. Both approaches are at the stage of data correlation, interpolation, and lim-

ited extrapolation rather than prediction. Simple to measure properties, such as density, possess large reproducibility uncertainties [8.32]. Heavy oils possess shear rate and thermal history-dependent viscosities, particularly at lower temperatures [8.33], which contribute to the reproducibility uncertainty of viscosity measurements [8.5]. Sample acquisition methodology, sample storage, subsampling, and handling methodologies for specific measurements are equally significant contributors to the apparent variability of measurements. Heavy oils are inherently multiphase and basic questions such as whether a subsample is representative or not are not readily answered.

From the foregoing, it is clear that there are few simple answers and there is much debate on the phase behavior and properties of heavy oils. The authors of this chapter do not always agree on specific methods or approaches, and have no doubt disagreed in print with one another over the years, but do share a vision of a structured and principled approach for moving measurement and modeling in this field from ambiguity toward certainty, as illustrated in Fig. 8.1, by integrating learning across all length scales. Our mandate is to be brief. Key thermophysical property and phase behavior topics are surveyed. Starting points and references for access to needed data, measurement methods, and computational tools are provided. We suggest tools that are usable, expose their limits, and discuss basic concepts and principles for when calculation or measurement methods fail.

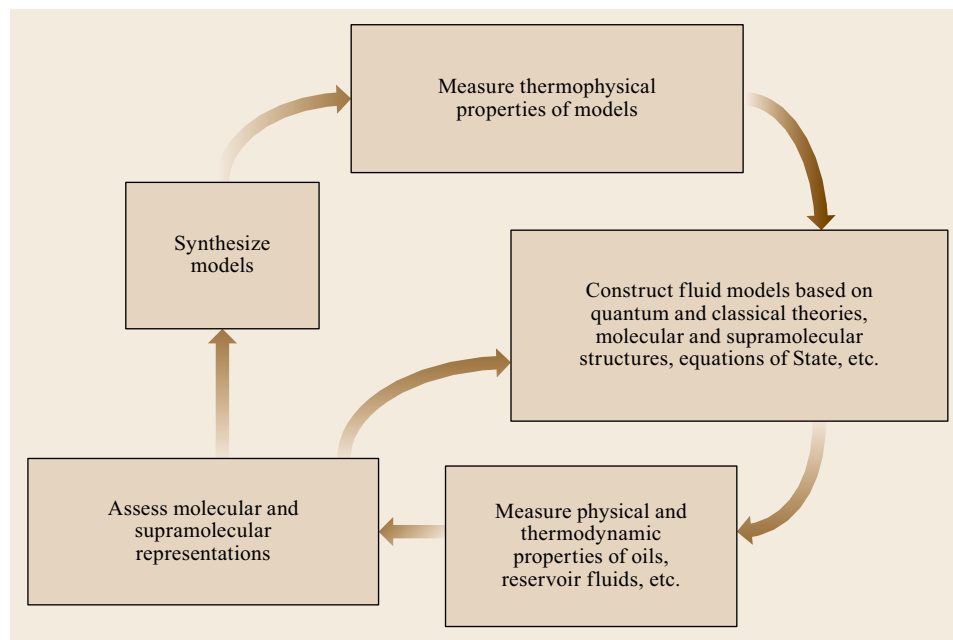

Fig. 8.1 Simultaneous validation of molecular structure, nanostructure, and thermophysical property prediction is required to transition from ambiguity toward certainty

8.2 Phase Behavior and Phase Composition Measurement

Phase behavior and phase composition measurement present numerous challenges not the least of which is the diversity of length scales that are active (nanoscopic, microscopic, bulk) and the complexity of the phase space itself both for the heavy oil and bitumen resources, which exhibit solid, liquid, and vapor behaviors, and for their mixtures with water, organic solvents, organic or inorganic gases, etc., that introduce added complexity because such mixtures are asymmetric and often polar from a thermodynamic perspective. Even simple binary asymmetric mixtures, such as ethane + tetracosane ($C_{24}H_{50}$), where one constituent tends to dominate on a mass fraction basis and the other on a mole fraction basis, can exhibit up to four phases in equilibrium [8.34]. Further, the diversity of conditions under which data are needed span reservoir, mining, pipelining, and in situ refining processing conditions. Thus, data are needed from below 270 K to above 700 K and from subatmospheric pressure to more than 20 MPa. This Herculean task is further complicated by the fact that there is not a coherent framework to describe the phase behavior of heavy oils and bitumen from a composition perspective and the concurrent development of experimental techniques targeting the observation of phase behaviors. Sample acquisition and integrity pose additional challenges. Consequently, the literature on this topic is fragmentary and episodic. Phase diagrams and phase composition data are incomplete and incompatible with one another. Researchers and engineers must exercise caution in the generation, interpretation, and use of phase behavior and phase composition results for process conceptual development, design, and optimization. Reliance on thermodynamic models and workflows that have been successful in the past must be tempered by the limited knowledge concerning material composition, diffusion and rheology, and the extreme nature of property values relative to databases on which conventional models and workflows are based.

8.2.1 Resources on Their Own

Heavy oil and bitumen are inherently multiphase materials and interact with reservoir rock. Use of pressure/heat to extract samples from cores leads to unrepresentative samples because materials not preferentially sorbed are over represented in the samples retrieved. An early contribution from *Henry and Fuhr* [8.35] who ultracentrifuged Athabasca oils and samples without adding solvent showed that the bitumen adhering to the sand grains was asphaltene deficient relative to the supernatant bitumen. Addition of solvents is also

problematic because they lead to preferential deposition of organic materials on acidic (FeS , SiO_2), and basic ($Fe_2O_3/FeOOH/FeO$, $Ni/NiO/NiOH$) substrates. On basic substrates, deposits are thinner and are enriched in sulfur [8.36]. On acidic substrates, deposits are thicker and are sulfur deficient relative to Athabasca vacuum residue (AVR), even though asphaltenes, which are rich in sulfur, sorb more strongly on acidic substrates in the absence of competition from other species. Solvents also contaminate phase behavior measurements by altering the phase behavior of condensed phases [8.1] and by altering bubble pressures and other phase behavior boundaries. Further, due to the costs associated with handling the so-called live oil samples, phase behavior data are largely available only for dead oils or at best reconstituted samples. So, phase behaviors observed in laboratory experiments approximate those arising in undisturbed reservoirs. For processed or partially processed heavy oils, the agreement is better because samples are more accessible and more representative.

The phase behavior topology of heavy oil and bitumen resources or their fractions can be presented in terms of a maltene-rich and a pentane asphaltene-rich pseudo-components partitioned directly from the parent sample using 5–100 nm nominal pore size filters to obtain subsamples with varying mass fractions of these two pseudo-components, without solvent addition. While the size of the asphaltene-rich domains varies significantly, their elemental compositions appear to be size independent other than for elements associated with clays that tend to be large [8.24]. Elemental analyses of these subsample are a linear function of pentane asphaltene content. For Maya crude oil, samples from 1.5 to 73 wt% pentane asphaltenes can be partitioned. For Athabasca bitumen, the range is 5–57 wt% and for Safaniya vacuum residue, the range is 5–56 wt%. The range of heptane asphaltene contents is narrower, for example, 0.7–36 wt% for Safaniya vacuum residue [8.4]. The calorimetric behavior of subsamples is then measured and analyzed in a framework that includes linear interpolation and extrapolation to 0 and 100% of each pseudo-component and comparisons with baseline heat capacities for solids and liquids with the same elemental composition [8.37–39]. In this way, the proof of the independence of the pseudo-component thermal behaviors, and phase transitions, corresponding to deviations from solid- or liquid-phase heat capacities, are identified. Rheological data are also obtained for each subsample, in order to detect the nature of transitions (solid–liquid or glass–liquid) found calorimetrically. For the hydrocarbon resource samples studied so far, these pseudo-components have been shown to be

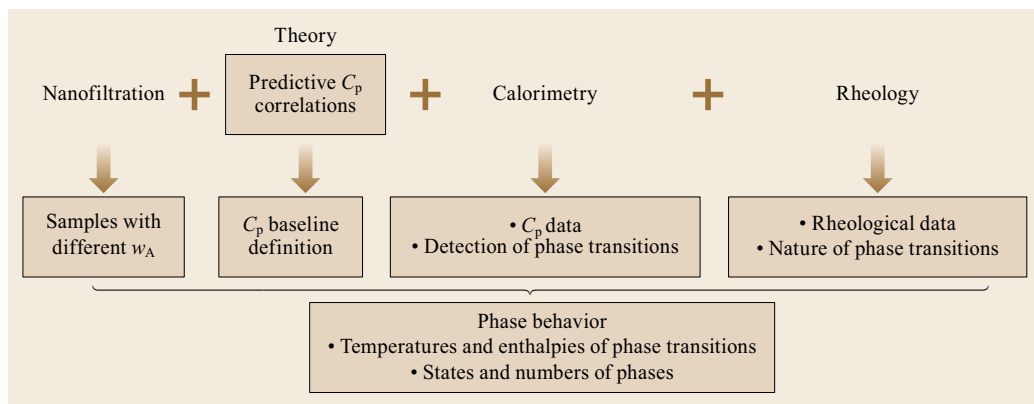

Fig. 8.2 Phase behavior assessment scheme for heavy oils (w_A is mass fraction of asphaltenes and C_p is isobaric heat capacity)

independent of one another, and to undergo phase transitions independently, within experimental error, over broad ranges of temperature [8.4]. The phase diagram construction framework is illustrated in Fig. 8.2. See Fulem et al. [8.2] for a detailed explanation of the method and experimental procedures.

Phase diagrams for individual resource samples arising from this framework are unique but share numerous features [8.4]. Figure 8.3 shows the phase diagram of Athabasca bitumen. Athabasca bitumen (Alberta, Canada) was obtained from Syncrude Canada Ltd. The sample was characterized as a coker feed. It is derived from mined bitumen subjected to warm water extraction, naphtha dilution, and naphtha recovery by distillation between 523 and 623 K. Some volatile constituents present initially were lost during sample preparation. Aliquots of this sample were nanofiltered at 473 K, and the subsamples were stored at 280 K for several weeks prior to phase diagram construction. To construct Fig. 8.3a, subsamples were cooled to 173 K prior to calorimetric and rheological measurements. For nanofiltered samples, a series of phase behaviors and phase behavior transition were observed. The maltene-rich component comprises crystalline (C_M) and glass (G_M) phases at low temperature and both phases undergo transitions to liquid (L_M) at higher temperatures. The asphaltene-rich component is solid (S_A) at low temperatures and undergoes a transition to liquid (L_A) at higher temperatures. The resulting phase diagram, Fig. 8.3a, is complex and includes three and four phase regions. Chemically separated pentane maltenes and asphaltenes undergo similar transitions, but the temperatures at which these transitions take place differ significantly from the nanofiltered subsamples. These sets of transitions are also shown in Fig. 8.3a – at the 0.0 and 1.0 w_A axes. The boundary at 350 K is particularly noteworthy, because the crystalline maltene phase is responsible for the non-Newtonian rheological behavior of heavy oils [8.4].

To construct Fig. 8.3b, subsamples were cooled to 258 K at a rate of 0.08 K/s followed by a repetition of the procedures used to construct Fig. 8.3. In this way, the impact of recent thermal history on observed phase behaviors was assessed. There is an indistinct transition of unknown nature in the maltene-rich material arising during the second heating cycle that is indicated by the x 's in Fig. 8.3b, and no transitions are detected in the asphaltene-rich material. At 400 K and above, maltene-rich and asphaltene-rich liquid phases are present. For chemically separated pentane maltenes, no transitions were detected and for chemically separated pentane asphaltenes, a glass transition (G_A) was detected at low temperature. Clearly, the phase behavior of heavy oils is sensitive to thermal history and transitions to solid or glass on cooling are kinetically slow. Impacts of thermal history on thermophysical and transport properties are significant and may account for the dissonance encountered among various types of measurements in the literature, particularly under conditions where solid and glass phases arise or persist and where their mass fractions are significant.

8.2.2 Heavy Oil and Diluent Phase Behavior

Two general types of phase behavior have been observed. Addition of low molar mass hydrocarbons such as n -alkanes or inorganic solvents such as CO_2 partition heavy oil and bitumen into diluent-rich and diluent-poor liquid phases and asphaltene aggregation is impacted concurrently. For this case, temperature plays a significant role in phase behavior because at low temperatures liquid–liquid and liquid–liquid–vapor regions arise over a range of compositions, while at temperatures significantly greater than the critical temperature of the diluent, a diluent-rich liquid phase does not arise. Addition of diluents such as 1-methylnaphthalene does not introduce additional bulk liquid phases, and impacts on asphaltene aggregation are not evident.

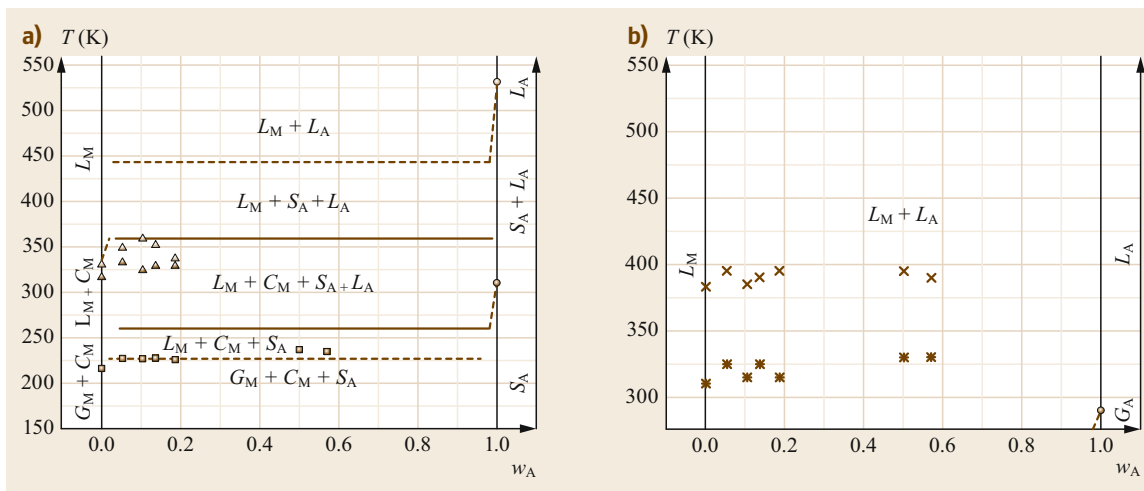

Fig. 8.3a,b Phase diagram for Athabasca bitumen: (a) heating cycle 1 and (b) heating cycle 2. (After [8.3])

However, at the microscopic scale, low molar mass hydrocarbons, such as toluene, and *n*-alkanes do disrupt microscopic liquid crystal domains in heavy oils and bitumen, including Athabasca bitumen [8.40]. So, from a processing perspective, nanoscale and bulk scale effects must be tackled simultaneously at a minimum. This is not feasible in general, and small and wide angle x-ray-scattering (SAXS/WAXS) measurements targeting nanoscale impacts must be performed separately from more conventional phase behavior studies performed in view cells.

Zou et al. [8.42] and Long et al. [8.43] provide a comprehensive and illustrative example for AVR + pentane mixtures where Zou et al. [8.42] report bulk phase behavior measurements, as shown in Fig. 8.4, and Long et al. [8.43] report nanoscale effects for the same mixtures at comparable pressures as shown in Fig. 8.5. At 433 K, AVR possesses a single bulk phase and a nano-dispersed asphaltene-rich phase. As pentane is added to the mixture, there is only one bulk liquid phase until the pentane content reaches ≈ 40 wt% (60 wt% AVR). However, in this composition range, level-2 (large) asphaltene-rich domains with leading dimensions exceeding 25 nm become more important and level-1 (small) asphaltene-rich domains become smaller, possess lower surface-to-volume ratios, and become more structured. At ≈ 45 wt% pentane (55 wt% AVR), a small mass fraction of a second bulk liquid phase appears, but along with it, there is large upward step change in the size, surface-to-volume ratio and the scattering coefficient of the level-1 and a downward step change in level-2 asphaltene-rich domains in the principal liquid phase.

While there are no other examples available with such detailed phase behavior data for mixtures con-

taining heavy oil at these three length scales, the complexity of the bulk phase behavior of reservoir fluids and heavy oils + low molar mass hydrocarbons or nonhydrocarbon gases such as CO₂ and hydrogen have been known for some time, and these behaviors have been placed in the context of phase diagram theory using model mixtures for both production and refining conditions [8.34, 44–46]. Such mixtures normally exhibit type-III pseudo-binary phase behavior where up to four phases in equilibrium (low-density liquid, high-density liquid, solid, and vapor) are observed at low temperatures. At higher temperatures, up to three phases (low-density liquid, high-density liquid, and vapor) are observed at approximately the vapor pressure of the added low molar mass component. At a temperature and a pressure exceeding the critical temperature of the added component, a three-phase critical point is observed where the low-density liquid and vapor phases become critically identical in the presence of a dense heavy hydrocarbon-rich liquid phase. This type of critical point is known as a K-point. Above the K-point temperature, only liquid, liquid vapor, and vapor phase behavior are possible. For example, heavy hydrocarbon + CO₂ mixtures exhibit this type of behavior, and the maximum observed K-point temperature and pressures are ≈ 320 K and 103 bar for heavy oil sample [8.46]. The critical temperature and pressure of CO₂ are 304 K and 74 bar, respectively. The maximum observed K-point temperature and pressure of AVR + pentane mixtures, which also exhibit type-III pseudo-binary phase behavior, are 486 K and 43 bar, respectively [8.47] versus the critical temperature and pressure of pentane, which are, respectively, 469 K and 34 bar. Retrograde behavior and other classical phenomena are also observed, and the

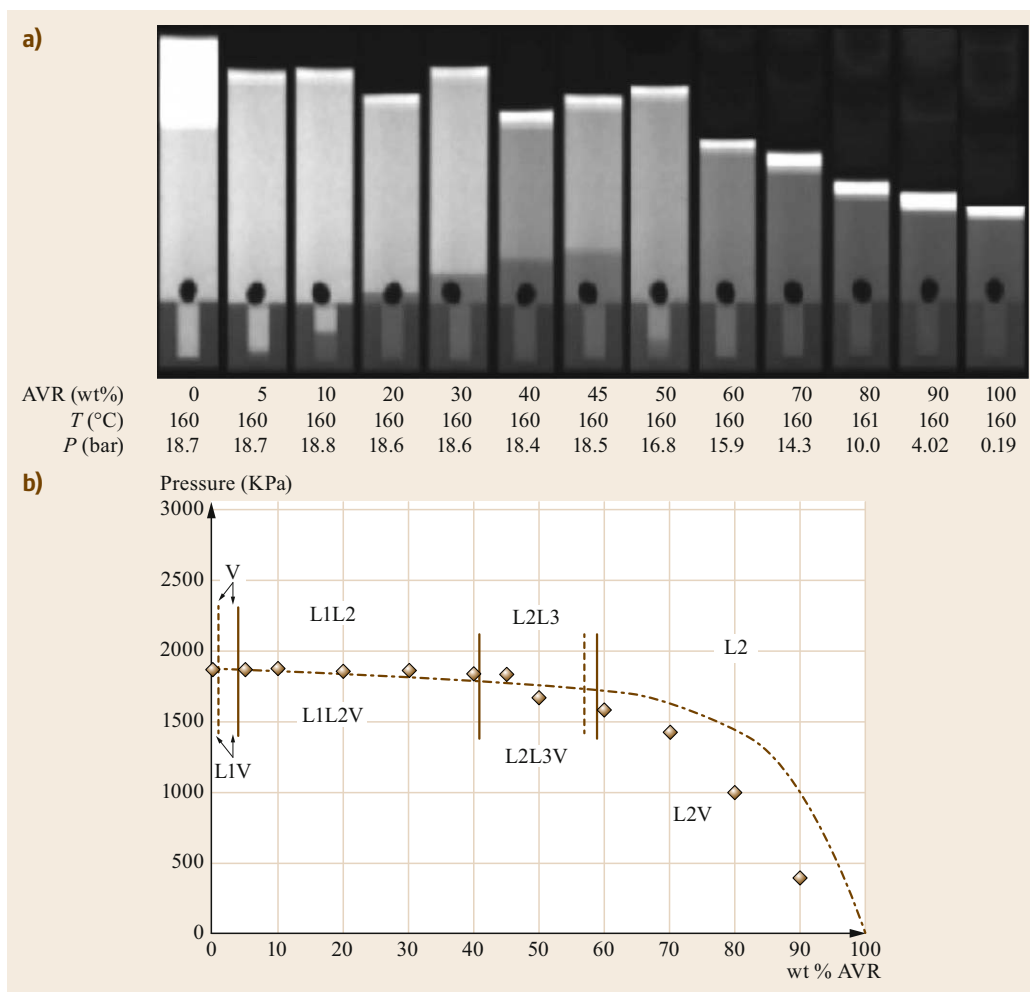

Fig. 8.4a,b Phase behavior for AVR + pentane mixtures at 433 K: (a) example x-ray images (after [8.41]) showing liquid–vapor phase behavior at 0 wt% AVR, liquid–liquid–vapor phase behavior from 5 to 60 wt% AVR, and liquid–vapor phase behavior from 60 to 100 wt% AVR (in these images the vapor phase is clear; the liquids designated L1, L2, and L3, are various shades of gray that link to their density; the black circle in the images is the stirrer); (b) partial phase diagram including only bulk phase behaviors, where the solid vertical lines and points denote experimental measurements and the dashed lines denote computed boundaries. (After [8.30])

phase behaviors of all heavy oil + all low molar mass hydrocarbons and nonhydrocarbons are qualitatively similar. The literature is replete with studies for specific petroleum + light hydrocarbons/nonhydrocarbons and model asymmetric mixtures. *Khaleghi* [8.48] reviewed the oil + CO_2 literature. The literature related to the appearance or deposition of large asphaltene-rich domains within the phase diagrams for specific oils or oils + light hydrocarbon/nonhydrocarbon mixtures is also well developed and this phenomenon is typically most pronounced at mixture bubble pressures [8.49].

8.2.3 Heavy Oil and Water Phase Behavior

Water + hydrocarbon mixtures may exhibit type-II, type-IIIa, or type-IIIb phase behavior. All binary water + hydrocarbon mixtures show similar LLV behavior at low temperatures. At high temperatures, the LLV three-phase behavior terminates at an L-point where the two liquid phases become critically identical (type II) or at a K-point where one of the liquid phases becomes critically identical to the vapor (type III). The distinction between types IIIa and IIIb is that, at high temperatures, the single liquid phase present in the phase diagram

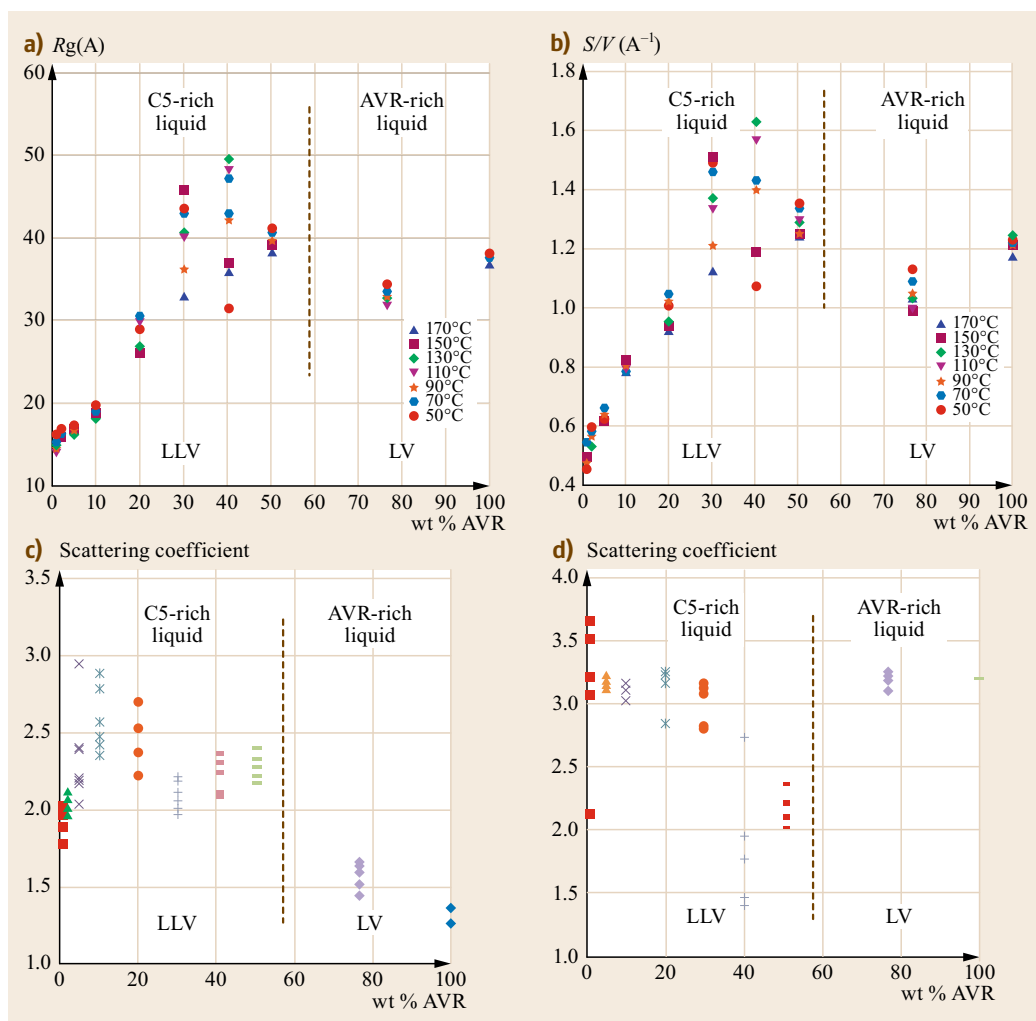

Fig. 8.5a–d Nanoscale behaviors arising in AVR + pentane mixtures: (a) radius of gyration, (b) surface-to-volume ratio, scattering coefficient for (c) level one (small) and large, (d) nanostructures. The vertical line is the approximate location of the liquid–vapor (LV) to liquid–liquid–vapor (LLV) phase transition. (After [8.43])

is water-rich for type-IIIa and hydrocarbon-rich for type IIIb. The solubility of water in the hydrocarbon phase, for all cases, tends to be in the order of a few parts per million at room temperature, and the solubility increases sharply with temperature. Mixtures of water + light hydrocarbons, where the critical temperature of the hydrocarbons is less than the critical temperature of water, exhibit type-IIIa phase behavior [8.50, 51]. Mixtures of water and heavy hydrocarbons, where the critical temperature of hydrocarbons are comparable to or exceed that of water, exhibit type-II or type-IIIb phase behavior [8.50, 51]. Water + Athabasca bitumen is an example of type-IIIb pseudo-binary phase behavior [8.52]. While water affects the enthalpy of solution of asphaltene in solvents [8.53], the impact of soluble

water on asphaltene precipitation is unresolved [8.54]. Tharanivasan et al. [8.54] demonstrated that emulsified water had no impact on the onset or amount of asphaltene precipitation at ambient conditions. However, water solubility is low at these conditions, and there may be more of an effect on asphaltene aggregation and precipitation at higher temperatures.

Composition measurements for hydrocarbon saturated water and water-saturated hydrocarbons present numerous challenges because hydrocarbon solubility values in water range over 11 orders of magnitude, while water in hydrocarbon solubility values range over four orders of magnitude. The solubility of hydrocarbons in water is also a strong function of molecular structure, where, for example, at fixed molar mass, aro-

matics exhibit higher solubilities than *n*-alkanes. For water solubility data in pure hydrocarbons and pure hydrocarbon solubility data in water, readers are referred to an extensive, critically evaluated series of papers on hydrocarbon + water solubility [8.55–65] which reviewed the previous extensive work done in the IUPAC Solubility Series, Volumes 37 and 38 [8.66, 67] but including corrections and new published work up to 2006. This recent work provides solubility data as a function of temperature for paraffins, naphthenes, aromatics, and other hydrocarbons ranging from C₅ to C₃₆. The available data points were individually examined and quality identifiers were assigned to them. Reference data are provided based on especially constructed correlation functions for specific chemical families. Experimental data differing from the reference data by less than 30% at similar temperatures from different sources are classified as *recommended*, while those that differ from the recommended data by more than 30% are classified as *doubtful*.

In addition to water solubility data in typically pure hydrocarbons and mixtures, water solubility results for five ill-defined heavy oils (Coalinga, Huntington Beach, Peace River, and Cat Canyon crude oil) reported by *Glandt* and *Chapman* [8.68] and Athabasca bitumen reported by [8.52] are available. In addition, water solubility data for Athabasca bitumen + toluene mixtures, comprising 44.3 and 66.8 wt% toluene, respectively, are also available [8.69]. The database is restricted to a narrow temperature range ≈ 400 –570 K. The lower temperature is restricted by the ability to make meaningful measurements and the upper temperature by the thermal instability of the hydrocarbons. The dataset provided by *Amani* et al. [8.52] attempts to compensate for the impact of thermal decomposition of Athabasca bitumen to provide approximate water-solubility values up to 644 K, which is close to the critical temperature of water. There are no data for water solubility in hydrocarbons above the critical temperature of water. In general, water in hydrocarbon and hydrocarbon in water-solubility data must be carefully scrutinized due to partial solidification of hydrocarbons at low temperature and thermal cracking at high temperatures.

8.2.4 Equilibrium Compositions

Equilibrium composition data for heavy oil containing mixtures is fragmentary at best. Some saturated single-phase composition data for light hydrocarbons or nonhydrocarbons in heavy oils or heavy oil fractions are available. Such data are available because they are more readily measured than multiphase data and are of specific importance. The solubility of inorganic gases such as hydrogen at high temperatures and pres-

ures is important for hydrotreating and hydrocracking. Fracking and in-situ combustion processes and the associated gases – carbon dioxide, hydrogen sulfide, and ammonia – are also important because they play roles in the oil phase as well as in the water phase where they form weak acid–base solutions. Heavy oil + CO₂ mixtures were reviewed by *Khaleghi* [8.48], heavy oil + water mixtures were reviewed by *Amani* et al. [8.69], and heavy oil + hydrogen mixtures were reviewed by *Saajanlehto* et al. [8.70]. Readers are referred to the literature for additional datasets and reviews of this type. Multiphase equilibrium data for heavy oil + light hydrocarbon liquids or gases or nonhydrocarbon gases are rare. *Zou* et al. [8.41–43] report on liquid–liquid partitioning of saturate, aromatic, resin, and asphaltene (SARA) fractions, and elements for AVR + pentane mixtures that include phase volume information and constitutes a comparatively complete dataset from this perspective. This is an underdeveloped topic, particularly in the public domain, and a subject of ongoing research from the perspective of multiphase visualization and sampling, and more intensively from the perspective of fluid characterization, the subject of Sect. 8.4.

8.2.5 Summary

The phase behavior complexity of heavy hydrocarbon resources and resource fractions is not encountered in conventional petroleum reservoirs. Many aspects of their phase behavior, including liquid crystals and solid maltenes, cannot be observed in conventional phase behavior experiments. Phase compositions, the subject of Sect. 8.4, fall largely outside the scope of conventional composition assays. Phase behavior and phase composition measurement for heavy oils and bitumen or mixtures that contain them impose a number of challenges including: the diversity of length scales at which phase behaviors arise and over which measurements must be made simultaneously, if at all possible; the time scales required to reach equilibrium, the need to develop new phase behavior measurement and fluid characterization techniques. A key concern is that the measured phase behavior of heavy oil and bitumen resources at a specific temperature and pressure is a function of sample thermal history. This suggests that there are likely to be significant differences between phase behaviors and hence properties encountered in the field or in processes, where thermal gradients are steep and timeframes are typically shorter than in laboratories where timeframes are typically much longer and where sample thermal histories arising from transport and storage differ qualitatively and quantitatively from those encountered in the field or in processes.

8.3 Thermophysical Property Measurement

As with phase behavior measurement, sampling and sample handling are sometimes the most challenging aspects of measurements. Heavy oil and bitumen deposits are heterogeneous even in oil properties. For example, *Larter et al.* [8.71] have reported viscosity variations of several orders of magnitude both vertically and laterally in a single reservoir. Some knowledge of this variation is required to obtain a set of representative samples.

Sample handling is particularly important when viscosity is to be measured because bitumen viscosity is very sensitive to even small amounts of contaminant [8.72]. Bitumen samples usually contain water and solids that must be removed for accurate property measurements. There are no guaranteed methods to remove water and solids without altering the sample. Heating and centrifugation can be an effective method for less viscous oils but heating can remove lighter components. Dilution and centrifugation are an effective means of removing water and solids, but it is impossible to remove all of the diluent afterward. Distillation and filtering are less intrusive methods particularly when any distilled hydrocarbons are recombined with the sample. While it can be argued that the most accurate results are obtained from samples squeezed from compressed cores if mud invasion is eliminated [8.73], such samples may not fully represent the fluid [8.35] because organic materials sorbed preferentially on the inorganic substrates are not removed during compression. Further, core samples are relatively rare and provide only small volumes of oil. Errors in viscosity measurements can arise from viscous heating and evaporation of light ends, and large variations in measured viscosity values can also arise from the thermal and shear prehistory of samples prior to measurement and the details of the measurement itself [8.5]. *Miller et al.* [8.74] noted viscosity differences in the order of 100% in blind tests on the same sample sent to different labs.

Live oil sample preparation is even more challenging. First, the correct solution gas composition must be determined and either a bubble point pressure or solution gas–oil ratio specified. Field data for these specifications are often unreliable because the gas volumes are small and production is not uniform. Second, equilibration times are long because the viscosity is high and mutual diffusion rates are low. It can take hours to days to reach an apparent equilibrium when mixing gases into bitumen or even when changing the pressure in an ongoing experiment. It is strongly recommended to evaluate the experimental procedures used in any heavy oil study before accepting the data. With this

proviso, the data available for heavy oil properties are outlined below.

8.3.1 Density

Apart from the everpresent challenge of sample handling, density measurements are straightforward and dead oil density is reported in most experimental studies. The AOSTRA handbook provides data for a number of dead heavy oils and bitumens [8.75]. By definition [8.76], the density of heavy oils lies between 934 and 1000 kg/m³ (°API from 20 to 10) and bitumen above 1000 kg/m³ at standard conditions (60°F and 1 atm). Bitumen densities as high as 1020 kg/m³ have been reported at standard conditions [8.32].

As expected for a hydrocarbon liquid, heavy oil density decreases as temperature rises and as pressure falls (Fig. 8.6). For dead oils, the trends are approximately linear over spans of a 100 K and tens of mega Pascals. Dead heavy oil density data [8.77] can be fit to within 1 kg/m³ with the following relationship

$$\rho = \rho_o[1 + c_o(P - 0.1)], \quad (8.1)$$

where ρ_o is the density in kg/m³ at atmospheric pressure, P is the pressure in MPa, and c_o is the oil compressibility in MPa⁻¹. The atmospheric density and oil compressibility are related to temperature as follows

$$\rho_o = A - BT, \quad (8.2)$$

$$c_o = C \exp(DT), \quad (8.3)$$

where T is the temperature in K, and A , B , C , and D are the fitting parameters.

Because heavy oil solution gas consists mainly of methane and some carbon dioxide, the solution-gas-to-oil ratio and therefore the live oil density are largely dictated by the solubility of these two components in the heavy oil at reservoir conditions. *Badamchizadeh et al.* [8.78, 79] showed that CO₂ molar solubilities in a broad range of crude oils fall on the same trend versus pressure. These CO₂ solubility data and data for methane solubility in bitumen [8.80] were fitted with Henry's law

$$x_i = \frac{y_i P}{H_i}. \quad (8.4)$$

For pure gases, $y = 1$, and for CH₄ and CO₂, Henry's constants are

$$\text{CH}_4: \ln(H) = 11.521 - \frac{500}{T} + \frac{0.1234P}{RT}, \quad (8.5)$$

$$\text{CO}_2: \ln(H) = 11.817 - \frac{872}{T} + \frac{0.1464P}{RT}, \quad (8.6)$$

Fig. 8.6 Density of a Western Canadian WC-B2 bitumen as a function of temperature and pressure. Data fitted with (8.1). (After [8.77])

where x and y are the mole fractions in the gas and liquid phases of component i , respectively, H is Henry's constant in kPa, P is pressure in kPa, T is temperature in K, and R is the universal gas constant. When both gases are present, the solution gas composition must be specified and the solubilities in the oil are solved with a bubble point calculation. The density of the live oil can then be calculated from the liquid-phase composition and the mixing rules presented later in Sect. 8.6.

Heavy oil and bitumen are commonly diluted with solvents to reduce their density and viscosity. Typical solvents range from n -alkanes to condensate and naphtha. Densities of pure components are available from a number of sources, including the CRC chemistry handbook series and the NIST chemistry webbook database. Densities of multicomponent solvents can be estimated with an equation of state based on their compositional assays (Sect. 8.6), but measurements are required for accurate values. Experimental density and viscosity data for diluted bitumen are available for the following mixtures:

- Athabasca bitumen with methane, ethane, carbon dioxide, carbon monoxide, and nitrogen [8.80, 83]
 - Peace River bitumen with methane, ethane, carbon dioxide, carbon monoxide, and nitrogen [8.84]
 - Cold Lake bitumen with methane, ethane, carbon dioxide [8.85]
 - Bartlett heavy oil with carbon dioxide [8.85]
 - Athabasca bitumen with propane and propane+carbon dioxide [8.78, 79]
 - Western Canadian bitumen with ethane, propane, n -butane, n -pentane, n -heptane, and carbon dioxide [8.77, 86]
 - Western Canadian bitumen with solution gases and condensate [8.87].
- Diluted bitumen densities are well approximated with regular solution mixing rules remote from diluent critical points [8.32] but are more accurately predicted with excess volume-based mixing rules as discussed in Sect. 8.6.

8.3.2 Heat Capacity

Isobaric heat capacity values for heavy oils, and heavy oil fractions such as maltenes and asphaltenes are available in the literature from temperatures approaching absolute zero [8.37], where these materials are solid,

to over 600 K where they are liquid [8.38]. These data were obtained in order to test predictive correlations for heat capacity as described in Sect. 8.6. Data are also available for a variety of nanofiltered heavy oil and bitumen fractions as well that were obtained as part of the workflow related to phase diagram generation [8.2–4]. At room temperature, the values range from approximately 1.2 kJ/(kg K) for Athabasca pentane asphaltenes up to 1.6 kJ/(kg K) for Athabasca pentane maltenes. The corresponding range for Maya crude oil and for Safaniya vacuum residue is 1.3–2 kJ/(kg K). If the elemental composition and phase state of a fluid are known, isobaric heat capacity can be predicted with an absolute uncertainty of less than 0.1 kJ/(kg K) using the predictive correlations.

8.3.3 Bitumen and Heavy Oil Rheology Measurement

The Newtonian and non-Newtonian rheological behaviors of heavy oils and bitumens are key properties for production, transport, and refining. Conventional viscometers and viscosity measurement protocols do not detect shear-rate- and strain-rate-related non-Newtonian rheological effects that are important at and below ambient temperature for whole crudes, but which persist to up to 400 K for vacuum residues [8.4]. A whole crude example is shown in Fig. 8.7 where the apparent viscosity of Maya crude oil is a function of the shear rate at low temperature under steady shear conditions (Fig. 8.7a). Typical frequencies for viscometry measurements range up to more than 100 Hz, and it is clear that at low temperatures, orders of magnitude differences in apparent viscosity values result if the shear rate is not controlled. In oscillatory shear

measurements, varying the angular amplitude of the shear at fixed frequency also impacts the apparent viscosity (Fig. 8.7b) and suggests that Maya crude oil is thixotropic under these conditions. Care must be taken to ensure that a *viscosity* measurement is robust and not simply a condition specific rheological response.

With the caveat noted above, viscosity is arguably the most important property of heavy oil and bitumen because most processes for these fluids must include measures to reduce viscosity in their design. By definition [8.76], the viscosity of heavy oils lies between 100 and 100 000 mPa s and bitumen above 100 000 mPa s at room temperature. Bitumen viscosities of the order of a million mPa s have been reported at room temperature and, in practice, the most viscous bitumens are immobile at ambient conditions. The AOSTRA handbook provides data for a number of dead heavy oils and bitumens [8.75], but care must be taken with respect to their application unless the measurement temperature is significantly above ambient. Above approximately 298 K, whole crudes including Athabasca bitumen [8.5] may be treated as a Newtonian fluid and, like any other hydrocarbons, bitumen viscosity correlates with its density, illustrated in Fig. 8.8a. Bitumen density and viscosity decrease as temperature rises and pressure falls, as shown in Fig. 8.8b, but the effect of temperature is beyond exponential for viscosity. Correlations for dead bitumen viscosity are presented in Sect. 8.6.

Liquid solvents and dissolved gases dramatically decrease heavy oil and bitumen viscosity as shown in Fig. 8.9. Viscosities of pure components are available from a number of sources, including the CRC chemistry and chemical engineers handbook series, the NIST chemistry webbook and the NIST database [8.88]. Vis-

cosities of multicomponent solvents can be estimated with correlations based on their compositional assays (Sect. 8.6). But measurements are required for accurate values. Experimental viscosity data for diluted bitumen are available for the same mixtures reported in the density section. There are several correlations to

determine diluted bitumen viscosities as discussed in Sect. 8.6. Live oil viscosities can be estimated with the same methods based on solution gas compositions and/or liquid-phase densities as discussed for density measurements.

8.3.4 Mutual Diffusion Coefficient Measurements

Liquid-phase mutual diffusion coefficients are important parameters describing oil and gas reservoirs as they help define the time scale for secondary recovery processes such as miscible flooding with carbon dioxide or alkanes, or the SAGD + solvent production processes for heavy oil and bitumen. Normally, mixtures are treated as pseudo-binaries for the purpose of mutual diffusion coefficient determination, where the oil is lumped and the added hydrocarbon or nonhydrocarbon comprises the second component. Mutual diffusion coefficients are not measured directly but are inferred from experimental data. Diverse experimental methods and data interpretation techniques, including the computation of diffusion coefficients from measured composition profiles (preferred) or from pressure drops arising from the dissolution of a gas into a liquid (not recommended), are employed. There are a number of experimental and computational pitfalls related to mutual diffusion coefficient determination and care must be taken to avoid the misinterpretation of measurements that lead to unrealistic values, unrealistic trends in values with composition, and time-dependent values. Such artifacts arise in the applied literature, typically from

shortcomings in data interpretation. These issues are addressed elsewhere in detail [8.89–91]. Reported mutual diffusion coefficient values and trends must be used with care in design calculations, and it is important to note that liquid-phase mutual diffusion coefficient values fall between the self-diffusion coefficients of the constituents at the same temperature and phase state. Consequently, the values have defined upper and lower bounds that typically differ by no more than one order of magnitude [8.89]. So, for example, in mixtures of heavy oil + CO₂ at room temperature, the mutual diffusion coefficient values must be below the self-diffusion coefficient of *liquid* CO₂ at the same temperature. The most reliable lower bounds for whole heavy oils + low molar mass species, by analogy with polymers, place values at or above $\approx 3 \times 10^{-11} \text{ m}^2/\text{s}$ at room temperature. From mutual diffusion coefficient measurements for heavy oil + low molar mass species, constant values in the range $\approx 1\text{--}2 \times 10^{-10} \text{ m}^2/\text{s}$ are valid for the composition range 15–90 wt% heavy oil at room temperature. For atmospheric and vacuum residues, lower values, $\approx 5 \times 10^{-11} \text{ m}^2/\text{s}$, are valid over a comparable composition range [8.92]. Sharp increases in mutual coefficient values anticipated from theory close to the low molar mass constituent composition axis have not been observed, and measurements close to the heavy oil composition axis have yet to be reported. While further improvement in experimental measurement technique is needed, *Hosseini* et al. [8.93] recently reported on a promising microfluidics-based mutual diffusion coefficient measurement technique that greatly facilitates

the experimental acquisition of composition profiles, and *Sadighan* et al. [8.92] reported on forced versus diffusive mass transfer between immobile heavy oil and mobile low molar mass liquids. New data for Athabasca bitumen + solvents are also reported in these latter two publications.

8.3.5 Summary

There are a limited number of experimental thermo-physical property measurements available for heavy oils and bitumens. The measurements are of variable quality because the experimental techniques and data-processing approaches employed may not capture the physics and chemistry present (low-temperature rheology versus viscometry) or may indicate the presence of effects that are not real (mutual diffusion coefficients). Researchers may also not be aware of the limitations of the techniques employed or the impacts of these limitations. Measurement reproducibility as opposed to measurement repeatability is rarely reported. There is also a need for the use of measurement standards and standard calibration protocols, measurement method validation, and the use of control experiments during data acquisition. These along with the precise conditions of measurements and sample history are frequently lacking in publications. Finally, sample characterization presents challenges, and there is a pressing need for better characterization protocols so that the most productive use can be made of data as they become available.

8.4 Heavy Oil Characterization

Crude oils comprise innumerable molecular species [8.6, 7] encompassing a wide range of properties such as boiling point, molecular weight, density, and critical properties. Characterization involves representing the distribution of these properties in the oil in sufficient detail for modeling purposes. The amount of detail required depends on the application. For example, elemental analysis and phase state are sufficient for heat capacity calculations [8.38, 39, 94]. A compositional description is required for modeling phase behavior and for predicting the thermophysical and transport properties of each phase. A yet more detailed compositional description may be required to model reactions such as thermo- and hydrocracking. An extra level of sophistication is required if dispersed phases (hydrocarbon particulates such as asphaltenes, waxes, hydrates, water in oil, or oil in water emulsions) must be described in order to model the complex rheological behavior of dispersions or deposition phe-

nomena. Here, we focus on the characterizations used in phase behavior modeling whether for reservoir or refinery applications. Typically, a crude oil is characterized into a number of pseudo-components where each represents a narrow range of properties but collectively approximate the full distribution of properties of the oil. The most common choices of pseudo-components for heavy oils are based on boiling-point cuts (distillation or simulated distillation), and molecular weight ranges (gas chromatography, mass spectroscopy) plus residue fractions, and solubility cuts such as SARA fractions [8.95–98]. An alternate approach is to choose a set of representative molecules [8.30, 31] that reflect the molecular diversity of a fluid including residue fractions and can be used to populate group contribution-based models for fluid properties. Each of these methods is briefly presented below, but first some background in crude oil chemistry is provided.

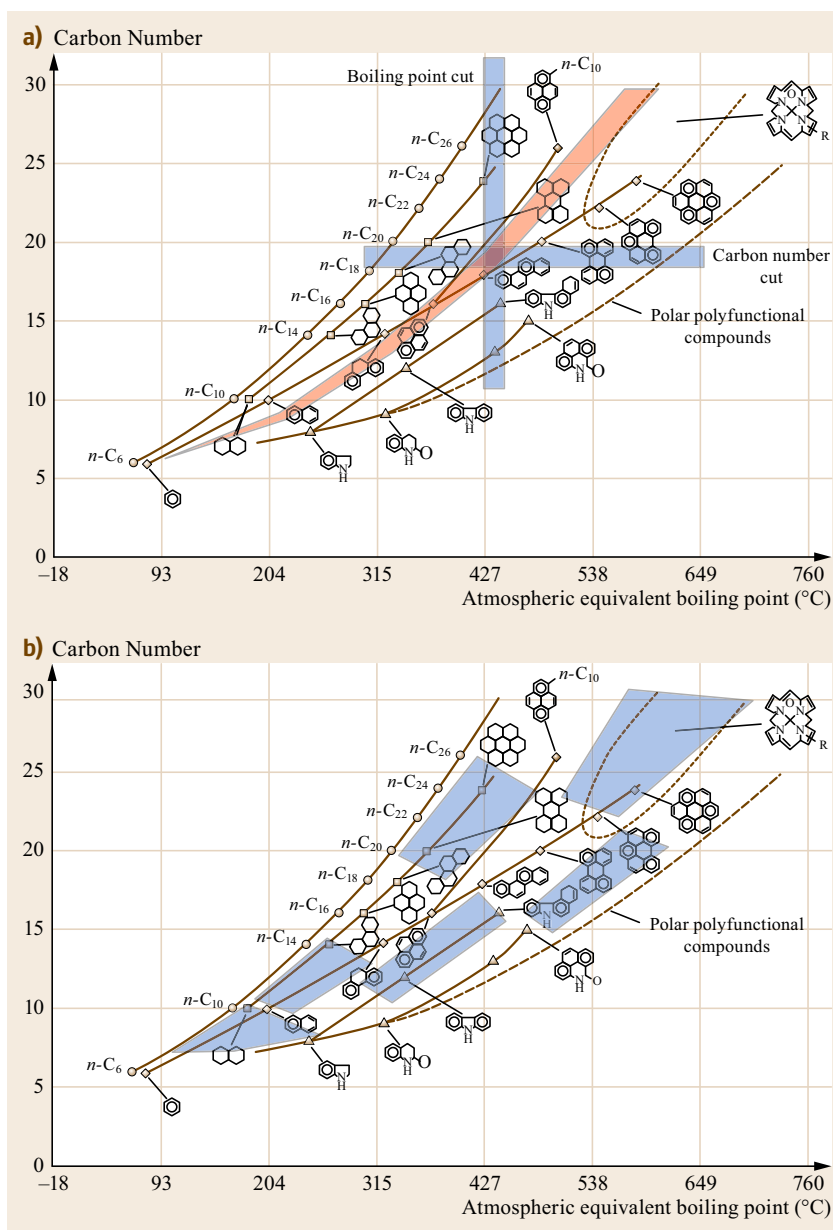

Fig. 8.10a,b Oil characterization approaches overlaying a graphic adapted from *Merdignac and Espinat* (after [8.99]) that shows the relationship between the carbon number and the boiling point for the components present in crude oils: **(a)** the highlighted vertical slice represents a boiling cut, the horizontal slice represents a carbon number cut, and the diagonal slice indicates the trajectory of average cut properties for a hypothetical crude oil; **(b)** highlighted and clear segments indicate components/properties encompassed by individual representative molecule pseudo-components

8.4.1 Heavy Oil Chemistry

In any crude oil, the variety and complexity of the constituent molecules increase with increasing boiling point and carbon number, as do the aromaticity, polarity, and heteroatom and metal content, as illustrated in a simplified manner in Fig. 8.10a [8.76, 99–101]. A single carbon number contains a wide variety of compound types with a wide range of boiling-points. For example, $C_{12}H_{26}$ has 900 possible isomers including stereoisomers with differences in boiling points of up

to approximately 30°C . The boiling-point difference is even greater with different hydrogen contents. For example, the boiling-point difference between acenaphthene, $C_{12}H_8$, and 2,2,7,7-tetramethyl octane, $C_{12}H_{34}$ is 94°C . These differences increase as the carbon number increases. Similarly, a boiling cut contains a wide variety of carbon number species. For example, the boiling point difference between octacosane, $C_{28}H_{58}$, and chrysene, $C_{18}H_{10}$, is only 8°C . In both cases, the representative fractions include diverse molecular species. Characterizations constructed on the basis of

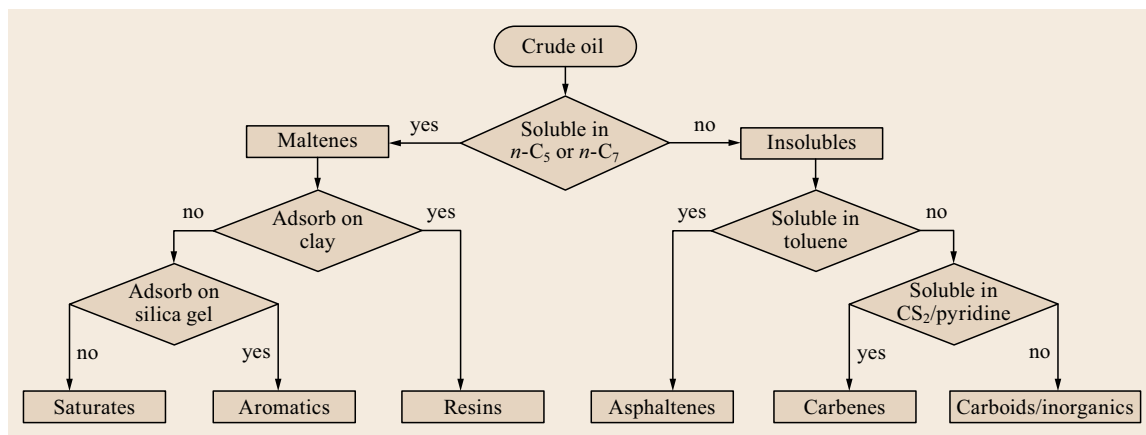

Fig. 8.11 Simplified representation of crude oil by solvent fractionation. (After [8.96, 98])

boiling or carbon number cuts have proven successful because the average properties of the cuts follow a consistent trend for naturally occurring hydrocarbon fluids, and consequently property estimation for a specific fluid requires limited tuning from properties linked to standard correlations for each cut. Issues arising with this characterization approach include uncertain extrapolation to undistillable fractions, and to processed hydrocarbon fluids found in refineries that can be prepared by blending in proportions that create materials which cannot be represented by a simple statistical distribution; no matter how it is defined. The property distributions as shown in Fig. 8.10a can also be considered as a large and complex collection of overlapping homologous series with increments in many structural elements, including ring number, side chain length and location, and heteroatom content and location. Note, for the sake of simplicity, the only homologous series shown in Fig. 8.10 is the *n*-paraffin series.

Group contribution methods attempt to represent these overlapping series with a set of representative molecules. In effect, individual molecules are used to reflect particular regions of the carbon number – boiling-point space. An illustrative subdivision is shown in Fig. 8.10b where each shaded and unshaded patches are represented by a representative molecule. To define sets of molecules and their representative mole/mass fractions for specific oils, measurable composition properties of the oil (aromatic carbon content, elemental analysis, gas chromatography with mass spectrometry (GC-MS), and physical properties (density, bubble pressure)) are fit numerically. A standard set of molecules or a customized set of molecules may be employed. In principle, it is possible to capture the chemical behavior of individual oils in production and refining environments and to provide composition models of varying but linked complexity. For example, more

constituents are desired for refinery models, where it is desirable to track fluid chemistry, and fewer constituents are needed for production models, where the emphasis is primarily on flow properties. This holistic approach to speciation requires more experimental research for its full potential to be realized, particularly for heavy oils, because of the uncertainty of the molecular level properties, and the distribution of properties of their undistillable fractions, but this characterization approach is already finding application in selected production and refining environments.

Solubility/adsorption-based fractionation methods also slice the distribution based on both size and chemical family. For example, a heavy oil can be divided into saturates, aromatics, resins, asphaltenes, carbenes, and carboids, as shown in Fig. 8.11. The saturate fraction consists mainly of long nonpolar carbon chains of linear, branched, and cyclic saturated hydrocarbons. Aromatics, resin, and asphaltenes consist of aromatic ring aggregates with aliphatic substitutions. The molecular weight, polarity, and heteroatom content increase from aromatics to resins to asphaltenes. Carbenes and carboids form a minor part of the heavy oil and include highly associated and condensed products that are insoluble in most of the solvents used for petroleum assays [8.102]. If the CS₂/pyridine separation is neglected, the diagram corresponds to the more common SARA fractionation. Asphaltenes are known to self-associate into nanometer-scale structures [8.20, 103] and their high molecular weight arises from dispersion forces rather than chemical bonding. Hence, a second distribution of nano-aggregate properties overlays the distributions, as shown in Fig. 8.10.

Conventional crude oils consist of relatively low carbon number species and most of the oil can be fractionated by distillation or characterized by gas chromatography (GC) [8.104]. However, only a rel-

atively small fraction of heavy oil (of the order of 30 wt%) is distillable or can be meaningfully assayed with gas chromatography. In addition, while conventional oils usually contain a low mass fraction of asphaltenes, whole heavy oils and bitumen can contain more than 20 wt% asphaltenes, and heavy oil fractions comprising more than 60 wt% asphaltenes have been reported [8.24]. Hence, heavy oil characterization is challenging for the two reasons:

1. Relatively little of the fluid can be assayed meaningfully using conventional distillation-based characterization.
2. The oil contains a significant fraction of asphaltenes which self-associate and may not follow the property trends observed for the lighter components.

8.4.2 Characterization Based on Distillation Data

Distillation data are obtained from direct measurements or GC data empirically converted to boiling points (simulated distillation or SimDist). Directly measured distillation assays are limited to temperatures below 330 °C [8.105] to avoid thermal cracking. Vacuum distillation (ASTM D-86, D-1160, D-2892, and D-5236) can fractionate to atmospheric equivalent boiling points up to approximately 838 K (565 °C). Typically, 80–95 wt% of a conventional oil, but only 20–30 wt% of heavy oil or bitumen, is distillable with these methods. SimDist can, in theory, be extended to atmospheric boiling points above 565 °C. However, the empirical conversion to boiling temperature cannot be validated above 565 °C and should be treated with caution. No standard methodology is yet available to extend a distillation assay above 565 °C [8.106].

There are two main options for crude oil characterization:

1. Extrapolate the boiling points based on measured trends and tune models with other parameters, such as binary interaction parameters, as outlined by *Whitson and Brulé* [8.97].
2. Adjust the extrapolated boiling point to optimize model fits similar to *Pedersen's* [8.95] approach for GC cuts.

One must also decide whether to include the asphaltenes in this extrapolation or to treat them separately. Once a complete boiling curve is constructed, it is divided into pseudo-components. The number of components is dictated by the needs of the model the characterization is intended for, computational effort, and data availability. For example, from 5 to 20 pseudo-

components are considered sufficient to define a crude oil for phase behavior modeling [8.97, 98, 107, 108]. For each pseudo-component, physical property correlations are then used to predict the critical constants and thermodynamic properties (the former are especially important when modeling the oil with an equation of state). Mixing rules are used to obtain the full characterization of the fluid.

Castellanos-Diaz et al. [8.107] recommended a characterization approach for heavy oil phase behavior modeling where the boiling-point distribution of the maltenes was extrapolated assuming a Gaussian distribution, as suggested by *Huang and Radosz* [8.108]. The asphaltenes were represented with a Gamma distribution of molecular weights (Fig. 8.12). The combined distribution was cut into 12 maltene and 6 asphaltene pseudo-components. Both the Lee–Kesler and modified Twu correlations were found to provide workable estimates of the critical properties. These methods provide reasonable fits when processing data from a characterization and are further used as inputs for the development of thermodynamic models for mixtures of interest. Other approaches may perform similarly if the *characterization* is modified and different extrapolations for maltenes and asphaltenes are used. *Characterizations and the model are intrinsically connected*. The connection between characterization and thermodynamic models is further explored in Sect. 8.5 and the equation-of-state model based on the above characterization is also presented there.

8.4.3 Characterization Based on GC Data

GC compound distributions are based on the retention times of the constituents of a crude oil sample carried over a carrier gas, such as helium or hydrogen through a fused silica capillary column after the sample is injected onto the injector (split/splitless, on-column, temperature-programmed vaporizer, etc.). A packed column is occasionally used. If a nonpolar-packed column, such as methyl silicone coated, is used, the retention times of the constituents are related to their boiling points. There are many types of detectors that can be chosen depending on the purpose of the analysis. The universal detector is a flame ionization detector (FID) in which the response is proportional to mass concentration. A fraction of the oil, the residue, does not vaporize or elute and stays in the injector or column head. The retention time is calibrated with *n*-paraffin standards. Apparent carbon number distributions of crude oils are reported relative to this standard and are used to characterize them. Actual carbon numbers and thus the molar masses at the same retention vary depending on the molecular structure. When a metal (such as aluminum)

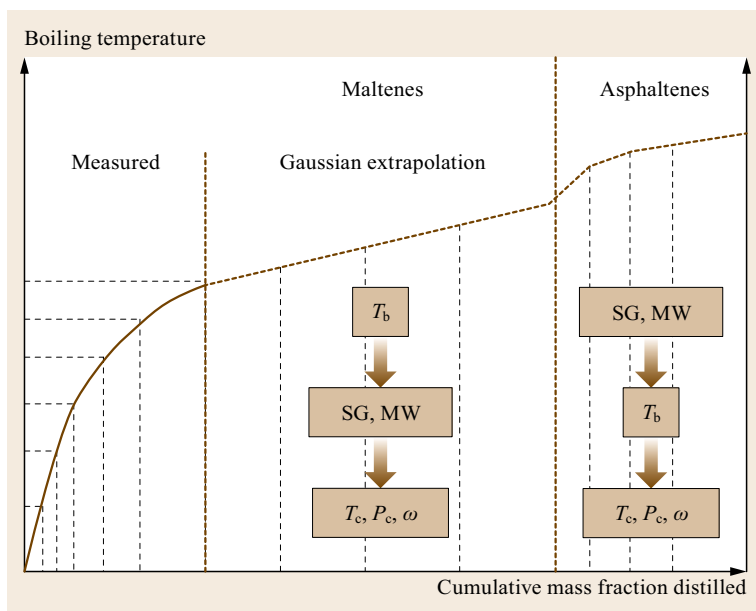

Fig. 8.12 A lumped characterization method for heavy oil based on extrapolating distillation data. The maltene fractions could also be based on SARA or liquid chromatography fractions. In this latter case, the maltene cuts would also represent a wide range of boiling points

column is used, the GC oven can be heated beyond 400 °C that would destroy the external polyimide coating of a fused silica column. Thus, it can be used for SimDist using a nonpolar column for boiling-point correlations. Hence, high-temperature GC is widely used as a rapid and inexpensive alternative to determine the distillation yields, including residues. Also, SimDist requires sample sizes in microliters, rather than liters as used in the distillation laboratory for a crude assay.

GC assays for crude oils include ASTM D-2887, ASTM D-3710, and ASTM D-7169. ASTM D-2887 is the most common procedure to provide carbon number data ranging from $< C_5$ to $\approx C_{44}$, corresponding to a maximum boiling point of 538 °C. ASTM D-3710 is recommended for gasolines with final boiling points less than 260 °C. ASTM D-7169 is the high-temperature SimDist procedure for a final boiling point up to 750 °C (equivalent to C_{120}). In general, the accuracy of the GC assay data above C_{25} is questionable because C_{25} is the upper limit of reliable true boiling point (TBP) distillation data for *n*-paraffins because TBP involves vacuum distillation [8.97]. In addition, based on the authors experience, the reproducibility of the residue determination (C_{30+} fraction) for bitumen is only ± 5 wt%.

Characterizations are constructed from GC data following the same steps as for boiling point data:

1. Extrapolate the carbon number (or calculated molecular weight) distribution
2. Divide the distribution into pseudo-components

3. Assign properties to the pseudo-component using correlations.

As with boiling point characterizations, tuning is accomplished by adjusting either the extrapolated molecular weight distribution or the binary interaction parameters in the phase behavior model [8.95, 97]. Tuning is essential because the characterization method does not include the molecule structure, and thermophysical properties and phase behavior are sensitive to the molecular structure.

The main challenge in the characterization of heavy oils is the large residue fraction. Figure 8.13 compares GC assays from a conventional oil and a bitumen. The residue (nonvaporized) fraction of the conventional oil was 33 wt%, compared to 70 wt% for the bitumen. The mass fractions of the higher carbon numbers in the conventional oil decrease following a clear and consistent trend. No clear trend is observed in the bitumen assay. With no trend to guide the extrapolation and relatively high uncertainty in the amount of residue, GC-based heavy oil characterization is not very reliable. The reliability can be improved when the characterization is constrained with other data such as the density and molecular weight of the oil and/or residue.

8.4.4 Characterization Based on SARA Data

SARA analyses possess a large number of operating definitions and a standard has not emerged [8.23]. The ASTM D2007 SARA assay of a crude oil starts by the separation of the asphaltenes using excess volumes of

Fig. 8.13 Comparison of GC assays of a conventional oil and a bitumen. Their residue fractions were 33 and 70 wt%, respectively

a paraffinic solvent, commonly *n*-pentane or *n*-heptane (Fig. 8.11). The de-asphalted oil (DAO), also called maltenes, is recovered by evaporating the excess solvent. Then, the maltene fraction is further separated into saturate, aromatic, and resin fractions using liquid chromatography. The SARA composition is determined from the mass of the recovered SARA fractions and we stress that SARA-type components are distributed over boiling-point ranges as illustrated in Fig. 8.10. The resins and asphaltenes are present in the higher boiling ranges (middle distillates and above), while aromatics and saturates are concentrated in the lower boiling ranges.

SARA assays provide only four fractions and are coarse relative to distillation and GC assays. There is no standard method of constructing a TBP curve based on SARA components. Furthermore, there is no clear distinction between the properties of the aromatic, resin, and asphaltene fractions, and their relative amounts and properties depend on the details of the protocol used to separate them. SARA assays do provide an indication of the relative amount of saturated and aromatic components in an oil, and SARA assays are commonly used to characterize crude oils and for modeling asphaltene precipitation with regular solution theory-based models.

8.4.5 Characterization Based on Representative Molecules

Molecular level characterization of ill-defined hydrocarbons is a challenging task both experimentally and theoretically, and it leads to ambiguous outcomes because a broad range of pseudo-components can represent any of the subregions as shown in Fig. 8.10b and because the number of subregions may be chosen arbitrarily. Quantification of functional groups in molecules and the definition of mean molar mass for boiling fractions, or whole crudes, remain key challenges. For ex-

ample, *Jaffe* et al. [8.109] proposed more than 150 sub-molecular motifs in petroleum residues. These include chain and branched chain motifs of varying length, including chains with some double bonds; aromatic, naphthenic, and mixed naphthenic + aromatic motifs of various sizes; sulphur, nitrogen, oxygen, and metal substituted motifs. *Sheremata* et al. [8.110, 111] proposed molecular pseudo-components for the AVR using a Monte Carlo construction method. Only 10 motifs were used to build these molecules that respected elemental analysis, including heavy metals such as nickel and vanadium, and aromatic carbon content. Based on the same motifs, *Sheremata* [8.111] proposed an alternate set of molecules to represent the same fluid by respecting SimDist data as well. However, there is little agreement on the nature of the molecular motifs that comprise the AVR. Asphaltenes, for example, make up approximately 30 wt% of this residue, depending on the asphaltene definition employed. Both pericondensed [8.13, 112] (continental) and archipelago-type [8.14, 111] molecular pseudo-components [8.15, 113] have been proposed for Athabasca asphaltenes. The ambiguity appears to be linked to the molecule construction algorithms [8.10] because the pericondensed pseudo-components proposed by *Boek* et al. [8.112] were based on the same input data used by *Sheremata* et al. [8.110].

While the representative molecules, the motifs they comprise, and their molar masses remain ambiguous, there is greater agreement on the functional groups present and the types of carbon they comprise, because many of the groups are measured and quantified experimentally using more than one technique. These functional groups typically include one to a few atoms and range from specific carbon types to simple alkyl/aromatic groups, to sulfur, oxygen, and nitrogen containing groups. Therefore, group contribution methods based on pseudo-components are an emerging

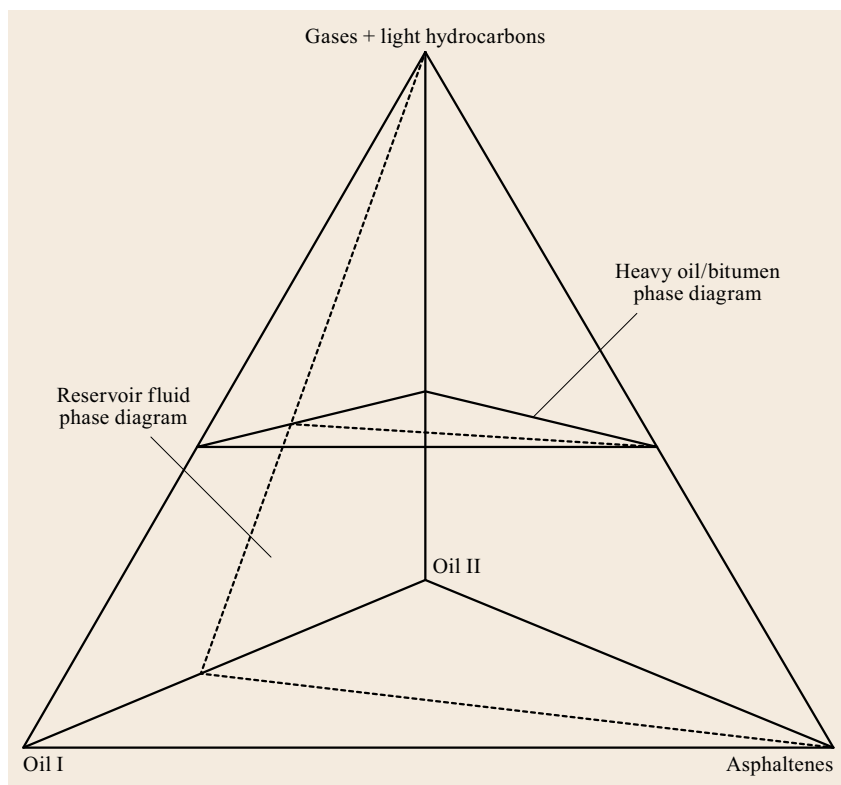

Fig. 8.14 Simplified characterization of heavy oils in reservoir and refining environments. (After [8.114])

alternative approach for characterizing thermophysical and transport and thermodynamic properties of individual fluids, as well as phase behavior and phase composition properties related to separations or mixing, whether in reservoirs or refineries. From the work of *Saber et al.* [8.30, 31, 115], the group contribution method proposed by *Marrero and Gani* [8.116] in combination with the Peng–Robinson cubic equation of state (CEOS) is a suitable basis for such calculations. In this approach, critical temperatures and pressures, and acentric factors for each pseudo-component that comprise required inputs for the equation of state are calculated on the basis of functional groups defined by the method. The approach was tested using simple ternary mixtures [8.115] where the results show that the Marrero and Gani group contribution method outperforms even the Peng–Robinson equation of state, even if critical temperatures, pressures, and acentric factors for the components are available exogenously. Illustrative phase behavior calculations with the AVR and *n*-alkanes are also available [8.30, 31]. While this approach offers advantages over refinery-type characterizations for thermophysical property and phase behavior calculations, a comparative study reveals that for the time being both approaches can be used for simulation but not prediction [8.114], as discussed in Sect. 8.5.

8.4.6 Heavy Oil Characterization Summary

Oil characterization, whether based on distillation or SimDist data, SARA analysis, spectroscopic data, direct measurement of specific properties, or a combination of these analyses, provides insights into the chemistry and physics of fluids. Characterizations of individual fluids do not exist in isolation, and are not an end in themselves. Characterizations provide bases for the generalization of properties and behaviors, and inputs tailored to specific types of calculations in diverse processing environments. The coexistence of primitive and sophisticated characterization schemes may at first glance appear to arise as an historical artifact, and one might imagine that more primitive schemes may disappear rapidly with advances in analytical chemistry. While both of these contentions are certainly true in the longer term, it is important to recognize that the diversity of the processing environments, and economic (analysis costs) and technological (computing power) constraints will continue to impose limits and permit diverse perspectives on this topic to flourish into the future. For example, in production environments, characterization relies primarily on GC analysis and focuses on low molar mass species (light hydrocarbons (C_1 – C_7), CO_2 , H_2S , etc.), while larger hydrocarbons are

lumped as maltenes and asphaltene fractions. These composition variables affect production rates, and only a limited number of parameters can be included in reservoir models due to computational constraints. Composition is frequently defined on the basis of five or fewer lumped components. In refining, low molar mass species are readily modeled. While these species are included in refining models, the focus is on fine-grained and high-cost speciation of the maltene fraction as these constituents affect process selection and design, process operation and product quality/value. Heavy oils are frequently represented by 50 or more components in refinery models. As illustrated in the simple schematic, Fig. 8.14, the compositions and hence the phase dia-

grams and properties are largely defined on the basis of vertical slices in composition space (reservoir models) and horizontal slices (refinery models). Currently, literatures related to phase behavior and property prediction, based on these divergent and in some respects incompatible characterization approaches, continue to co-exist as discussed in Sects. 8.5 and 8.6. The long-term goal of a single universal characterization approach, providing the required detail for refining but which can be systematically simplified to meet the computational constraints imposed by reservoir models, remains a work for the future. Currently, characterization approaches must be selected with care to ensure their relevance to a particular application.

8.5 Phase Behavior Correlation and Prediction

The successful correlation and prediction of phase behavior of hydrocarbon mixtures are dependent on good experimental assay data, good characterization, good thermodynamic models, and finally on a good flash algorithm for the proper determination of the numbers and natures of phases present, and the amount and composition of each phase at thermodynamic equilibrium. The definition of a good assay, notwithstanding the need of rigorous analytical procedures, reproducibility, and sample preparation, is its ability to characterize a fluid in such a way as to define a set of relevant and reliable inputs for a particular process model.

The definition of good characterization and good thermodynamics follow their ability to provide users with useful models that can be used to describe actual processes being designed or analyzed. Since the common denominator for modeling activity is the desire to simulate a process, and since processes of interest occur in widely different parts of the thermodynamic space (pressure, temperature, and composition), including areas where chemical reactions are important and where varying levels of details are required, no single set of experiments, characterization procedures, and thermodynamic models is sufficient. In this section, we assume that the characterization approach is selected and the data are collected in such a way as to provide meaningful information for the process of interest, and that the components are defined and lumped in such a way as to provide a reasonable basis for process modeling. Some examples and their limitations are discussed in Sect. 8.4.

8.5.1 Thermodynamic Model Selection

The number of available thermodynamic models appears to be almost unlimited. However, useful thermo-

dynamic models for the correlation and prediction of phase equilibrium behavior of interest for petroleum are, in practice, limited by the amount of useful information that can be provided as input to the model. For example, highly complex equations of state exist, but the determination of their parameters is essentially impossible due to the small amount of characterization data available, usually limited to a small set of average physical properties for the pseudo-components such as liquid density, molecular weight, and normal boiling point. From this small set of properties, critical properties and interaction parameters must be estimated. In other words, formal mathematical complexity does not equate to usefulness or accuracy. Further, petroleum is not simply a mixture of hydrocarbons. Petroleum also contains inorganic compounds such as water, carbon dioxide, and hydrogen sulfide, as well as trace materials such as metals and mineral fines. Any contribution of these components to the phase behavior, physical properties, and processing of petroleum must be accounted for. Meaningful thermodynamic models must also provide pertinent information for the computation of transport and other properties for process calculations such as viscosities. For high-pressure processes such as gas production, thermal upgrading, and hydrogenation, critical phenomena are important and the continuity of physical properties between gas and liquid phases is fundamental. It is useful to organize the key process questions we would like to answer in order to narrow modeling choices as suggested in Table 8.2. In general, model choices for the simulation of petroleum processes include equations of state (cubic, cubic plus association (CPA), statistical associating fluid theory (SAFT), and activity coefficient models (nonrandom two liquid (NRTL), regular solution theory).

Table 8.2 Matrix for model selection for typical hydrocarbon/petroleum-based processes

Main process to be modeled	Thermodynamic model	Example	Typical assay	Typical characterization
Gas processing	Cubic equations of state Corresponding states Reference equations	Gas plant, gas transportation in pipelines	C ₇₊ Chromatography	Lumped model Gamma distribution Pseudo-components
Refining, distillation	Cubic equations of state Modified Antoine	Atmospheric crude tower	Light ends Distillation assay SimDist	Curves to TBP Pseudo-components
Refining, reactors	Cubic equations of state	Hydrocracker, Hydrotreater, Coker, Upgrader	Light ends Distillation assay SimDist PNA	Curves to TBP PIONA Family pseudo components Surrogates
Heavy oil production	Cubic equations of state SAFT Activity coefficient	Bubble pressure calculations Determination of gas dissolved in oil	Light ends Distillation assay SimDist SARA	Curves to TBP Gaussian for maltenes, Gamma for asphaltenes Surrogates
Heavy oil treatment with solvents	Cubic equations of state Activity coefficient	Removal of asphaltenes from heavy oil	Light ends Distillation assay SimDist SARA high vacuum fractionation Yield versus solvent concentration	Curves to TBP Gaussian for maltenes, Gamma for asphaltenes Surrogates

After selecting an appropriate thermodynamic model, the importance of the representation of the physical-chemical properties of the fluids for the calculation of interest must be assessed. For example, if the primary concern is phase behavior, then good enough models can frequently be constructed using pseudo-components where the chemistry is only represented by average physical properties, such as liquid density and boiling point. For more detailed calculation of phase compositions or accurate modeling of chemical reactors, more detailed information about the chemical nature of the pseudo-components is necessary in order to capture the chemical transformations resulting from thermal or catalytic reactions, or the partitioning of specific species or species classes arising during liquid–liquid or liquid–vapor separation operations. This more detailed information can be expressed by using special pseudo-components determined using PIONA-type characterization [8.117] where specially determined family trends as a function of carbon number are used, or through the use of representative molecules that approximate the chemical characteristics of materials that constitute the different oil fractions [8.115]. The advantage of using surrogate molecules arises from their defined molecular structures that are amenable to modeling using group contribution methods [8.30, 118, 119].

It is important to recognize that the compositions of interest for a process being modeled may differ from the compositions defined through characterization. For

example, pseudo-components are defined on a water-free basis, but it is frequently necessary to estimate the mutual solubilities of water and hydrocarbons. Typically, the solubility of water in hydrocarbon streams is the main focus and this condition is not far from the original characterization. However, the solubility of hydrocarbons in water (e.g., contamination of water by trace hydrocarbons) at a composition vastly different (e.g., essentially pure water) from the original characterization may be needed. The simple equations of state used for refinery modeling are usually tuned to match the solubility of water in hydrocarbons, and the solubilities of hydrocarbon in water are not well modeled [8.120], and additional correlations, as noted in Sects. 8.2.3 and 8.5.6, are needed. Robust thermodynamic models must accommodate these compositional changes in a reliable and hopefully theoretical manner to provide a meaningful insight into the material and energy balances of interest.

The final selection of a thermodynamic model is then a function of intrinsic characteristics of the thermodynamic model and the type of derived information that can be obtained from the model given the inputs resulting from the assay and characterization data. Invariably, the outputs provided by the model comprise a small set of well-defined compounds (light ends, light portion of SimDist, solvents, water, inorganics such as ammonia, hydrogen sulfide, nitrogen, and carbon dioxide) and a set of pseudo-components (cuts or representative molecules) and their compositions. Based on this

information, thermodynamic models perform two major tasks. They define the necessary physical properties for the pseudo-components and the binary interaction parameters among all binary pairs present, and provide reliable fugacities for any phase composition of interest so that phase behaviors are adequately represented and that physical property calculations, for example, phase densities and enthalpies, and phase transport properties are supported by the thermodynamic model. These intermediate results are then used to compute viscosity, thermal conductivity, and other transport properties.

8.5.2 Essential Thermodynamic Equations

In order to model phase behavior, the most useful place to start is the equality of the chemical potential or equivalently the fugacity of each component in each phase at thermodynamic equilibrium given by

$$f_i^V = f_i^{LI} = f_i^{LII} = \dots f_i^{LN} = f_i^S = \dots, \quad (8.7)$$

where f is the fugacity of any component i , V stands for vapor, LI–LN denote the different liquid phases that may exist (light hydrocarbon, heavy hydrocarbon phases, aqueous phase, liquid carbon dioxide phase, etc.) and S stands for solid phases. While solids are important and may include hydrate phases, wax phases, ice phases, these comprise specialized topics and they are not discussed here.

For fluid phases, fugacity expressions can be written in two principal ways depending on whether activity coefficient or equation-of-state models, (8.8) and (8.9), are used

$$f_i = \gamma_i x_i f_i^{OL}, \quad (8.8)$$

$$f_i = \phi_i x_i P. \quad (8.9)$$

In (8.8), γ stands for the activity coefficient, x is the mole fraction, and f^{OL} is the standard state fugacity. At low pressures, the standard state fugacity is often represented by the vapor pressure or, for gases such as methane, hydrogen, nitrogen in the liquid phase, by a Henry constant which is solvent dependent. In (8.9), ϕ stands for the fugacity coefficient and P is the pressure. Formally, activity coefficients and fugacity coefficients are functions of pressure, temperature, and composition, and (8.8) and (8.9) can be freely applied to liquid and vapor phases. From a practical point of view, (8.8) is usually applied only to the liquid phase and due to small dependency on physical properties exhibited by liquids on pressure away from the mixture critical points. Consequently, liquid-phase activity coefficients are typically assumed to be pressure independent. Equation (8.9) can be applied to the vapor and liquid phases.

If an equation-of-state model is selected, liquid and vapor properties can be calculated formally to be consistent with critical phenomena. This choice improves the robustness of model predictions and facilitates interpolation and extrapolation of available data.

The formal relationship between fugacity coefficients and fugacities is given by

$$RT \ln \frac{f_i}{x_i P} = \int_V^\infty \left[\left(\frac{\partial P}{\partial n_i} \right)_{T,V,\bar{n}_j} - \frac{RT}{V} \right] dV - RT \ln Z, \quad (8.10)$$

where R is the universal gas constant, T is the absolute temperature, V is the volume, n is the number of moles, and Z is the compressibility factor defined as PV/RT . Equation (8.10) is basic for the modeling of natural gas processes where important phenomena such as retrograde condensation and other complex phase behaviors occur at high pressures and must be properly captured by the model. Heavy hydrocarbons are frequently processed at high temperatures and pressures, whether in situ, during deasphalting, or during hydrocracking where hydrogen is provided for the reforming of heavier materials into more useful lighter fractions. Thus, the ability to model high-pressure equilibria and to treat asymmetric mixtures, that is, mixtures comprising both light and heavy components that exhibit complex phase behaviors are important features of a model. Another benefit derived from using equation-of-state models is that they can be used to calculate residuals for enthalpy, entropy, heat capacity, and other physical properties, thus only requiring the availability of ideal gas heat capacities for the development of complete, self-consistent physical property calculation systems.

By contrast, activity coefficient models are semiempirical expressions derived from a model for the excess Gibbs excess free energy of mixing. Activity coefficient models require interaction parameters fitted against experimental data at each temperature of interest. Sometimes useful generalizations are possible, for example, for correlating solubility parameters [8.121]. However, activity coefficient models always require the development of separate procedures for the calculation of physical properties such as densities, enthalpies, and entropies. A separate model must also be selected for the gas phase. These separate phase models make activity coefficient models inherently inconsistent when extended to the mixture critical region. This significant disadvantage can be transformed into a formidable advantage. This is particularly true when modeling liquid–liquid equilibrium phenomena that arise from

the treatment of oils with solvents or water–oil phase equilibrium [8.69, 122, 123].

Effective use of equations of state is usually based on the use of van der Waals conditions at a critical point for a pure component, given by

$$\left(\frac{\partial P}{\partial v}\right)_T = 0, \quad (8.11)$$

$$\left(\frac{\partial^2 P}{\partial v^2}\right)_T = 0, \quad (8.12)$$

which define parameters appearing in equations of state based on the critical pressure and critical temperature. Equations-of-state parameters also must be adjusted to provide reasonable vapor pressure predictions. For example, by correlating the attractive parameter to the acentric factor [8.124, 125] or through the use of specialized functions [8.126]. Equations-of-state parameters are frequently tuned to liquid density data [8.127, 128]. In order to calculate enthalpies and entropies, ideal gas heat capacities are also required. Liquid-phase densities are frequently calculated using a form of the Rackett equation [8.129], and enthalpies and entropies are calculated using an equation of state for the gas phase and an empirical residual equation such as the Watson equation or generalized formulation of the corresponding states principle such as *Pitzer's* acentric factor [8.130].

A large number of methods are available for the estimation of pseudo-component physical properties [8.98, 131], but two methods that have been proven useful for widely different types of pseudo-components obtained

from oil characterization. These are the *Lee–Kesler* method [8.132] and the *Twu* method [8.133] for the calculation of critical properties for hydrocarbon cuts. For characterizations based on representative molecules, group contribution methods are required for the determination of critical properties [8.134, 135]. Thus, useful models for phase equilibrium and physical property calculations require, for each pseudo-component as well as defined components, the input properties summarized in Table 8.3.

8.5.3 Cubic Equations of State (CEOS)

Due to their simplicity, accuracy, robustness, and speed, models based on CEOSs are extensively used for the calculation of phase equilibria and physical properties for hydrocarbon mixtures. Although many CEO models exist, they all share some common characteristics. CEOS can be broadly categorized into two-parameter CEOS [8.124, 125, 136, 137], three-parameter CEOS [8.138–141], and four-parameter CEOS [8.142].

Two-parameter CEOS are by far the most commonly used type because only critical temperature, critical pressure, and acentric factor are necessary for the calculation of pure component properties. Since there are correlations for the critical properties and acentric factor that are functions of normal boiling point and liquid density, properties normally available through oil characterization, it is straightforward to build models based on exceptionally little data. However, correlation extrapolation to large molecules found in heavy oils in-

Table 8.3 Basic pure component properties required for thermodynamic model development—equations of state or activity coefficient based

Property	Data	Objective
Vapor pressure	Normal boiling point Acentric factor Antoine or Wagner coefficients Raw data	Calculate accurate vapor pressures.
Liquid density	Specific gravity Standard density at 60 °F Standard density at 25 °C Rackett coefficients Raw data	Calculate accurate liquid densities, in particular saturated liquid densities
Critical temperature	Correlations Raw data	Specify van der Waals conditions at critical point
Critical pressure	Correlations Raw data	Specify van der Waals conditions at critical point
Solubility parameter	Correlations Enthalpy of vaporization data	Used for regular solution activity coefficients
Ideal gas heat capacity	Correlations	Used for H , S , and C_p calculations and the associated energy balance calculations
Molar mass	Correlations Raw data	Material balance calculations

roduces uncertainty because the critical properties for large molecules cannot be measured experimentally due to their thermal instability. It is evident that equation-of-state parameters based on vapor pressure are at least ambiguous for pseudo-components that in many cases will be present in the solution at temperatures well below their melting point.

All two-parameter CEOSs suffer from the poor representation of liquid densities and usually this is corrected through the use of volume translation [8.128] where the volume computed from the cubic is empirically corrected through the addition of a constant. It is frequently found that, for high-accuracy liquid-density calculations, a constant volume translation is not enough and a correction that is a function of temperature is required. Although this type of correction makes the equation-of-state inconsistent from a thermodynamic point of view, it extends the range of usefulness considerably [8.143]. The vapor–liquid-phase equilibrium calculations for volume-translated equations of state are not changed by the volume translation, but computations related to hydrate phase formation or wax formation where accurate fugacities are required sometimes benefit from volume-translated equations of state. Some equations of state use a temperature-dependent volume translation or a temperature-dependent co-volume [8.142, 144] for accurate liquid density calculations, and significant improvements on the quality of the predicted fluid fugacity can be gained at the expense of thermodynamic consistency (either in the form of isotherm crossings, negative heat capacities at high pressures, or discontinuities at the critical point). These issues are well documented in the literature [8.145, 146].

Three-parameter equations of state provide better predictions for densities than two-parameter equations since the third parameter is frequently fit to liquid density data, but one often finds that the improvements are still not of sufficient accuracy for engineering calculations. Four-parameter equations of state are rarely used since the improvements over two- and three-parameter equations of state are unfortunately small from a phase equilibrium point of view, and it is difficult to justify the additional complexity versus the accuracy gained. These features are better illustrated through the examination of the actual model equations.

The typical structure for a CEOS is

$$P = \frac{RT}{v-b} - \frac{a_c \alpha(T)}{v^2 + ubv + wb^2}, \quad (8.13)$$

where v is the molar volume, a_c is the attractive term, b is the co-volume, $\alpha(T)$ is an empirical function designed to model vapor pressures, and u and w are the

numerical constants that define the actual shape of the equation of state. The term $\frac{RT}{v-b}$ represents a repulsive contribution to pressure to represent that the finite size molecules have and consequently the fact that fluids are not infinitely compressible. The term

$$-\frac{a_c \alpha(T)}{v^2 + ubv + wb^2}$$

represents the attractive forces between molecules. The terms a_c and b are determined based on the van der Waals conditions at the critical point (8.11) and (8.12). $\alpha(T)$ is frequently generalized for hydrocarbons [8.124, 125] as shown below, for the Peng–Robinson equation of state in (8.14) and (8.15)

$$\alpha(T) = \left[1 + f_w \left(1 - \sqrt{T_r} \right) \right]^2, \quad (8.14)$$

$$f_w = 0.37464 + 1.54226\omega - 0.26992\omega^2, \quad (8.15)$$

where T_r is the reduced temperature for a component and ω is the component acentric factor. Other general expressions for $\alpha(T)$ have been proposed [8.126] and as (8.14) and (8.15) are not accurate enough for the modeling of polar compounds frequently found in hydrocarbon processing, notably water and methanol, specialized $\alpha(T)$ have found extensive use [8.120, 147].

The volumes calculated from the equation of state are usually not accurate enough for technical calculations and the values are refined through the use of the volume translation technique briefly described above. The molar volume actually used for calculations is given by

$$v = v^{\text{EOS}} + s, \quad (8.16)$$

where v is the molar volume used for density calculations, v^{EOS} is the molar volume calculated from the equation of state, and s is the volume translation parameter. More elaborate forms of volume translation are also available [8.143, 148], including temperature-dependent forms.

Equations of state are usually extended to mixtures through the definition of mixing rules for the calculation of its parameters. For two-parameter equations of state, mixing rules are required for the calculation of the parameters a and b . The simplest mixing rules are the van der Waals rules and although too simple for accurate modeling of polar mixtures, they are useful for the modeling of hydrocarbon mixtures as well as mixtures of hydrocarbons with a series of important inorganic compounds for hydrocarbon processing, such as nitrogen, argon, carbon dioxide, and hydrogen sulfide. The

mixing rules are given by

$$a = \sum \sum (1 - k_{ij}) \sqrt{a_i a_j} x_i x_j, \quad (8.17)$$

$$b = \sum x_i b_i, \quad (8.18)$$

$$k_{ij} = k_{ij}^0 + \frac{k_{ij}^1}{T} + k_{ij}^2 \ln T. \quad (8.19)$$

The term k_{ij} is the interaction parameter and is an empirical term required for correcting the inaccuracies of the mixing rule for the a term (a similar formulation can be used for the b term, although really useful only when dealing with highly asymmetric mixtures such as hydrogen and heavy oils) and must be determined based on experimental vapor–liquid equilibrium data. Common values for k_{ij} can be found in the literature [8.149], although care must be exercised when using interaction parameters calculated by others due to inconsistencies between critical properties and acentric factors.

With multicomponent mixtures such as crude oils, the number of interaction parameters becomes large but experimental data are limited to determine their values. An attractive alternative is to correlate the interaction parameters with properties defined in the oil characterization such as critical volumes or temperatures [8.150]. The ability of a simple model to correlate and extend experimental data is remarkable as shown by Agrawal et al. [8.151] and illustrated in Fig. 8.15. Agrawal generalized the interaction parameters into binary classes (carbon dioxide/bitumen cuts, methane/bitumen cuts, ethane/bitumen cuts, n -pentane/bitumen cuts, and bitumen cut/bitumen cut binaries). For hydrocarbons characterized using representative molecules,

Saber et al. [8.30] showed that quantitative multiphase boundaries could be predicted using the Peng–Robinson CEOS, where parameters appearing in the model were defined using group contribution methods as shown in Fig 8.16. Use of boiling range characterization of the heavy oils and the same CEOS did not predict observed three-phase equilibria [8.152].

Notwithstanding their success, quadratic mixing rules are not satisfactory for liquid–liquid equilibrium calculations for highly asymmetric mixtures. While phase behavior is well represented, neither phase mass fractions nor their compositions are well represented [8.30], and it is necessary to relax the imposition of symmetric interaction parameters. Johnston et al. [8.153] illustrate this point clearly and show how a phase equilibrium model based on quadratic mixing rules fails to provide the quantitative representation of asphaltene precipitate yields, as shown in Fig. 8.17. Different methods for developing asymmetric mixing rules abound [8.154, 155], but the lack of complete mutual solubility data for oil–solvent mixtures limits the development of unambiguous models. Asymmetric mixing rules are an active area of research, but the accurate prediction of asphaltene yields with a CEOS has not yet been achieved.

8.5.4 Noncubic Equations of State

The theoretical weaknesses of CEOS are well known and many attempts to correct them have been reported. Sandler [8.154] provides an exhaustive review on equations of state. Here, we briefly examine the SAFT family of equations of state as these equations,

Fig. 8.15a,b Saturation pressures of ethane/bitumen (a) and n -pentane/bitumen, (b) mixtures. Symbols are experimental data and solid lines are APR model fits using independent interaction parameters

Fig. 8.16 Predicted and experimental liquid–liquid–vapor phase boundaries for 10 wt% AVR and *n*-decane mixture as a function of temperature. Red dots show the experimental L1L2V–L1L2 boundary, red lines values computed by the group-contribution CEOS. K ($L1 = V + L2$) and L ($L1 = L2 + V$) are three-phase critical points

Fig. 8.17 Use of symmetric mixing rules to model asphaltene yields from oil diluted with *n*-pentane. Note that the onset is properly modeled but the yield of precipitate as a function of *n*-pentane concentration is not. An asymmetric mixing rule is likely required for proper model construction

based on statistical mechanics, have begun to be applied to petroleum processing. Although SAFT-derived equations of state are mathematically complex, the underlying concepts are straightforward. SAFT-based equations are constructed based on summing intra- and intermolecular contributions to the Helmholtz energy

(A) of components until all the major contributions are accounted for. With a complete Helmholtz energy expression, the pressure is calculated using (8.20)

$$p = - \left(\frac{\partial A}{\partial V} \right)_T \quad (8.20)$$

The expression for A is given by

$$A = A^{\text{ideal}} + m(A^{\text{HS}} + A^{\text{Disp}}) + A^{\text{Chain}} + A^{\text{Assoc}}, \quad (8.21)$$

where molecules are treated as chains of hard spheres. A brief explanation of each term in (8.21) is provided in Table 8.4

For nonassociating mixtures, the major parameters required for each component are the hard sphere diameter (σ), usually treated as a temperature-dependent term, the energy well depth (ϵ), and the number of segments (m). The hard sphere diameter and m model the fluid finite size and compressibility behavior at high pressures and the energy well models the intrinsic energy characteristics of the fluid such as vapor pressures and enthalpies of vaporization. In practice, these parameters are determined through simultaneous fitting of vapor pressures and saturated liquid densities. This simultaneous fitting and the better repulsive term used by SAFT vis-à-vis the simpler $\frac{RT}{v-b}$ term used by most CEOS are likely to provide better compressed density, especially when volumes calculated by the cubic results are not volume translated or are limited to two-parameter formulations. It is also found that the hard

Table 8.4 Main terms used for the construction of SAFT equations of state

SAFT term	Meaning
Ideal	Ideal gas contribution to the Helmholtz energy (ideal gas C_p)
HS	Hard sphere contribution, calculated using the Carnahan–Starling equation (1972)
Disp	Contribution from dispersion forces, that is, weak forces between hard spheres, usually modeled a simple energy well model like Lennard–Jones or square well
m	Spheres are joined tangentially to form chains and corresponding molecules. M is the number of segments required to build a molecule
Chain	Additional contribution for chain formation
Assoc	Contribution coming from association, for example, hydrogen bonding

sphere diameter and well depth energy can be correlated through group contribution methods and a theoretically based, predictive model can be constructed. For example, great regularity of SAFT parameters is observed for n -alkanes.

It is also frequently observed that SAFT-based equations of state can provide at least qualitative predictions when interaction parameters are set to zero and usually smaller interaction parameters are required than for CEOS used to model similar mixtures. This is undoubtedly linked to their more rigorous theoretical formulation. Interaction parameters are introduced through the energy well

$$\varepsilon_{ij} = \sqrt{\varepsilon_i \varepsilon_j} (1 - k_{ij}) . \quad (8.22)$$

The literature on SAFT has become large. For oil processing applications, the review by *de Hemptinne* et al. [8.155] is recommended. As noted in their review, promising results related to modeling heavy oils and solvents through SAFT have been obtained, for example, by *Chapman's* group at Rice University [8.156]. SAFT-based equations do provide a better theoretical platform for development than CEOS, and the use of a rigorous hard sphere reference allows for better modeling of compressed fluid behavior, an important factor for oil processing. At the same time, SAFT equations do not provide exact matches for the critical pressure and temperature as CEOSs do and sometimes exhibit unphysical behavior such as liquid–liquid de-mixing for pure components [8.157]. Perhaps more importantly, well developed and accepted characterization procedures using SAFT are not yet generally available, although there has been progress in this direction [8.158, 159].

SAFT-based theoretical enhancements, such as the explicit addition of association with model develop-

ment, are a potentially useful development for heavy oil modeling applications. The addition of explicit association terms is not necessarily limited to SAFT-like equations but rather can be applied to CEOSs as well, as shown by *Kontogeorgis* et al. [8.160] in the CPA equation of state. This model has a weaker theoretical basis than SAFT since it preserves the cubic equation framework as the reference for the Helmholtz energy calculation, but has the attractive feature of allowing engineers to work within the CEOS structure for hydrocarbon mixtures and to add complexity, and hence introduce noncubic EOS behavior into calculations only as needed, for example, for important polar compounds encountered in hydrocarbon processing, such as water, methanol, and glycols.

8.5.5 Activity Coefficient Models

While activity coefficient models do not provide many derived properties of interest for process calculations, they do provide an excellent platform for specific phase equilibrium challenges, especially for developing models for asphaltene precipitation from oils when in contact with light solvents. A useful, self-contained structure for modeling the behavior of heavy oils and their mixtures with diverse solvents is the model originally proposed by *Hirshberg* et al. [8.161] and elaborated by *Yarranton* and *Masliyah* [8.123]. The modeling approach is based on the Scatchard–Hildebrand theory extended to large asphaltene *molecules* through the Flory–Huggins term

$$\ln \gamma_i = 1 - \frac{v_i^1}{v_m} + \ln \left(\frac{v_i^1}{v_m} \right) + \frac{v_i^1}{RT} (\delta_m - \delta_i^1)^2 , \quad (8.23)$$

where v_i^1 is the molar volume of component i , v_m is the molar volume of the mixture, δ_i^m is the solubility parameter for component i , and δ_m is the solubility parameter for the mixture. The solubility parameter is defined using

$$\delta_i = \sqrt{\frac{\Delta U^{\text{vap}}}{v_i^1}} , \quad (8.24)$$

where ΔU^{vap} is the internal energy of vaporization, also expressed as $\Delta U^{\text{vap}} = \Delta H^{\text{vap}} - RT$.

The solubility parameters for asphaltenes and maltene fractions have been fitted as functions of liquid density and temperature, density being one of the key variables that are available from the oil characterization procedure. The molar volumes are functions of pressure and temperature, thus providing the model with additional accuracy and also the ability to estimate pressure effects on the solubility of asphaltenes

in oils [8.121]. The model has one adjustable parameter per pure component (δ_i) and is easily tunable if experimental data are available through changes in the statistical distribution describing the asphaltene nano-aggregate molecular weights. Figure 8.18 shows the model results for asphaltene yields upon contact with light solvents calculated for several heavy oils and bitumen. This model has also been successfully implemented in process simulators [8.162].

8.5.6 Prediction of Water and Heavy Oil Phase Behavior

Water is a permanent issue related to hydrocarbon processing, and accurate modeling of water composition in hydrocarbons and hydrocarbon composition in water are key factors for reliable process design and process simulation. Due to the low mutual solubility of water and hydrocarbon mixtures at temperatures and pressure removed from the critical point of water, simple models for engineering use have been developed and have found extensive use in process simulators through CEOSs. Perhaps the earliest general formulation for simple modeling of water and hydrocarbons is to use of a constant interaction parameter between water and hydrocarbons equal to 0.5 in CEOS [8.163]. This approximation provides a qualitative representation for

water solubility in hydrocarbon mixtures. Variants of this idea have been presented [8.164] and are included in process and reservoir simulation thermodynamic models. This approach does provide meaningful values for material and energy balances related to hydrocarbon phases, as long as water is modeled using a compound specific $\alpha(T)$ function [8.120].

However, modeling the mutual solubility of water and hydrocarbons with a single interaction parameter using a CEOS and quadratic mixing rules can only match one side of the solubility curve. Most process simulators are designed to provide meaningful values for refinery design and simulation, especially the simulation of crude distillation towers, and therefore the solubility of water in hydrocarbons is the key. This solubility is reasonably well modeled using a constant binary interaction parameter of the order of 0.5 and can be significantly improved if the interaction parameter is allowed to vary with temperature. However, this approximation causes the thermodynamic model to underestimate the solubility of hydrocarbons in the aqueous phase, typically by several orders of magnitude [8.120, 147], and the computed compositions cannot be used for the design of water-processing facilities.

Soreide [8.165] and *Kabadi and Danner* [8.166] proposed asymmetric mixing rules to better fit both sides of the solubility curve. Gibbs excess-based mixing

Fig. 8.18 Fractional asphaltene yield as a function of solvent wt% at 23 °C

rules, notably the Huron–Vidal mixing rule, can be used for very accurate modeling of water–hydrocarbon mixtures. Other models for water solubility have been applied, including density-dependent mixing rules [8.167] and the CPA model [8.160].

Notwithstanding the usefulness and convenience of having generalized interaction parameters for equations of state, it is useful to have methods independent from any specific thermodynamic model for the estimation of mutual solubility of hydrocarbons and water. These estimates then can be used directly for calculations or used to tune interaction parameters for specific thermodynamic models. Some of the more traditional models were reviewed by *de Hemptinne* et al. [8.155], and recent developments in this area include a method proposed by *Satyro* et al. [8.122], where mutual solubilities are estimated using only normal boiling points and specific gravities, properties commonly available when characterizing oils through pseudo-components. A method proposed by *Amani* et al. [8.69] for the estimation of water solubility in heavy oil and heavy oil + solvent mixtures is also available and offers advantages over other approaches, particularly at high temperatures near the critical temperature of water.

8.5.7 Phase Behavior Prediction Summary

Phase behavior prediction for heavy oils and heavy oils + hydrocarbon and nonhydrocarbon mixtures is based largely on the extension of methods with a long history of application for fluids well characterized by boiling fractions, carbon number fractions, individual molecules for which benchmark property data of most if not all components are available, and where time scales for systems to reach equilibrium are negligible compared to processing times. Computation approaches outlined in Sect. 8.5 all suffer from limited experimental data and consequently computed phase compositions, in particular, are poor. Phase behaviors can at best be simulated. Prediction remains infeasible. There are a number of possible explanations for this outcome and they comprise active areas for research.

8.6 Thermophysical Property Simulation and Prediction

Ideally, thermophysical properties should be calculated based on an equation of state to ensure consistency and adherence to exact boundary conditions determined by the first and second laws of thermodynamics and all ensuing relationships. Through careful parameterization and data fitting, accurate equation of state

With inherently high viscosities and low mass transfer rates, equilibration times may be orders of magnitude longer than process time scales, in some cases, and thermodynamic equilibrium may not be reached within time scales that are meaningful for certain process modeling problems:

1. Characterization is clearly a weak link because parameter identification is under constrained.
2. There is a small and growing body of literature that suggests that the molecular basis for phase behavior and property prediction implicit in the models may not capture all of the relevant physics and chemistry. This is particularly true for asphaltene-rich fractions which appear to form filterable nanoscopic phase domains with behaviors independent of the bulk fluids [8.25], and where depletion–floculation and other nonmolecular physical and chemical effects have been shown to drive phase behavior [8.26].
3. Interfacial phenomena may also play key roles in shaping fluid behaviors in specific processes [8.1]. So, even though classical thermodynamics is a powerful tool, it may not be the sole basis for the development of process and property models for heavy oils. In addition to the main thermodynamic variables for process engineering: pressure, temperature, and the number of phases present and their composition, other variables such as areas, interfacial tension, and surface coverage (e.g., for surface phenomena like adsorption) may play a role and the thermodynamic expressions – and associated need of more process engineering knowledge – must be augmented to include additional thermodynamic potentials.
4. At high temperatures, phase equilibrium thermodynamic models do not, in general, account for thermal cracking and although phase boundaries can be computed at arbitrarily high temperatures, they do not necessarily correspond to actual phase equilibria since the composition changes due to chemical reactions. The thermodynamic models are typically not corrected for reaction outcomes.

derived properties can be determined for many hydrocarbon mixtures [8.120] and extended, sometimes surprisingly, to highly nonideal systems using simple mixing rules [8.168].

For heavy oils, typically the thermophysical properties of most interest are, enthalpy, entropy, heat capac-

ity, density, and viscosity, and these are the properties discussed in this section. Density can be obtained directly from an equation of state or from independent correlations. Viscosity cannot be determined directly from an equation of state, although it can be linked to equation of state calculations, for example, by correlating viscosity to density. Nor can an equation of state directly determine thermal properties. Equations of state provide departures from the ideal gas state (residual property). Ideal gas properties must be known experimentally or estimated independently. These departures are defined through rigorous thermodynamic relationships [8.131] for caloric properties

$$\Delta A_{\text{res}} = A^{\text{real}} - A^{\text{ideal}} = \int_{\infty}^V \left(P - \frac{RT}{V} \right) - RT \ln Z, \quad (8.25)$$

$$\Delta S_{\text{res}} = - \frac{\partial \Delta A_{\text{res}}}{\partial T}, \quad (8.26)$$

$$\Delta H_{\text{res}} = \Delta A_{\text{res}} + T \Delta S_{\text{res}} + RT(Z - 1), \quad (8.27)$$

$$\Delta C_{p,\text{res}} = \int_{\infty}^V \left(\frac{\partial^2 P}{\partial T^2} \right) dV - T \frac{\left(\frac{\partial P}{\partial T} \right)_V^2}{\left(\frac{\partial P}{\partial V} \right)_T}, \quad (8.28)$$

where subscript “res” indicates a residual property.

So, for example, to determine the enthalpy of a real fluid at a fixed temperature and pressure (H), the ideal gas enthalpy (H_0), known exogenously, must be added to the residual enthalpy obtained from (8.27)

$$H = H_0 + \Delta H_{\text{res}}. \quad (8.29)$$

The enthalpy of an ideal gas is a simple integral of the ideal gas heat capacity from a reference temperature to the temperature of interest. Ideal gas heat capacities are pressure independent and the ideal gas heat capacity of a mixture is a weighted sum of the component heat capacities. Equations (8.25)–(8.29) underline the importance of hydrocarbon characterization methods and the associated estimation methods for physical properties. Ideal gas properties for pseudo-components, however defined, must be accessible, and critical properties and vapor pressure data are required by equations of state for the calculation of residual properties. Usually, the molar average normal boiling point, specific gravity, and mean molar mass are used for the estimation of ideal gas heat capacities. Comprehensive reviews of estimation methods for pure components are available [8.98, 131, 169], and they are usually adequate for hydrocarbon mixture simulation, although we stress that for important polar compounds associated with hydrocarbons, fitting to experimental data is frequently

necessary. Armed with an equation of state, and an ideal gas heat capacity model or data, and (8.25) to (8.29), volumetric and all caloric information for fluids and related processes can be obtained. The volumes obtained from the equation of state can be used along with temperature as inputs for viscosity calculations [8.170].

8.6.1 Caloric Physical Properties – Enthalpy, Entropy, and Heat Capacities

CEOSs are frequently used to estimate caloric departure functions for enthalpy, entropy, and heat capacity. Typically, the values obtained for fluid enthalpy, entropy, and heat capacity for both nonideal gases and liquids are in good agreement with data [8.171], particularly for light hydrocarbons and mixtures. The Lee–Kesler equation [8.131] in particular has been found useful for such applications. The common practice is to use CEOSs for the estimation of enthalpies, entropies, and heat capacities for hydrocarbon systems in general and rely on more complex equations of state [8.172] for high accuracy if the molecules/mixtures are simple. Although much data is available on excess enthalpies and excess heat capacities for binary hydrocarbon mixtures [8.173], there are no comprehensive reviews on the general accuracy of engineering equations of state related to the prediction of enthalpies and heat capacities and it is difficult, if not impossible, to provide comprehensive guidelines related to estimate’s accuracies. In general, enthalpy and entropy estimates from simple equations of state provide estimates within 10% of experimental values away from the critical point, but calculation outcomes should be checked against experimental data for detailed design and performance warranties as large errors arise. For example, CEOS, normally provide skewed fits vis-à-vis experimental values for isobaric liquid heat capacity, with systematic overestimation of values at low temperature and systematic underestimation at high temperature [8.174]. However, most calculations are performed in the $0.6 < \text{Tr} < 0.85$ region, where the fits are best and errors are typically small.

For heavy hydrocarbons, such as Athabasca bitumen, and high boiling fractions, little work has been done on the validation of generalized estimates of caloric properties other than isobaric heat capacity where a new approach for the estimation of ideal gas [8.94], liquid [8.37, 175], and solid [8.37, 38, 176] heat capacities based on atomic compositional analysis that are rooted in statistical thermodynamics have become available. The predictive equations comprising this new approach are based on the observation that the heat capacity of a molecule is primarily a function of the number of internal vibration per mass of molecule

captured by a similarity variable given by

$$\alpha = \frac{\sum_{i=1}^n v_i}{\sum_{i=1}^n v_i M_i}, \quad (8.30)$$

where w_i is the stoichiometric coefficient of element i in the molecule, and M_i is the molecular mass of element i . The value of the similarity variable, α , is easily determined from known molecular structures or elemental analysis. For methane, the numerator appearing in (8.30) is $5 = (4H + 1C)$ and the denominator is $16 = (4 \times 1.008 + 1 \times 12.08)$ and the similarity value is 0.311. The elemental analysis of an oil (or its fractions) should be part of the oil characterization procedure and the heat capacity is then correlated as a function of phase state, the value of α , and temperature. Pseudo-component chemical elemental analysis can be estimated [8.177] if values are not available from the oil assay.

The results from this new approach [8.94] compare well with ideal gas isobaric heat capacity estimates from the more complex Benson's method, a commonly used group contribution-based technique that requires detailed knowledge of a molecular structure [8.131] as illustrated in Fig. 8.19. *Dadgostar* and *Shaw* [8.39, 174] showed that elemental composition-based correlations make a priori predictions for liquid heat capacity values within 10% or 0.2 J/(g K) of experimental data even for

heavy oil and bitumen. This new approach was successfully adapted into oil characterization procedures available in a commercial process simulator [8.178].

8.6.2 Density Prediction

Vapor and liquid densities are usually estimated using simple equations of state, although complex, highly accurate equations of state [8.173] can be used for volumetric computations for specific pure compounds and mixtures of light hydrocarbons. Simple two-parameter CEOSs suffer from a simplistic repulsive term that makes them, in general, too *soft*, thus underestimating liquid densities. Vapor densities are typically more accurate away from critical points. For example, the Soave-Redlich-Kwong (SRK) equation of state provides reasonable estimates for liquid densities of light hydrocarbons (C_1 – C_2) but underestimates the liquid densities of other important hydrocarbons, typically by 15–25% making it unfit for design. The Peng–Robinson equation of state, designed to provide reasonable densities for liquid hydrocarbons in the gasoline range, attempts to correct this handicap related to liquid density calculation. The outcome is only partially successful, and it can be shown that no two-parameter CEOS provides good liquid densities. A third (or fourth) parameter is necessary [8.142].

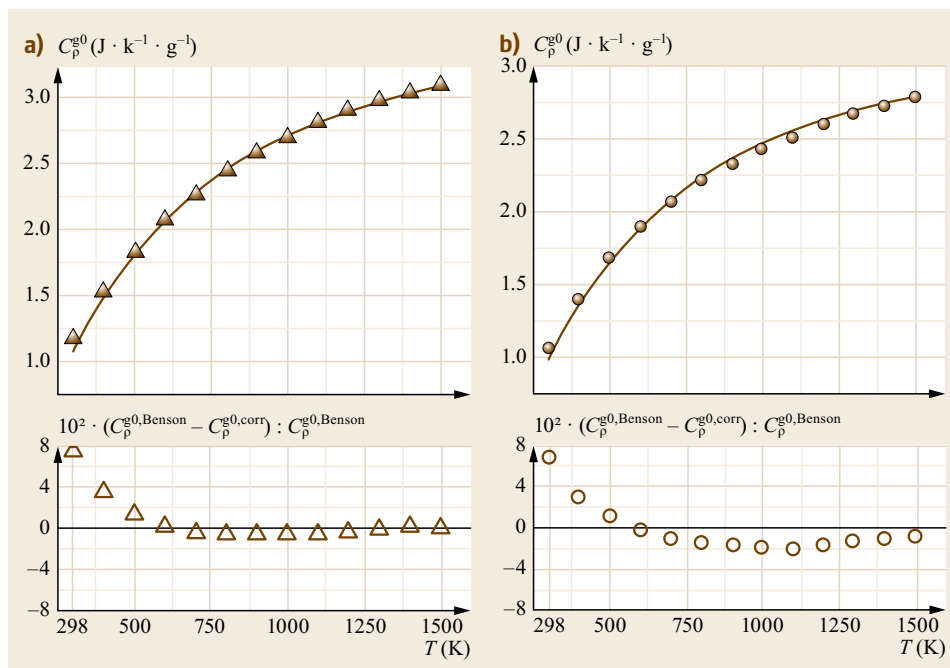

Fig. 8.19a,b Estimated c_p^{g0} values for: (a) $C_{283}H_{337}N_3O_4S_9$ ($M = 4133.3 \text{ g mol}^{-1}$, $\alpha = 0.1539 \text{ mol g}^{-1}$), (b) $C_{64}H_{52}S_2$ ($M = 885.2 \text{ g mol}^{-1}$, $\alpha = 0.1333 \text{ mol g}^{-1}$) evaluated from 298.15 K to up to 1500 K. Filled triangle Benson's group contribution method; filled circle, (after [8.94]); open triangle and circle relative deviations. (After [8.94])

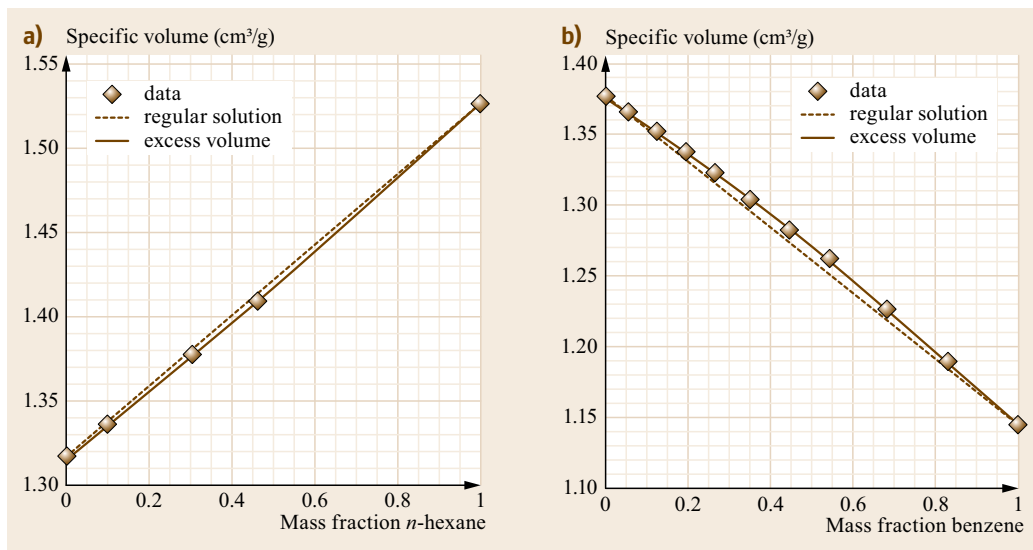

Fig. 8.20a,b
Specific volumes of mixtures of liquid hydrocarbons at 25 °C and 0.1 MPa modeled with regular solution mixing rules and excess volume mixing rules: (a) *n*-hexane and *n*-tetradecane; (b) benzene and *n*-decane. (After [8.77])

Three-parameter CEOSs do provide better liquid density estimates, the most famous being the *Patel–Teja* equation [8.138], but more commonly, this handicap of CEOS is addressed using volume translation as discussed in Sect. 8.5.

Some non-CEOSs do provide better density estimates than CEOS, notably the Lee–Kesler equation and the SAFT family of equations of state. The Lee–Kesler equation is particularly useful for light hydrocarbon mixtures. SAFT parameters are fitted to vapor pressure and liquid density data, and the equation of state benefits handsomely from this parameterization as well as from a more theoretically based repulsive term – the Carnahan–Starling expression for hard spheres. This comes at the cost of not reproducing the critical pressure and temperature of a compound, and the importance of this trade-off is always dependent on the objectives of the simulation at hand.

Vast amounts of data are available related to the excess volumes of liquid hydrocarbon mixtures but no comprehensive evaluation of this information is available, and it is impossible to provide guidelines related to the accuracy of density estimates for mixtures computed using equations of state. Some process simulation vendors recognized this handicap early on [8.178] and added an empirical correction to the volume translation parameter implemented as an excess function. This approach is useful when modeling highly asymmetric hydrocarbon mixtures such as light organic solvents and bitumen. While the additional term makes the equation of state inconsistent from a formal point of view, this is of no consequence for subcritical bitumen + solvent extraction process modeling.

For high-accuracy liquid density calculations for heavy oils and especially heavy oils and light hydrocarbon solvent mixtures important for upgrading via dilution through asphaltene precipitation, transportation, underground extraction through solvent injection and surface facility design, it is common to use a separate model for the calculation of liquid densities decoupled from the equation of state predictions

$$v = v^{\text{ideal}} + v^{\text{excess}}(T, \bar{x}), \quad (8.31)$$

where the liquid density is obtained as

$$\rho = \frac{MW_{\text{avg}}}{v}. \quad (8.32)$$

The excess term is small, but due to the large volumes of material usually processed, it may not be negligible. It is also important to note that the actual value of excess volumes (and even their *sign*) can be a function of the way the bitumen is processed and this apparently simple physical property exhibits an irreducible uncertainty and is not easily determined [8.32]. Also, for the calculation of actual densities, the average molecular weight of the material is required, thus underlining once more the importance of characterization methods.

Liquid mixture density calculation, independent of equation of state calculations, has a long history. Frequently, liquid densities for mixtures are well approximated by assuming ideal solution behavior

$$\rho = \sum_{i=1}^{nc} \frac{\omega_i}{\rho_i}, \quad (8.33)$$

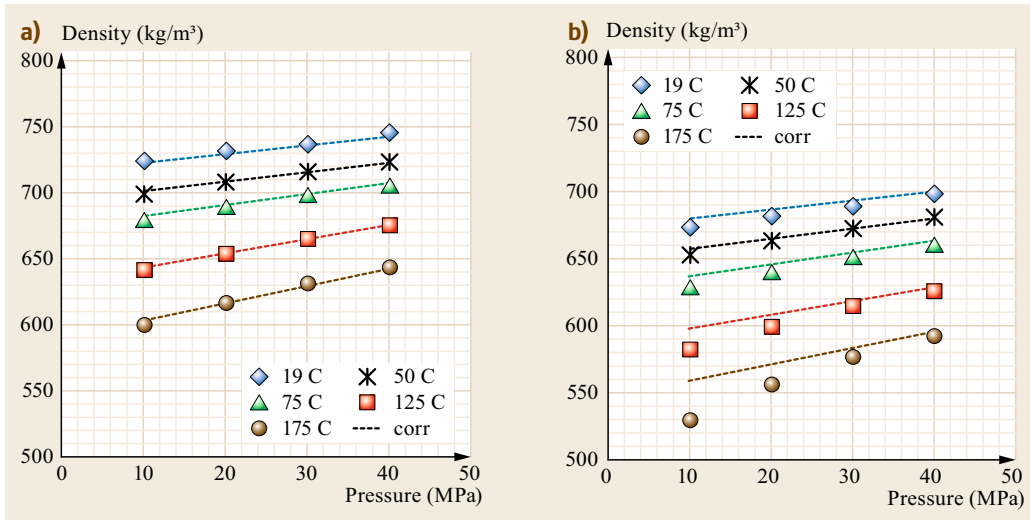

Fig. 8.21a,b Measured and predicted densities for mixtures of propane and *n*-decane: (a) 6.0 wt% propane; (b) 25 wt% propane. (After [8.77])

where the mixture density is simply a weighted sum of the component densities. Many hydrocarbon mixture densities are closely approximated on this basis as illustrated in Fig. 8.20. Nonideal mixing impacts can be introduced through the use of a mixing rule

$$\rho = \left[\sum_{i=1}^{nc} \sum_{j=1}^{nc} \frac{\omega_i \omega_j}{2} \left(\frac{1}{\rho_i} + \frac{1}{\rho_j} \right) (1 - \beta_{ij}) \right]^{-1}, \quad (8.34)$$

where β_{ij} is an adjustable parameter determined based on experimental mixture data.

For heavy oils and bitumen, the effect of dissolved gases and light solvents on mixture density can in principle be captured using (8.34) or a simple and accurate alternative approach reported by *Saryazdi et al.* [8.77] based on effective densities for light components that is illustrated in Fig. 8.21.

8.6.3 Heavy Oil Viscosity Prediction

While heavy oil fractions derived from the Safaniya vacuum residue have been shown to exhibit non-Newtonian rheological behavior up to more than 400 K [8.4], whole heavy oils such as Athabasca bitumen and Maya crude oil may be considered Newtonian fluids above ambient temperature. Below ambient conditions, non-Newtonian behaviors become important [8.5, 33, 179] and may impact pipeline and mixing operations. The transition from Newtonian to non-Newtonian behavior is governed by phase transitions

occurring in the maltene fraction and is not related to asphaltene content. Asphaltene content impacts the absolute value of the viscosity.

These two effects are frequently conflated and there is only limited work on parsing the distinct roles played by these two key components of heavy oils [8.180, 181]. Development and testing of computational approaches related to the rheological property prediction of complex fluids are ongoing fields of study and treatment of heavy oils as a combination of a Newtonian continuous fluid + a separate asphaltene-rich dispersed phase or as a combination of a structured non-Newtonian continuous phase + a separate asphaltene-rich dispersed phase to treat high- and low-temperature calculations is an open area of study.

For the moment, available viscosity correlations for heavy oil, and more broadly hydrocarbons, presume that they are single-phase Newtonian fluids, and viscosity simulation as opposed to pure prediction is targeted. Newtonian viscosity correlations for heavy oil can be divided into two groups, liquid-phase correlations and full phase correlations. *Monnery et al.* [8.182] and *Poling et al.* [8.131] provide extensive reviews of this class of viscosity models and the most relevant are reviewed below.

Liquid-Phase Newtonian Viscosity Correlations

Viscosity reduction by heating is a crucial aspect of many heavy oil processes, and therefore, it is a common practice to fit the temperature dependence of heavy oil viscosity. A simple correlation relating crude oil viscosity to temperature is the Arrhenius relationship [8.183]

given by

$$\log(\mu) = A + \frac{B}{T}, \quad (8.35)$$

where μ is viscosity, T is absolute temperature, and A and B are the fitted coefficients. This form of equation works well for conventional crude oils over small ranges of temperatures but provides poor predictions for broad ranges of temperature. For example, Fig. 8.22 shows the failure of the Andrade correlation to fit viscosity data from a Western Canadian bitumen over a temperature range from 20 to 175 °C. The accuracy of (8.35) is significantly improved by adding an extra term as shown in [8.184]

$$\log(\mu) = A + \frac{B}{T + C}. \quad (8.36)$$

Adding the third fitting parameter, C , provides an excellent fit to the data of Fig. 8.22 with an average absolute relative deviation (AARD) of 6%.

Amazingly, the best fit of viscosity to temperature is achieved with a simple linear relationship of double log viscosity to log temperature [8.185], given by

$$\log[\log(\mu + 0.7)] = A + B \log(T). \quad (8.37)$$

The value of 0.7 is added to the viscosity term to avoid negative logs at low viscosity; values of 0.8 and 1.0 have also been employed. With only two fitted parameters, the Walther correlation fit the viscosity of Western Canadian bitumen, as shown in Fig. 8.22, with an AARD of 4%. *Svrcek* and *Mehrotra* [8.186] correlated the slope with the intercept to reduce the correlation to one adjustable parameter, although with some loss of accuracy. Note that none of the above correlations include the effect of pressure.

Heavy oil viscosity is also reduced by dilution with a solvent and a variety of mixing rules have been employed to predict the viscosity of blends of oils and of heavy oils diluted with solvent. *Centeno* et al. [8.187] review many of these mixing rules. Some of the rules used for heavy oils are listed below.

Arrhenius [8.188]: molar

$$\log(\mu_{\text{mix}}) = \sum x_i \log(\mu_i), \quad (8.38)$$

Arrhenius [8.188]: mass

$$\log(\mu_{\text{mix}}) = \sum x_i \log(\mu_i), \quad (8.39)$$

Mehrotra [8.189]

$$\log(\mu_{\text{mix}}) = \sum \sqrt{x_i w_i} \log(\mu_i), \quad (8.40)$$

Fig. 8.22 The viscosity of a Western Canadian bitumen at 2500 kPa fitted with the Andrade, Vogel, and Walther correlations

Kendall and Monroe [8.190]

$$\frac{1}{\mu_{\text{mix}}^{1/3}} = \sum \frac{w_i}{\mu_i^{1/3}}, \quad (8.41)$$

Chirinos et al. [8.191]

$$\log[\log(v_{\text{mix}} + 0.7)] = \sum w_i \log[\log(v_i + 0.7)], \quad (8.42)$$

Yarranton et al. [8.20]

$$\log[\log(\mu_{\text{mix}} + 1)] = \sum w_i \log[\log(\mu_i + 1)], \quad (8.43)$$

where v is the kinematic viscosity.

Figure 8.23 compares the different mixing rules for a Western Canadian bitumen diluted with a condensate. Here, and in general, we have found that the double log mixing rule provides the best results for diluted heavy oils. Note, refiners use a variation of the double log mixing rule to predict blend kinematic viscosities such as in the Ruftas and Chevron methods where a viscosity blend index (VBI) is defined as a function of the double log of the viscosity and then mass-based mixing rules are applied [8.97, 192, 193]. Another option is to include adjustable parameters in a given mixing rule [8.194–200]. Most of these mixing rules use generalized fitting parameters based on a particular dataset of diluted crude oils.

Fig. 8.23 Prediction of viscosity from different mixing rules for a mixture of 30 wt% condensate in dead Western Canadian bitumen at 2500 kPa. (After [8.20])

There are relatively few reliable methods available to predict heavy oil viscosity when no data are available. The viscosity of conventional crude oils is often predicted from correlations to temperature, API, and solution gas–oil ratio using the following steps:

1. Calculate the dead oil viscosity ($\mu_{od} = f(T, API)$)
2. Calculate the live oil viscosity at and below the bubble point based on the dead oil viscosity ($\mu_o = A\mu_{od}^B$, where A and B are the parameters that depend on the solution–gas–oil ratio)
3. Calculate the live oil viscosity above the bubble point based on the bubble point viscosity. ($\mu_o = f(\mu_{ob}, P - P_b)$).

The most well known of these correlations, such as the Standing, Beggs and Robinson, Bergman, and Glasø correlations, are reviewed by *Whitson and Brulé* [8.97]. These correlations are designed for black oil characterizations where viscosity is desired as a function of pressure at a fixed reservoir temperature. Each correlation was tuned to a regional dataset and does not necessarily provide accurate predictions for heavy oil. Since these correlations were designed for one specific temperature, they do not provide accurate predictions of the temperature dependence of oil viscosity. Finally, live oil viscosity prediction requires a gas–oil ratio and heavy oil–gas oil ratios are challenging to measure accurately and are often not available.

There are a number of correlations for the kinematic viscosity of crude oils characterized into boiling cuts, usually based on normal boiling point and specific gravity [8.201, 202]. *Yazdani and Maini* [8.203] have demonstrated the inadequacy of these models when applied to heavy oils despite their extensive use for light and medium reservoir fluids. The LBC correlation [8.204] relates the dense fluid viscosity to only the reduced density with a fourth degree polynomial. The correlation can be unreliable for heavy hydrocarbon fluids [8.205] and it is common to tune the correlation to the available experimental data by adjusting the critical volumes of the C_7+ fractions. The API [8.177] correlation for kinematic viscosity is a popular choice. This correlation has numerical problems depending on the Watson K and API gravity which arise when applied to heavy oils. These shortcomings were removed by *Loria* [8.206].

Yarranton et al. [8.20] developed a procedure to predict the viscosity of crude oils and their cuts solely from gas chromatography assays. They characterized the oil into molecular weight-based pseudo-components and correlated the Walther parameters with molecular weight. They calculated the parameters of the whole oil using a simple mass-based mixing rules. They also included pressure dependence in the correlation and were able to predict the viscosity of a variety of conventional and heavy crude oils over a range of conditions to within approximately 30%. A straightforward tuning procedure was also provided to fit available data including a binary interaction parameter for mixtures of bitumen and solvents (Fig. 8.8).

Full Phase Newtonian Viscosity Correlations

Full phase viscosity correlations encompass the gas, liquid, and supercritical regions and are usually designed to work with the fluid characterization used in process and reservoir simulation. Models which meet this criterion include corresponding states methods, friction theory, and the expanded fluid model.

The corresponding state models relate the reduced viscosity of the fluid to the reduced viscosity of a reference fluid at the same reduced temperature and either density or pressure [8.207, 208]. *Ely and Hanley* [8.209] used temperature and density for their reduced coordinates and introduced shape factors to correct for any noncorrespondence. Variations of their method are often used to model the viscosity of the light fraction of the crude oils. This model has been applied to heavier hydrocarbons, such as crude oil distillation cuts, using aromaticity corrections or mass shape factors [8.210, 211].

Pedersen et al. [8.208, 212] used temperature and pressure for their reduced coordinates and methane

as the reference fluid. Instead of shape factors, their model is tuned with a rotational coupling coefficient as well as an effective molecular weight of the mixture. Empirical correlations for these parameters were developed from a database of viscosity data, including pure components, characterized reservoir fluids, and petroleum distillation cuts. The model provides reliable viscosity predictions for most conventional reservoir fluids [8.205] but is not easily applied to heavy petroleum fluids since these fluids often correspond to methane at temperatures below its freezing point [8.213].

Friction theory or F-theory [8.214] relates the viscosity of the dense fluid to the friction between fluid layers. The friction force is related to the repulsive and attractive internal pressures of the fluid determined from the van der Waals pressure terms from the PR and SRK equations of state. A version of the model with one adjustable parameter per fluid component, called a characteristic critical viscosity, was developed for pure hydrocarbons and then extended to characterized crude oils [8.215]. The pseudo-component critical viscosity values were correlated with molecular weight and critical pressure and temperature through a single common proportionality factor which is tuned to match crude oil viscosity data. For heavier oils, those with molecular weights higher than 200 g/mol, a second tuning parameter was introduced to correct the estimation of the repulsive and attractive pressure terms [8.216]. Tuned one- or two-parameter models successfully fit experimental data above the saturation pressure and provided predictions at lower pressures to within experimental uncertainties. The two parameters were later made into functions of temperature to more accurately model the viscosity of the characterized oils at different temperatures [8.217].

The expanded fluid (EF) model [8.170, 218] is an empirical correlation of viscosity to density designed for modeling the viscosity of hydrocarbons. The inputs to the model are the gas viscosity from *Wilke's* [8.219] method, the fluid density, pressure, and three fluid-specific parameters. The fluid-specific parameters have been determined for a variety of hydrocarbons and are correlated with molecular weight for crude oil pseudo-components [8.220]. Predicted viscosities had an AARD of 50% and a maximum deviation of 100%. Tuning with a single multiplier applied to one parameter reduced the maximum deviation to less than 30% in all cases. Tuning two parameters reduced the deviation to within the experimental error, see Fig. 8.9. The EF model was successfully implemented in a process simulator [8.178], integrated with the oil characterization procedure and associate fitting procedures for heavy oil

and solvent interaction parameter estimation or regression.

8.6.4 Property Simulation and Prediction Summary

Property simulation and prediction are not normally done as standalone activities, and are best performed as part of an integrated package of cross-linked and cross-validated models embedded in process simulation software packages. Notwithstanding the sheer amount of work, creativity and time spent on the development of fluid characterization methods and thermodynamic models, few of the final users of this effort – process, production, and chemical engineers – are interested in the data or the models per se but rather on the results produced by the simulation software. This fact should never leave the minds of the data or model producers and no matter how much time is spent on the development of a technique or the mathematical prowess displayed when developing a model, if data or models cannot be used in a simulation their value is diminished. Simulations shape to a large extent production and refining process requirements, from strategies for field exploration, to the size of equipment, and the estimated capital and operating costs. They also deeply influence the financial decisions related to an engineering projects.

Users of property simulation and prediction software should not adopt a passive attitude toward the use of simulators and blindly accept values produced by them, even when pressed to *get the project moving*. The development of proper simulation models for heavy oil processing is not a cookie cutter type of activity and success arises from a combination of high-quality data, proper material characterization, understanding of the question models are required to answer and the questions they cannot answer. The greatest challenge physical property modelers face when addressing the needs associated with the understanding of heavy oil behavior is ignorance. Heavy oils are ill defined. More than 50 wt% of these materials are undistillable, and little quantitative information is available regarding their chemical makeup and composition.

With clever parameterization of undistillable fractions, simulation models for unit operations where property models are rooted in the behaviors of simple well-defined fluids can be quickly extended to cases where heavy oils and bitumen are principal constituents. However, fluid-specific properties are relevant and it is, for example, difficult to develop high-quality predictive models for heavy oil + solvent mixture viscosity.

8.7 Perspectives and Conclusions

Phase behavior and property measurement simulation and prediction for heavy oils and bitumens present sample handling and measurement challenges. Capturing the physics and chemistry at all of the relevant length scales required even for simple properties like density and viscosity not to mention phase equilibrium compositions can become Herculean tasks, especially at low temperatures, or where standard measurement techniques fail. Innovative and hypothesis-driven measurements that target the capture of underlying or overlooked aspects of thermophysical properties and phase behavior are needed in addition to essential but routine measurements that drive process design and development calculations.

Fluid characterization and property and process modeling present additional challenges because thermodynamic models are dependent on quantitative information about individual components and their mixtures. It is hard to develop meaningfully general models when little is known about components and their physical interactions. Consequently, the current state of the art of phase behavior and property calculation is driven by correlation and simulation rather than pure prediction, with few exceptions. We count these exceptions among the successes of a principled and rigorous approach involving simultaneous development and validation of

molecular structure, nanostructure, and thermophysical property concepts and models that will over time build toward prediction in other areas as outlined in Fig. 8.1.

Our specific recommendations are pragmatic and based on many years of helping people to get value from their investment in experimental data and simulation models. In our own work, we strive to keep models simple so that they can be tested and validated as clearly as possible and so that their range of application can be clearly delimited as we have done for viscosity and water in oil solubility models in this chapter.

Fundamentals

9. Fundamentals of Petroleum Geology

Hendratta N. Ali

This chapter provides an overview of the fundamental concepts, processes, and theories associated with petroleum exploration and exploitation. The content of this chapter is structured into four main topics. The first topic provides a brief history of the modern petroleum industry and the role that petroleum plays in the society today. The second topic covers the geological basis, and discusses the material, processes, time span, and conditions under which petroleum forms and migrates in rocks. The third topic discusses how petroleum accumulates and concentrates in economic quantities in rocks to warrant exploitation, and the last topic describes the sophisticated methods and techniques that are used in finding, locating, and extracting the petroleum that is found deep in the subsurface. Modern prospecting uses methods of exploration such as three-dimensional seismic surveying and geophysical well logging that have revolutionized how we explore and locate new petroleum reservoirs in the subsurface, to fuel today's fossil fuel addiction. Although petroleum and fossil fuel derivatives have been around for thousands of years, the dominance of petroleum as a global source of energy and petrochemicals products, only developed in the last couple of centuries. Extensive research has led to detailed understanding of the geological and geochemical processes that generate, migrate, and accumulate economic quantities of this essential resource. Additional studies on the source, nature, and composition of petroleum will continue to improve our ability to find, produce, refine, and utilize petroleum products. The chapter concludes with a look at the future of petroleum and its exploration in the world.

Petroleum is comprised of diverse chemical compounds that are mostly made up of hydrogen and carbon, that is, hydrocarbons (HCs). It also contains minor amounts of hetero-atoms including sulfur, nitrogen, oxygen, and trace metal contaminants. Hydrocarbons are today's main source of energy and petro-chemicals, and will continue to be so for the foreseeable future. Fossil hydrocarbons occur as crude oil, natural gas (including gas hydrates), oil shale, oil sands, and coal. They are formed from the thermogenic transformation of ancient remains of organic material that was buried in sediments millions of years ago.

Petroleum geology is a branch of geology that studies how petroleum (and other fossil hydrocarbons) is sourced, generated, migrated, concentrated, and accumulated. Such studies enhance our ability to discover, map, and produce petroleum for economic benefit. Petroleum geology is a broad area of study, which integrates several basic sciences, technology, and engi-

neering. It touches on other areas including business, art, psychology, politics, and even speculation. However, the core subjects in the study of petroleum are found in the geological sciences: fundamental geology (physical and historical geology) and specialty areas like geophysics and geochemistry. These apply the basic sciences of physics and chemistry, statistics and probability, sedimentology, stratigraphy, structural geology, and subsurface mapping.

In our modern society, advances in technology have provided some major tools for the study of petroleum geology. Supercomputers have enabled the generation of specialty areas like seismic studies (acquisition, processing and interpretation), petrophysics, reservoir characterization, and subsurface modeling, to name a few. A petroleum geologist is someone who uses geologic information and studies geochemical processes to find, locate, and describe economic accumulations of petroleum for exploitation purposes.

9.1 The Petroleum Cycle

This section focuses on the petroleum cycle that describes the essential steps involved in the search, production, and use of petroleum products.

Several steps are required to transform petroleum into useful products and goods. First of all, professionals have to identify and locate parts of the Earth where the petroleum can be found and extracted from deep within the rocks before it can be processed and used. Figure 9.1 shows a schematic representation of the steps that constitute the cycle of petroleum:

- *Exploration* is a step that mostly involves the search for and location of petroleum in rocks. Once petroleum that is found underground has been located and assessed, it has to be brought to the surface of the Earth.
- *Production* involves the processes of drilling and extracting petroleum from the subsurface rocks. Once petroleum is extracted from the ground, *processing* and *refining* techniques are used to purify, separate, and reform components of the complex mixture into useful fractions.
- Products obtained from processing and refining may undergo *transformations* to further improve their quality, or these products may be used in the *manufacturing* of other products by reacting and blending them with other chemicals.
- End *products* are *distributed* and sold for public consumption.

At every stage in the cycle of petroleum from its hide-out in the bowels of the Earth to the use of its finished products, other resources are consumed or altered, and undesirable *waste products* are generated and have to be disposed of properly. A major challenge in the business of petroleum is dealing with and managing the waste products.

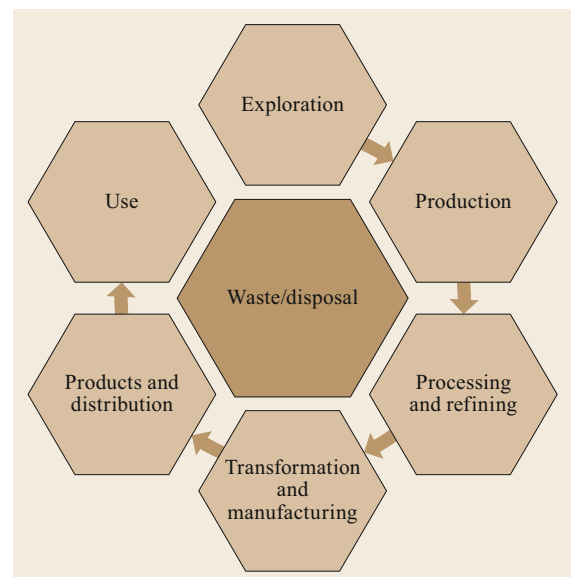

Fig. 9.1 Schematic of the cycle of petroleum in the modern world

9.2 Historical Perspective

Petroleum has been in existence for millions of years, well before the evolution of humans. However, the discovery of petroleum as a valuable product happened only in much more recent times (thousands of years ago) and its subsequent use as an energy source progressively developed over the last couple centuries. Long before petroleum was discovered, fire was the dominant source of energy, and came naturally from lightening, volcanic eruptions, and possible sparks from friction. After the discovery of fire, humans started using plant material such as wood, leaves, and grass, as well as animal material such as bones, fat, and dung to generate energy. In those days, it must have been a real challenge to keep a good fire going as is still the case in many developing countries and poor communities around the world today. In the quest to make hotter fires and keep them burning longer, humans through time discovered other material that could burn more easily and longer. By the 1800s, wood was the dominant source of heat energy and contributed more than 90% of the energy needed by humans. Gradually, the use of solid petroleum products like pitch/peat/bitumen and coal increased and became dominant toward the end of the nineteenth century, when kerosene from crude oil became the fuel of choice for illumination.

9.2.1 Pre-Industrial Use of Petroleum

Records from ancient Chinese, Persian, Mesopotamian, Greek, and Egyptian civilizations describe pre-industrial uses of petroleum components [9.1]. References in the Old Testament of the Christian Bible suggest that petroleum may have been used to waterproof Noah's boat and Moses' basket. In Persia (present day Iran) and Mesopotamia (present day Iraq), pitch was used for waterproofing the hanging gardens of Babylon (one of the seven wonders of the ancient world), boats for sailing, and for medicinal purposes to heal/cover wounds, etc. In ancient Egypt, some mummies were persevered with pitch and the ancient Chinese reportedly used flaming arrows in warfare.

9.2.2 Early Industrial Exploration and Production

The exploration for petroleum began late in the seventeenth century, when in about 1679, during the reign of King Charles II of Great Britain, the first patents to produce oil were issued. In 1745, the first well dug to find oil was sunk in France [9.2]. It is not clear how successful this search was. More than 100 years later, the industry began to see a boom in the pro-

duction and use of coal gas in the Eastern United States to light the streets of Maryland and Baltimore.

According to some sources [9.3–5], the big hit for the petroleum industry began in Canada around 1849, when Abraham Gesner first distilled kerosene from coal and later from crude oil. In 1857, the invention of the flat-wick kerosene lamp by Michael Dietz increased the demand for kerosene. Kerosene began to replace whale oil, which until then had been the most popular source of lamp fuel.

The rise in the demand for kerosene led to the scramble across the Western world to find new sources of petroleum. Around 1847, James Young discovered how to use heat to extract oil from shale [9.2], and opened a synthetic fuel plant to extract oil in Scotland. A couple of years later, Ignacy Lukasiewicz began to refine oil on an industrial scale, mainly to distill oil into kerosene. He set up his crude oil refinery in the city of Ulaszowice, Poland, in 1856. In 1859, in Titusville, PA, USA, W.A. Smith drilled a well using a spring pole, under the direction of Edwin Drake [9.5].

In 1863, J.D. Rockefeller and M.B. Clark financed a joint venture with a chemist Samuel Andrews to start an oil refinery in Cleveland, OH, USA. At the time, there were about 30 other refineries in Cleveland. After Clark sold out in 1865, the company became Rockefeller's and Andrews, which chartered the Standard Oil Company in 1870. By 1877, through mergers and acquisitions, Standard Oil grew to control 90% of petroleum refining in the United States [9.4, 5].

The demand for kerosene for lighting decreased due to the electric light bulb, which Thomas Edison patented in 1879 [9.6].

Meanwhile, the invention of the gasoline-powered internal combustion engine in France by Alphonse Beau De Rochas in 1862 [9.7] brought about a new market for petroleum. The German engineer Karl Friedrich Benz designed the first practical motorcar which is widely regarded as the first gasoline-powered automobile. By 1891, Daimler Motor Corporation was producing gasoline engines in the United States.

In 1908, the Ford Motor Company started the first mass production of cars, notably the Model T [9.8].

Meanwhile the production of petroleum continued to expand. In 1901, the giant spindle top gusher was drilled in east Texas. And in 1908, oil was discovered in Persia (present Iran), leading to the creation of the Anglo-Iranian Oil Company, which later became the British Oil Company [9.4, 9].

In 1911, citing violations of anti-trust laws, the US Justice Department ordered the breakup of Standard

Oil into 34 companies, including five regional *majors* (Fig. 9.2).

By 1920, there were seven major petroleum companies in the world (Fig. 9.3). Five of these companies were based in the United States – three of the spinoffs of Standard Oil (SOCONY, ESSO, and SOCAL) and two Midwestern companies (Texaco and Gulf Oil) – and two were based in Europe. The European companies were Royal Dutch Shell and British Petroleum.

Between 1920s and 1980s, the global search for new oil resources increased. Oil prices (Fig. 9.4) increased significantly and reserves were discovered in several parts of the world. Technology continued to develop, new inventions were made including wireline logging and seismic surveys, the Organization of Petroleum Exporting Countries (OPEC) was formed and oil became our dominant source of fuel.

Increased production, distribution, and use of hydrocarbons lead to increased awareness of the impact of the petroleum industry on the environment. In response to the issues, in 1970 the Nixon administration created the US Environmental Protection Agency (EPA), and the US Congress passed the Clean Air Act. For the petroleum industry, the Alaskan environmental catastrophe caused by the Exxon Valdez tanker in 1989 and the burning of the Kuwait oil fields in 1991 brought increased attention to the environmental issues associated with the activities of the petroleum industry into mainstream. These and other environmental disasters are discussed in another chapter. As a consequence, some tougher legislation was introduced in the United States, the country that consumes about a quarter of the world's fossil fuel energy, where in 2003–2004 the US Senate rejected oil exploration in the US Arctic National Wildlife Refuge, even though the country was importing 11.3 million barrels of oil per day. In 2005, Hurricanes Katrina and Rita struck the Gulf Coast of the United States, damaging some petroleum industry infrastructure. This led to increased hiring in the industry in 2006–2007, but the global financial recession in 2008 created another bust that affected the petroleum

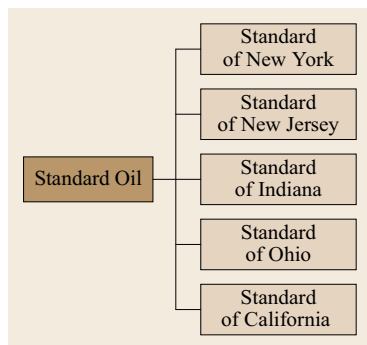

Fig. 9.2 Five major spinoff companies from Rockefeller's Standard Oil Co

sector. In 2010, the *Deepwater Horizon* oil disaster on the US Gulf coast added to the environmental concerns and increased activities from environmental and safety groups.

The present global petroleum dynamics is changing with the projections from the International Energy Agency (IEA), that the United States will lead global energy production and become energy independent by 2035. Emerging and high population economies like China and India are increasing their demand for global oil. This means that the search for petroleum will continue all over the world with the aide of new technologies and a skilled workforce.

Summary

Fossil fuels still represent the most important source of global energy today. The debate about the amount of oil that is available and how long it will last continues, but the search for more resources and improved technology to extract present reserves is essential to maintain the world's energy needs and sustain the global economy for the foreseeable future.

9.2.3 Measurements

Petroleum and other HC products in fossil fuels occur as solids, liquids, and gases under different temperature and pressure conditions. They are therefore measured and expressed in terms of mass, volume, energy content, viscosity, etc. Petroleum is measured differently depending on whether we are referring to gaseous components or liquid components. The common measurement expression for oil throughout the world is the US barrel (US bbl). 1 US bbl is equal to 42 US gallons (gal), which is approximately equivalent to 159 l, 5.62 cubic feet (ft³), 0.159 cubic meters (m³) and 34.97 UK gal. In most of the world, the common measurement of crude oil is metric tons (t). One metric ton (t) equals 1000 kg, 2204.6 lb, 1.102 tn sh used in the United States and 0.984 tn l used in United Kingdom. Volume in much of the world is expressed in cubic meter and liter. The mass of petroleum is expressed in kilogram (kg), pound (lb) and ton (t). Details of units and conversions for petroleum and other energy resources can be obtained from several sources such as <http://www.iea.org>, <http://www.bipm.org> among others.

9.2.4 Energy Equivalence

The bulk of petroleum and other fossil hydrocarbons are used to generate energy in different forms. For this reason, it is sometimes common to express petroleum products in terms of their heat content, calorific value,

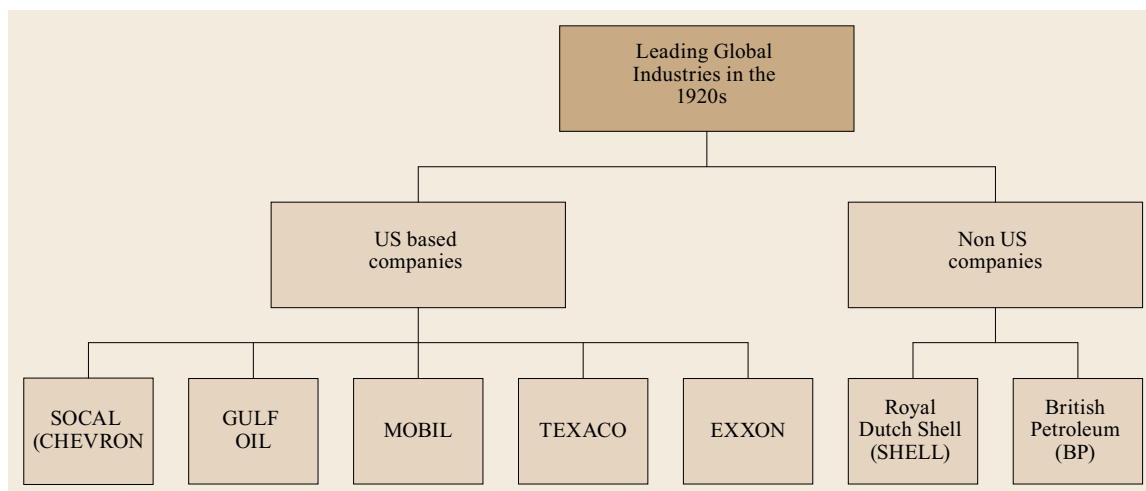

Fig. 9.3 Seven major global companies of the 1920s

Fig. 9.4 Change in average annual oil prices from 1860–2016. (after [9.10, 11], courtesy of BP Statistical Review of World Energy)

electrical energy, or other terms of energy equivalence. The common expression of heat or energy content from petroleum is the British thermal unit (BTU), gigawatt-hour (GWh) and megatons of oil equivalent (Mtoe). The total energy (calorific) value of HCs refers to the amount of energy that can be produced from burning the HC molecules. For petroleum products, it is sometimes worthwhile to convert from mass or volume to heat in order to determine the equivalent amount of energy that

will be generated per unit quantity. For natural gas, the IEA calculates that 1 m^3 is equivalent to 37.912 BTU and 1 kg is equivalent to 54.40 MJ or 51 560 BTU. Oil and gas can be compared in terms of their energy content. This process helps us determine how much gas produces the same amount of energy as a given quantity of oil and vice versa. For example, 1 bbl of oil energy (boe) is equivalent to about 6300 standard cubic feet (scf) of gas.

9.3 Geological Overview

Petroleum geologists are mostly concerned with finding and locating petroleum resources that are buried underground in locations that are not directly visible to the eye. They must use proxies to *see* petroleum in these subsurface environments. The scientists study material from which petroleum formed, rocks in which petroleum is found, the way it appears and the state in which it occurs in the rocks, the changes that the presence of petroleum causes in the rocks and how these changes transform and alter the physical and chemical properties of rocks.

9.3.1 Origin of Petroleum

Petroleum originates from the chemical transformation of organic material that was deposited, trapped, and buried in sedimentary rocks millions of years ago. Several books and articles [9.12–14] have succinctly highlighted some evidence that confirms the predominantly organic source of petroleum. The evidence points to the composition of petroleum, the environments where petroleum forms, the rocks in which petroleum is found and even some experimental evidence. Petroleum mostly forms from microscopic plants and animals like algae, bacteria, spores, or planktons. Higher plant material, woody cellulosic plants, and cuticles mostly form coal. For petroleum to be formed from organic material, a series of conditions must be satisfied:

- *High productivity*: A lot of organic material must be produced from the demise of large amounts of micro organisms caused, for example, by massive kills due to anoxia, lack of nutrients, or natural hazards
- *Rapid burial*: The organic material must be trapped and buried very quickly to avoid decay.
- *Absence of oxygen*: The organic material must be buried under anoxic conditions deep enough so that trapping and burial excludes oxygen.
- *Pressure and heat*: The organic material must be buried deeply, typically with an overburden of more sediment above the organic rich layer to increase pressure and temperature.
- *Time*: There must be time for the geochemical transformation of the organic material into petroleum.

Once the organic material is buried, the next step is to transform and mature the organic material. The maturation process of organic material occurs through three main stages:

1. The first stage of *diagenesis* involves the early stages of anoxic burial of the organic matter-rich sediments. This step leads to the expulsion of wa-

ter, compaction, and cementation of the sediments containing the organic material. During this stage, kerogen (a type of disseminated organic material that is not soluble in most organic solvents) is formed.

2. The second stage, *catagenesis*, involves the transformation of kerogen to oil, gas or coal. This stage generates mostly large HC molecules in the early stages, and in the later stages it generates smaller HC molecules (including C₅ to C₁₂ molecules) and wet gas.
3. During the third stage, *metagenesis*, mostly dry gas (methane) is produced, followed by the onset of *metamorphism*.

9.3.2 Chemical Composition and Occurrence of Petroleum

As mentioned previously, although petroleum is dominantly composed of hydrogen and carbon, these atoms combine to form a variety of HC molecules that together occur as a very complex mixture to which may be associated non-hydrocarbon atoms commonly referred to as hetero-atoms occur in lesser amounts. The petroleum mixtures can contain gas, liquid and solid state components.

Gaseous Petroleum (Natural Gas)

The gaseous form of petroleum is generally referred to as natural gas. Natural gas can *occur* as associated (with oil) or non-associated gas. The *composition* of natural gas can be described as dry gas, and wet gas. Dry gas mostly contains methane molecules that are typically in the range of 85% or more. If natural gas is not dry, it is described as wet gas, which contains less than 85% methane and relatively more ethane and propane. Hydrocarbons that occur as gases in a well under bottom-hole temperatures and pressure, but condense to form liquids once brought to the surface are described as *condensates*. Natural gas can also be described based on the quantity of *impurities* that it contains. Thus, natural gas is described as *sweet gas* if it does not contain high amounts of impurities such as hydrogen sulfide (H₂S), and/or high amounts of carbon dioxide (CO₂(g)). This form of natural gas – sweet gas – is valued in the market. *Sour gas*, on the other hand, is natural gas that contains high amounts of H₂S(g) and a lot more CO₂(g). Sour gas is less economically valuable than sweet gas. Gas processing plants convert the H₂S in sour gas to sulfur for commercial purposes if the hydrogen sulfide occurs in significant amounts. Unrecovered H₂S(g) is burned in flares to form SO₂ and SO₃, com-

Fig. 9.5 Generation of petroleum from biological organism

monly known as sulfur oxides (SO_x). In many countries, environmental regulations restrict SO_x emissions from natural gas plants, usually to less than 0.5 mol%.

Natural gas plays a significant role during exploration because it has some properties that can be easily diagnosed using exploration techniques. Characteristics properties of natural gas are discussed in more detail later in this section. These properties are density, compressibility, acoustic velocity, composition, etc. These properties can help exploration geologists identify and map rocks and formations that contain petroleum. From an economic perspective, natural gas is more abundant and cleaner than liquid petroleum but it is more difficult to store and transport once it has been produced because of its high diffusivity.

Natural gas may also contain inert gases such as argon and helium, which are products of radioactive decay.

Liquid Petroleum (Crude Oil)

Unrefined crude oil has some distinctive characteristics which include viscosity, color, smell, flammability, fluorescence under UV (when some specific molecules are present), and immiscibility in water. These characteristics vary based on the size and type of molecules present in the crude oil. The *color* could be brown, black, straw, etc. The *smell* can be described as sweet, foul, weak, strong, fruity, etc. *Fluorescence* under UV oc-

curs when certain molecules (especially polyaromatics) are present. These characteristics are applied in identifying petroleum containing rocks samples during well site analysis while drilling an oil well. Typical components of liquid petroleum:

- Alkanes (paraffins) are chain structures in which the number of carbon atoms ranges from C_1 to C_{80} . The chains can be straight or branched with millions of possible structures. Generally, C_1 – C_4 molecules are gases and C_5 – C_{18} are liquids; C_5 – C_{11} are dominant in gasoline and C_{10} – C_{25} are dominant components in kerosene and diesel. Most alkanes with $> \text{C}_{20}$, are solids and waxes.
- Naphthenes (cycloalkanes) and polynaphthenes (Table 9.2) are fully saturated HCs which contain 5- and 6-membered carbon ring structures. Light naphthenes and polynaphthenes are liquids at standard temperatures and pressure and can occur in significant amounts (up to 50% or more) in some crude oils.
- Aromatics also contain 5- and 6-membered carbon ring structures, but they are unsaturated with conjugated double bonds. Polyaromatics can include several condensed rings. Due to a phenomenon called resonance, polyaromatics fluoresce (glow) under ultra violet light. Many polyaromatics are carcinogenic. Aromatics and polyaromatics are dense

molecules, so they are more common in heavy oils.

- Naphthoaromatics (Table 9.2) are partially saturated condensed-ring compounds. They are abundant in synthetic crudes and some naphthenic conventional crude.

As mentioned earlier, in addition to HCs, crude oil contains molecules with hetero-atoms, especially oxygen, nitrogen, and sulfur. Heavy asphaltics contain trace metals such as nickel (Ni) and vanadium (V). Sulfur compounds are the most abundant heteroatom compounds. They include mercaptans (thiols), sulfides, disulfides, thiophenes, and other cyclic compounds. As shown in Table 9.1, the sulfur content of a crude oil can range from 0.03 to nearly 5 wt%. Oxygen-containing compounds are common in young, immature, and biodegraded oils. Nitrogen compounds include amides, pyridines, indoles, and pyrroles (Table 9.3). The nitrogen content of a crude oil sample can range from less than 0.01–0.9 wt% (Table 9.1). Native sulfur is abundant in young shallow oils and reacts with hydrogen at temperatures above 100 °C to form H₂S(g). Heavy HC fractions include all of the above, plus asphaltics. Asphaltics contain trace metals like Ni and V. Ni and V are abundant in oils from young, shallow basins, and basins with degraded oil. They are rela-

tively rare in old deep basins, where mostly high API gravity crude occurs. During geochemical analysis, it is sometimes difficult to determine if trace and rare metals are produced from within reservoir rocks or introduced from elsewhere.

Crude oil can be described by its composition, impurity content, degree of viscosity and other physical characteristics. The density of crude oil is measured as the ratio between the specific gravity of the crude oil and the specific gravity of water. It is expressed in degrees of gravity units developed by the American Petroleum Institute (API) according to the formula

$$\text{API} = \frac{141.5}{\text{Specific gravity at } 60^{\circ}\text{F}} - 131.5 .$$

For example, the density of water is 1 g/cm³, and the gravity of water = 10° API. Crude oil floats on water when its gravity is greater than 10° API. In general, low API crudes have high density and high viscosity, while high API crudes have low density, and low viscosity. Light crude oil typically has an API gravity of more than 40° (Table 9.1).

Raw oil comes directly from the wellbore, before it is treated in a petroleum separation plant. Usually, raw oil contains contaminants, such as dissolved salt, sediment, metals and water, along with non-hydrocarbon

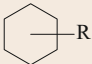

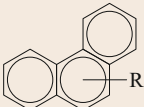

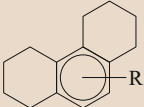

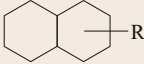

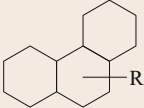

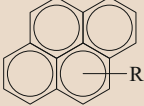

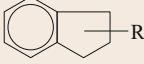

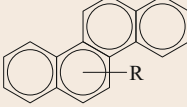

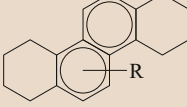

Table 9.1 Properties of 21 selected crude oils

gases. Processed oil has been treated, either at the well site or in a refinery. Sour crudes contain high amounts of sulfur. Sweet crude oil contains small amounts of sulfur. Typically, sour crudes are less valuable than sweet crudes.

Crude oil has several other characteristics that are measured and described for different purposes. For example, pour point describes the lowest temperature at which oil will flow before solidifying or becoming waxy as it cools. *Volatility* measures how easily oil can evaporate at standard temperature and pressure, and it is used to describe the tendency of oil to undergo shrinkage. Nonvolatile (black or low shrinking) oil has a low API gravity and contains relatively high amounts of long carbon chains (heavy) molecules. Low shrinking oils typically have a gravity significantly less than 40° API. Volatile (light or high shrinking) oil typically has a high API gravity, and has shorter carbon chain molecules than the low shrinking oil. A *flash point* describes the temperature above which crude oil or its components spontaneously ignite. The flash point is low for light oils and high for heavy oils. The viscosity in-

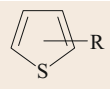

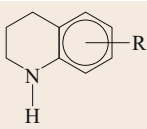

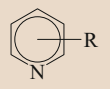

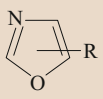

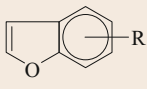

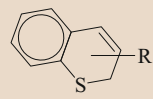

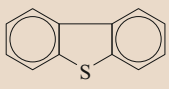

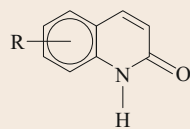

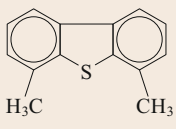

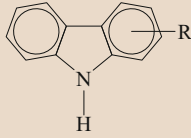

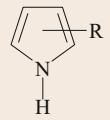

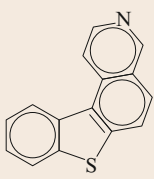

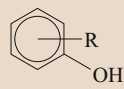

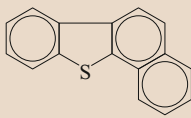

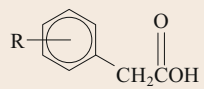

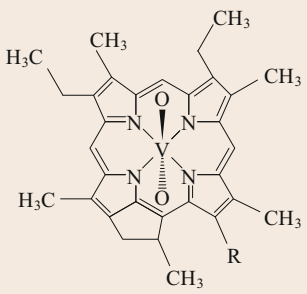

dex (VI) measures the extent of change in the viscosity of the oil as temperature changes.

The standard for measuring crude oil is the barrel (42 US gal), while gas is measured in standard cubic feet (scf). In addition to fuels, petroleum is used to produce numerous other products, from plastics to pharmaceuticals. These are described in the overview of petroleum processing section.

9.3.3 Rocks in Which Petroleum Is Found

Petroleum is typically found in rocks known as *reservoir rocks* and/or *source rocks*. Reservoir rocks are rocks in which petroleum can accumulate and concentrate. Source rocks are rocks in which petroleum was generated and mostly matures. The presence of petroleum in these rocks is caused by changes that occur inside the Earth, particularly increases in pressure and temperature. These changes can be biological or environmental, such as biological mass extinctions or climatic changes. To understand what happens in reservoir rocks and source rocks, it is important to take a step

back and look at the geologic characteristics of rocks and minerals, so that we can better understand why petroleum will occur in these specific rocks and not other rocks.

Fundamentals of Rocks and Minerals

Rocks are dominantly made of minerals. Rocks form when a variety of minerals (discussed in Sect. 9.3.4) are *glued* together into a cohesive solid mass. When

we describe a rock, we are typically referring to a representative sample that contains a characteristic solid assemblage of minerals that comprises a large portion of the Earth. For this reason, geologists define a rock as an *aggregated solid of minerals*. As rocks form, other materials, such as trapped organic matter, smaller solid fragments, fossils and air bubbles, can be included. These are known as inclusions and may get integrated and consolidated in the rock and form valuable resources, for example, petroleum.

Major Categories of Rocks

There are three major categories of rocks that are found on Earth:

- Igneous rocks
- Metamorphic rocks
- Sedimentary rocks.

These categories have been extensively analyzed and described in various books and articles [9.15, 16]. In this section, we present the basic properties of these rocks that influence and affect petroleum exploration (Fig. 9.6).

Igneous rocks crystallize from molten or partially molten rock material called lava (when it is at the surface of the Earth) or magma (when it is still underground).

Metamorphic rocks form from the deformation of other rocks that are changed and transformed under high temperature and pressure without melting. This is called *solid-state transformation*. The process of metamorphism only occurs deep underground.

Sedimentary rocks form from weathered or altered particles and fragments of pre-existing rocks and other materials created by physical, chemical or biological action. This classification of rocks does not depend very

much on the material that the rock may contain, although in some cases some type of mineral or material may commonly occur in a particular category, for example, biogenic type material will most likely occur in sedimentary rocks because of the way in which, and environments where, sedimentary rocks form. How a rock forms, and the arrangement of the minerals that make up the rock will affect the generation and/or accumulation of petroleum in the rock. Therefore, you may have deduced that the category of rocks that is most valuable and significant in petroleum exploration is the *sedimentary rock category*. Another interesting aspect about these three major categories of rocks is that they are interrelated in what geologists call the *rock cycle*. Figure 9.7 represents a simplified diagram of the rock cycle showing some major processes that connect each category to the other.

Our discussion about rocks will not be fully complete if we do not discuss the nature of the minerals that are the building blocks of these rocks. A *mineral* is a naturally occurring inorganic crystalline solid substance that has a specific chemical composition and can be described by characteristic physical properties.

To break this definition down a little more, a *naturally occurring substance* comes from Earth's raw material and is not produced, engineered, or manufactured in a laboratory or factory. Today, due to technological and engineering advances, some engineered substances can have identical composition and characteristics as some naturally occurring minerals. For example, silica (SiO_2) is the molecule that makes up both glass and the mineral quartz. An *inorganic substance* (compound) that makes up the mineral cannot come from living things or be biogenic in nature (although an inorganic mineral like calcite (CaCO_3) is sometimes created by biological process). This raises a question for the

Fig. 9.6 The three major categories of rocks: igneous, metamorphic, and sedimentary. These categories are classified based on the processes that form the rocks and the determine the texture of the rock. The texture of rocks control the generation and accumulation of oil and gas in the rocks

Fig. 9.7 Simplified diagram of the rock cycle showing major processes that connect the major categories of rocks and influence the generation of petroleum

material that makes up coal, which is widely considered a rock in its own right. (It is worth noting here that the material that makes up coal is called a *maceral* and not *mineral*). A *crystalline solid* must have an orderly, repetitive pattern of its molecules and create a unique crystal form. *Specific chemical composition* means that the substance has a unique or narrow range chemical formula and *characteristic physical properties* means that the mineral can be easily identified or recognized from its appearance. For this reason, minerals are typically described and classified on the basis of their physical and chemical properties. The more specific the properties the more easily the mineral can be identified and recognized in a sample.

9.3.4 Some Common Rock-Forming Minerals Important in Petroleum Exploration

There are several minerals that are of significance in petroleum exploration. Silicate minerals like *quartz* and *feldspar*, which are typically abundant in sandstones and conglomerates, will make good reservoir rocks. *Calcite* and *dolomite* are minerals that make up most carbonate rocks like limestone and dolostone. Carbonate rocks can make very good reservoir rocks, and to a lesser extent, source rocks, and other rocks known as overburden rocks. *Halite* (the mineral found in ta-

ble salt) makes up rock salt and salt domes and makes good seals and cap rocks. Clay minerals, for example, smectites, chlorites etc., iron oxides, and micas that are found in shales and some *mudstones* (but occur in lesser amounts in silicates, carbonates or evaporite rocks) make good source rocks, seal, and cap rocks. Oil shales are also unconventional reservoir rocks. Other minerals like anhydrite (CaSO_4), a mineral with high density, and gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) are sulfate minerals that form cap rocks on salt domes and other sedimentary layers. Examples of rock forming minerals are shown in Fig. 9.8.

The *chemical properties* of minerals depend on both the atomic composition and the arrangement of the atoms in the mineral. Atomic composition and arrangement are specific to each type of mineral. Consider for example, calcite (CaCO_3) the mineral in limestone. Because of its composition, calcite can easily react with acids to release calcium ions and carbon dioxide. This reaction can create cavities, vugs, channels, and pores in a calcite-containing rock. These cavities and pores are known as *secondary porosity* and are important for good reservoir rocks. Quartz (SiO_2) is abundant in most sandstone rocks, because it is very resistant to weathering and does not break down (or weather) easily when minerals are being transformed during sedimentary processes. It can therefore accumulate and creates good reservoir rocks. Magnetite is a magnetic oxide of iron.

Fig. 9.8 Examples of common minerals: Note the colors and distinctive appearance of some of the minerals

It forms during weathering processes or bacterial degradation of petroleum compounds in rocks.

Physical properties of minerals associated with the appearance of the mineral can be observed or measured relatively easily (Fig. 9.8). Common mineral properties are color (obvious and recognizable), luster (describes how *shiny* a mineral looks), cleavage (how the mineral breaks along surfaces), streak (describes the color of the powdered mineral), crystal form (describes the orderly, repeating pattern in the mineral, e.g., cubic crystal form), fracture (describes the indiscriminate cracks in the mineral), hardness (a measure of how easily the mineral can be scratched by other minerals or tools), smoothness (how the mineral feels to the touch), taste (not advisable), magnetic quality (e.g., attraction to a bar magnet), and density (the weight of the mineral).

Significance of Mineral Properties for Petroleum Exploration

The physical and chemical properties of a mineral directly control the role that mineral plays in the generation, accumulation, concentration, or trapping of petroleum. Hard minerals like diamond are hard enough to crush other minerals in rocks during drilling. Resistant minerals like quartz can be transported over long distances to sedimentary basins, where they accumulate and are cemented to form reservoir rocks. Other crystalline minerals like halite (NaCl) prevent petroleum from leaking out of a reservoir (i. e., they create a seal) and can be used in some cases to store oil and gas from refineries underground. Minerals like calcite dissolve readily in weak acids (carbonic acid, H_2CO_3 that form from dissolving carbon dioxide in water). The dissolution of calcite can create pores in rocks, making spaces where oil and water can accumulate. Tiny platy minerals in clays and shales can trap and hold other elements and organic matter between their sheets, thus creating ideal conditions for organic matter accumulation and the transformation of organic matter into oil.

Significance of Igneous and Metamorphic Rocks for Petroleum Exploration

In the previous section, we presented the major categories of rocks. In this section, we will summarize the role of igneous and metamorphic rocks in petroleum exploration. The significance of sedimentary rocks for exploration will be discussed in more detail in the next section.

Igneous rocks and metamorphic rocks tend to have interlocking (fused) crystals that contain little to no pore spaces for the accumulation of any oil or other fluids (Fig. 9.6). In addition, in igneous rocks the high temperatures of magma and volcanic lava exceed what is called the *oil and gas window*, which is the optimum tempera-

ture range at which oil and gas can form. In cases where igneous rocks are fractured and/or faulted, the fractures can provide pathways for oil and gas to migrate between different layers or accumulate in significant amounts. Igneous rocks are also important for the energy industry. When the magma chambers are shallow and hot enough, they can serve as sources that contribute heat for maturation in source rocks or as geothermal energy sources.

In metamorphic rocks, solid state transformation due to high pressure and temperature decrease pore spaces in the rock by compression and smelting. This alters reservoir rocks and source rocks by squeezing and fusing sediment grains and organic material. The high temperatures and pressures from metamorphism exceed oil and gas window. Similar to igneous rocks, metamorphic rocks may be fractured and/or faulted to provide pathways for oil and gas migration and possible accumulation in these rocks. They are also important for the overall energy industry because they can be sources of precious minerals, including radioactive substances like uranium.

9.3.5 Sedimentary Rocks

Sedimentary rocks make up only about 5% of the rocks in Earth's crust, but they represent up to 75% of all rocks exposed at the surface of Earth. This is because sedimentary rocks are formed from material that originates at or near Earth's surface before it is buried and transformed into a rock. Materials that form sedimentary rocks include fragments of pre-existing rocks, dissolved substances precipitated/evaporated from water, organic material that is trapped and buried in the Earth and other inclusions such as fossil remains. The materials that form sedimentary rocks are generally called *sediments* and can be grouped into 3 major types based on their source or process that formed them:

- Chemical sediment (typically dissolved ions)
- Detrital secondary particles and fragments or clasts
- Biogenic formed from or by organic processes.

Here are some common examples of rocks that are formed from these sediments. Sandstone forms from detrital material, limestone can form from biogenic or chemical substances, and evaporates from chemical substances. Detrital sedimentary rocks are the most widely distributed type of sedimentary rocks in the world. Billions of tons of detrital sediments are generated in all environments and transported to the world's oceans, lakes, ponds, and valleys. Detrital sediments are primarily classified based on their grain/particle size. The typical particle sizes are:

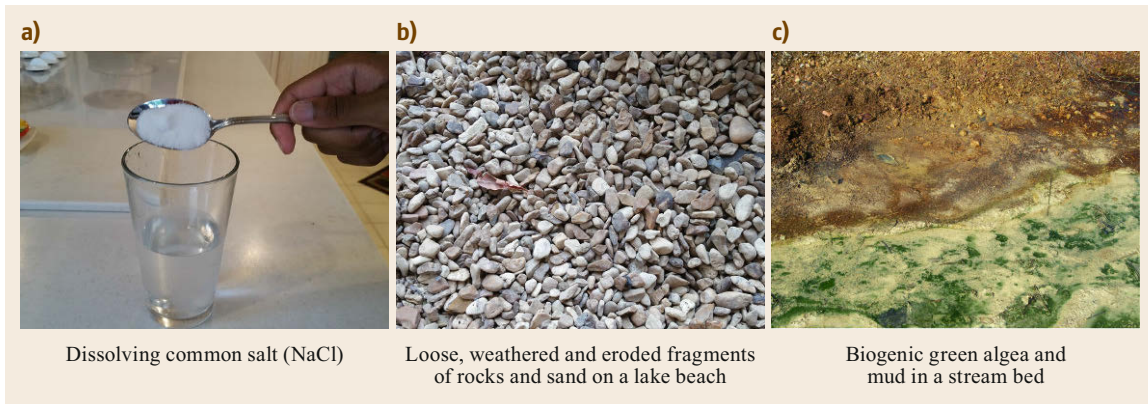

Fig. 9.9a–c Different types of sediments that can form sedimentary rocks: (a) Chemical sediments from dissolved substances, (b) detrital sediments from fragments and eroded remains of rocks, (c) biogenic sediments from microscopic algae

- Gravel (greater than 2 mm)
- Sand (2.00–0.0625 mm)
- Silt (0.0625–0.0039 mm)
- Clay (less than 0.0039 mm).

How Sediments Become Sedimentary Rocks

Sediments are loose unconsolidated materials or dissolved ions that form at the surface of the Earth. A group of sediments called clastic sediments occurs from the weathering and erosion (physical breakdown and loosening) of pre-existing rocks into smaller components. The loose fragments are displaced and *transported* by wind, water, glacier, or gravity and *deposited* into depressions known as sedimentary basins, where they accumulate and are buried through increasing deposition or other processes. Continuous burial creates higher, increasing pressure on underlying sediments, squeezing out fluids (water or air) and creating *compaction* of the sediments. The precipitation of dissolved minerals from the fluids bind and glue the sediments during compaction, leading to *cementation*. Common cement materials are composed of fine or amorphous calcite, silica, or iron oxides.

The process of compacting, cementing, and sometimes *crystallization* of similar sediments together is called *lithification*. This is the final process that transforms loose sediment material into a rock. Lithification is significant in petroleum exploration, because it leads to changes in the rock material that may affect the accumulation and concentration of oil and gas, altering the nature of reservoirs or source rocks by decreasing porosity and permeability.

Sedimentary Structures and Their Significance

When sedimentary rocks form, different types of features called sedimentary structures may form on, in, or

between the sedimentary layers at different times during the process. The two categories of sedimentary structures are *primary sedimentary structures* and *secondary sedimentary structures*, based on when they form.

Primary sedimentary structures provide stratigraphically relevant information about structures that formed when the layers of the rocks were deposited. Secondary sedimentary structures provide information about the changes that occurred after the rocks had been deposited such as the deformation processes that affect the rock layers and the types of structures that resulted from the deformation. Examples of primary sedimentary structures that form contemporaneously with the deposition of sediments are:

- Stratification
- Cross beds
- Ripple marks
- Mudcracks
- Fossil remains

Stratification (layering) is formed by the successive deposition of different sediments. Stratification is controlled by the geologic laws of original horizontality and superposition. Cross bedding is created by the changes in the direction or movement of currents and wind during deposition of sediments. Ripple marks are caused by flow and movement of water and wind on sediments. Mudcracks are formed when muddy surfaces dry up and contract from water loss. Mudcracks indicate drought conditions. Fossil remains are tracks, traces, prints, mold, casts, etc., of organisms that existed when the sediments were deposited.

Secondary sedimentary structures created after the rock is formed are known as post-depositional structures. These include fractures, folds, faults and secondary diagenetic features.

Categories of Sedimentary Rocks

Sedimentary rocks are categorized into three main groups based on the processes and/or the type of sediments (Fig. 9.10) that form the rock. The three main categories of sedimentary rocks are:

- Detrital sedimentary rocks
- Chemical sedimentary rocks
- Biochemical sedimentary rocks.

Detrital sedimentary rocks form from several types of material including:

1. Unaltered fragments of pre-existing rocks
2. Weathered remains of the fragments of pre-existing rocks
3. Secondary minerals that formed from the chemical transformation of the weathered substances from the fragments and composed of mostly clay minerals.

Chemical sedimentary rocks are typically salts, formed from either the precipitation of substances dissolved in water to form the rocks, or from the evaporation of water during droughts, leaving behind rocks known as *evaporites*. These rocks are mostly composed of one type of mineral. Examples include halite (NaCl), and anhydrite (CaSO₄).

Biochemical sedimentary rocks are formed from biogenic processes, which are caused by the action of living organisms. Biogenic sedimentary rocks can be chemical or detrital rocks. For example, limestone (a chemical sedimentary rock) may form from shells of

marine organisms, and coal forms from detrital material of woody plants.

Examples of Sedimentary Rocks

Sandstones are sedimentary rocks made from cemented sand sized sediments, mostly quartz and feldspars. Sandstones can be classified based on their textures, the environments where they are formed, and sometimes their composition.

The *texture* of a rock describes the size, shape and arrangements of the grains that make up the rock. Properties that describe the texture of these rocks are grain size, grain shape (sphericity), rock matrix or cement, grain smoothness (roundness), grain sorting, and grain orientation (fabric). The conditions under which sediments are transported and the environments where the sediments are deposited will affect the textural properties of the rock. *Sedimentary environments* where the rocks form represent the location (typically depressions), where sediment deposition occurs. Sandstone deposition occur in the following environments: deltaic (river deltas), aeolian (desert), fluvial (rivers and streams), marine (open oceans and seas), lacustrine (lakes), and glacial environments. Sandstone that forms in one environment can have characteristics that are different from sandstones formed in a different environment. For example, sandstones formed in desert environments will have different types of ripple structures than sandstones formed in deltaic or beach environments. The composition of sandstones can vary, although most sandstones are made of quartz. Other

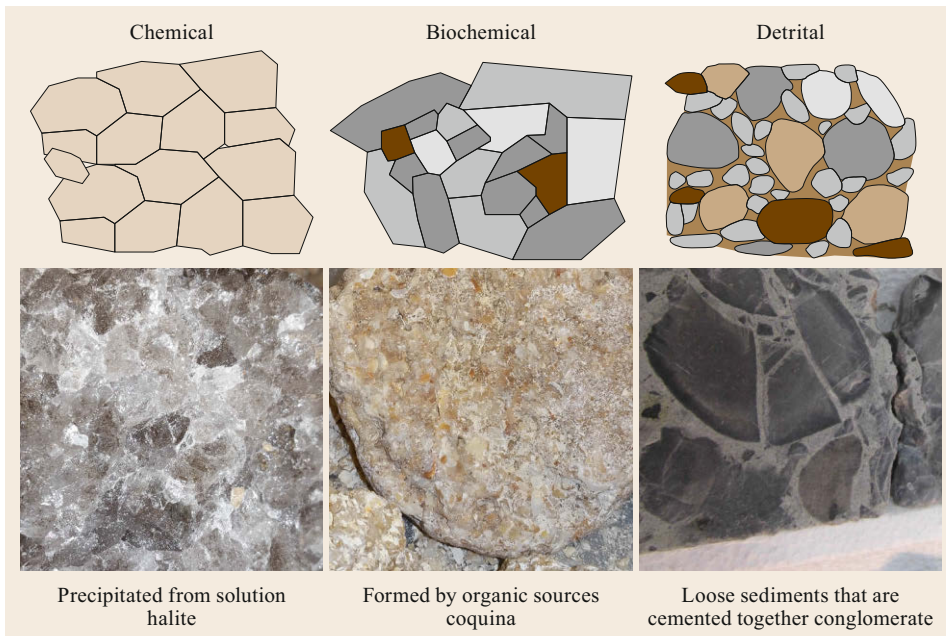

Fig. 9.10 Three categories of sedimentary rocks

components of sandstones are arkosic (feldspathic) minerals, nonsiliceous cements, and lithic (fragments of other rock) materials. The category of sandstones sometimes include breccia and conglomerates. Breccia and conglomerates are made of sediments that are typically larger (gravel) in size than grains in classic sandstones. Breccia mostly contains angular sediments, and conglomerates contain rounded (smooth) sediments. Sandstones are the most important *conventional reservoir rocks*.

Shales and *mudrocks* are formed from fine clay-sized grains either from weathered remains of detrital material or from secondary clay minerals. They occur in several colors (gray, black, red, green, etc.) based on their composition and may contain sufficient organic material to be petroleum source rocks. If organic material is absent from shales, they can form important seal and cap rocks, which prevent petroleum from leaking out of the rocks. Shales mostly contain clay minerals, and mudstones mostly contain siliciclastic minerals.

Carbonate rocks contain carbonate (CO_3^{2-}) ions in their minerals. They are formed by both biogenic and inorganic processes. Inorganic carbonate rocks are formed by the precipitation of carbonate minerals (like calcite) or by the reaction of calcite minerals with salt water. Biogenic carbonates are formed from skeletal materials of living organisms such as shells. *Marls* are fine grained carbonate and calcium rich rocks similar to mud rocks.

Evaporites form when water evaporates, leaving behind solute substances. Examples of common evaporites include salts like halite, gypsum, and anhydrite. Evaporites (like carbonate rocks) are mostly composed of one type of mineral, although varying traces of other minerals (impurities) maybe present in them.

Distribution of Sedimentary Rocks

Sedimentary rocks are formed in depressions on Earth's surface called sedimentary basins. For thick accumulations of sediments to occur, a source or supply of sediments and a depression to hold the sediments have to be available. Sedimentary basins can be created by plate tectonic activity, leading to subsidence, folding, faulting, and rifting of Earth material. These depressions can be any shape (bowl-shaped, irregularly shaped, elongated, polygonal), and they can be symmetrical or not. Sediments in basins typically come from detrital sources found on land masses or are created in situ by chemical and/or biological processes.

Sedimentary basins occur in all types of environments on Earth. These are:

- Continental environments (land masses)
- Ocean environments (aquatic)
- Transition or mixed environments.

These are the largest *megascopic* environments and each can be further subdivided into smaller environments to a *mesoscopic scale*, *macroscopic scale*, *microscopic scale*, *nanoscale*, etc. For example, *continental sedimentary environments* include large bodies like lakes, fluvial (river) valleys, and desert environments. These in turn can harbor smaller macroscopic (medium sized bodies) environments. For example, fluvial environments could contain a meandering river, a braided river, incised river valleys, etc. A meandering river environment in turn has a point bar, flood plains, river bed, and levees etc., where sediments are deposited. A braided river will include channel bars, floodplains, sand beds, channels, bed etc., where the sediments being moved by the rivers are deposited. Mixed or transitional sedimentary environments are areas under the influence of both land and ocean processes, such as deltas, bays, marshes, and barrier islands. The sediments and rocks that are formed in mixed or transitional environments will indicate the dominant processes that affected their deposition and formation as well as the source of the sediments. The ocean environments (Fig. 9.11) are areas that extend beyond the direct influence of land masses and continental sources or processes. The ocean environments can include the continental shelf, continental slope, continental rise, deep marine environments, and the abyssal plain.

Summary

Rocks are consolidated solids of minerals that can contain other material. Petroleum forms and occurs in rocks. The composition and arrangement of mineral crystals in rocks determines whether oil and gas can be formed, accumulated, and trapped in the rocks. Crystalline rocks (igneous and metamorphic rocks) do not create conditions that are favorable to generate, accumulate, and concentrate petroleum. Rocks that provide the ideal conditions favorable to the generation and accumulation of petroleum are sedimentary rocks. Sedimentary rocks in which petroleum is generated are called *source rocks* and sedimentary rocks in which petroleum accumulates and is concentrated are called *reservoir rocks*.

9.3.6 When Petroleum Formed

Petroleum formed millions of years ago, when a series of ideal conditions occurred all at the right times to generate and accumulate economic quantities of HCs. This ideal time span when favorable conditions occur to generate economic amounts of HC, is referred to as a *critical moment* (interval of time) in geologic history. The critical moment covers the time span when there was sufficient production and preservation of organic

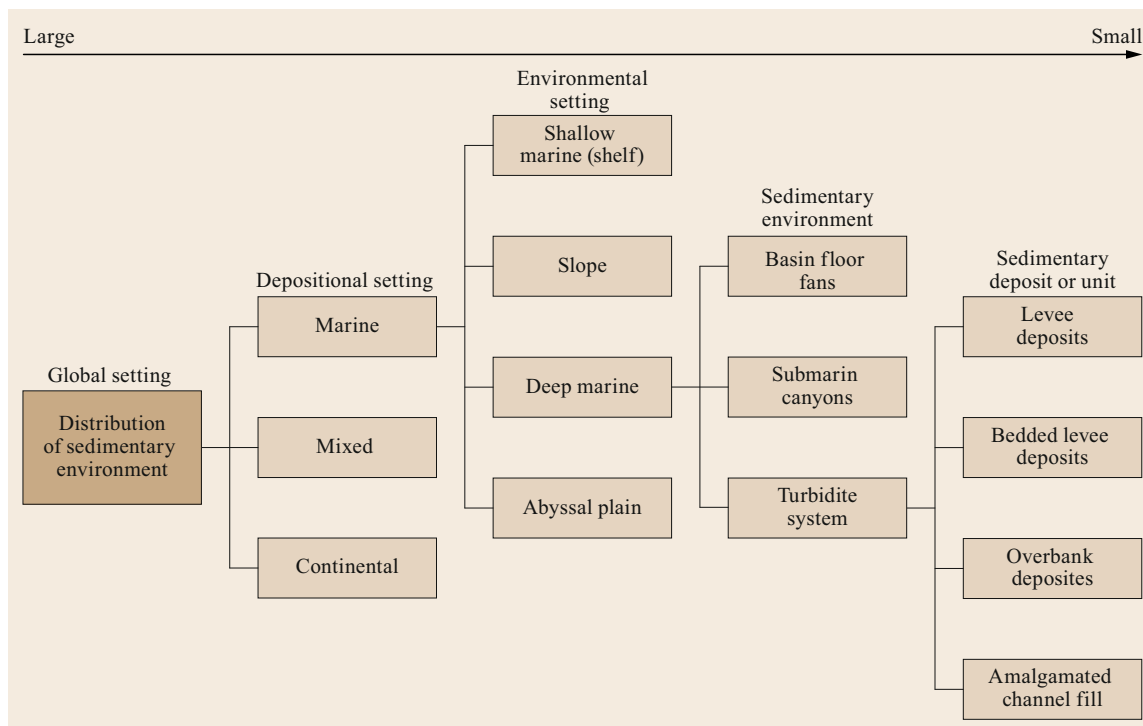

Fig. 9.11 Schematic representation of locations where sediments can be deposited in a marine environment

material, rapid burial of the organic material to ideal depths, ideal temperature, and ideal pressure to generate petroleum and enough time to migrate and accumulate the petroleum. The time period when petroleum formed can be determined by applying techniques of geologic dating. *Relative dating* establishes the sequential occurrence of events by establishing the order in which the events occurred with respect to the other events. This method of dating is based on and applies geologic laws and principles. Relative dating requires comparing at least two or more events.

Basis of Relative Dating

As mentioned earlier, geologic laws and principles are the basis of relative dating. Important geologic laws and principle used in relative dating are:

- *The law of original horizontality and lateral continuity* (Nicolaus Steno) [9.17]: Rocks that are formed from sediments are initially deposited horizontally and are laterally continuous. This law means that, in an environment where sediments are deposited (e.g., in a lake as illustrated in Fig. 9.12), the sediment layers (A, B, and C) that form the rock layers are stacked horizontally and continue laterally in all directions until they encounter a barrier.
- *The law of superposition* (Nicolaus Steno) [9.17]: In an undisturbed sequence of rocks in a sedimentary basin, the older layers are at the bottom and the younger layers are on the top. The older sediments are deposited first (found at the bottom of the lake), and successive layers above are younger with the top most layer being the youngest. In the example in Fig. 9.12, C is older than B, and B is older than A. Note that this order may change if the rocks are disrupted by tilting, bending or breaking.
- *Principle of cross cutting* (James Hutton) [9.17]: When a rock or an event cuts or intrudes through a sequence of rocks, for example, a dike (Fig. 9.13), it must be younger than the rock(s) through which it cuts. In the example illustrated in Fig. 9.12, the dike D is younger than layers C, B, and A.
- *Law of inclusions* (James Hutton) [9.17]: This law means that if a rock layer contains fragments of another rock or substance, then this rock layer must be younger than the fragments of other rocks or substance that it contains. In the illustration in Fig. 9.12, F is younger than the fragment E that it encloses. It is worth noting here that inclusions should not be confused with intrusions. Intrusions are younger and inclusions are older than the rocks they are in.

Fig. 9.12 (a) Schematic representation of original horizontality and lateral continuity in lake sediments, (b) schematic representation of cross cutting in lake sediments, and (c) the inclusion E is older than the surrounding rock F

- **Principle of Faunal succession** (William Smith) [9.17]: This principle states that sedimentary rock layers in any given location will contain a specific sequence of fossils that succeed each other through time. William Smith suggested that specific groups of fossils follow or succeed one another in the rock record over time, and that some fossils can thus be representative of the time when different types of rocks were deposited and formed. In terms of size, two classes of fossils exist. Macrofossils are large remains or traces of organisms distinctively visible to the human eye, and microfossils are tiny remains or traces of ancient organisms not distinctly visible to the human eye.

Fossils are evidence of past life in the rock record and can tell us something about the kind of organisms that lived when a group of rocks were formed, the type of environment that existed at the time, and climate conditions of the time. Thus, we can determine the paleo-environmental conditions from rocks and fossil records, for example we can tell, wet versus dry conditions, deep versus shallow water environments, hot versus cold temperatures, macro versus microscopic organisms, clear versus muddy waters and other climatic conditions that existed when the rocks formed. Fossils that help us to identify specific rocks and past conditions are termed index fossils.

Index fossils have to meet the following key conditions:

1. The fossilized organisms lived over a short time span
2. The fossils are geographically widespread around the world
3. The fossils are abundant
4. The fossils that are easily recognizable and identifiable
5. The fossils were easily preserved.

Fossils are important for dating rocks that have been deformed, overturned, or eroded and thus no longer obey fundamental geologic laws or principles, such as the laws of superposition and horizontality stated earlier. Another important point to remember is that because fossils are preserved from living organisms, they are also important in the generation of hydrocarbons.

9.3.7 Significance of Fossils in Petroleum Exploration

- **Microfossils:** These are tiny fossils that can only be identified with a microscope. They represent the important source material that generates petroleum. Microfossils are used in fingerprinting the source of oil in rocks. Some microfossils can also be useful as index fossils. Examples of microfossils

sils include planktonic organisms such as diatoms, foraminifera, radiolarian, and coccoliths.

- **Macrofossils** (Fig. 9.14): These are large fossils that are visible to the human eye or clearly visible with the aid of a hand lens. They are useful in subdividing layers of rocks into relative age and position in the geologic sequence. The subject of biostratigraphy studies rocks based on their fossil content. Macrofossils also aid in identifying depositional settings where rocks were formed. For example, fossils of woody plants will indicate an environment that was on or near land masses such as swamp and marshes.
- **Law of unconformities** (James Hutton) [9.17]: Unconformities are gaps in the geologic record of

Fig. 9.13 Intrusion in granitic rocks of the Rocky Mountains, USA

Fig. 9.14 Images of macroscopic fossils preserved in rocks

rocks (Fig. 9.16). They indicate time spans when rocks were missing from the sequence either because during that time span sediments were not deposited, an interruption occurred, or the rocks were removed by erosion or other processes. Missing rocks in the geologic sequence can be established from different fossil records in the succession of rocks, different types or categories of rocks that are side by side, and different orientation of the sequences rocks.

Four main types of unconformities are described based on the orientation, rock type and sequence of succession:

1. **Nonconformity** occurs when a sedimentary rock layers are in contact with metamorphic or igneous rocks, for example, intrusions of igneous dikes.
2. A **disconformity** occurs when rocks are missing between parallel layers of two different groups of sedimentary rocks. The formation of a disconformity is often due to the prior erosion of the older layers of rock before the younger layers of rocks are deposited.
3. **Paraconformity** occurs when sedimentary layers below and above the unconformity are parallel. Typically there is neither irregular erosional surface indicating erosion in a paraconformity, nor is there another visible change that occurs when no sediments were deposited over a long period.
4. **Angular unconformity** occurs when horizontal layers of sedimentary rock are deposited on tilted, folded and often eroded layers of older sedimentary rocks (Fig. 9.15).

Numeric (radiometric or absolute) dating relies on radioactivity, using the half-life of radioactive atoms to determine the age of an event. Unlike relative dating, it can be successfully applied to a single event or rock layer. Some common radioactive isotopes important to geology are uranium-238, thorium-232, potassium-40 and carbon-14 (Table 9.4).

For example, carbon-14 has a half-life of 5730 years. This is the number of years it will take the

Table 9.4 Table of parent atoms, daughter atoms, and half-lives of some common radioactive elements employed in petroleum geology

Parent	Daughter	Half-life (years)
^{238}U	^{206}Pb	4.6 billion
^{235}U	^{207}Pb	0.7 billion
^{232}Th	^{208}Pb	14.1 billion
^{87}Rb	^{87}Sr	47 billion
^{40}K	^{40}Ar	1.3 billion
^{14}C	^{14}N	5730

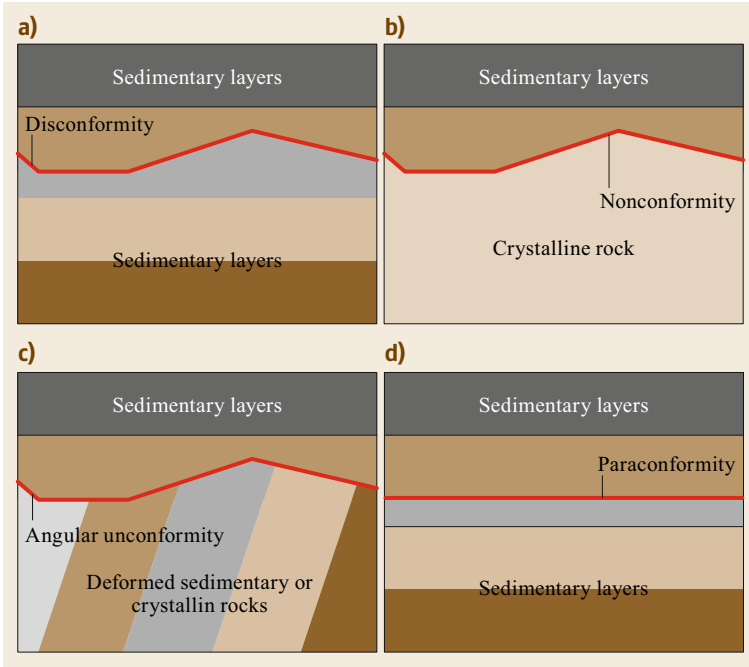

Fig. 9.15a–d Types of unconformities (shown as a *thick red line*): (a) disconformity, (b) nonconformity, (c) angular unconformity and (d) paraconformity

Fig. 9.16 Erosional unconformity in rocks of the Grand Canyon, USA

original number of atoms to decrease by half. When carbon-14 decays, it forms nitrogen-14 with the release of a β particle. This means that after 5 half-lives – 28 650 year – almost all the radioactive carbon-14 atoms would have dis-integrated into nitrogen-14 with the remaining carbon-14 being too low in concentration for detection. Due to its relatively short half-life, carbon-14 cannot be used to date rocks that are older than about 30 000 years. To date older rocks, a different isotope with a longer half-life has to be used, for example, uranium-238.

9.3.8 Summary of the Significance of Geologic Time in Petroleum Exploration

Dating rocks allows us to compare the age of one rock to that of other rocks. Relative dating establishes the order in which two or more rock units are formed. Relative dating techniques use geologic laws and principles, which are mostly applied to rocks in sedimentary environments, the most important category of rocks in petroleum exploration. Absolute dating is a technique

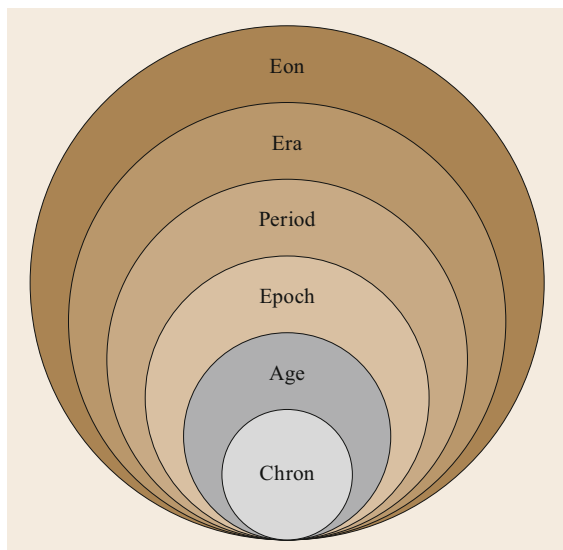

Fig. 9.17 Major divisions of the geologic time scale. In this case, the largest division is the Eon and the smallest is the Chron

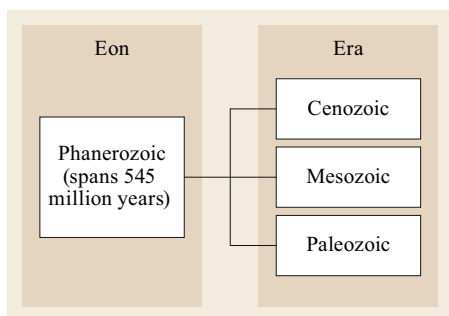

Fig. 9.18 The three Eras of the Phanerozoic Eon. Most oil and gas formed and accumulated during the Paleozoic through Mesozoic Eras

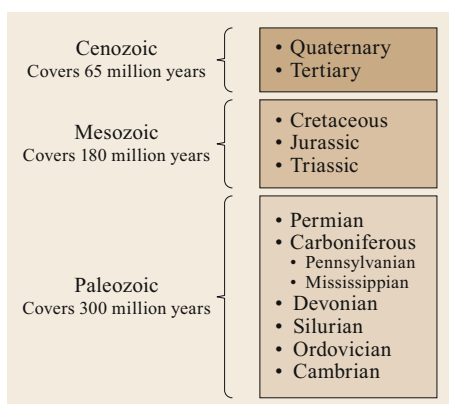

Fig. 9.19 Twelve subdivisions of the three geologic eras of the Phanerozoic

that uses the half-life of radioactive isotopes to determine numeric ages of rock units or events in the geologic record. By determining the numerical age of rocks, we can better understand the critical moment

in time when oil formed, when it migrated from the source, and when it became trapped in a reservoir rock.

The Geologic Timescale

Once the geologic sequence of rocks has been established and the numeric ages determined, combining these relative and numeric dating allows geologists to classify the 4.6 billion years of Earth's history into intervals of meaningful time segments on a chart that represents intervals of significant geologic events or processes of varying durations. Significant geologic events that occurred in the past, and can be used in subdividing the geologic record are events like the appearance and disappearance of unique life forms, mass and major extinctions, major climatic changes, catastrophic events, and the rise and fall in sea level glaciation, significant physical and chemical changes. Depending on the geologic subjects, different terminology for the divisions of the geologic timescale are used.

In geochronologic nomenclature, the *Eon* is the largest division of the geologic time scale, and covers time intervals of about 500 million years to more than a billion years long. There are four Eons in Earth history. These are listed below:

1. Phanerozoic: 545 million years–present
2. Proterozoic: 2.5 billion–545 million years
3. Archean: 3.8 billion–2.5 billion years
4. Hadean: 4.6 billion–3.8 billion years.

The most recent Eon, the Phanerozoic, represents the time interval when most of the petroleum formed and accumulated around the world. Henceforth, we will focus mostly on events that occurred during the Phanerozoic Eon.

Eons are subdivided into *Eras*. The events that delineate the Phanerozoic into 3 Eras (Fig. 9.18) are *major extinctions* of organisms that populated the Earth. For example, the boundary between the end of the Paleozoic Era and the beginning of the Mesozoic Era represents the time when about 90% of all marine species and about 70% of terrestrial species became extinct. Similarly, the boundary between the end of the Mesozoic Era and the beginning of the Cenozoic Era delineates the time when about 50% of all species on Earth went extinct, including the famous dinosaurs. The time span for each era covers tens of million to hundreds of millions of years (Fig. 9.19).

The Era is subdivided into smaller segments known as the *Period*. The Period is the most commonly used subdivision and the Fundamental unit of the geologic time scale. The Paleozoic Era has six Periods (or seven if you are using the United States-based classification), the Mesozoic has three Periods and the Cenozoic has two Periods as shown in Fig. 9.19. The most recent ge-

ologic Period is the Quaternary Period, which includes the industrial and technological age of humans and continues to the present time.

Periods cover time spans between thousands to tens of thousands of years. The geologic Periods are subdivided into smaller units known as the Epoch. The Epoch is subdivided into the Age and the Age into Chron representing successively smaller time spans in the geologic record of rocks.

9.3.9 Significance of Time in Petroleum Exploration

During the Paleozoic era, most hydrocarbon source rocks around the world were deposited mostly be-

tween the Devonian and Permian Periods. The mass demise of living things (including microscopic organisms) likely contributed to produce large amounts of organic material, and as a result led to the preservation of some of the organic matter in sedimentary rocks. Large accumulations caused the organic material to be buried deep enough to attain the oil and gas window for high temperatures and pressures to transform the organic matter to oil. The maturation process of organic matter into oil takes a long time. The accumulation of thick overburden layers of sediments buries the organic rich layer deeper and provides sufficient pressure and temperature to transform the organic matter into oil and gas (Fig. 9.5).

9.4 How Petroleum Accumulates and Concentrates

Once petroleum forms in source rocks, it may be moved from the source rock into other rocks known as *carrier beds* or *reservoir rocks*. The process of moving petroleum from source rocks to carrier beds or reservoirs rocks is called migration. *Primary migration* occurs when the petroleum leaves the source rock and migrate into a carrier or reservoir rock. *Secondary migration* occurs when petroleum leaves a carrier or reservoir rock and moves to another rock, or leaks and is lost to the surroundings. Migration of petroleum stops in *traps* where the petroleum is concentrated and accumulates.

The mechanism of how primary migration occurs from source rocks is not fully understood and several mechanisms have been proposed and described [9.12–14]. Secondary migration is controlled by oil viscosity, rock porosity, buoyancy and permeability of carrier beds.

9.4.1 Petroleum Accumulation

During *petroleum accumulation*, oil is concentrated and trapped in conventional reservoir rocks like sandstones. Petroleum *migrates* and *accumulates* in reservoir rocks because reservoir rocks can store and transmit fluids (liquids and gases). Rocks must have characteristic properties to qualify as good reservoir rocks. Important characteristics are:

- Temperature
- Pressure
- Porosity
- Permeability
- Fluid saturation

- Capillarity
- Wetting
- Trapping.

In the Earth, temperature increases with depth. Data from thousands of oil wells show that the surface temperature is always lower than the temperature measured at the bottom of a well. This increase in temperature with depth can also be observed in deep mines (the deeper you go the hotter it is). The sources of heat in the subsurface are varied but include heat that was trapped during the formation of the Earth, heat absorbed from sunlight, and heat that is converted or generated from other types of energy sources (mechanical energy, electrical, chemical, biological energy, and radioactivity). The rate at which temperature increases with depth is described as the *geothermal gradient*. Factors that affect temperature in the subsurface are fluid movement and type, drilling mud circulation, the type of rocks, depth, deformation, and radioactivity. Temperature is important for petroleum exploration and production because:

1. It controls oil and gas generation and maturation
2. It affects oil viscosity and flow
3. It affects the phase of the fluid (liquid or gaseous)
4. It influences pressure (generally high heat can cause expansion in gases, thereby increasing pressure)
5. It is useful in modeling, calibrations, and well-log interpretations.

There are three types of subsurface pressures, including *lithostatic pressure*, *hydrostatic pressure*, and *abnormal pressure*. The lithostatic pressure in the sub-

surface is caused by the weight of the sediments above a point under the sediments. Hydrostatic pressure is caused by the weight of the water column above a point underneath. In general, hydrostatic pressure is typically lower than lithostatic pressure (Fig. 9.20).

Porosity describes the ratio of total volume of pore space in a rock compared to the total volume of the rock. It can be expressed as a percentage or a fraction of the total volume

$$\text{Porosity (\%)} = \frac{\text{volume of pores}}{\text{total volume of rock}} \times 100 .$$

Porosity provides information about the amount of fluids (liquids and gases) a rock can hold. The common oil field symbol is the (ϕ). Three types of pores can be described in a rock based on how interconnected they are (Fig. 9.22).

Open or connected pores are linked to other pores creating a continuous connection between the pores. *Dead-ended pores* are open on only one side of the sediment creating a *cul-de-sac* on the other end. *Isolated pores* are not connected to other pores in the rock (they occur in isolation as one might see in bubble wrap). Geologists and engineers have different classifications of pores based on the pore size, when and how the pores form, or how the pores behave under different pressure conditions. The classification of pores directly relates to how the different groups of professionals interact with the information. Geoscientists (including petroleum geologists) are interested in understanding when, how, where and why rocks and pores are formed, while engineers are interested in the production conditions such as how well the pores are connected or the size of the pores and the capillarity. Geoscientists classify porosity as *primary porosity* if the pores were formed at the time

when the sediments were transformed into rocks. These are mostly the spaces that exist between the sediment grains in the rock after compaction and cementation have taken place. They describe *secondary porosity* as the porosity that forms after the rock was deposited. This may be formed by processes of boring, borrowing, fracturing, or dissolving rocks.

Geologists can also describe pores based on their *size*. Large pores that are visible to the eye or the aid of a hand lens are *macroscopic pores* (macroporosity). Tiny pores that are not visible to the eye are *microscopic pores* (micro-porosity).

Engineers classify porosity based on the connectedness of the pores and their response to pressure changes. *Total or absolute porosity* describes the total volume of pores in the rock. *Effective or open porosity* refers only to the volume of pores that are interconnected and can transmit fluids in the rock. *Dynamic porosity* refers to the amount of pores that can transmit fluids under a given pressure difference. In general, total porosity is always greater than effective porosity which is greater than dynamic porosity.

Generally, high-porosity rocks make better and more desirable reservoir rocks. The typical porosity ranges vary significantly for common reservoir rocks. In general, sandstone rocks that have less than 5% porosity are considered *very tight*. Rocks with 5–10% are considered *tight* (poor porosity), those with 10–15% have *fair*, those with 15–20% have *good*, and those with more than 20% have *excellent* porosity.

Permeability describes the ability of a rock to transmit fluids through porous media. It is commonly expressed in millidarcies (mD), a sub measure of the darcy (D). 1 D is equal to 1000 mD. A common symbol for permeability is *K*. Permeability depends on the connectedness of pores. This means that, although a rock must have porosity before it can have permeability, high porosity does not always mean good permeability. Permeability can occur in any direction within a rock layer depending on how the pores are formed. For example, vertical and lateral permeability in a rock sample can be significantly different due to the orientation of the sediments or minerals in the rocks. Rocks with layered minerals like clays will have preferentially more lateral permeability than rocks with spherical minerals like sandstones.

Permeability is classified into three main types:

1. *Absolute permeability* describes the ability of a rock to transmit a fluid when it is 100% saturated with the fluid, for example an aquifer filled with water.
2. *Effective permeability* describes the ability of a rock to transmit a fluid in the presence of another fluid

Fig. 9.20 During migration, oil and gas move from source rocks to carrier beds or reservoir rocks

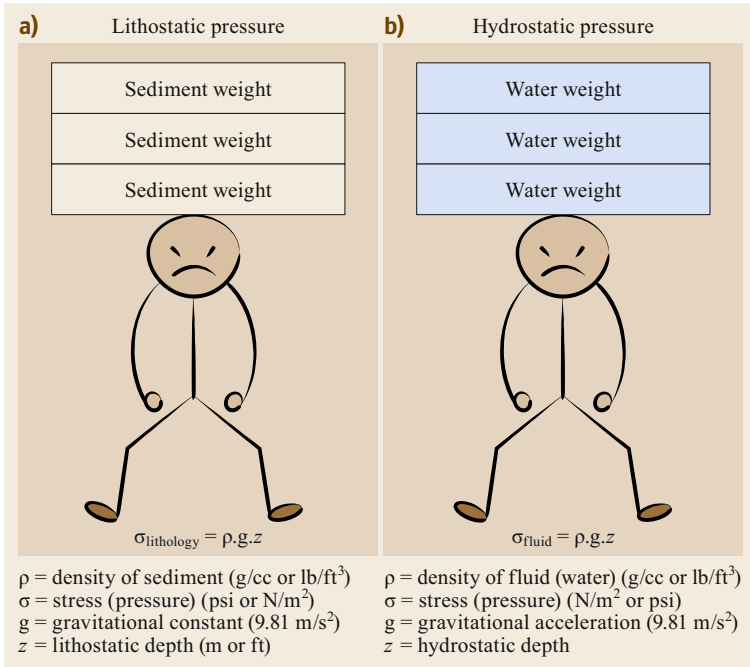

Fig. 9.21a,b Cause of lithostatic and hydrostatic pressure in the subsurface: **(a)** Lithostatic gradient (average rate at which lithostatic pressure increases) = 1 psi/ft **(b)** hydrostatic gradient (average rate at which hydrostatic pressure increases) = 0.43 psi/ft or 0.68 Nm²/ft

Fig. 9.22a-c Three types of pores based on their connectivity: **(a)** Connected or open pores, **(b)** dead-ended pores and **(c)** isolated pores

when the two fluids are immiscible such as oil and water in a reservoir.

3. *Relative permeability* describes the ratio between the effective permeability of a fluid at partial saturation and the absolute permeability of the fluid

$$\text{Relative } K = \frac{\text{Effective } K}{\text{Absolute } K}$$

Permeability in rocks is described as excellent when it is more than 100 mD, good when it is between 10–100 mD, and poor (tight rock) when it is less than 10 mD. It is worth remembering that a rock with low permeability could still have significant porosity.

Factors that Affect Porosity and Permeability

Textural characteristics of reservoir rocks will affect porosity and permeability. These sediment character-

istics are controlled by most of the processes that lead to the formation of the sedimentary rock as well as processes that affect the rock after it has been formed. Common textural characteristics of rocks include *shape, size, sorting, fabric, smoothness* and *packing* of the sediments in the rock (Fig. 9.25).

Primary porosity is affected by the processes that occur during the formation of the sedimentary rock. During the transport of sediments, *sorting* which is the redistribution of grains into similar sizes increases with increasing distance from sediment source. This increase in sorting can also enhance porosity. Sediment *packing*, which is the way the sediments are arranged and stacked in the rock relative to one another, also changes porosity. Efficient packing decreases porosity. The *compaction* of sediments squeezes the sediment grains close together and decreases porosity. The process of *cementation* that binds sediments together by

Fig. 9.23a-c Different types of macroporosity in core and slabs of Mississippian aged rock samples from Midwestern USA: (a) Large cavity, (b) intergranular pores and (c) vugs

Fig. 9.24 Schematic of flow through a permeable rock sample

Fig. 9.25a-d Common textural characteristics of rocks: (a) shape (b) size (c) fabric (d) sorting

precipitating dissolved substances in spaces between the grains decreases porosity. Post-depositional processes like fracturing and dissolution tend to increase porosity and the connectedness of the pores and will thus increase permeability, while precipitation of solutes in fractures or vugs between sediments will decrease porosity as well as pore throat size, and thus decrease permeability.

Fluid Saturation, Capillarity and Wetting

Fluid saturation describes the relative amount of a given fluid (water, oil or gas) that occupies the pore spaces in a rock (Fig. 9.26). Saturation is expressed as a fraction or percentage of the volume of the fluid in the rock to the total pore volume. Generally, if the pore spaces in a sedimentary rock are not occupied by water, then they are probably occupied by oil or gas (which is

mostly hydrocarbon gas). Therefore, knowing the relative fraction of one fluid allows us to determine the fraction of the other. Thus the HC saturation (S_h) in the rock is simply computed as $S_h = 1 - S_w$ where S_w is the water saturation in the rock.

Capillarity measures the ability of a fluid to flow in very narrow pore spaces under the influence of forces of surface tension. Capillary pressure increases with decreasing pore throat diameter.

Wetting describes how a fluid interacts with the surface of sediments in the reservoir rocks (Fig. 9.27). Particularly, oil and water interact differently with the surfaces of different types of minerals in porous reservoir rocks. For example, sandstones are usually water wet (preferentially attract water to sand grain surfaces compared to oil) and carbonate rocks are typically oil wet. Generally in a reservoir, there is a continuum in wettability due to the presence of many different types of sediments.

Seals and Cap Rocks

Seals are rocks that prevent petroleum from leaking out of reservoir rocks and being lost. Important characteristics of seal rocks include low or no porosity, low or no permeability, and high ductility. Tightness is favorable in seal rocks because it prevents the accumulation and flow of petroleum into or out of them. Ductile rocks do not break and fracture readily when they are deformed thus minimizing connectivity between pores.

Fig. 9.26 Schematic of a medium that is completely (100%) saturated with water and the same medium with no visible water saturation (0–5%) or dry

Fig. 9.27a,b Schematic illustrating two types of wetness: (a) Water wet sediment, for example, quartz grain and (b) oil wet sediment, for example, calcite grains

Seals rocks can cover large areas (regional seals) and as such can influence the migration pathways of oil and gas, or they can be limited (local seal) to a particular reservoir rock area and help in concentrating oil. Examples of common seal rocks are tight rocks e.g., shales, anhydrites, tight carbonates, and rock salt.

9.4.2 Petroleum Traps

A *petroleum trap* is a unique geometric arrangement of rocks and structural features that allow for economic quantities of HCs to be concentrated and contained in the reservoir unit [9.13]. This means that a trap does not only depend on the presence of reservoir rocks but also depend on the shape and how the rocks are arranged with respect to other rocks. Important components associated with a petroleum trap are:

1. A structural high
2. A geometric closure
3. Permeable rock containing oil/gas
4. Seal and cap rocks
5. Source rock/migration path (carrier bed)
6. Overburden rocks
7. Time.

Thus the key features of a petroleum trap (Fig. 9.28) include the reservoir, seals and cap rocks, underburden, closure, pay, zone, gas cap, crest, oil–water contact (OWC), oil–gas contact (OGC) (when there is a gas cap), and spill point. These features describe the relationship and the geometric arrangements of the trap elements and trap content.

Petroleum traps can be grouped into four categories based on the geologic processes that mostly influence the traps:

1. Structural traps
2. Stratigraphic traps
3. Hydrodynamic traps
4. Combination traps.

Structural traps are created during the deformation of rocks. Rock deformation is caused by stresses resulting primarily from tectonic activities and intrusions or other piecemeal features that cause local scale deformation on overburden rocks as a result of loading or differential compaction, bending, breaking, pulling and pushing. Bending leads to folds, breaking leads to faults and compaction or upward pushing causes piecemeal. *Fault-associated* traps are traps that are formed by, or because of, the occurrence of faults. Faults occur when rocks break and the rock blocks are displaced upward, downward or laterally relative to each other. Two main groups of faults can form when rocks are broken and displaced. These are (a) *dip-*

Fig. 9.28 Schematic of a simple anticlinal-type trap showing common trap features

slip faults that form when faulting is accompanied by vertical displacement. Examples of dip-slip faults are normal faults and reverse faults. (b) *Strike-slip faults* form when faulting is accompanied by lateral motion. Examples of strike-slip faults are right lateral and left lateral strike-slip faults. When rocks break without any accompanying displacement of the rock blocks, then fractures and joints form. Fractures are different from joints in that fractures have gaps and joints closed.

Faults can create or prevent leaks from a reservoir depending on whether the rock layers on the other side of the reservoir rock, along the fault, are permeable or not. *Fold-associated traps* are structural traps that form when rocks are compressed and folded. Folds form anticlines and synclines that may be symmetrical, asymmetrical, plunging, or not. Special forms of folds exist; these are domes/basins, diapiric doming, chevron, kinks etc.

Diapirs and *piercement* features deform overlying rocks. The deformation occurs when rocks that are buried underground are pushed toward the surface due to buoyancy, increasing compaction stress, or from rising intrusives. This can happen because rocks like salts and shales can only be compacted to a certain limit beyond which they tend to *flow*, pushing and doming the rocks above them. The upward movement of diapirs may induce fractures and faults to create a variety of traps that are associated with the fault, stratigraphic pinch outs, and doming around the intrusion.

Stratigraphic traps are formed from changes that are caused by sedimentary processes. Primary stratigraphic traps are caused by the depositional processes and the characteristic environment where the sediment is deposited. For example, point bar sands form in meandering river systems, when rivers bend and de-

posit sediments in the inner parts of the curves to create a pinch-out feature, carbonate reefs form in shallow clean seas or ocean water which are rich in ions and have high light levels. Primary stratigraphic traps can also be associated with unconformities. For example, channel fill sands form traps associated with unconformities in an ancient buried river channel. Secondary stratigraphic traps can form from diagenetic processes that occur after the rock has been formed (post-depositional alteration of the rock layer). Examples of diagenetic processes include cementation, dissolution and dolomitization.

Combination traps are traps that are formed from a combination of structural and stratigraphic traps. For example, angular unconformity traps develop when tilted or folded sedimentary layers are overlain by horizontal layers of rocks, to create a trap.

Hydrodynamic traps are traps that are modified and influenced by flowing water. These can also be considered combination traps because they are typically associated with a structure containing petroleum underneath which water flows. The movement of water modifies the shape and position of the oil accumulation and can also trap oil in a location where it would otherwise not accumulate. If oil and gas are present in the reservoir, the gas which is less dense (lighter) will be displaced ahead of oil and the overall fluid distribution in the reservoir will somewhat deviate from the conventional manner.

Petroleum trap assessment and evaluation is of prime importance in petroleum exploration. They help geologists and engineers to assess petroleum traps in order to evaluate their potential and their limitations. Assessing a trap from a three-dimensional perspective is essential for reservoir characterization. *Map or bird's eye views* provide additional information about

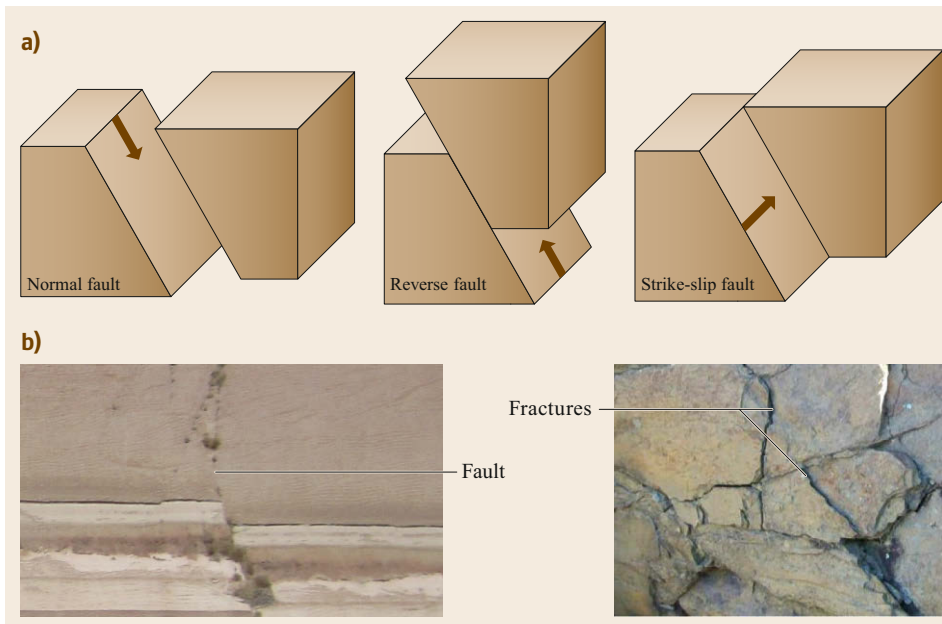

Fig. 9.29a,b
Faults and fractures: (a) types of faults (b) images of a normal fault and fractures in rock sample

areal extent and coverage of the reservoir within the trap. *Cross sections or vertical views* provide information about depth and thickness of a reservoir unit. Both views are essential in reservoir characterization and volumetric calculations for reserve estimation. During trap evaluation for reserve potential, it is important to keep in mind that traps can also have limitations. Sometimes very geometrically viable traps have no productive zones (i.e., the traps formed outside of the *critical moment*). The trap may contain multiple impermeable layers interbedded in the reservoir unit or very thin reservoir beds nested in impermeable units, or the trap could have some poorly productive transition zones and leak points caused by porous beds, faults, or diagenetic changes.

Overburden and underburden rock layers stacked above and below the trapped reservoir rock reinforce the seals and cap rock layers, and by virtue of their thickness provide increased temperature and pressure on the reservoir units. The ideal arrangement of a petroleum trap, reservoir rock, seal, cap rocks, and overburden rocks, together with source rocks generation, maturation, and migration pathways of petroleum, as well as the time that it takes for these processes to occur, constitute the elements of a *petroleum system*. Magoon and Dow [9.13] define the petroleum system as a *dynamic petroleum generating and concentrating system functioning in a geologic space and time*. A petroleum system is therefore critical for the creation of economic accumulations of oil and gas.

Fig. 9.30 Folded bed unit in the Ouachita outcrop in south central USA

9.4.3 Elements of Plate Tectonics and Petroleum Deposits

Plate tectonics is a theory that explains why fragments of Earth's outer solid layer (lithosphere) are in constant motion relative to one another. These motions are very slow and almost imperceptible. In plate tectonics, the lithosphere of the Earth is subdivided into a number of relatively thin and rigid fragments called *tectonic plates* that move very slowly relative to one another. The main processes that cause the motion of Earth's lithospheric plates are *seafloor spreading* and *subduction*. Seafloor spreading and subduction are caused by the movement of molten material in the mantle of the

Earth. The theory of plate tectonics began around 1912 when the German scientist, Alfred Wegener, hypothesized that approximately 200 million years ago, all the continents on Earth were joined together into one supercontinent called *Pangaea* (meaning *All Lands*) and over time the continents have drifted apart . . . and continue to do so today. This was called the *continental drift hypothesis*. Wegener pointed to several clues as evidence:

1. Some continents (e.g., the western portion of Africa and eastern portion of Latin America) appeared to fit like pieces from a puzzle.
2. The same type of fossils of land organisms have been found on different continents separated today by large oceans.
3. Similar rock types and structural features have been found on continents across opposite sides of the Atlantic Ocean. For example in the western edge of Africa and the eastern part of North America.
4. Paleoclimate evidence that shows that in present day tropical and subtropical parts of Africa, glaciers were present in the geologic past, indicating that continents were not always at their present location.

However, there were objections to Wegener's hypothesis because he could not provide evidence of a mechanism that caused these motions. Years later, evidence to support Wegener hypothesis was established when *seafloor spreading* was proposed and *paleomagnetism* was observed. Paleomagnetism is based on observations that:

- Earth's magnetic field is imparted onto iron-bearing minerals present in magma (e.g., magnetite) when it cools below a certain critical temperature known as the *Curie point temperature*.
- Earth's magnetic pole periodically reverses of over time. The reversal of Earth's magnetic field is called *magnetic reversal*.
- *Polar wandering* where Earth's magnetic pole appears to have shifted (wandered) over the past 500 million years.

In the 1960s, a US navy officer and geologist (Harry Hess) and others proposed and explained the concept of seafloor spreading that validated Alfred Wegener's continental drift hypothesis, and thus establishing plate tectonics theory. Seafloor spreading explains the spreading of Earth's crust at ocean ridges, where new crust is created as basaltic magma erupts out of Earth's interior. The seafloor spreads along relatively long narrow stretches called rift zones located in the middle part of the oceans where magma rises to the ocean floor cre-

ating elevated ridges. The spreading of the sea floor creates new crust on either sides of the spreading centers (rift zone). The continual spreading of sea floor is balanced by the destruction of lithospheric material at the other edge of these plates known as *subduction zones*, where older, colder, and denser lithospheric rocks collide with another plate, descend and melt in to Earth's mantle. The edges of tectonic plates, where subduction or spreading occur, form the plate boundaries. There are three types of plate boundaries that can exist between two different tectonic plates. *Divergent plate boundaries* form at constructive margins where new crust is being formed. *Convergent plate boundaries* form at destructive margins where the crust is damaged and *transform plate boundaries* form at strike-slip fault zones where no crust is formed or destroyed.

The movement of plates causes collisions, spreading, and deformations, which are responsible for major topographic features on Earth; like mountains, valleys, and ocean floor. Petroleum mostly formed in sedimentary depressions that contained water bodies some of which have disappeared today, and/or as in the case of present day oceans and seas where sediments continue to be deposited.

There are three major parts of the ocean environment:

1. Continental margins
2. Abyssal plain (deep-ocean basins)
3. Oceanic ridges.

Here is a brief description of these ocean environments and how they relate to petroleum. The oceanic ridges are the longest topographic features on Earth's surface. They extend over 70 000 km (43 000 mi) in length and cover about 20% of Earth's surface. They are relatively elevated deep ocean features with many faults, earthquakes and volcanic activities. Ocean ridges are present in all the major oceans of the world and have widths of 1000–4000 km. These oceanic ridges are not conducive to the formation, generation, or accumulation of petroleum, because of the depth and extremely high temperatures and associated volcanic activities. Abyssal plain and deep-ocean basins have been described as the most level places on Earth, with thick accumulations of sediments that were deposited into the basin over millions of years. They are also found in all oceans around the world. In portions of the deep-ocean basins that are close to the oceanic ridges, it is not uncommon to find isolated volcanic peaks that may emerge as an island above the ocean water surface to form volcanic island or stay below the water surface to form flat-topped seamounts called guyots. In addition, if large vast basaltic lavas oc-

cur on the ocean floor, they create extensive volcanic structures called oceanic plateaus. Due to the high temperatures and molten rock associated with volcanic activities these structures by themselves are not likely to host petroleum. In addition, due to the depth, and location of the deep-ocean basins (which are far from productivity sites for petroleum source material), little interest has been associated with these deep-ocean basins in the exploration for petroleum despite the massive amounts of sediments and associated sedimentary rocks.

The parts of the ocean closest to the continental land masses are known as the *continental margins*, and they separate the continents from the oceans. There are two types of continental margins: the active continental margins and the passive continental margins. The nature of the continental margins is closely dependent on whether tectonic activity is occurring at the margin. *Active continental margins* are mostly located around the Pacific Ocean. Parts of the active margin are the continental slope, deep-ocean trenches, and accretionary wedges. The *continental slope* is the dipping part that descends abruptly from continents into the deeper part of the ocean basin, including the oceanic trenches. The *deep-ocean trench* is a relatively long and narrow V-shaped depressions at subduction zones where plate boundaries occur. Trenches are currently known to be the deepest parts of the ocean. Most of the deep-ocean trenches in the world are located around the Pacific Ocean. The deep-ocean trenches contain accumulations of deformed sediments, fragments and scraps of ocean crust, scraped off of plates during subduction and known as accretionary wedges. It is not yet clear at this time if exploitable economic accumulations of HCs abound in deposits of the accretionary wedges. *Passive continental margins* are not directly associated with tectonic plate boundaries. A passive continental margin is made up of three parts that progress from the coastal environments into the deep ocean. The first part of the passive margin closest to land is the *continental shelf*, a more or less broad gently sloping, flooded extension of the continent that typically contains some of the largest deposits of clastic sediments, large accumulations of petroleum and important mineral deposits. The shelf steepens into the continental slope. The continental slope is a relatively steep surface found at the open sea/ocean edge of the continental shelf and can also contain important accumulations of sediments and HCs. The slope gently levels out onto the abyssal plain. The continental rise stretches into the abyssal plain. The continental rise contains thick accumulation of sediment made up of various types of deposits, including turbidity current deposits, slump deposits, and deep-sea fans. Passive continental mar-

gins are mostly associated with the Atlantic Ocean. There are no deep-ocean trenches in the passive ocean margins. Many petroleum accumulations around the world are found in passive margin basins, for example, there are large accumulations in the Atlantic Gulf coast of the United States, the Atlantic Coast of Brazil, Venezuela, and the Niger Delta region of west and southern Africa.

Tectonism and Rock Deformation

The relative motion of tectonic plates causes stresses that creates deformation to form sedimentary basins in which sediments can accumulate, if sediment sources are present. *Rock deformation* refers to all changes that affect the original form, shape, or size of a rock body after it formed. Deformations mostly occur along tectonic plate margins and are affected by temperature, pressure, rock type, and time. There are mainly two types of deformation that affect a rock body: *folding* (bending) or *faulting* (breaking). *Folds* are the result of bending rocks (without completely breaking) into wavy structures. Folds form when compressional stresses (pressure) are applied to rocks. Compression causes the rocks to be shortened and thickened forming arched or upfolded rocks called *antiform* and hollow or downfolded rock layers called *synforms*. Folds can be symmetrical or asymmetrical. Special types of folds are *domes* – circular, or slightly elongated, upward displacement of rocks with the oldest rocks in center of the fold, and *basins* – circular or slightly elongated downward displacement of rocks with the youngest rocks in the center of the fold. Faults form when rocks break under stress and are displaced. Two groups of faults can be described: dip-slip faults and strike-slip faults (Sect. 9.4.2).

Dip-slip faults are faults that show the vertical movement due to either compressional stress (reverse faults and thrust faults) or extensional stress (normal faults) resulting in movement along the inclination (dip) of the fault plane. The two main parts of the dip-slip fault on either side of the fault plane are known as the *hanging wall* – the rock above the fault surface and the *footwall* – the rock below the fault surface. In the normal fault, the hanging wall block moves downward. They are created by tensional forces or extensional stress regimes. The other types of dip-slip faults are reverse and thrust faults, where the hanging wall block moves upward. These are caused by strong compressional stresses. Reverse faults are high angled with dips greater than 45° and thrust faults are low angle faults with dips less than 45°.

Strike-slip (transform) fault are vertical or nearly vertical faults with dominant horizontal motion. Strike-slip faults are formed by shear stress. Transform faults

are large strike-slip faults that cut through the lithosphere and are often associated with plate boundaries. Two types of strike-slip faults are right-lateral strike slip and left-lateral strike-slip faults.

Tectonic Uplift and Reburial of Sediments and Rocks

Diagenetic processes are the primary processes responsible for the formation of sedimentary rocks that host oil and gas deposits. Subsequent uplift and reburial of these rocks and/or sediments can further transform and alter the rocks, obliterating the organic matter that is trapped in them, or they can create structures and cause the right temperature and pressure conditions, for the generation and accumulation of petroleum.

Plate tectonics has a big influence on the areas where oil and gas reservoirs are located around the globe. It also provides the logical explanation as to how present day arid and sometimes desolate environments came to host large accumulations of petroleum. For example, it can explain the presence of petroleum in present day glacial environments. The simple explanation is that these areas, which were underwater millions of years ago, were later uplifted and deformed by tectonic forces or moved to their present position.

Not all accumulations of petroleum are found in desert or arctic environments. Petroleum accumulations are also found in ancient rivers, lakes, coastal, and present day offshore environments. This is because several mechanisms are involved in the formation of sedimentary basins and the rocks in which petroleum forms or accumulates. For example, a basin can be formed by *crustal thinning*, which occurs when magma from deep within the Earth heats up the crust, causing it to stretch and thin as tectonic plates are pulled apart in a divergent setting, like you would pull a piece of hot plastic. *Lithospheric thickening* happens when molten material rising from the mantle pushes the overlying lithosphere to bulge and dome upward, resulting in depressions on the sides. *Sedimentary or volcanic loading* occurs when overburden sediments or volcanic structures create excessive weight that causes depressions around the sides of the structures. Compressional stresses that occurs at convergent boundaries during subduction can result in the uplift of sedimentary layers previously buried deep underground. Tectonic uplift

creates upfolded and downfolded rocks (anticlines and synclines), and may further overturn and bury these rocks by a process called reburial. The buckling and bending of stressed rocks creates conditions favorable for petroleum accumulation and concentration through folding and faulting. When brittle rocks are subjected to compressional stress, they break and form faults (reverse and thrust faults) that can create excellent conditions for petroleum accumulation and concentration (see the section on petroleum traps). When nonbrittle or ductile rocks are subjected to compressional stress, they too will buckle and create anticlines and synclines. Anticlines have been known to host some of the most prolific petroleum reservoirs in the world. *Tectonic loading* and *subsidence* are additional processes that can create sedimentary basins.

Implications of Plate Tectonics for Petroleum

Sedimentary rocks form in shallow and deep sedimentary environments. Tectonic activities make or break HC traps. Most of the world's major oil fields are found in present day ocean basins or ancient ocean basins. Most basins are created as a result of plate tectonic processes and a good understanding of the processes that create elements of a petroleum system, including plate tectonics, can help us to narrow our exploration focus.

Summary

All elements of the petroleum system are necessary for the accumulation of economic quantities of petroleum to occur. Time is one of the most essential components for the generation and accumulation of petroleum. This is because it takes time to produce sufficient amounts of organic source material, and it takes time to sufficiently bury and transform the organic material to generate petroleum. After generation, more time is required to expulse the petroleum from the source rock and accumulate sufficient amounts in reservoir rocks. Therefore, although the processes that produce, bury, transform organic matter, and generate petroleum are happening in the world today, the time component is not yet sufficient to allow for the accumulation and concentration of economic quantities of petroleum. The right conditions need to all happen at exactly the right times or *critical moment* to create economic traps.

9.5 Finding and Locating Petroleum

The methods and techniques used to search for and find petroleum have changed significantly since the early days of visual identification of seeps. Modern technol-

ogy and sophisticated equipment have revolutionized how we locate subsurface oil reservoirs. This section will summarize some of the methods and techniques

used for petroleum exploration. Methods of exploration can be organized into different categories, but it is important to remember that there is overlap in the use and exploitation of data obtained by any one of these methods during the exploration, extraction, production, and processing of petroleum products. Methods of exploration can be classified according to the techniques employed as follows:

- Geophysical methods
- Geochemical methods
- Geological methods
- Remote sensing/satellite imagery
- Drilling methods.

Most exploration projects start with an idea and prior knowledge that may or may not be exhaustive. Ideas and prior knowledge are typically followed by literature review, reading and some form of data collection.

9.5.1 Geological and Geochemical Methods of Exploration

These methods involve collecting samples, mapping, and analyzing data in/and from the field. They include active field work, sample handling, processing, analysis and interpretation. The goal of geological and geochemical exploration is to identify the types of rocks, minerals, structures, composition, and to identify outcrop analogs for the subsurface. The ultimate objective is to generate subsurface structural maps that show the rock units, how they were arranged when they formed and how they were deformed afterward during faulting or folding and variations in various subsurface geologic properties or characteristics.

Geological field methods and surface mapping involve the following activities:

- Data gathering
- Identifying structures
- Mapping strike and dip
- Identifying minerals and rock type
- Preparing sketches
- Analyzing photographs
- Collecting accurate location data etc.

The subsurface mapping of surfaces and structures is an essential part of geology and has been discussed in several classic publications [9.17–20].

Geochemical methods mostly involve the analysis of rock or fluid samples collected in the field or the interpretation of previously acquired data. The main objectives of geochemical methods are to determine chemical and mineral composition of rocks; identify anomalous (unusually) high or low concentrations of substances in the rocks; analyze composition and prop-

erties of samples to determine the quality and source material; and estimate quantities.

Structural methods determine how geologic units were arranged when they formed and after they were altered or deformed to generate a true representation of the subsurface arrangement and geometry of rocks. Structural methods are important to identify petroleum traps, to define trap geometry, and for reservoir characterization.

9.5.2 Geophysical Methods of Exploration

Geophysical methods of exploration are by far the most popular methods at present. These methods use physical science techniques to collect data from the subsurface. The data is then analyzed, interpreted, and converted into maps and models.

Several geophysical methods exist and can be grouped into two categories: the *noninvasive methods* like gravity and magnetics, and *invasive methods* like seismic and geophysical well logging. *Gravity methods* measure acceleration of Earth's gravity at a given location using an instrument called the gravimeter. The gravity method relates to density differences in rocks and is measured in Gals. *Magnetic methods* measure the strength of Earth's magnetic field in rocks at a location, to determine the magnetic properties of the rocks underground. Specific techniques can be used to determine how easily the rocks can be magnetized. The instrument used in magnetic surveys is the magnetometer and the measurements are expressed in gauss (G), nanotesla (nT) or other units depending on the magnetic property measured. Magnetic methods can be conducted on land, at sea or by air. For petroleum exploration, gravity and magnetic surveys are mostly applied at the early stages of exploration. *Geophysical well logging* is the collection of geophysical data in boreholes and plotting variations of the data with depth. It is used to interpret, qualify, and quantify the value of specific geophysical variables at specific depths. Geophysical well logging is also useful to correlate changes in different parameters at the same depth in a well. Common examples of geophysical logs are:

- Resistivity logs
- Spontaneous potential logs
- Porosity logs
- Nuclear magnetic resonance logs
- Gamma radiation (natural and induced) logs
- Acoustic wave interval transit time logs.

Several authors [9.21–23] have documented the types and applications of geophysical well logs used in exploration. The *seismic method* uses the propagation of natural or artificial seismic (elastic) waves in

the subsurface to measure the properties of rocks and fluids. The information obtained is used to *image* the subsurface. Seismic exploration uses the basic relationship between velocity and travel time to estimate the distance (depth) of subsurface structures and the variety of wave properties to characterize rocks and fluids. In the subsurface environment, the velocity of seismic waves varies with rock type and rock properties. The arrival times of reflected waves are measured at the surface and are used to locate underground structures conducive to oil accumulation, and to collect data for basin analysis, volumetric analysis, structure maps, etc. Over the years seismic exploration has progressed from 1-D to 4-D, time-lapse surveys and other variations.

Petroleum exploration aims to find oil and gas resources in the Earth. Applying the different methods of exploration allows the explorationists to narrow the search from a large to small scale as shown in Fig. 9.31. The ultimate goal is to identify the ideal location where a well can be drilled, in the acquired lease within a prospect in a good play in the sedimentary basin.

9.5.3 Extracting and Producing Petroleum

Drilling

Key components of a drilling rig are shown in Fig. 9.32. To drill a well, a bit is attached to the end of a drill string, which is comprised of sections of steel pipe that are 30 ft (9 m) long. The drill string is lengthened as the well gets deeper by attaching additional sections of pipe to the top. Drill collars are thick-walled sections of drill pipe at the bottom of the drill string; collars apply extra weight to the bit. As the bit crushes through rock, mud is pumped down through the inside of the drill string,

out the bit, and up through the space between the drill string and the well bore. Despite its dirty name, drilling mud is a designed blend of fluids, solids and chemicals. It cools the drill bit and brings rock cuttings back to the surface. The cuttings are removed in shakers, and the fluid goes back to the mud pit, from which it is recycled.

The derrick must be tall enough to accommodate a 90-ft-long *triple* comprised of three sections of pipe. The derrick, pulleys, and hawser must be robust enough to support the lifting and manipulation of the entire drill string. The kelly is the top joint of a drill string. It has flat sides that fit inside a bushing on the rotary table, which turns the drill string and bit. Note that not all drilling rigs use a kelly system.

A surface blowout is a sudden increase in well pressure resulting in loss of containment and uncontrolled flow of oil and gas into the atmosphere. The blowout preventer (BOP) is a safety valve or other device beneath the floor of the drilling rig. When activated, it stops a blowout by sealing off the top of the well.

The density of drilling mud is crucial. If the mud density is too low, a well is susceptible to a surface blowout. If the mud density is too high, it can cause an underground blowout – the rupture of the reservoir underground – pushing drilling mud into another formation. Underground blowouts are the most common of all well control problems. Many surface blowouts begin as underground blowouts. Prompt, correct reaction to an underground event can prevent a dangerous and costly surface blowout [9.22].

Completion

Wells are completed by casing the well bore with steel pipe and cementing the casing into place. Casing pre-

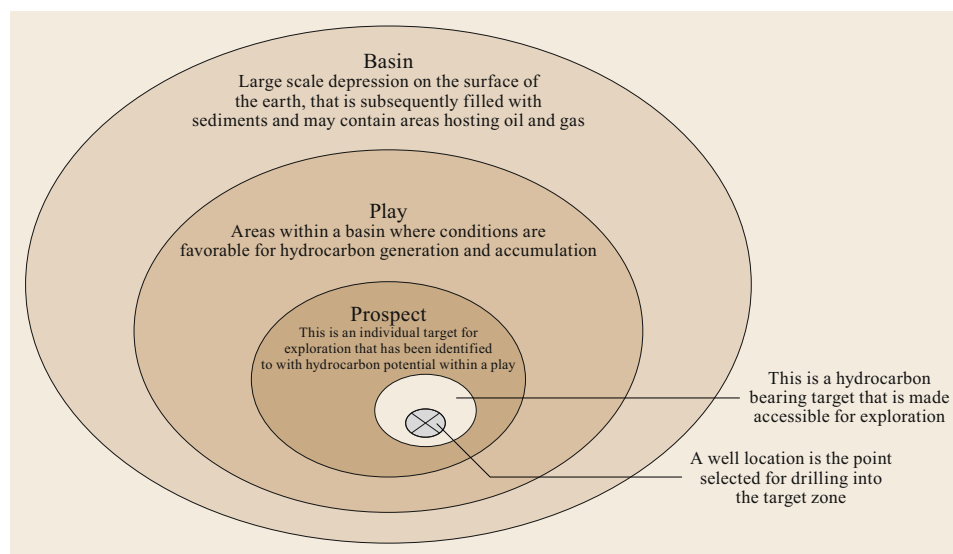

Fig. 9.31 Relationship between the scales of exploration. The basin scale is a largest scale, which progressively narrows to the well location, the smallest scale in this hierarchy

vents the well from collapsing. The outside diameters of casing pipe range from 4.5 to 16 in (114–406 mm). Cementing is a key step. In a good cement job, the entire space between the casing and the well bore is filled with cement. Centralizers keep the casing from resting against the well bore, which could block the flow of cement, resulting in a poor cement job and increasing the risk of a blowout.

After cementing, perforation guns punch small holes through the casing into the reservoir rock, providing a path for the flow of oil and gas into the well. In open-hole completion, the last section of the well is uncased. Instead, the installation of a gravel pack stabilizes the casing and allows fluids to enter the well at the bottom. After perforation, special acid-containing fluids are pumped into the well to increase porosity and stimulate production. Usually, a smaller diameter tube is inserted into the casing above the production zone and packed into place. This provides an additional barrier to HC leaks, raises the velocity at which oil flows under a given pressure, and shields the outer casing from corrosive well fluids.

Drilling and producing a well is the ultimate way to explore for petroleum. But they are the most expensive. If the well is successful, then oil will be produced and additional information is collected and analyzed to maximize oil recovery. If the well is unsuccessful, data

are collected and the well is plugged and abandoned. Unsuccessful wells may have no petroleum present in the reservoir, or contain petroleum but not in economic quantities.

During exploration, several steps lead up to the decision on the exact location where a well will be drilled. Before exploration, funding has to be arranged, and the land or lease has to be acquired. This involves understanding the rules and regulations that apply to each country or state. Contracts, staffing, and pricing, are all important arrangements prior to engaging in the drilling exercise. Once the preliminaries have been taken care of, the drill site is selected and a location picked, based on prior interpretations and studies. A surveyor is called to mark the exact location and collect elevation data. A site map is generated and the area is cleared, leveled where needed, and pits for muds and water are prepared before the drilling rig and equipment are put in place [9.24, 25].

Before modern day rotary drilling rigs, wells were drilled using various techniques including digging using picks, spades, shovels, etc., punching holes in the ground using large chisel-shaped devices, or with heavy duty ground-moving equipment, as in the strip mining of oil sands. Cable tool drilling is still used in specialized situations today, and rotary drilling is the most used drilling technique today.

Fig. 9.32 Components of a typical drilling operation

The three ways of drilling wells are vertical drilling, deviated drilling, and horizontal drilling. During drilling, well completion begins and continues to the end of the project. The basic elements of well completion are casing and tubing, well head infrastructure, lifting, and well stimulation and/or treatment. Well casings are heavy metal pipes used to maintain the integrity of the hole and add strength to the sides of the hole, prevents seeps into and out of the hole, control and prevent blowouts, and isolate the hole from the groundwater system. The type of casing used depends on subsurface conditions. When drilling is complete and the well is declared successful, then completion in a stricter sense is carried out.

Completion is the process of finishing a well so that it is ready to produce petroleum. Several different types of completion techniques exist. They depend on whether or not casings are used in the producing zone, how the casings are made, and how many producing intervals are under consideration. Wells that are completed with no casing are open-hole completion wells and those that have casing are cased-hole completion wells. Several different types of completion techniques exist but the common method is the conventional perforated completion. The use of any completion method depends on the characteristics of the formations along the borehole, and the location and number of producible zones in the well. The last step of well completion is to install the well head which comprises the casing head, tubing head that is attached to the casing and production tubing, and the Christmas tree or lifting device if the well needs lifting.

9.6 Future for Petroleum

Quantifying HC reserves is a complex process that requires the use of approximations, extrapolations, and probabilistic analysis to various extents. It is also true that sociopolitical and economic considerations directly or indirectly filter into estimates of petroleum reserves. Results can depend on who does the calculations and why they do it.

The amount of petroleum still available on Earth is debatable. Most of the world's sedimentary basins have been identified, and estimates of reserves in these basins have been assessed. Large amounts of petroleum have already been produced from easily accessible reservoirs. The United States Geological Survey (USGS) [9.26] and other organizations and institutions like the International Energy Agency [9.27] provide assessments of the world petroleum resources.

Lifting Stimulation and Treatment

Lifting is the process of mechanically pumping or sucking oil or gas out of the well using artificial equipment. Different lifting techniques are used depending on the properties in the reservoir. Such techniques may include sucker rod pumps, hydraulic pumps, and fluid injections etc. In some cases, before installing the lifting equipment wells may need treatment or stimulation. Well *stimulation* is an artificial or engineered method that is used to increase the flow of fluids (permeability) in reservoirs drilled for oil. Some methods of stimulating a well include fracturing, acidizing, and an old technique called shooting. Well *treatment* involves adding chemical substances to reservoirs to increase the recovery of oil and minimize water. An example of a well treatment is the polymer treatment.

Before, during, and after production, wells can be tested and surveyed for different characteristics. Most formation tests are designed to provide information about fluid flow, pressure, oil-to-gas ratios, etc. For example, a drill stem test provides information about pressure conditions in a producing reservoir. Oil produced from successful wells is pumped into storage tanks or other holding facilities from which it is transported to refineries. Moving oil from the well head involves a network of flow lines, pipelines, trucks, and rail. Raw oil is first separated in the field in a separator tank in which the fluids are allowed to separate naturally by gravity. Water and heavy particulates sink to the bottom, oil floats on the water and gas is at the top. The oil is piped out and held in storage tanks for commercialization.

In the last couple of decades, the price of a barrel of crude oil has generally increased, making previously noneconomical petroleum resources like oil shale into valuable reserves. The continuing increase in petroleum reserves can be attributed to the improved exploration skills and technological development in computation, extraction and mapping.

It is undeniable that petroleum and its derivatives provide some of the greatest benefits in quality of life in society today. However, it is fully accepted that the problems associated with production, processing, distribution, and use of petroleum are unquestionable. Consumption of petroleum products continues to increase and it is debated whether this consumption is too much, too fast, and sustainable. Most scientists agree that petroleum is a finite, nonrenewable resource, but that it may continue to be available for several gener-

ations. The urgent question today is whether we have reached peak oil production. Although there is no con-

sensus on peak oil, the only certainty is that we will eventually reach peak oil if it is not yet the case.

Origin of Petroleum

10. Origin of Petroleum

Clifford C. Walters

Theories concerning the origin of oil on Earth fall into two camps: *biogenic*, where oil is generated by the thermal conversion of sedimentary organic matter derived from living organisms, and *abiogenic*, where oil is formed from mineral catalyzed reactions of nonbiological carbon deep within the Earth. Most geochemists believe that there are multiple and overwhelming lines of evidence supporting biogenic origins for petroleum. While there are known occurrences of abiogenic methane generated by geologic processes, these contribute little to petroleum resources. Economic reserves require all specific elements and processes occur within a sedimentary basin. The *Petroleum System* must contain: (1) at least one formation of organic-rich sediments (source rock) that has been buried to a sufficient depth by overburden rock such that petroleum is generated and expelled, (2) pathways (permeable strata and faults) that allow the petroleum to migrate, (3) reservoir rocks with sufficient porosity and permeability to accumulate economically significant quantities of petroleum, and (4) seal rock (low permeability) and structures that retain migrated petroleum within the reservoir rock. In the case of many unconventional resources, the source rock itself serves as source, reservoir, and seal.

Petroleum, composed of hydrocarbons and heteroatomic molecules, is the most complex mixture occurring in nature. The composition of petroleum generated within its source rock is influenced by the type of organisms that contributed organic matter, the environment of deposition, and thermal exposure. Most of the deposited biomolecules are chemically altered, broken apart,

and reassembled into an insoluble carbonaceous material termed *kerogen*. Upon burial and heating, the kerogen reacts producing mostly compounds that have lost their biochemical signature; however, some of these generated molecules, termed *biomarkers*, preserve enough of their chemical structure that their original biological precursor can be identified. Expulsion from the source rock chemically fractionates the generated petroleum, with the expelled product enriched in gases and hydrocarbons, and retained bitumen enriched in heteroatomic polar species and asphaltenes. Petroleum composition can be further altered as it migrates and resides in reservoir rocks by physical, chemical, and biological processes. Collectively, these processes result in petroleum accumulations with a diverse range of compositions and physical properties.

10.1 Historic Overview

Man has used petroleum since Biblical time as a fuel, sealant, adhesive, construction material, or in medicinal and military purposes [10.1]. The earliest documented use of the term *petroleum*, derived from Latin *petra*+*oleum* or *rock-oil*, is by Constantinus Africanus (c. 1020–1087) [10.2]. Classical literature, however, is devoid of insight on the origin of oil and bitumen. Two theories on petroleum emerged during the Renaissance. In his 1546 text *De Natura eorum quae Effluunt ex Terra*, Georgius Agricola, a German physician, expanded on the Aristolian concept of exhalations from deep within the Earth [10.3] and proposed that bitumen, like other minerals, condensed from sulfur. Andreas Libavius, another German physician, theorized in his 1597 text *Alchemia* that bitumen formed from the resins of ancient trees. These early discussions mark the beginnings of one of the longest running scientific debates: whether petroleum is formed by abiogenic processes that occur deep within the Earth, or from sedimentary organic matter that was once living organisms.

As fossil evidence emerged during the eighteenth century that coals were derived from plant remains, many scientists proposed similar origins to explain petroleum. The historic record is somewhat questionable, but Mikhailo Lomonosov is credited by some to have proposed the theory that liquid oil and solid bitumen originate from coal through underground heat and pressure as early as 1757 [10.4] and certainly by 1763 [10.5]. Various biogenic theories emerged during the early nineteenth century suggesting that petroleum was derived directly from biological remains or through a distillation process [10.6].

Modern theories that petroleum originated from ancient sedimentary, organic-rich rocks emerged during the nineteenth century. T.S. Hunt of the Canadian Geological Survey concluded in 1863 that the organic matter in some North American Paleozoic rocks must be derived from marine vegetation or marine animals, and that the transformation of this organic matter to bitumen must be similar to the processes involved in coal formation [10.7]. *Leo Lesquereux*, the American father of paleobotany, reached similar conclusions after studying Devonian shales in Pennsylvania [10.8], as did *Newberry* in his study of Devonian shales in Ohio [10.9]. Early twentieth century field [10.10] and chemical [10.11] studies of the Monterey Formation by the US Geological Survey provided convincing evidence that oil was derived from diatoms in the organic-rich shales. Similar studies of organic-rich shales conducted in Europe during this time arrived at the same conclusion for the origin of associated oil [10.12, 13].

Full ascendancy of the biogenic hypothesis began in the mid-twentieth century with a convergence of scientific advances in paleontology, geology, and chemistry. In 1936, *Alfred Treibs* established a link between chlorophyll in living organisms and porphyrins in petroleum [10.14]. Additional geochemical evidence followed with the discoveries that low to moderate maturity oils still retained hydrocarbon fractions with optical activity [10.15], that the stable isotopes of carbon of petroleum bear a biological fractionation [10.16], and that oils contain in addition to porphyrins, a host of hydrocarbons that can be traced back to specific biological precursors [10.17]. Concurrent with these findings were field studies recognizing that organic-rich strata occur in all petroliferous sedimentary basins, that this sedimentary organic matter (kerogen) is derived from biota, that it has been chemically altered from its initial state [10.18, 19] and, that oil and gas is produced from kerogen as the sediments are buried and heated [10.20].

Although there is overwhelming evidence for a biogenic origin [10.21, 22], some still advocate abiotic theories. The development of the modern abiogenic concept is rooted in the mid-nineteenth century. The prolific French chemist *Marcelin-Pierre Berthelot* described in 1860 experiments where *n*-alkanes formed during the acid dissolution of steel [10.23]. *Dmitri Mendeleev* reasoned in 1877 that surface waters could percolate deep within the Earth, react with metallic carbides forming acetylene that could then condense further into larger hydrocarbons [10.24]. *Mendeleev's* abiotic theory, further refined in 1902 [10.25], was viewed initially as particularly attractive as it offered an explanation for the growing awareness of the widespread occurrence of petroleum deposits that suggested some sort of deep, global process.

Advocates of an abiotic origin for petroleum dwindled under the mounting evidence for a biogenic origin of petroleum. By the 1960s, there was little support for an abiotic origin, except among a small group within the Former Soviet Union. First proposed in 1951 by *Nikolai Kudryavtsev* [10.26] and advanced over the years in numerous Soviet publications, a modernized version of *Mendeleev's* hypothesis emerged. This theory relies on a thermodynamic argument, which states that hydrocarbons greater than methane cannot form spontaneously except at the high temperatures and pressures at the lowermost crustal depths. The theory ignores the fact that all of life relies on being in thermodynamic disequilibrium with its environment.

In the West, astronomers have been the most vocal advocates for abiotic petroleum. Carbonaceous chon-

drites and other planetary bodies, such as asteroids, comets, and the moons and atmospheres of the Jovian planets, certainly contain hydrocarbons and other organic compounds that were generated by abiotic processes [10.27]. *Sir Fredrick Hoyle* reasoned in 1955 that as the Earth was formed from similar materials, there should be vast amounts of abiogenic oil [10.28]. In more recent years, *Thomas Gold* was the strongest promoter for abiogenic petroleum [10.29, 30]. Against the advice of nearly all geochemists and petroleum geologists, Gold convinced the Swedish government to drill two deep wells (Gravberg 1 in 1986–1990 and Stenberg 1 in 1991–1992) into fractured granite under the Siljan ring, the site of an ancient meteorite crater. The wells failed to find economic reserves and evidence for

even trace amounts of abiogenic hydrocarbons is controversial [10.31].

Geochemists favoring biogenic origins for petroleum do not deny the existence of abiogenic hydrocarbons on the Earth [10.32]. Small amounts of abiogenic hydrocarbon gases are known to be generated by rock–water interactions involving serpentinization of ultramafic rocks [10.33, 34], the thermal decomposition of siderite in the presence of water [10.35], and during magma cooling as a result of Fischer–Tropsch-type reactions [10.36, 37]. However, the contribution of abiogenic hydrocarbons to the global crustal carbon budget is considered to be inconsequential [10.38]. The theory that abiogenic liquid hydrocarbon accumulations exist on Earth is considered to be invalid by most [10.39].

10.2 The Petroleum System

The accumulation of economic volumes of petroleum (oil and/or gas) in the subsurface requires that several essential geological elements and processes be present at specific time and space [10.40, 41]. *Source rocks* generate and expel petroleum when sufficient thermal energy is imparted to the sedimentary organic matter (kerogen) to break chemical bonds. This heating is usually induced by burial by *overburden rock*. Once expelled, petroleum migrates either along faults or highly permeable strata. Accumulations form only when high porosity strata (*reservoir rocks*) are charged by migrating petroleum that is prevented from further migration. These petroleum *traps* form when geologic movements result in subsurface topographies (structural) or changes in lithology (stratigraphic) block migration and when the reservoir rocks are covered by

low permeability strata (*seal rocks*). The mere presence of these geologic elements is insufficient to form petroleum reserves. Traps must be available at the time of oil expulsion and, once charged, their integrity must be preserved until exploited. These elements and processes constitute the *petroleum system* (Fig. 10.1).

As shown in Fig. 10.1, all petroleum systems contain:

1. At least one formation of organic-rich sediments that has been buried to a sufficient depth by overburden rock such that petroleum is generated and expelled.
2. Pathways (permeable strata and faults) that allow the petroleum to migrate.

Fig. 10.1 Elements of a petroleum system

3. Reservoir rocks with sufficient porosity and permeability to accumulate economically significant quantities of petroleum and
4. Seal rock (low permeability) and structures that retain migrated petroleum within the reservoir rock.

The top and bottom of the oil window is approximated as a function of burial depth. In actual basins, these depths are not uniform and vary as a function of organic matter type, regional heat flow from basement, in thermal conductivity of the different lithologies, and burial history (e.g., deposition rates, uplift, erosion, and hiatus events).

A rigorous discussion of the origin of petroleum should encompass all of the interrelated elements of

the petroleum system. Such a discourse is beyond the scope of this review, which will focus only on the deposition of organic-rich strata and the generation of petroleum from these sources. The reader is referred to *Exploring for Oil and Gas Traps*, a publication of the American Association of Petroleum Geologists, for a complete discussion of all aspects involved with defining the petroleum system for effective exploration [10.42]. Books by *Tissot and Welte* [10.43] and *Hunt* [10.44] provide detailed discussions of the principles of petroleum geochemistry, and a publication by *Peters and Fowler* [10.45] is an excellent review of the application of modern geochemical techniques to exploration and production practices.

10.3 Deposition of Organic-Rich Sedimentary Rocks

Petroleum *source rocks* are water-deposited sedimentary rocks that contain sufficient amounts of organic matter to generate oil and/or gas when heated. The generated petroleum may be retained or expelled within the source rock matrix. Such organic-rich strata were deposited throughout Earth's history, in nearly all geologic environments, and in most sedimentary basins. Source rocks, however, typically represent only a minor amount of basinal strata and are formed only when specific conditions exist.

Three general factors control the deposition of organic-rich sediments: productivity, dilution, and preservation (Fig. 10.2) [10.46–48]. Biological productivity determines the amount of organic matter that is contributed to sediments. Dilution refers to the amount of inorganic minerals that mixes with the organic matter. Once deposited, the organic matter must be preserved in a form that may later generate petroleum. There was once an active debate as to which factor was the most important in forming organic-rich sediments [10.49]. It is now recognized that these three factors are interrelated in a highly complex, and variable manner.

Photosynthetic organisms, which include aerobic cyanobacteria, algae, phytoplankton, land plants, and some anaerobic bacteria, provide most of the initial organic matter by fixing CO₂ into biomass. The contribution of organic matter by nonphotosynthetic chemotrophs is minor, except in some unusual environments, such as the deep-sea hydrothermal vents. Most of the nonphotosynthetic biosystems, such as methanotropic communities [10.50], rely on recycled carbon that was fixed originally by photosynthetic organisms. Many factors moderate the biota and the primary pro-

ductivity (e.g., such as nutrient input from rivers and coastal upwellings, pCO₂, temperature, and turbidity) that are influenced by global climatic and tectonic conditions. Figure 10.3 shows generalized redox cycle for organic carbon.

Production of new organic matter by the photosynthetic fixation of CO₂ (primary productivity) can occur with (aerobic) or without oxygen (anaerobic) as a byproduct. Respiration and other processes result in the nearly complete oxidation of organic matter back to CO₂. A small amount of the organic matter in sediments escapes biological recycling and is preserved in rocks. Eventually, this carbon is recycled to the surface as CO₂ by geologic processes, such as subduction and venting, erosion and weathering, and more recently, by the combustion of fossil fuels.

Much of the primary organic matter created by photosynthetic or chemosynthetic autotrophs undergoes degradation by other organisms during the secondary production of organic matter. Heterotrophic organisms in the water column, sediments, and rock continually degrade and rework primary aquatic and terrigenous organic matter (Fig. 10.3). Aerobic respiration is very rapid and efficient and primary organic matter may pass through a chain of water and mud dwelling animals, protozoa, and bacteria, until fully consumed and returned to the atmosphere/hydrosphere as CO₂. Anaerobic microbes also degrade organic matter either by fermentation or respiration using terminal electron acceptors other than O₂ (e.g., nitrate, sulfate, iron). These microbial metabolisms are generally slower and may be curtailed by limited nutrients and electron acceptors within the sediment porewaters. Consequently, some of sedimentary organic matter, both from primary and

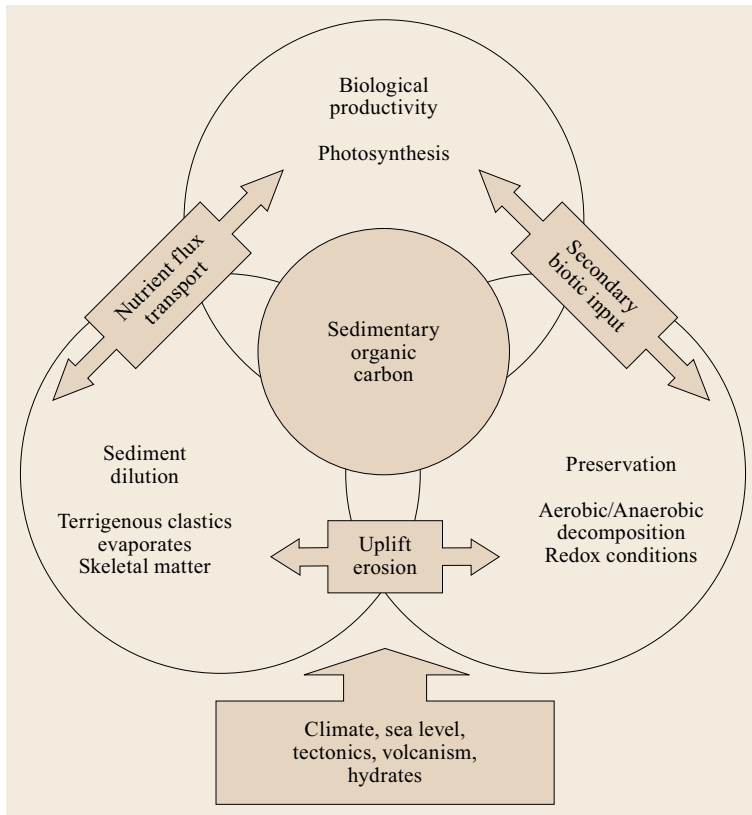

Fig. 10.2 Three major factors, primary productivity, preservation, and dilution, determine if organic-rich source rocks are deposited

secondary biogenic sources, may escape recycling and become preserved in lithified rock. Hence, anoxic conditions enhance the preservation of oil-prone organic matter and promote the deposition of potential source rocks (Fig. 10.4).

As shown in Fig. 10.4, oxic (a) and anoxic (b) depositional environments generally result in poor and good preservation of deposited organic matter, respectively [10.51]. The solid horizontal line separates oxic (above) from anoxic (below). In oxic settings, bottom dwelling metazoa bioturbate the sediments and oxidize most organic matter. In anoxic settings, especially where the oxic–anoxic boundary occurs in the water column, bottom-dwelling metazoa are absent and sediments are not bioturbated.

The amount of oxygen in bottom waters or sediments is determined by the rate of influx from the photic zone (via circulation and/or diffusion) and its rate of consumption (biological oxygen demand). Topographical barriers, currents, or water stratification due to temperature and salinity gradients may limit water circulation and diffusion. A high supply of primary organic matter raises the biological oxygen demand, rendering pore waters, and even the lower water column, anoxic. This mechanism is seen in terrigenous

environments with high input of land-plant material (e.g., swamps, and coastal plains), and in lake and marine environments with high nutrient influx (e.g., seasonal rains and stagnant water columns, and upwelling zones).

In anoxic marine environments, the most prevalent organisms are sulfate-reducing bacteria that produce H_2S . If not precipitated as pyrite by iron from clays and other clastic minerals, H_2S may react with organic matter, incorporating sulfur. If the production of H_2S is greater than the rate of sequestering, *euxinic* conditions (waters with free H_2S) occur. The transition between oxic and euxinic waters may occur within the sediments or water column. Some strata with excellent source potential were deposited where euxinic conditions extended into the photic zone [10.52]. Anoxia also occurs in hypersaline environments, such as playa lakes, lagoons, and restricted marine settings.

Sedimentation rate influences both the preservation and concentration of organic matter. The inorganic materials may be clastic (eroded clays and sands), chemical precipitates (carbonates, salts), or biogenic (siliceous and carbonate shells). Organic matter may be removed from biological recycling by rapid burial, such

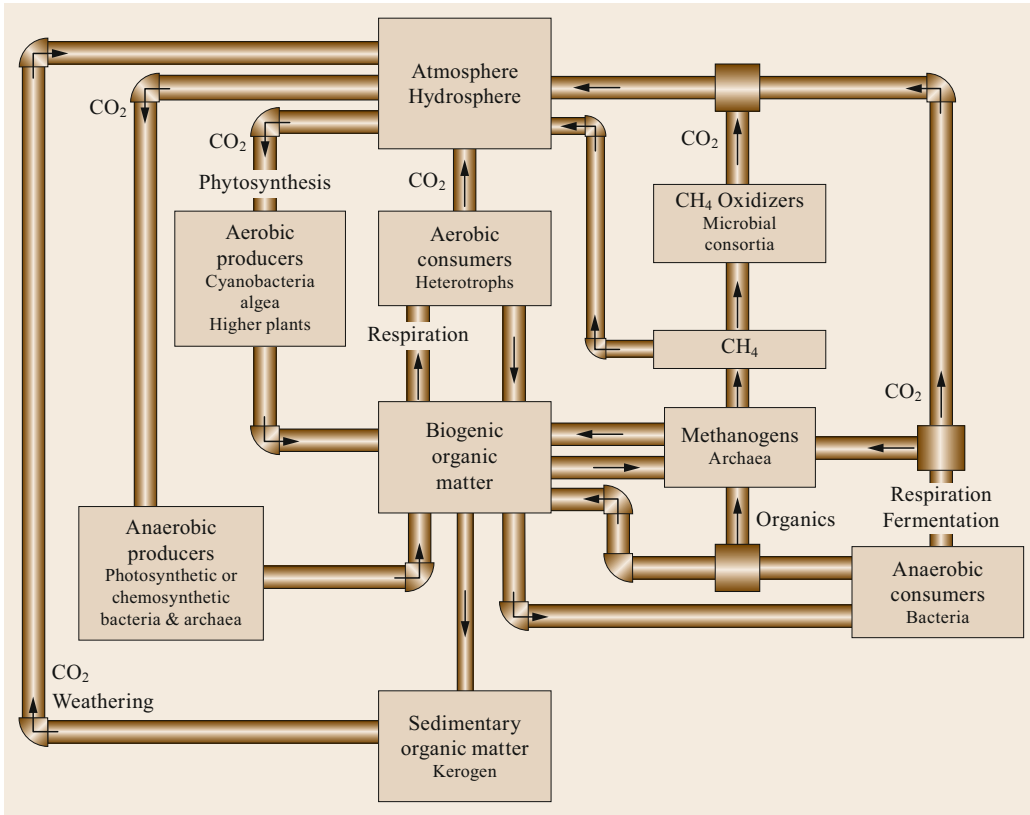

Fig. 10.3 Generalized redox cycle for organic carbon

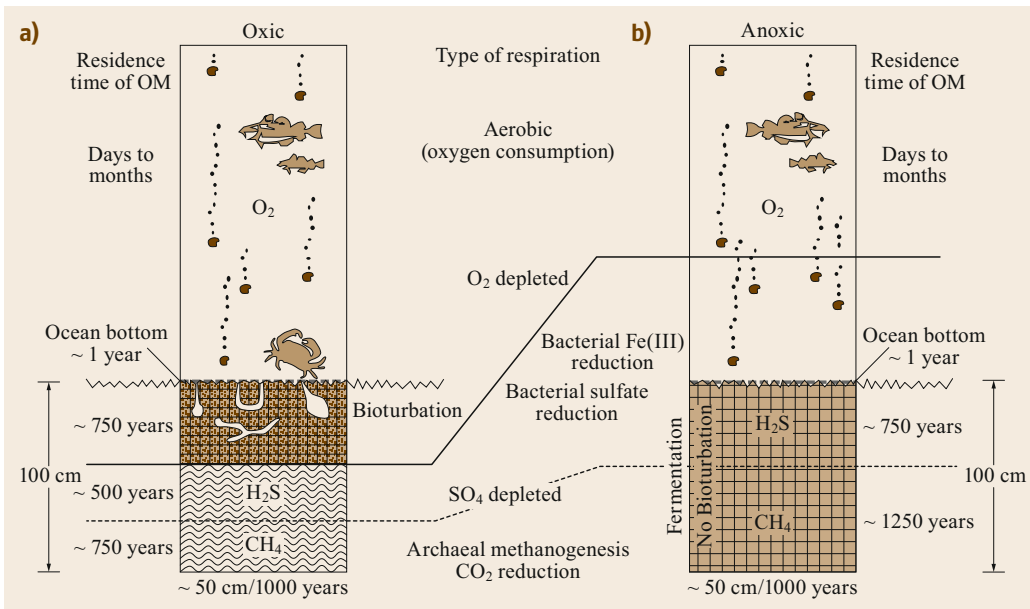

Fig. 10.4a,b Oxic (a) and anoxic (b) depositional environments

as in deltaic settings. However, preservation can be offset by dilution and the resulting rocks may be relatively low in organic carbon. This is why most deltaic shales do not exceed 4–5 wt% total organic carbon (TOC). Similarly, sediments resulting from high primary productivity, such as diatomaceous cherts, may have an

upper limit in organic carbon because of high autodilution. In general, sedimentary rocks with the highest concentrations of organic matter are deposited under conditions of moderate to high influx of primary organic matter, anoxic (possibly euxinic) bottom waters, and low sedimentation rates.

10.4 Kerogen Formation and the Generative Potential of Source Rocks

Although derived from biochemicals, the sedimentary organic matter in source rock is markedly different in chemical composition. Living organisms are composed mostly of proteins, carbohydrates, nucleic acids, and lipids. Structural materials, such as lignin and cellulose, and various resins are fairly well-defined biopolymers composed of a limited number of monomers. With the exception of some halophilic green algae and a few bacteria [10.53], only trace amounts of hydrocarbons are produced directly as biomass by most living organisms. In contrast, immature sedimentary rocks contain only low concentrations of the functionalized biomolecules. Most of the organic carbon is bound in a condensed, insoluble macromolecular material, termed kerogen, which has comparatively few functional groups. Kerogen has been called a *geopolymer* but this is a misnomer, as the term implies that there is a repetition of distinct monomers and some structural order. Kerogen has no unique molecular structure and can only be defined in terms of bulk elemental composition and average molecular distributions.

Optically, kerogen is often described as mixtures of amorphous organic matter and *macerals*, morphologically distinct particles from various organisms. Much of the terminology describing macerals is from organic petrography of coals where the macerals are mostly derived from land plants. The amorphous matter was once thought to be derived from the complete breakdown of biological macromolecules that then reassembled in a random fashion with low molecular-weight biomolecules (e.g., lipids) [10.55]. We now realize that there are biological macromolecules that are alkyl rich and resist microbial recycling [10.54]. These bio-macromolecules (e.g., cutan, sporopollenin, tannins, and algaenan) may constitute only a small fraction of the initial biomass, but are selectively preserved and enriched during early diagenesis (Fig. 10.5). They provide a core for the incorporation of functionalized low molecular-weight biomolecules, such as membrane lipids and the breakdown products of less resistant bio-macromolecules. A small fraction of this material may

remain soluble, which along with biogenic hydrocarbons and lipids that resist incorporation, becomes the bitumen that can be extracted from immature source rocks using organic solvents.

Kerogen formation begins at the point when living cells die and their biomolecules are exposed to the geologic environment. Microbial processes are mostly responsible for the breakdown of biological macromolecules and the recycling of lower molecular-weight biomolecules, resulting in the selective preservation of the more bio-resistant compounds. Low-temperature chemical reactions further alter kerogen through the loss of functional groups (e.g., $-\text{NH}_3$, $-\text{COOH}$), sulfur incorporation, condensation, cross-linking, and aromatization. The processes and thermal regime under which kerogen forms, termed *diagenesis*, occur under mild thermal conditions ($< 80^\circ\text{C}$).

As shown in Fig. 10.6, the quantity and quality of organic matter preserved during diagenesis of sediment determines the generative potential of the source rock and whether it will be prone to expel oil or gas. Quantity is determined by amount of organic input, the degree to which it is preserved (either as primary or secondary biogenic matter), and by its dilution with inorganic mineral matter. Typical oil-prone, marine source rocks contain 2–5 wt% TOC, but strata in the range of 10–20% are known to occur in high yield petroleum systems. Basins with world class reservoirs may contain source units with appreciably higher amounts of carbon. Expulsion of oil may be difficult from rocks with < 1 –2% TOC. Oil shales, many of which are lake deposits, contain over 10% TOC. Coals are $> 80\%$ TOC, and may be diluted by varying amounts of clastic minerals to yield coaly shales with a wide range of carbon content.

The hydrogen content of kerogen influences the quality of the expelled hydrocarbons (during metagenesis). Kerogens with high H/C ratios tend to generate oil, while those with low H/C ratios tend to generate gas. The hydrogen index (HI) is based on the Rock-Eval measurement. This pyrolysis method, commonly used by petroleum geochemists to rapidly screen rocks

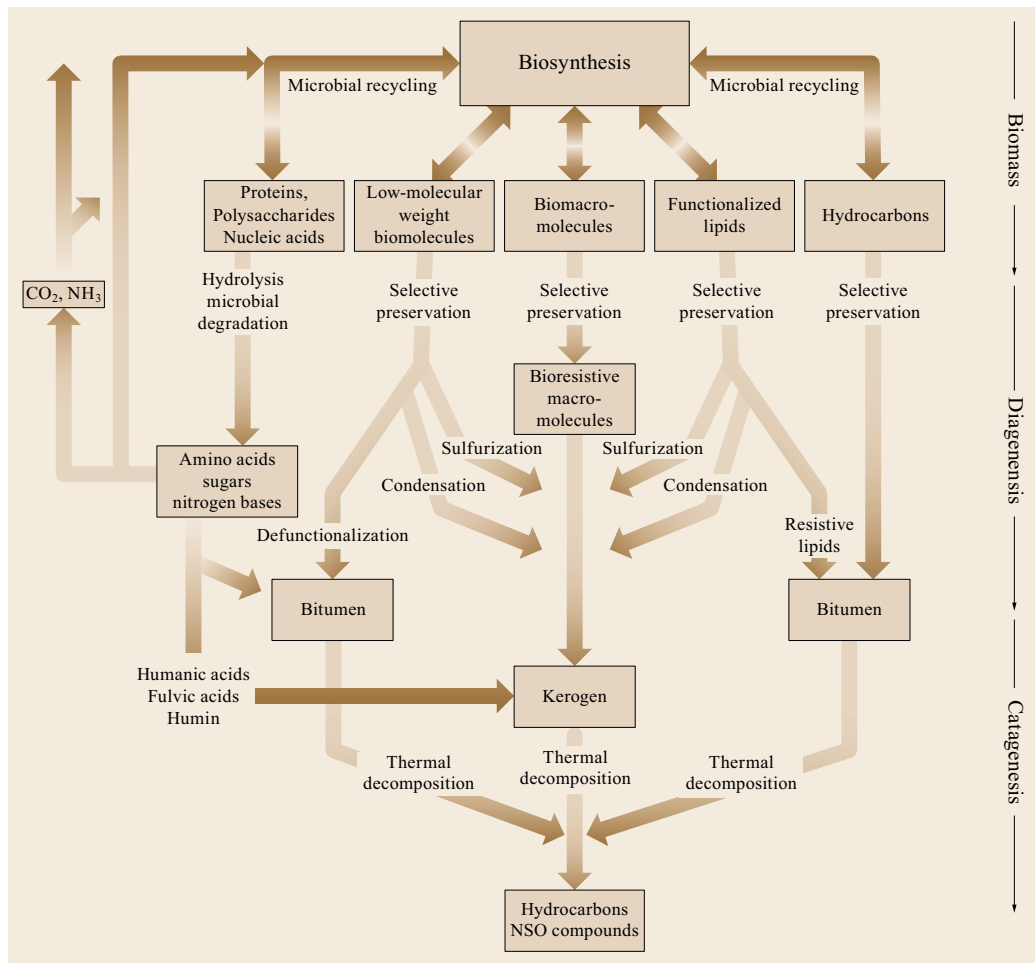

Fig. 10.5 Kerogen is formed during diagenesis by the selective preservation of bio-resistive macromolecules and from the incorporation of lower-molecular weight species (after [10.54])

for their generative potential, heats a ground sample and measures the pyrolyzate response using a flame ionization detector and the CO_2 response using an infrared detector [10.56]. These responses can be calibrated to a rough approximation of the kerogen H/C and O/C atomic ratios.

Kerogen quality is mainly a function of hydrogen content – kerogens with high H/C ratios (> 1.2) are oil prone, while those with lower H/C ratios (0.5–0.8) tend to generate mostly hydrocarbon gas. Biogenic input of organic matter and the manner of its preservation determine the hydrogen content of kerogen. Some algae and bacteria are extremely rich in membrane lipids and aliphatic biopolymers, such as algaenan. Sediments that receive this input have the potential to be hydrogen rich (kerogen H/C > 1.5). Conversely, land-plant lignins have low H/C ratios and sediments that received

only this input are hydrogen poor (kerogen H/C ratios < 1.0). The hydrogen, sulfur, and oxygen content of kerogen can be modified greatly during deposition and diagenesis. Oxidic conditions favor rapid and fairly complete heterotrophic consumption of primary organic matter. The organic matter remaining in the sediments tends to be oxidized or inert. Anoxic conditions conserve, or even enhance, the initial H/C ratio of the primary organic matter via selective preservation and/or contributions from secondary biota. Euxinic conditions promote the incorporation of sulfur, resulting in high S/C ratios [10.57].

There are many schemes that attempt to classify kerogen types by their morphology, maceral, and palynological assemblages, and/or bulk chemical composition. The most widely used is a modification of a method developed for coals [10.58], whereby the H/C

Fig. 10.6 The quantity and quality of kerogen determine the generative potential of source rock

Table 10.1 Kerogen types, their occurrence and bulk chemistry (at end of diagenesis)

Type	Depositional setting	Primary biotic input	H/C	O/C	S/C
I	Lakes, restricted lagoons	Green algae Cyanobacteria Dinoflagellates	> 1.4	< 0.1	< 0.02
IS	Lakes with a source of sulfate (rare)	Green algae Cyanobacteria	> 1.4	< 0.1	> 0.04
II	Marine shales	Marine algae, phytoplankton	1.2–1.4	~ 0.1	0.02–0.04
IIS	Marine carbonates, evaporites, silicates	Marine algae, phytoplankton	1.2–1.4	~ 0.1	> 0.04
III	Coals, coaly shales, deltas	Vascular land plants	0.7–1.0	> 0.1	< 0.02 ^a
IIIC	Coastal plains (oil-prone coals)	Vascular land plants, algae	1.0–1.2	> 0.1	< 0.02 ^a
IV	Inert carbon due to oxidation or advanced maturity	All possible	< 0.5	< 0.15	< 0.02 ^b

^a Coals generally are low in sulfur. Depositional settings with marine influence may result in coals with S/C > 0.02.

^b Some inert pyrobitumens may have higher S/C ratios as a result of secondary sulfur incorporation.

and O/C ratios are plotted (Fig. 10.7). Kerogens are assigned designations as being Type I, II, III, or IV depending where they fall on the plot. Type I and II are oil-prone, Type III is gas-prone, and Type IV is inert carbon. A substantial portion of the oxygen content is lost during diagenesis. Oil generation occurs during catagenesis, whereby the H/C ratios of the residual kerogens decrease. When the H/C ratio is < 0.5, the residual kerogens are capable of generating only methane.

This classification scheme can be subdivided further by considering the variation in sulfur content (Table 10.1). Since the incorporation of sulfur into sedimentary organic matter involves H₂S generated by sulfate reducing bacteria, kerogens with high S/C ratios (0.04 to > 0.10) are found mostly in marine (nonclastic) rocks where euxinic conditions prevail. Type I kerogens are deposited typically in continental lakes, which have no contact with marine waters and lack a ready supply of sulfate. Consequently, sulfur-rich Type IS kero-

Fig. 10.7 van Krevelen-type diagram showing the distribution of kerogen types and some of their precursor macerals

gens arise only in unusual geologic settings where older evaporite beds (e.g., gypsum or anhydrite) are exposed and dissolved into normally fresh lake water [10.59, 60].

Type II kerogens are deposited primarily in marine settings dominated by photosynthetic organisms. During early diagenesis, this organic matter may react with H_2S produced by sulfate-reducing bacteria that thrive in marine, anoxic waters, and sediments. H_2S also reacts with iron and other metals, forming inorganic sulfides. Consequently, marine Type II kerogens may have varying sulfur content. Marine shales and mudstones, which contain iron oxides and iron-rich clays, yield low-sulfur Type II kerogens and pyrite. Carbonate, evaporite, and chert deposits, which are iron poor, commonly yield high-sulfur Type IIS kerogens.

Type III kerogens form in swamps and coastal plains. As these depositional environments may or may not have marine influence, the sulfur content of coals can vary, but is generally low. Type III kerogens are frequently allochthonous; that is, they are transported by fluvial systems into delta and nearshore marine sediments where they may mix with locally produced (autochthonous) Type II kerogens. Most Type III kerogens are dominated by vitrinite, a land-plant maceral that has a low H/C ratio and is gas-prone. Some coals, however, contain oil-prone materials (Type IIIC) that are derived from associated algae or from the selective preservation of cutinous macromolecules. Many oils from Southeast Asia are generated from Tertiary coaly shales that contain this type of kerogen.

10.5 Generation and Expulsion of Oil and Gas

During *catagenesis*, kerogen thermally cracks and produces bitumen. Weak C–S and C–O bonds break preferentially during the early stages of catagenesis producing bitumen that is highly enriched in polar (NSO) compounds. With additional heating (≈ 90 – 140°C), C–C bonds break within the evolved polar compounds and from residual kerogen, yielding a hydrocarbon-rich fluid that is then expelled from the source rock mineral matrix. With additional thermal stress, kerogen yields primarily condensate and then wet gas (C_1 – C_6). Catagenesis is complete when the kerogen has expended its capacity to generate C_{2+} hydrocarbons (≈ 150 – 175°C). *Metagenesis* may then take place under still more severe thermal alteration, where only methane is produced as methyl-groups are cleavage from highly condensed, aromatic structures.

Oil generation is a kinetic process – both time and temperature are critical [10.61]. The kinetic parameters of kerogen decomposition can be determined by artificially heating immature source rocks using relatively fast heating rates (≈ 300 – 550°C at ≈ 1 – $50^\circ\text{C}/\text{min}$) or lower isothermal temperatures (275 – 350°C for sev-

eral days) and measuring either product yield or the residual generative potential. Data fit to kinetic models defined by a series of parallel first-order reactions, usually at a single frequency factor. When geologic heating rates are applied (≈ 1 – $10^\circ\text{C}/\text{Ma}$), the derived kinetic models yield kerogen maturation results comparable to what is observed in petroliferous basins [10.62, 63]. More advanced models describe the fluid composition of the expelled products and include secondary cracking reactions (Fig. 10.8).

The rate of kerogen conversion is assumed to follow a series of parallel first-order kinetic reactions defined by the Arrhenius equation, $k = Ae^{-(E/RT)}$, where k is the rate coefficient, A is a constant termed the frequency factor, E is the activation energy, R is the universal gas constant, and T is the temperature. The kerogen model was derived by fitting the yield curves of pyrolyzates that evolved from a marine shale source rock containing Type II kerogen heated at several different heating rates under anhydrous conditions. In this case, the frequency factor was fixed at $A = 10^{14} \text{ s}^{-1}$. The evolved products are predicted from a more advanced model

Fig. 10.8 Example of a kerogen decomposition kinetic model with predictions of expelled fluid composition

that accounts for expulsion and secondary cracking of retained bitumen and residual kerogen.

Although simple thermogenesis adequately describes petroleum generation, geocatalysis involving reactive mineral surfaces, clays, trace metals, or organic species has been proposed [10.64, 65]. Such processes are highly speculative, and it is difficult to image how inorganic agents would remain activated under subsurface conditions or how mass transport limitations inherent in solid–solid interactions could be circumvented [10.66].

Once generated from the kerogen, petroleum is expelled into mineral pore spaces (primary migration) and then through permeable rock and faults to the trap (secondary migration). Oil expelled from source rock is enriched in saturated and aromatic hydrocarbons relative to the bitumen that remains (Fig. 10.9). The factors that control primary expulsion and bitumen fractionation are largely unknown; and, although there is generally a lack of experimental or observational evidence for the underlying mechanisms, there is no shortage of hypotheses. Expulsion models that attempt to account for these chemical differences generally assume rate-limiting processes occur during the release of generated hydrocarbons from the kerogen or the movement of hydrocarbons within the mineral matrix.

Hypotheses based on kerogen–oil interaction postulate that the expulsion of oil is controlled by absorption or adsorption of the products onto the surface of the kerogen [10.67–69], diffusion of the hydrocarbons through the kerogen [10.70–73], and/or relative solubility [10.74]. These hypotheses attribute little importance to movement of petroleum within the source rock mineral matrix and the efficiency of the release of oil is controlled primarily by the amount of organic carbon and its composition (see [10.69] and references therein). Expulsion models based on interactions of generated products with the source kerogen have gained favor in recent years as they have the potential to account for compositional differences between bitumens and expelled oil and for expulsion efficiencies that depend on kerogen type and richness. This thinking can be traced to observations made on source rocks [10.75] and recognition of the absorptive capacity of solid organic matter as revealed by solvent swelling experiments [10.76–79]. It is now clear that Type I and II kerogens and Type III and IIIC coals have sufficient sorptive properties to explain residual oil concentrations in mature source rocks.

There are many expulsion models that target chemical or physical processes of oil moving within the source rock mineral matrix as the rate determining step.

Fig. 10.9 Comparison of C_{15+} chemical group type distributions of expelled oil and retained bitumens for typical Type II (marine shale) and Type IIS (carbonate) source rocks (middle of the oil window)

Different aspects have been considered to be important in this movement. Some consider the amount and type of organic matter as being critical to generating sufficient bitumen to exceed a pore saturation threshold [10.80–82]. Others postulate that the establishment of effective and continuous migration pathways within the source rocks is critical [10.83–85].

Other factors suggested to be key elements in expulsion are: pressure build-up from generation and compaction and the failure of the rock fabric result-

ing in micro-fracturing [10.86], gas availability, and movement of oil in a gas or supercritical phase [10.87, 88], or movement of oil in an aqueous phase [10.89, 90]. For the most part, the conditions that determine these elements are controlled by the primary sedimentological conditions in the depositional environment of the source rock and secondary diagenetic processes. Consequently, the mechanisms that define oil movement differ according to the lithofacies of the source rock.

10.6 Composition of Produced Petroleum

Petroleum may be the single most complex chemical mixture that occurs in nature. As such, our knowledge of its molecular composition has advanced as new analytical methods become available. The first compositional study is attributed to *De la Rue and Miller*, who in 1856 identified several aromatic hydrocarbons by forming and crystallizing barium salts of sulfonic acids [10.91]. This was followed by several other studies in the second half of nineteenth century that relied on distillation and wet chemical methods [10.92]. In 1927, American Petroleum Institute Research Project 6 was launched to investigate the composition of petroleum. The collaborative program, which ran until 1959, was able to isolate and identify 169 individual hydrocarbons using laborious procedures involving distillation, selective solvent extraction, selective absorption, and finally crystallization [10.93, 94]. Characterization of the crystallized isolates advanced from elemental analysis to optical and mass spectrometric measurements. Gas chromatography provided the next advance in molecular characterization. Using pack columns, *Bray and Evans* in 1961 were able to separate individual *n*-alkanes and discover that their distribution changed with increasing maturation [10.95]. The separations were barely adequate to show pristane and phytane as shoulders on the nearly co-eluting *n*-C₁₇ and *n*-C₁₈. Starting in the 1970s improving hydrocarbon separation offered by capillary columns coupled to mass spectrometry launched an explosion of hydrocarbon characterization [10.96]. Today, all major and minor C₄₀-hydrocarbon species and many of the trace components, including a host of biomarkers are relatively easily characterized [10.21].

The same cannot be said for higher molecular-weight species, particularly the polar and asphaltene compounds. Only recently has *Petroleomics* emerged as a science that is attempting to provide a comprehensive molecular description of crude oil using advances in ultrahigh resolution mass spectrometry and ionization

methods [10.97, 98]. The number of distinct species detected by these methods is continually increasing and exceeds 100 000. The resolution and sensitivity of these instruments continue to improve and the petroporphyrins, discovered by *Treibs* in 1936 [10.14], can now be shown to be present in many forms, including sulfurized species [10.99]. These new techniques allow the distributions of these petroleum compounds to be described by their molecular formulae. There is now a consensus that asphaltenes have a centroid distribution of ≈ 750 Da with a full width half maximum of 500–1000 Da. However, structural configurations still remain mostly unknown. Some consider asphaltenes to be composed mainly of alkyl groups and other pendent moieties attached to a single large PAH core, the *Yen-Mullins* or *island* model [10.100]. Others consider asphaltenes to be multicore PAH structures with pendant groups that are linked together, the *archipelago* model [10.101]. It is likely that both types of species exist [10.102].

The molecular and isotopic composition of produced petroleum is determined by complex chemical, physical, and biological processes. As discussed above, the composition of petroleum is a function of the molecular nature of the source bitumen and kerogen, its thermal evolution and the fractional processes that occur during expulsion. Each source facies generates oil with distinct chemical composition that reflects biotic input, depositional setting, and thermal history (Fig. 10.10). For example, lacustrine and coaly source rocks generate waxy, low-sulfur crudes, while carbonate and evaporite source rocks generate asphaltic, high-sulfur crudes. These compositional differences are most apparent during the initial stages of oil expulsion and become less distinct as the source rock proceeds through catagenesis where secondary cracking reactions become prevalent.

Although petroleum is derived from biological matter, most of the individual compounds cannot be assigned to a specific biochemical precursor. Some

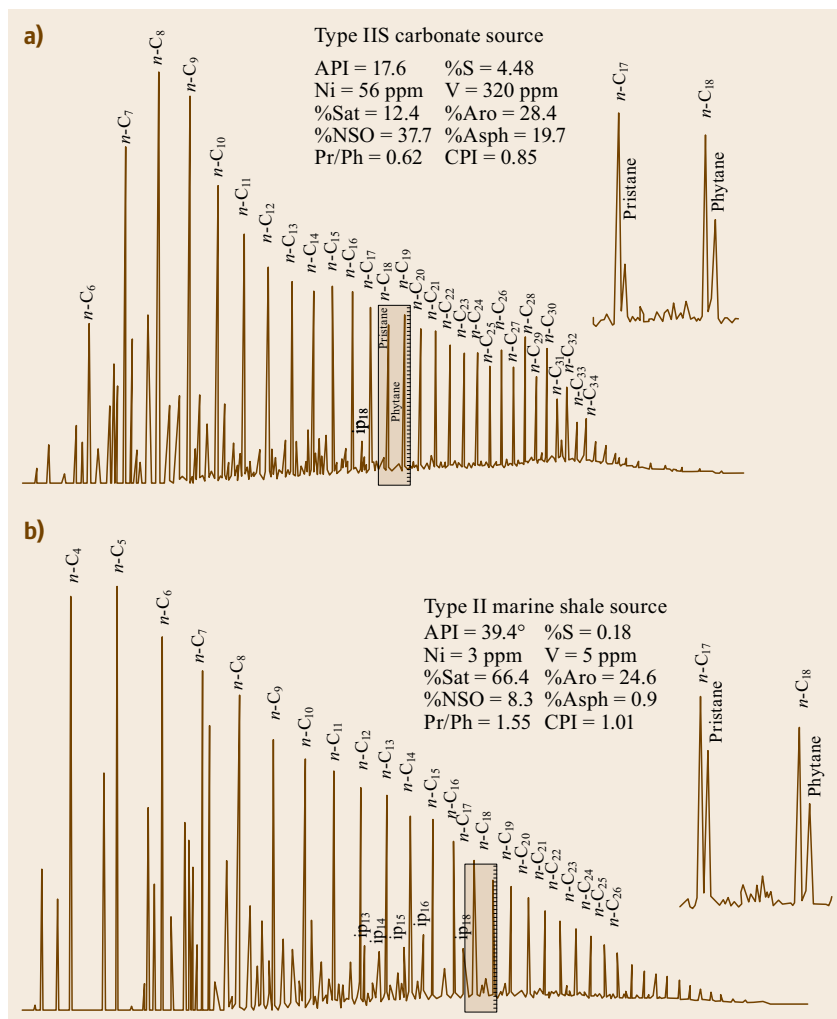

Fig. 10.10a-d Whole-oil gas chromatograms showing examples of oils from different source kerogens. The boxed area, showing the elution of n -C₁₇, pristane (Pr) and n -C₁₈, phytane (Ph), is enlarged. High pristane/phytane ratios (pr/ph) are associated with oxic depositional environments. Low pr/ph ratios are associated with evaporitic/anoxic environments.

petroleum hydrocarbons, termed *biomarkers*, retain enough of their original carbon skeleton structure that a likely biochemical precursor can be postulated [10.21]. The abundance and distribution of biomarkers allow geochemists to infer the origin and thermal history of oils and source rocks.

Once generated and expelled from the source rock, petroleum composition can be further modified during migration and entrapment within the reservoir. In most petroleum systems, the source formation is at greater temperature and pressure than the reservoir and migrating petroleum fluid may separate into gas and liquid phases that can then migrate independently [10.103–105]. Petroleum also interacts with water and the more soluble hydrocarbons may selectively partition into the aqueous phase [10.106].

Once in the reservoir, secondary processes can alter oil composition. Biodegradation, the consumption of

hydrocarbons by microorganisms, is likely to occur in shallow, cool reservoirs (< 80 °C) [10.107, 108]. This process selectively removes saturated hydrocarbons, enriching the residual crude oil in polar and asphaltic material. Biodegradation forms acids and biogenic CH₄, CO₂, and H₂S. Microbial alteration of crude oils is a relatively fast process and may occur naturally or result from poor production practices. Thermochemical sulfate reduction (TSR) is another reservoir alteration process that can affect oil quality and quantity. It is a chemical redox process that occurs at relatively high temperatures (> 120 °C), where hydrocarbons are oxidized to CO₂ and sulfate is reduced to H₂S [10.109, 110]. The residual oil is depleted in saturated hydrocarbons and enriched in sulfur-aromatic species. Reservoir charging and fill history can also alter oil composition. For example, mixing of gaseous hydrocarbons with oil can cause asphaltene to precipitate, forming a tar mat [10.111].

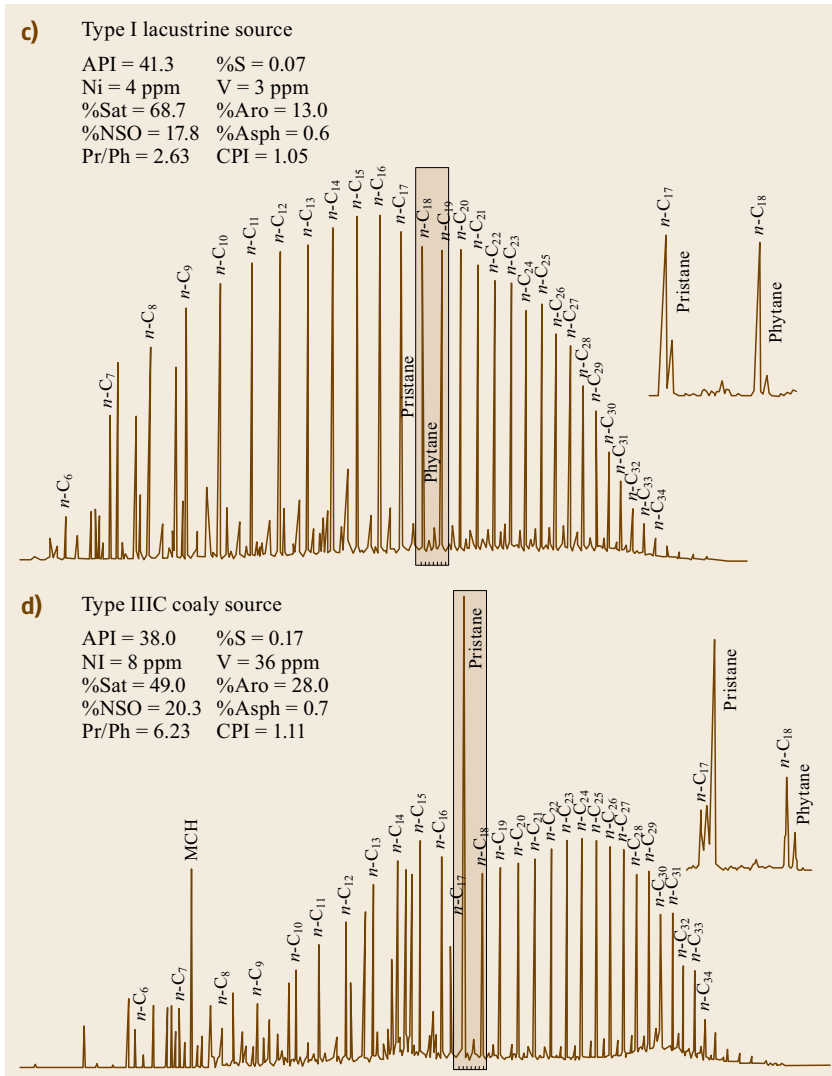

Fig. 10.10 (continued)

Figure 10.10 displays *whole-oil* gas chromatograms up to C_{44} of Types I, II, IIS and IIIC oils. Normal paraffins are predominant. The most noticeable isoprenoid hydrocarbons are pristane (Pr) and phytane (Ph), along with adjacent $n-C_{17}$ and $n-C_{18}$, enlarged in boxes. The pristane/phytane ratio, Pr/Ph, is used to infer the depositional environment (anoxic, hypersaline Pr/Ph < 1, oxic water column/anoxic sediments Pr/Ph 1~2, oxic deposition Pr/Ph > 2).

Carbon preference index (CPI) is defined as the ratio of sum of the C_{25} – C_{33} odd-carbon n -paraffins to the sum of C_{26} – C_{34} even-carbon n -paraffins [10.95]. A slightly modified version commonly used today is the ratio of twice of C_{25} – C_{33} odd carbon n -paraffins to the C_{26} – C_{34} plus the C_{24} – C_{32} even-carbon n -paraffins [10.112]. CPI is used to infer carbonate/evap-

orite source facies < 1, and higher land-plant input CPI > 1.

API gravity, the concentrations of sulfur (S), nitrogen (N), nickel (Ni), and vanadium (V) and the C_{15+} chemical group-type compositions are influenced by the organic matter, depositional environment, and thermal history of their source rocks and by reservoir alteration processes.

The composition of crude oil that arrives at a refinery is not identical to the original reservoir fluids. Gas and water is separated at the well head and emulsions are broken. Consequently, oils lose some light hydrocarbons (< C_6) by evaporation during production and transport. Pipeline and tanker oils are frequently blends of oils from multiple fields and reservoirs, which individually may be of varying composition and qual-

ity. In addition, refineries always blend many available crude oils, such as high and low acid as well as high and low sulfur crude oils, to meet the capacity and tolerance of refining operations. For these reasons, test-

ing of subsurface fluids, such as crude assay, from individual reservoirs is necessary to determine field economics and to design reservoir management practices.

10.7 Unconventional Resources

The petroleum system for conventional resources requires petroleum to migrate out of organic-rich source rocks and accumulate in reservoir rocks that are highly porous and permeable (Sect. 10.2). When sufficiently mature, source rocks generate and retain hydrocarbon gases, primarily methane. The source rock can also act as self-contained unconventional petroleum system where source, reservoir, and seal are contained within the same stratum. Unlike conventional reservoir rocks where the porosity is mainly in voids between mineral grains, the porosity within productive gas shale resides within the organic matter [10.113]. The potential for shale gas has long been known. Wells producing commercial quantities of gas from eastern US Paleozoic shales begin in the early 1820s and were developed as regionally, though minor, assets for decades [10.114]. The full resource potential of gas shales was finally recognized with the development of the Barnett Shale play starting in the 1980s [10.115]. Since 2000 when shale gas, mostly from the Fort Worth Basin, contributed only 2% of the total US production of natural gas, the use of horizontal drilling coupled with large scale, multi-stage hydraulic fracturing and rapid exploitation other US continental basins has increased its contribution to 30% in 2011 [10.116]. Shale gas production is currently mostly limited to the United States and Canada, but its global potential is now apparent and tests are being conducted worldwide [10.117].

Tight oil plays are unconventional in that their exploitation depends on the same technological advances in drilling and fracturing as shale gas; however, the successfully exploited plays geologically resemble conventional petroleum systems. For example, the Bakken Shale play, with reserves estimated at 2 billion bbl [10.118], produces primarily out of the middle member, a low permeability reservoir rock, which is sandwiched between two layers of organic-rich shale (avg. ≈ 12 wt% TOC [10.119]), and the basal Sanish/Pronghorn member and Three Forks Formation, which underlie the organic-rich lower member of Bakken shale. Eagle Ford shale, the conventional source rock for oil residing in overlying Austin Chalk, also is a self-contained petroleum systems producing oil and gas. However, the Eagle Ford is lithogenically heterogeneous with fossils, carbonates, sandstone laminae, and sand-filled bioturbation structures providing ample

internal porosity and permeability [10.120]. Tight gas plays are also considered by some as unconventional resources, but these too are really conventional petroleum systems where the gas is contained in low permeability reservoir rocks.

Methane desorbing from coal and associated water poses a constant safety issue in mines, where it is continually monitored (once by caged canaries) and vented to prevent explosive ignition. Long considered undesirable, coal bed methane (CBM) is now an economically exploitable resource. Spurred on by changes to the United States. Federal tax code in the 1980s, CBM has emerged as a global unconventional resource with the largest productive resources in the United States, China, Canada, Australia, and Russia [10.121, 122]. As lignite and coal matures it liberates organic nutrients that are consumed by microbial communities that produce biogenic methane [10.123]. At higher temperatures, the organic matter generates thermogenic methane. The methane is primarily absorbed within the organic matrix and storage capacity increases with thermal maturity. However, since CBM is typically produced from formations that have been uplifted and microbial activity can resume, it is not uncommon for CBM to have a mixed origin. The science and technology involved in shallow CBM production is fairly mature. Wells are drilled into coal beds that are fairly close to the surface (≈ 100 – 1500 m) and water and gas that are present in the cleats (fractures) are produced. As pressure is drawn down, methane desorbs from the coal matrix and is produced at comparatively low rates (typically $< 100,000$ m³ per day and well). The well performance depends on a number of factors, including cleat density, organic maceral composition and thermal maturity. Increased production and flow rates can be obtained using enhanced coalbed methane techniques that displace the sorbed methane while sequestering CO₂ [10.124].

Gas hydrates (clathrates) are ice-like crystalline solids that form when high concentrations of gases (e.g., CH₄, CO₂, C₂–C₄ hydrocarbons) and water contact at high pressures and low temperatures [10.125]. Occurring both onshore and offshore, methane hydrates represent a vast untapped reserve, with global estimates ranging from 10^{15} to over 10^{18} m³ (5×10^4 – 3.5×10^7 Tcf) [10.126]. However, most gas hydrates occurs

in low concentrations dispersed over large areas and are economically unrecoverable. It is likely that only deposits in Arctic and marine sands have sufficient resource density to ever be economic [10.127]. Several research programs have proven the occurrence and producibility of gas hydrates. Particularly notable are those conducted in the Nankai Trough, Mackenzie Delta, Gulf of Mexico, and Alaskan North Slope [10.128]. Gas can be liberated by destabilizing the hydrate structure through depressurization, heating, or chemical additives [10.129]. At present, the only commercially produced gas hydrates are those occurrences where a hydrate gas cap overlays a conventional gas reserve that has been drawn down in pressure [10.130].

Although the global abundance of abiotic hydrocarbons is inconsequential (Sect. 10.1), the occurrence of such gases is global and, in some local occurrences,

may contribute to minor amounts to economic reserves. Petroleum systems exist where fractured basement and igneous rocks are reservoirs [10.131, 132] and serpentinized rocks could contribute abiotic gases [10.133, 134]. The occurrence of minor amounts of abiotic gas in the economic accumulations in the Songliao Basin is supported by isotopic measurements of hydrocarbon gases and helium [10.135, 136]. Taking a larger view, the largest known hydrocarbon accumulations are not on the Earth, but on Titan, where lakes > 100 000 km² of liquid methane and ethane and pools have been found that exceed the known oil and gas reserves on Earth [10.137]. Considering the abiotic organic matter in comets, meteorites, and other planetary bodies, petroleum derived from biological sources is only tiny fraction of the total hydrocarbon inventory in the Solar System.

10.8 Summary

The theory that petroleum originates from sedimentary organic matter that was once living organisms is consistent with all natural observations, laboratory analyses and experiments, theoretical considerations, and basin simulations. The accumulation of economic quantities of petroleum (oil and gas) requires that a series of processes occur within sedimentary basins. Organic-rich sediments are deposited only under specific conditions that promote the production of biota and/or transport of biogenic organic compounds and the selective preservation of this material. The sedimentary organic matter converts to kerogen, an insoluble macromolecule with a composition that reflects the biotic input and chemical alterations (hydrogenation,

sulfurization, condensation, defunctionalization, and aromatization) that occur during diagenesis. These organic-rich strata have the potential to generate oil and gas when buried and heated to promote thermal cracking. Expelled petroleum migrates from the source rock through fractures and permeable strata. Economic reserves occur when geological conditions allow for the accumulation, retention, and preservation of significant volumes of migrated petroleum. The concept of source, reservoir, and seal applies to conventional petroleum systems, where each element may be a different formation, or to unconventional resources, where the elements exist within the same formation.

11. Basin and Petroleum System Modeling

Kenneth E. Peters, Oliver Schenk, Allegra Hosford Scheirer, Björn Wygrala, Thomas Hantschel

Since the early 1970s, basin and petroleum system modeling (BPSM) has evolved from a simple tool, used mainly to predict regional source rock thermal maturity, to become a critical component in the worldwide exploration programs of many national and international oil companies for both conventional and unconventional resources. The selection of one-dimensional 1-D, 2-D or 3-D BPSM depends on available input data and project objectives. Organic richness and rock properties must be reconstructed to original values prior to burial. For example, in geohistory analysis each unit is decompacted to original thickness and corrected for paleobathymetry and eustasy. Boundary conditions for thermal evolution include heat flow and sediment-water interface temperature corrected for water depth through time. Default petroleum generation kinetics available in most software should be used only when suitable samples of the source rock organofacies are unavailable. Kinetic parameters are best measured using representative, thermally immature equivalents of the effective source rock. 3-D poroelastic and poroplastic rock stress modeling are significant advances over the 1-D Terzaghi method employed by most software. Calibration should start with the available pressure data, followed by thermal calibration (e.g., corrected borehole temperatures or vitrinite reflectance) and calibration to other measurements (e.g., petroleum composition). The dynamic petroleum system concept has proven to be a more reliable tool for exploration than static play fairway maps used in the past, partly because BPSM accounts for the timing of trap formation relative to generation-migration-accumulation. Tectonic activity and other processes can result in remigration or destruction of accumulations and more than one critical moment on the petroleum system event chart. Organoporosity within the kerogen and solid bitumen accounts for much of the petroleum in unconventional mudstone reservoirs, and secondary cracking of oil to gas is par-

ticularly important. Hybrid unconventional systems, which juxtapose ductile organic-rich and brittle, more permeable organic-lean intervals are typically the best producers.

11.1 Overview

Computerized basin and petroleum system modeling (BPSM) [11.1–3] is a quantitative outgrowth of the earlier, largely qualitative petroleum system concept. A petroleum system consists of four essential rock elements comprising source, reservoir, seal, and overburden; the two processes of trap formation and generation-migration-accumulation; and all crude oil and hydrocarbon gas that originated from one pod of thermally mature organic-rich source rock. BPSM developed as a quantitative tool to test and refine models of petroleum generation, migration, and accumulation for conventional resources [11.5]. The concept of the dynamic petroleum system represents a significant paradigm shift in the way that major national and international oil companies explore for conventional resources [11.6]. Recently, BPSM has expanded to include modules that account for new advances in understanding of geochemical processes, such as a biodegradation module to predict oil quality in conventional reservoirs, a thermochemical sulfate reduction (TSR) module to predict H₂S, and a saturate-aromatic-resin-asphaltene (SARA) module to predict the composition of petroleum remaining in unconventional source rocks [11.7,8]. An unconventional resource contains petroleum that requires some type of stimulation to achieve commercial rates of extraction because of low reservoir permeability and/or high fluid viscosity, e.g., tight gas, coal bed methane, shale gas, shale oil, oil sands or methane hydrate.

11.1.1 BPSM Workflow

BPSM begins with a well-defined conceptual model of the study area based on the sum of all available geologic information [11.9]. BPSM is a form of forward deterministic modeling, in which input data and interpretations are used to calculate the rock and fluid properties forward in time from an original state, typically basement rock emplacement prior to deposition of the overlying basin fill (Fig. 11.1). Simulations are performed on discretized numerical representations of a conceptual model. All practitioners of BPSM must recognize that it is a research tool that provides scenarios that can be tested. The value of the scenarios can be incrementally improved by additional high-quality data, but in the final analysis, no model exactly replicates nature. On the other hand, well-constructed models certainly reduce the uncertainty associated with exploration and exploitation of conventional and unconventional resources.

BPSM is commonly described as *basin modeling* or *petroleum system modeling*, although these two

terms actually differ in meaning [11.3]. Basin modeling utilizes mathematical algorithms to reconstruct the geohistory and thermal evolution of the rocks, whereas petroleum system modeling uses linked algorithms designed to reconstruct the evolution of the petroliferous fluids (oil and gas). Hydrocarbons consist of carbon and hydrogen and include thermogenic oil and gas, as well as biogenic methane. Common usage of the term hydrocarbons includes other petroleum fractions, such as polar compounds or asphaltenes, which contain additional elements, such as nitrogen, sulfur, and oxygen (NSO compounds) or metals (e.g., porphyrins). The petroleum industry is mainly interested in the discovery and exploitation of petroleum fluids, but to model petroleum systems, one must first understand the geologic and thermal evolution of the rocks. Scenarios from BPSM studies are of little value unless they are iteratively calibrated to various measured parameters from the study area, such as pore pressure, vitrinite reflectance, and corrected borehole temperature.

11.1.2 Introduction to Sedimentary Basins

Basin is one of the most common terms in geology, but it is seldom defined in publications. A sedimentary basin is a depression that accommodates sediments as a result of long-term subsidence. Basin subsidence may result from one or more of the following interrelated processes [11.10–12]:

1. Isostatic
2. Flexural
3. Thermal subsidence.

Isostatic subsidence is the result of physical changes in lithosphere thickness, e.g., if crustal thinning is the result of lithospheric stretching, isostatic compensation results in subsidence. In contrast, flexural subsidence depends on elastic plate rigidity and bending of the lithosphere. Thermal subsidence is the result of density changes during cooling of a thermally destabilized lithosphere, e.g., during postrift cooling.

Most classifications of basin type account for the underlying lithosphere (continental versus oceanic), the plate tectonic setting (plate margin or intracraton), and the principal tectonic stress (convergent, divergent, or transform). The lithosphere consists of the upper mantle and crust. The base of the lithosphere ($\approx 1333^\circ\text{C}$) [11.13] is thought to range from the sediment-water interface at midocean ridges to 100 km below cooler parts of the oceans and from 100 to

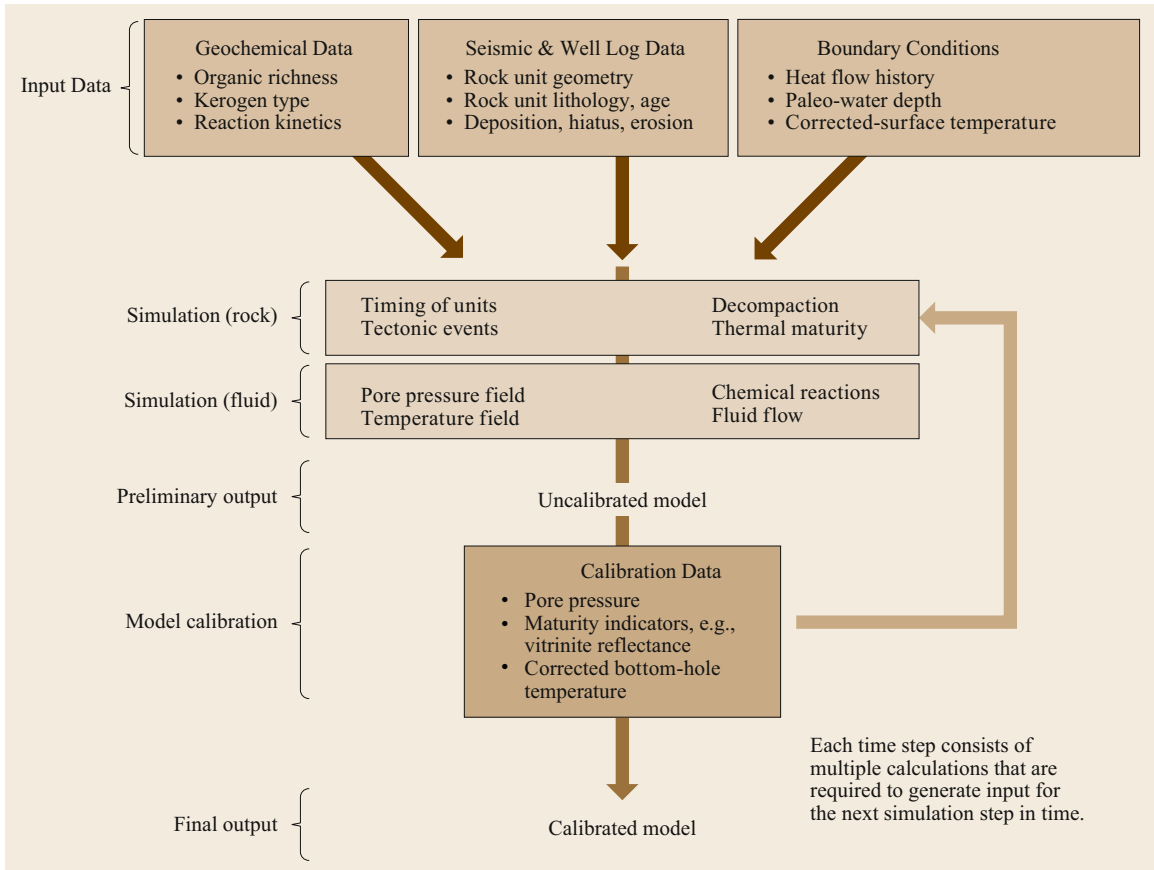

Fig. 11.1 Process workflow for basin and petroleum system modeling (BPSM) including simulation of the geohistory of the rock units and associated fluids. Modified from *Peters et al.* [11.4]

250 km under continents. Using the above criteria, six types of sedimentary basins were identified by *Dickinson* [11.14] and *Reading* [11.15]:

1. Oceanic
2. Rifted continental margins
3. Arc-trench
4. Suture
5. Intracratonic
6. Strike-slip.

Basin type is important in BPSM because it influences basal heat flow and the magnitude, timing, and distribution of temperature with depth (geothermal gradient). Understanding basin type allows the interpreter to narrow the range of possible heat flow scenarios. A simplified classification summarizes typical heat flow associated with extensional, compressional, and strike-slip sedimentary basins (Fig. 11.2) [11.11].

Although Fig. 11.2 is useful when no heat-flow data are available, it is best to determine heat flow for

each study area. Heat flow is the product of rock thermal conductivity and thermal gradient. Because thermal conductivity depends on mineralogy, texture, porosity, and fluid content of the rock, constant heat flow through heterogeneous rock units results in a piecewise linear geothermal gradient. For this reason, the temperature of a rock unit cannot be accurately estimated from average thermal gradients. *Peters and Nelson* [11.16] discuss various temperature measurements and their suitability for estimating heat flow. Thermal conductivities for a wide variety of lithologies were compiled by *Beardmore and Cull* [11.17, Table 4.2] and *Hantschel and Kauerauf* [11.1].

Acquiring accurate formation temperatures for BPSM calibration is laborious, but investigators must recognize the need for such data and they must rigorously exclude biased temperatures. Drill stem, production, or static tests provide generally reliable temperatures, but such measurements are rare. Most temperatures taken during drilling, logging, or well maintenance are inaccurate because drilling mud cools rock

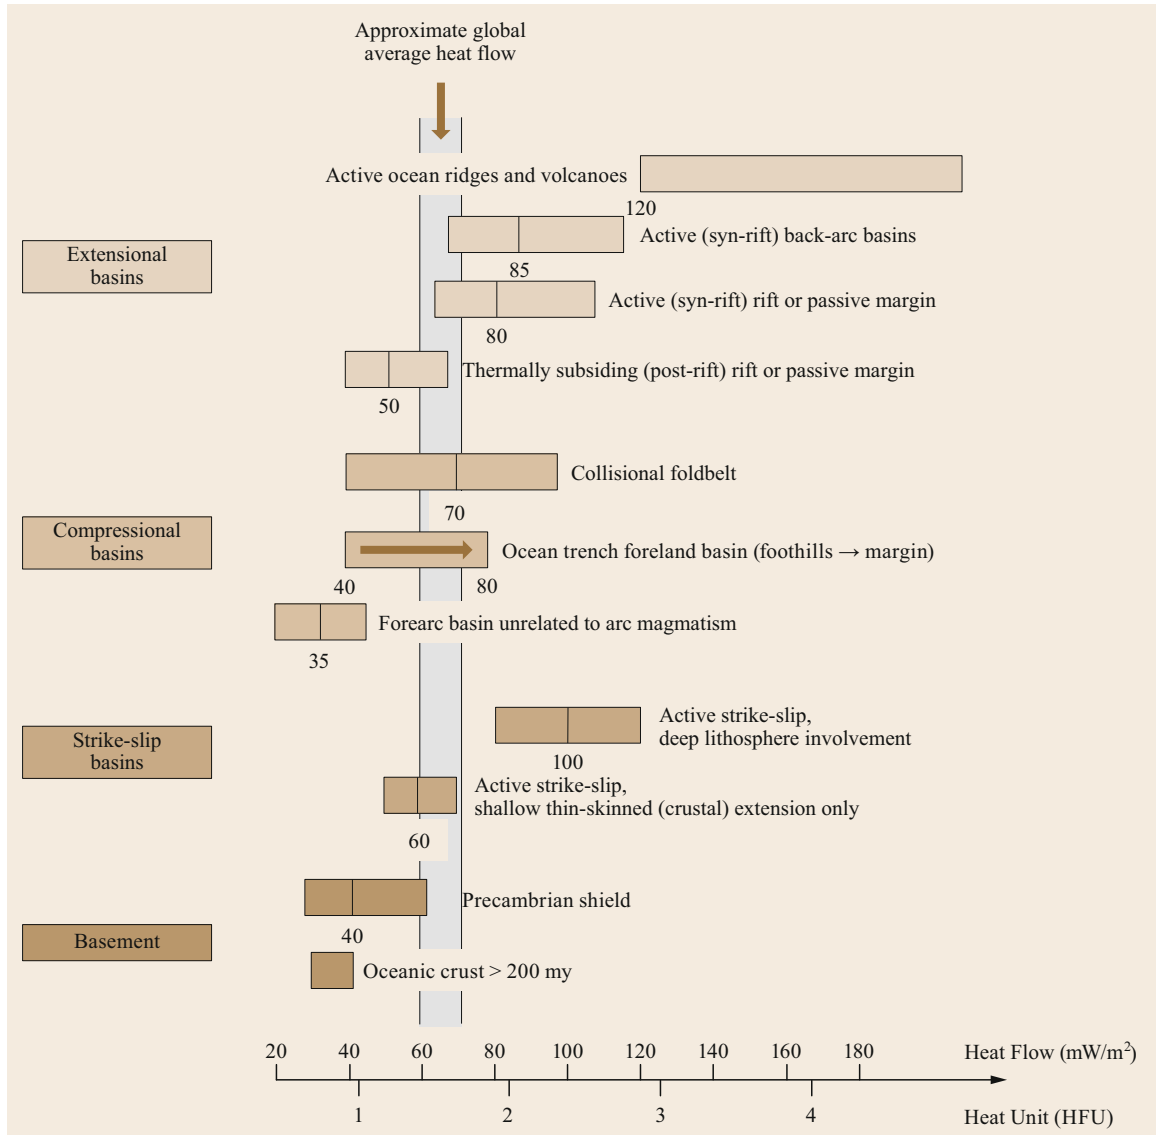

Fig. 11.2 Typical ranges of heat-flow values for extensional, compressional, strike-slip basins and basement rock (after [11.11])

adjacent to the borehole. Bottom-hole temperatures measured soon after circulation of drilling mud are common, but are generally biased to low values and require correction. Horner-corrected bottom-hole temperature (BHT) based on three time-temperature pairs measured at a single depth in a well can be useful for determining thermal gradients and for calibration of BPSM [11.16]. All interpretations of present-day thermal gradients based on temperature measurements must be constrained by the ranges of heat flow values for specific basin types in Fig. 11.2.

11.1.3 Model Input

BPSM describes the evolution of the rocks, kerogen, and generated petroleum throughout geologic history. Kerogen is the insoluble particulate organic matter in source rocks. Conceptual BPSM models can be constructed using minimal data, but abundant, high-quality input and calibration data, such as stratigraphy, subsurface structure, lithology, geochemistry, and age of the key rock units, can be used to enhance the predictive capabilities of BPSM. Geologic layers in BPSM are best

described as chronostratigraphic units in that each layer is constructed by combining time-equivalent units into a single layer [11.4] rather than lithostratigraphic units. The following is a list of recommended input data for conventional BPSM:

1. Maps of the study area, including location information (latitude, longitude) for all useful wells and culture data (e.g., block boundaries, field locations)
2. Key formations or other rock units expressed in a geologic column with standardized names across the study area that have been designated as source, reservoir, seal or non-source intervals
3. True vertical depth to formation tops relative to sea level
4. Formation ages, including diachronous units (i. e., strata having similar lithology, but differing in age at different locations); for salt basins, reconstructed salt movement through time and lithologic information
5. Age and duration of non-deposition (hiatus)
6. Amount of lost section and lithology; age and duration of erosion events
7. Lithofacies variations in maps, including porosity, permeability, capillary pressure, compaction behavior, thermal conductivity, and heat capacity
8. Structural elements, such as faults (including properties through time) and folds
9. Organofacies maps of original source-rock hydrogen index (HI, mg hydrocarbon/g TOC) and total organic carbon content (TOC, wt%) prior to thermal maturation
10. Kinetics of petroleum generation from laboratory analysis of thermally immature and representative source-rock samples
11. Boundary conditions, including sediment-water interface temperature (surface temperature corrected

for paleo-water depth) and basal heat flow through time (i. e., thermal events)

12. Calibration data, including present-day pore pressure, porosity, permeability, reservoir fluid properties (e.g., American Petroleum Institute (API) gravity, gas-oil ratio (GOR), petroleum composition, temperatures from drill stem tests (DST) or Horner-corrected BHT, vitrinite reflectance, Rock-Eval T_{max} and other maturity information, such as paleotemperatures from fluid-inclusion or fission-track analyses).

See Higley et al. [11.18] for a more comprehensive discussion of recommended input and the logistics of BPSM. Actual input can vary widely depending on the objectives of the study, including required turnaround time and availability of published information, commercial or in-house databases, seismic data, well logs, cross-sections, and lithology descriptions.

Additional input data are useful for unconventional shale plays. Although we use the term *shale* in this paper, it is important to recognize that source rocks for both conventional and unconventional petroleum consist of a wide variety of mudstones having distinct mineralogies. *Mudstone* is a general term that might be more appropriate than *shale* to describe the lithology of many source rocks, but the terms shale play, shale oil, and shale gas now represent common usage. Detailed organofacies maps of the source rock are particularly important for shale plays. Useful input for unconventional modeling includes Langmuir parameters (volume, pressure, isotherm temperature, sorption-desorption parameters), geomechanical parameters (e.g., Poisson's ratio, Young's modulus described later), and tectonic basin history (e.g., stress magnitude and direction).

11.2 Discussion

One-dimensional (1-D) BPSM reconstructs the geohistory at one location, commonly at the position of a well. Two-dimensional (2-D) BPSM reconstructs geohistory as projected along a plane. The plane is typically defined by a series of well positions, a seismic line, or a synthetic plane extrapolated from a three-dimensional (3-D) model. A 3-D BPSM reconstructs geohistory of an entire basin or portion of a basin. 3-D models are typically constructed from interpreted 3-D seismic data or multiple wells and seismic lines that are interpolated into a gridded (linear or nonlinear) array. True 2-D and 3-D models require that information, such as heat flow, fluid transport, and fluid properties, be communicated

between locations. Pseudo-2-D BPSM is simply a diagrammatic projection of 1-D results onto a plane with interpolation of information between the 1-D locations. Likewise, pseudo-3-D BPSM interpolates results from 1-D and/or 2-D models without complete information exchange within the study volume. Pseudo-3-D models can be helpful for maturity modeling in frontier areas.

11.2.1 One-Dimensional Models

1-D BPSM is based on burial histories constructed using formation tops from wells, seismic sections, outcrops, or extracts from 3-D models. Table 11.1 is an

Table 11.1 Example of input for a 1-D or 2-D basin and petroleum system model (after [11.19])

Age	Stratigraphic unit	Deposition (Ma) ^a		Thickness (m)	Erosion or hiatus (Ma) ^a		Erosion (m)	Lithology	Petroleum system element
		From	To		From	To

example of input for typical 1-D or 2-D models. Based on the lithology assigned to each rock unit, porosity and permeability can be calculated at any point in the burial history using empirical compaction curves from the literature. Given present-day location, the paleolatitude of the 1-D site can be reconstructed based on plate tectonic movement through time. Paleowater depth can then be used to calculate sediment-water interface temperature [11.20]. 1-D models assess the extent of thermal maturation using a combination of paleowater depth, sediment-water interface temperature, and heat flow. Once the temperature history of the rock units has been reconstructed, 1-D models can be used to infer the extent of oil and gas generation from the source-rock interval(s) through geologic time. This requires laboratory assessment of kinetic parameters associated with the transformation of organic matter to petroleum and extrapolation to geologic time, as discussed later.

The main limitation of 1-D BPSM is that the output is at a single location and cannot account for lateral temperature and pressure gradients or 3-D fluid flow. Therefore, pseudo-2-D and -3-D visualizations built from multiple 1-D models are of limited accuracy and depend heavily on the map density of the 1-D locations. Other sources of uncertainty must also be considered, including thermal boundary conditions, accuracy of the assigned lithologies (e.g., thermal conductivity, heat capacity, compaction behavior) and calibration measurements (e.g., measured vitrinite reflectance or borehole temperatures).

11.2.2 Two-Dimensional Models

Two-dimensional models consider additional geologic factors not possible in 1-D. For example, 2-D models can include sealing or transmissible faults and can employ all of the migration methods used in 3-D models. Migration of petroleum from source rocks through carrier beds to the reservoir can be shown. Both 2-D and 3-D models offer Darcy flow, flow-path, invasion percolation, or hybrid migration methods to determine fluid flow. Multicomponent pressure-volume-temperature (PVT) calculations can be used to predict the quantity, composition, density, and viscosity of liquid, vapor and water phases throughout the burial history. 2-D models can be used to predict the composition of liquid and vapor hydrocarbon phases. However, 2-D models only allow relative comparisons between scenarios for GOR and API gravity. For example, a 14-component compositional scheme includes C_1 , C_2 , C_3 , iC_4 , nC_4 , iC_5 , nC_5 , nC_6 , C_7 – C_{15} , C_{16} – C_{25} , C_{26} – C_{35} , C_{36} – C_{45} , C_{46} – C_{55} , C_{55+} hydrocarbons [11.21]. Various time-dependent processes, such as open or closed

faults, igneous intrusions, allochthonous salt movement, and gas hydrate formation can be modeled.

The main limitation of 2-D BPSM is that the selected section may not capture the structural closure needed to register an accumulation. For this reason, careful selection of a 2-D line that passes from the depocenter to a structural high or known accumulation is recommended. Although data from wells used to build structure and isopach maps are generally proprietary, published 2-D sections that include these data are common. Volumes of petroleum in accumulations can be only approximated in 2-D models by assuming a thickness for each displayed unit. Despite this limitation, 2-D models can be used to compare the relative sizes of predicted accumulations resulting from different model scenarios.

11.2.3 Three-Dimensional Models

There are many advantages offered by 3-D models, including reconstruction of petroleum migration pathways to traps that may or may not have been previously identified by drilling. Maps of the pod of active source rock based on calculated transformation ratio (TR, extent of conversion of kerogen to petroleum) through time can be prepared. Volumes of petroleum generated, accumulated, and lost during migration can be estimated and flash calculations can be used to predict the properties of trapped petroleum at surface conditions during production. As discussed above, both 2-D and 3-D models can utilize Darcy flow, flow-path, invasion percolation, or hybrid migration methods. 3-D modeling is the only method for quantitative analysis of API gravity, GOR, pore pressures, or volumetrics of accumulations, although relative volumes can be compared using 2-D models.

An additional advantage of 3-D models is that they can be broken into smaller areas within the greater model and run using finer grid spacing than the large model might allow due to computing restraints. This so-called local grid refinement (LGR), allows improved resolution of key regions within the study area without the need to rerun the entire model (Fig. 11.3), but reservoir-scale spatial resolution of the input data is required.

The principal disadvantages of 3-D BPSM are an important consideration when deciding on a 1-D, 2-D, or 3-D modeling study. Although appealing, realistic 3-D models generally require more data and time to construct than 1-D or 2-D models, and necessary computer processing time may impede the progress of other studies having deadlines. Computing speed and available computer hardware specifications strongly influence the resolution that is possible for model processing and display. In addition, 3-D models that are inade-

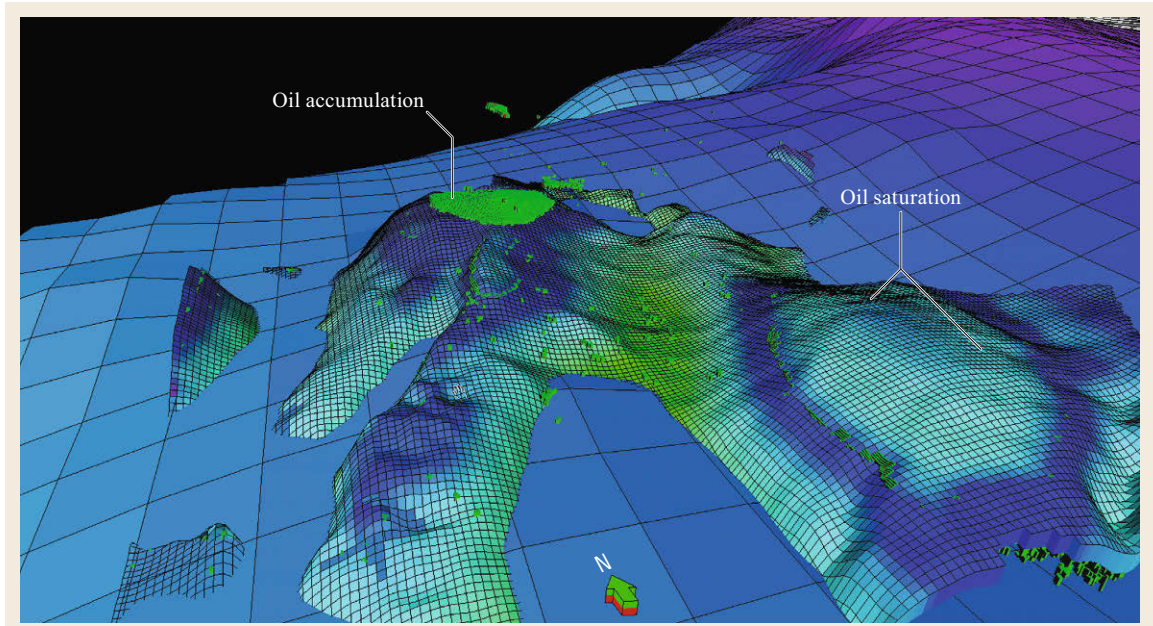

Fig. 11.3 Example showing a local grid refinement (LGR) within a larger discretized 3-D model. The oil accumulation (green cubes) initially modeled on the large grid ($3\text{ km} \times 3\text{ km}$) can be examined in more detail using the small grid ($200 \times 200\text{ m}$) in the LGR. Grid cell thickness varies, but is typically 400 m or less. Modified from *Al-Hajeri et al.* [11.2]. Figure copyright Schlumberger, used with permission

quately populated by measured data can be misleading compared to simpler 1-D or 2-D models that are better constrained.

11.2.4 Risk Analysis

A BPSM master run is based on input for each variable that is deemed to be the most accurate deterministic representation of nature. In effect, a master run assumes that uncertainties in the input data do not exist. However, every input variable in BPSM has associated uncertainty. The classical approach to address uncertainty is to run *high* and *low* scenarios in addition to the master run. For example, an uncertain temperature history might be addressed by low, master, and high heat-flow scenarios, while all other input variables are kept constant. Shortcomings of the classical approach are: (1) the choice of the most likely deterministic scenario depicted by the master run is at best a qualified guess, and (2) the approach is not systematic and it ignores the uncertainty associated with other input parameters.

Monte Carlo or Latin hypercube statistical sampling of the uncertainties associated with multiple input parameters can be used in BPSM to provide more quantitative assessment of risk. To perform such simulations, uncertainty distributions are assigned to key input parameters, such as heat flow, thermal conductivity, permeabil-

ity, capillary pressure, total organic carbon, hydrogen index, or kinetics. For most parameters, uncertainty distributions are based on measured variations from wells in the study area or modeled using normal, logarithmic normal, nominal, triangular, or uniform distributions. Other parameters, such as kinetics, can be modeled using two sets of kinetic parameters, which are alternately sampled during the simulation. Details of risk analysis are discussed in *Hantschel and Kauerauf* [11.1].

A tornado diagram (Fig. 11.4) compares the relative impact of risk among various input parameters. Tornado diagrams can be used to evaluate which parameters exert more influence on the calculated results and they are particularly useful to identify where further data acquisition might reduce model uncertainty. In the figure, source-rock HI, thermal gradient, and kinetics have the greatest impact on uncertainty for this model. A disadvantage of risk analysis is that long compute times and many simulations may be required for statistically meaningful results.

11.2.5 Rock Stress and Pressure Prediction

Subsurface pressure influences fluid expulsion and migration. Fluid-pressure modeling can be used to improve pore pressure prediction and reduce the drilling risk posed by unanticipated overpressures. Geomechan-

Fig. 11.4 Tornado diagram showing the relative impact of various input parameters on calculated prospect volumes (after [11.22], reprinted by permission of AAPG whose permission is required for further use)

ical modeling describes the response of rock to an external load and includes analysis of both fluid pressure and rock stress.

For pressure calculations, traditional BPSM generally treats dewatering as single-phase flow driven by changes in overburden weight caused by sedimentation (Fig. 11.5). Lithostatic pressure represents overburden weight. In contrast, hydrostatic pressure specifies the weight of the water column under equilibrium pressure conditions when there is no fluid flow. Fluid expulsion occurs as the sediments compact and overburden-induced pressure is reduced. The resulting pore pressure is usually less than lithostatic. The difference between lithostatic pressure and pore pressure is called effective stress, which specifies the amount of compaction. The difference between pore pressure and hydrostatic pressure is defined as overpressure (excess hydraulic pressure), which directly controls fluid flow. Rapid burial, which is common in deltaic settings, coupled with low permeability of fine-grained mudstones, results in the sediments being unable to dewater at rates in accordance with normal compaction. The resulting overpressure can retard compaction. Undercompaction also can be caused by fluid expansion during petroleum generation, as well as other generally less-important processes [11.23]. Compaction changes many lithologic properties, such as porosity, bulk density, thermal conductivity, and heat capacity, and this can be addressed in coupled pressure-temperature simulations.

11.2.6 Terzaghi Rock Stress Modeling

The traditional Terzaghi rock stress model [11.1] is based only on vertical stress. The vertical stress com-

ponent is the maximum principal stress (σ_1), which is identical to the overburden or lithostatic stress [11.1]. Extension of the Terzaghi model to a complete 3-D stress-strain poroelasticity model as originally formulated by *Biot* [11.24], or a 3-D poroplasticity model, allows improved predictions of stress-strain relationships, rock failure (fracture analysis), sealing capacity (fracture orientations and fault properties), and specific geomechanical effects caused by salt deformation and tectonic movement. Poroelasticity describes 3-D stress-strain relationships and can be used to differentiate subsurface regions that tend to be more strained and thus are more likely to fracture. Poroplasticity addresses rock failure based on the analysis of fractures and faults. Poroelasticity and rock failure are described in more detail later in the section on unconventional resources.

11.2.7 Compaction

Simple compaction modeling is based on assumptions that: (1) the volume of solids is conserved, i.e., mechanical compaction due to overlying water-sediment depends solely on porosity reduction, and (2) the sediments are normally (hydrostatically) pressured, i.e., water is free to be expelled from the pore space, while grain-grain contacts support the rock unit. Porosity-depth relationships based on laboratory and subsurface measurements can be expressed as negative exponential curves, which depend on the lithology of each rock unit. The porosity-depth relationship for normally pressured sediments is

$$\phi = \phi_0 e^{-cz}, \quad (11.1)$$

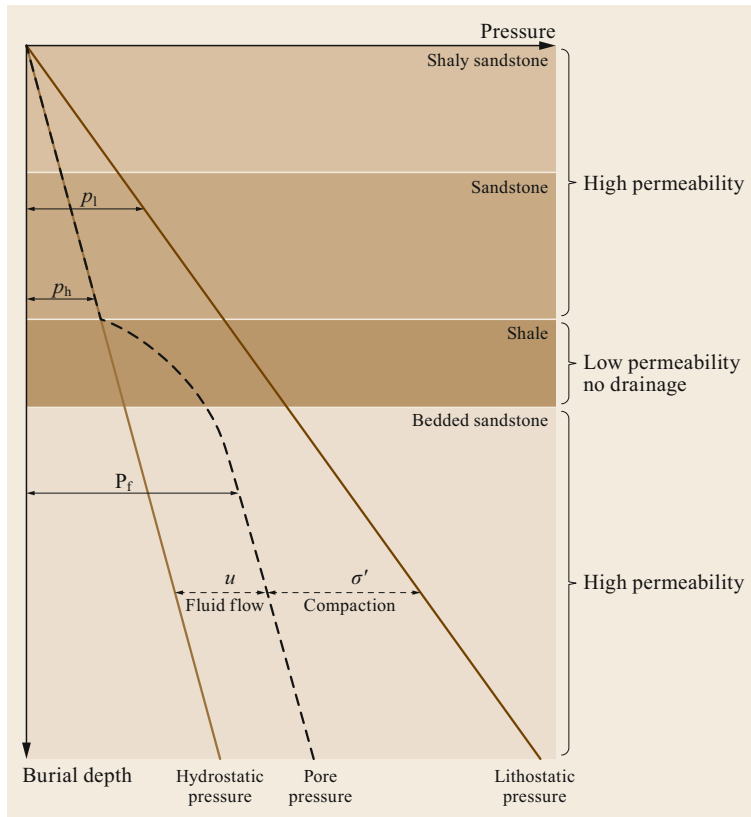

Fig. 11.5 Schematic of subsurface pressure conditions illustrating different types of pressure, fluid flow, and compaction. p_h = hydrostatic pressure, p_l = lithostatic pressure, u = excess hydraulic pressure (overpressure), σ' = effective stress. Pressures are commonly recorded in MPa (megapascal)

where ϕ is porosity at any depth z , ϕ_0 is depositional porosity at the surface, and c is a coefficient that depends on lithology and describes the slope of the porosity-depth curve.

Because (11.1) assumes that the volume of solids is conserved during compaction, the rate of compaction is mainly controlled by compressibility and porosity of the sediments and the expulsion rate of pore fluids. However, when fluids are trapped in sediments due to reduced hydraulic permeability, increased fluid pressure retards compaction. *Terzaghi's law* [11.25] describes the impact of fluid pressure on compaction by introducing the effective stress (σ') term

$$\sigma'_z = \sigma_z - p_f, \quad (11.2)$$

where σ'_z is the vertical component of the effective stress, σ_z is the vertical compressive (overburden) stress and p_f is the pore fluid pressure (Fig. 11.5). Assuming increased sediment load, the additional vertical stress is taken up by increased pore fluid pressure. Expulsion of pore water decreases fluid pressure and increases effective stress, resulting in compaction. Compaction can be formulated using effective stress (σ') instead of depth as follows

$$\phi = \phi_0 e^{-c\sigma'_z}. \quad (11.3)$$

Because the behavior of many rock types differs from ideal, variations of (11.3) for compaction have been published. *Hantschel* and *Kauerauf* [11.1] provide a list and description of various compaction models.

Muds generally compact faster with depth than sands as a result of their higher original porosity. However, the extent of compaction can be highly variable [11.26]. Therefore, it is best to use measured porosity to create a compaction model for each study area. If such data are unavailable, then a default compaction model can be used. Some popular default models for sediment compaction include *Sclater* and *Christie* [11.27], *Falvey* and *Middleton* [11.28], and *Baldwin* and *Butler* [11.29]. Wherever possible, measured porosity data should be used to validate the use of a default compaction model [11.17].

Bulk compressibility (C) is an important lithologic property for compaction and pore-pressure calculations. It describes the volumetric strain resulting from changes in rock stress, i. e., the ability of the rock framework to compact. For Terzaghi-type models, which are based on the lithostatic pressure concept, the compressibility is called Terzaghi-compressibility (C_T). It represents the ratio of volumetric strain to changes in vertical effective stress and defines the slope of the porosity-effective stress curve. Because mechanical compaction

is irreversible, porosity achieved during burial is largely retained, even when uplift reduces the effective stress. Therefore, effective stress is used for basins unaffected by uplift, whereas maximum effective stress is used for uplifted basins because the porosity was established prior to uplift.

Increased pore pressure with burial depth fails to completely counteract the effect of confining pressure. For this reason, *Biot* [11.24] established a more detailed poroelastic model that describes the decreasing effect of pore pressure with depth

$$\sigma'_z = \sigma_z - \alpha p_f, \quad (11.4)$$

where α is the Biot coefficient, which ranges between 0 and 1. For unconsolidated sediments, α is ≈ 1 and the Terzaghi effective stress formulation holds (compare to (11.2)). However, at greater depth and decreased porosity, α approaches 0, i. e., the effect of pore pressure is reduced.

Chemical compaction that accompanies cementation in sandstone and carbonate can be as important as mechanical compaction. This complex diagenetic process is mainly temperature-driven and becomes more important in deeply buried strata where porosity has already been reduced by mechanical compaction. Porosity reduction by chemical compaction may include dissolution, transport by diffusion, and precipitation. Chemical compaction can be described by an Arrhenius-type equation [11.30, 31], but it is also influenced by pore chemistry, effective stress, fluid viscosity, mineralogy, and rock fabric. Carbonate compaction is highly variable, and generally poorly understood. It depends mainly on cementation and pressure solution rather than mechanical compaction [11.32].

11.2.8 Pore-Pressure Formation

Pressure-driven fluid flow is the most efficient transport mechanism in sedimentary basins. The driving force for pore water flow is the overpressure gradient (Fig. 11.5). Overpressure formation couples fluid flow and compaction. Darcy's law describes this as a linear relationship between volume flux of the pore fluid (v) and the overpressure gradient

$$v = -\frac{k}{\nu} \left(\frac{dp}{dx} \right) = -\mu \left(\frac{dp}{dx} \right), \quad (11.5)$$

where dp/dx is the pressure gradient and μ is the mobility of the pore fluid, which depends on intrinsic permeability (k) and dynamic viscosity (ν). Fluid dynamic viscosity describes the resistance of the fluid

to flow depending on pressure, temperature, and fluid type. Intrinsic permeability is mainly affected by pore throat diameter and connectivity, which depend on the compaction state, and is thus a function of porosity. This exponential relationship must be adjusted for rock type. Multiphase pore fluids have different pressures in each phase. The pressure differences are represented by saturation-dependent capillary pressures, which can be significant in source and reservoir rocks. Rock permeability is also anisotropic, which is simplified in BPSM by introducing an anisotropy factor. Permeability is commonly derived from measurements on rock samples and needs to be upscaled for modeling (see below).

Overpressure can be caused by various processes, but the most influential are disequilibrium compaction due to rapid burial of fine-grained sediments [11.33] and hydrocarbon generation due to cracking [11.23]. Overpressure calibration can be complex. For basins in which sediments are affected mainly by mechanical compaction, the standard approach is to calibrate overpressure adjustments of compressibility (or effective stress versus porosity) and permeability in two steps: (1) the selected compaction law must be calibrated locally to measured porosity versus effective stress, and (2) permeabilities of the overpressured strata must be adjusted to fit calculated and measured pressures. Overpressure calibration can be difficult where the pressure regime is affected by other processes in addition to mechanical compaction, such as chemical compaction or fluid expansion. Because compaction causes changes in many lithologic properties, such as porosity, density, thermal conductivity, and heat capacity, overpressure calibration should be conducted prior to thermal calibration.

11.2.9 Mixing and Upscaling Rules

Most bulk properties in BPSM must be derived from measurements of mineral or fluid components using mixing or upscaling rules. For example, bulk densities, thermal conductivities, or heat capacities for rock units in the model must be calculated by averaging properties of the rock matrix and the pore fluid. Three basic methods for mixing and upscaling include arithmetic, harmonic, and geometric averaging. The mathematics for each method are given in *Hantschel and Kauerauf* [11.1, pp. 385–386] along with a table that identifies which mixing method applies for a given property. For example, arithmetic mixing is appropriate for calculations of bulk density, heat capacity, porosity, or critical oil saturation. Rock thermal conductivity or permeability are calculated using different mixture and upscaling rules, depending

on how the mineral grains are arranged in the rock unit:

1. Arithmetic for layering of the grains along flow direction
2. Harmonic for layering perpendicular to flow
3. Geometric for randomly oriented mineral grains.

11.2.10 Geohistory Analysis

Understanding of the dynamics of sedimentary basins and their associated fluids is required for evaluation of the timing of petroleum generation, migration, and accumulation in relation to trap formation. Geohistory analysis quantifies subsidence rates through geologic time [11.34] to visualize the vertical movement of each stratigraphic unit after deposition as an indicator of subsidence and uplift history. Geohistory analysis involves decompaction of each stratigraphic unit to its original thickness and corrections based on paleobathymetry and changes in eustasy. Several parameters are required for geohistory analysis:

1. Present-day thickness of stratigraphic units
2. Lithology
3. Stratigraphic age
4. Paleowater depth.

Additional data, such as porosity and maturity indicators, help to constrain and calibrate burial and thermal history. The resulting total subsidence can be expressed as a curve. To examine the tectonic contribution to subsidence, the effects of sedimentary loading must be removed from the total subsidence curve by backstripping, as discussed later.

Geohistory analysis of basins that have undergone minimal structural deformation involves four steps:

1. Plot sediment accumulation in the study area through time using present-day thickness of each stratigraphic unit
2. Decompact each unit to the thickness prior to burial and plot a corrected accumulation curve
3. Correct for depositional water depth through time, accounting for paleobathymetry and eustasy
4. Backstrip to reveal the tectonic component of subsidence (see below).

Sediment thickness can be obtained directly from well logs corrected to true vertical depth, or seismic data when accurate two-way seismic travel times are available. In addition, the geologic age of each formation top can be estimated by various methods, including biostratigraphy and radiometric dating.

11.2.11 Decompaction

To calculate decompacted thickness of a stratigraphic unit at any time in the past, the overlying rock units need to be removed sequentially. Using the basic assumption that the volume of solids is conserved, the decompacted thickness (d_0) can be calculated as follows

$$d_0 = d \frac{(1 - \phi)}{(1 - \phi_0)}, \quad (11.6)$$

where d is thickness and ϕ and ϕ_0 are the porosity and decompacted porosity respectively.

For clastic sediments, decompaction requires regional porosity-depth relationships. As described above, the porosity of normally pressured shale or sandstone typically decreases exponentially with depth (11.1). However, overpressure of pore fluids inhibits compaction. The porosity-maximum effective stress relationship (11.3) considers both pore fluid pressure and erosion.

Since pore pressure influences porosity evolution, depositional porosity can only be approximated from the relationships described above. Therefore, the first simulation run uses steady-state values for hydrostatic pressure conditions to decompact the sediments. Forward modeling that assumes that compaction is controlled by pore pressure then yields a present-day geometry that usually deviates from that of the input model. Model iterations using decompacted thickness allow improved optimization. Cementation, mineral transformations, fluid expansion (e.g., aquathermal or hydrocarbon generation), and chemical compaction by pressure solution are excluded in this decompaction approach, but modeling techniques can consider the effect of such processes on porosity evolution in iterative steps.

11.2.12 Paleobathymetry

Water depth changes through time during sediment deposition. To obtain the geohistory relative to a fixed reference level, the subsidence curve needs to be corrected for the effects of paleowater depth. Information on paleobathymetry can be obtained from biostratigraphy, sedimentary facies, and geochemical data [11.35]. For example, carbonate shells dissolve below the carbonate compensation depth (CCD) in the oceans [11.36]. If the sea floor is below the CCD, carbonate shells of calcareous plankton will dissolve. Depth to the CCD varies. For example, the present CCD occurs at about 5000 m in the temperate and tropical Atlantic Ocean and at about 4200–4500 m in the Pacific Ocean, except

near the equatorial upwelling zone where the CCD occurs at about 5000 m.

11.2.13 Eustatic Corrections

Eustasy describes global sea-level changes relative to a reference datum. Temporal changes in the sea-level datum can cause errors in calculations of basin subsidence history unless they are included in modeling. However, disagreement exists on details of global sea-level change, so it is advised to use only long-term eustatic fluctuations for modeling [11.11].

11.2.14 Backstripping

Decompaction and paleobathymetry determine the evolution of the basin floor and can be described by the total subsidence through time. Total subsidence is the sum of subsidence due to sediment loading and tectonic subsidence. Backstripping removes the isostatic effects of the sediment and water loads to reveal the tectonic component of subsidence. During successive removal of layers from the sediment column, densities, decompacted thicknesses, paleowater depths, and sea-level changes are used to calculate the hypothetical depth of the basin floor without isostatic response [11.10]. This is most commonly done using local (Airy) isostatic compensation. However, if the lithosphere supports the sediment load by regional flexure, backstripping is more complex [11.11].

Backstripping provides paleogeometries that are used again to forward-simulate deposition and compaction; such basin models are also called event-step models. This approach is satisfactory for basins that are characterized by simple sedimentary burial and subsidence with minimal structural deformation. However, complex tectonic events result in strongly deformed geometries that cannot be modeled by backstripping. Such settings include basins in compressional [11.37–39] or strike-slip tectonic regimes [11.40], and basins influenced by mobile salt [11.41]. To model such basins, predetermined paleogeometries are required as input. Structural restoration programs provide balanced and decompacted paleogeometries for individual tectonic phases. Forward modeling then interpolates from one paleostep to the next (paleostep model) and porosities are calculated from effective stress, whereas layer thicknesses are predefined [11.1].

11.2.15 Original Organic Richness

Petroleum generative potential depends on the original quantity and quality of organic matter in thermally

immature source rock. However, thermal maturation decreases generative potential. Thus, field measurements of the quantity and quality of organic matter in mature or postmature source rocks need to be corrected to original values for use in BPSM. By making some assumptions, the fractional conversion of source-rock organic matter to petroleum (f) and original TOC (TOC^0) can be calculated using the following equations (11.7) and (11.8) [11.42]

$$f = 1 - \frac{\text{HI}^x \left(1200 - \left[\frac{\text{HI}^0}{(1-PI^0)} \right] \right)}{\text{HI}^0 \left(1200 - \left[\frac{\text{HI}^x}{(1-PI^x)} \right] \right)} \quad (11.7)$$

PI^0 and PI^x are the original and measured Rock-Eval production indices ($PI = S1/(S1 + S2)$) respectively. PI^0 is assumed to be 0.02 for most thermally immature source rocks. The original hydrogen index (HI^0) can be estimated by various methods. For example, if thermally immature equivalents of a mature source rock are available and spatial variations in organic facies are minimal, measured HI^x is assumed to equal HI^0 . If no immature rock equivalents are available, then petrographic and paleoenvironmental information can be used to estimate HI^0 .

The original TOC in source rock prior to maturation is constrained by mass balance

$$\text{TOC}^0 = \frac{83.33(\text{HI}^x)(\text{TOC}^x)}{\text{HI}^0(1-f)(83.33 - \text{TOC}^x) + \text{HI}^x(\text{TOC}^x)} \quad (11.8)$$

where 83.33 is the percentage of carbon in the generated petroleum. For input to BPSM, maps of TOC^0 and HI^0 are superior to assuming constant TOC^0 or HI^0 in a given source rock.

11.2.16 Thermal Modeling and Temperature Prediction

Rocks achieve higher temperatures and pressures during progressive burial, which results in increased thermal maturity of kerogen. The most important parameters that control thermal maturity are temperature and time, as described by the Arrhenius equation (see later discussion). Thermal modeling of petroleum generation must account for heat provided by conduction, convection, and radioactive decay. The main thermal properties of rocks are conductivity, heat capacity, and radiogenic heat production. Details of these properties for various lithologies and fluids over wide temperature ranges are well known [11.1].

11.2.17 Heat Conduction and Convection

Heat conduction, the transfer of thermal energy by contact, is the primary thermal process in the shallow lithosphere [11.16]. The key parameter for thermal conduction is thermal conductivity, which depends on lithology, porosity, and temperature. Since rocks contain solid, liquid and vapor phases, bulk thermal conductivity, phase-behavior, and porosity need to be considered in the models. Simulations also need to take into account the influence of thermally anisotropic lithology. For example, thermal conductivity in shale is much higher parallel to rather than perpendicular to bedding.

Convection occurs when heat is transported by movement of solid or fluid. In sedimentary basins, heat convection generally involves the flow of pore water

and petroleum, which depends on fluid viscosity, temperature, rock porosity, and permeability. Convection can be more efficient than conduction when fluid flow rates are high, as might occur in foreland basins where water recharge from topographic highs displaces basin brines. A key parameter for heat convection is specific heat capacity, which describes the ability of the rock to store heat, and is largely controlled by lithology and porosity.

Radiogenic heat production can be significant when (1) the basin fill rests on relatively young granitic basement or (2) *hot shales* with abundant radioactive elements (uranium, thorium, potassium) occur within the basin fill. Radiogenic heat production is generally lowest in evaporite and carbonate rock, low to medium in sandstone, higher in shale and siltstone, and very high in black shale (organic matter) and granite (potassium)

Fig. 11.6 Transient effects influence the timing of temperature and heat flow. This example shows the effect of rapid sedimentation of pure shale without compaction (*left*), where basal heat flow is fixed at 60 mW/m^2 . Unlike the steady-state condition (60 mW/m^2 through 5 km), heat flow decreases toward the surface because heat is absorbed by each layer. During the depositional hiatus (*center*) heat flow gradually returns to steady-state values (example assumes no radioactivity). During rapid erosion, heat flow is higher than the steady-state solution and increases toward the surface (after [11.1])

feldspars). Spectral gamma logs can be used to locally calibrate radiogenic input. However, in most cases, the radiogenic contribution can be approximated by selecting an appropriate default lithology in the BPSM software.

Because the main direction of heat flow in sedimentary basins is upward, it is possible to approximate the process using 1-D models. The steady-state heat flow solution is the simplest pattern where all temperatures are in equilibrium based on thermal conductivities and boundary conditions. Transient thermal effects caused by thermal inertia increase the complexity of heat-flow analysis (Fig. 11.6). Transient heat can be quantified by the time required for the rock to reach thermal equilibrium. Transient effects can occur during rapid deposition or erosion, or when thermal boundary conditions change, e.g., geologically rapid removal of an ice sheet. A measure of the transient effect is the ratio of specific heat capacity to thermal conductivity [11.1].

11.2.18 Boundary Conditions

BPSM requires thermal boundary conditions at the top and base of the sedimentary column. The top boundary condition is a temperature, which varies with latitude and water depth through geologic time. These temperatures can be related to geologic age and mean surface paleotemperature based on plate tectonic reconstructions [11.20]. Based on plate reconstruction, the paleolatitudes can be reconstructed and used to estimate paleosurface temperature. Together with the paleowater depth, the sediment surface temperature can be estimated (onshore, surface temperature; offshore, sediment–water interface temperature).

The basal thermal boundary condition can be either the assumed temperature at the base of the lithosphere (1333 °C) or the calculated basal heat flow. The heat-flow boundary condition is commonly used because it summarizes all uncertainties in one parameter, which simplifies calibration. Heat flow is one of the most critical input parameters for BPSM due to its impact on the amount, composition, and rate of petroleum generation. Although present-day heat flow may be known, paleo-heat flow is usually poorly constrained. Basal heat-flow values are often predicted by crustal models in separate preprocessing programs or they are interactively calculated for each geological event. Partly for this reason, model simulations use heat flow as a primary variable to calibrate calculated maturity and temperature curves with depth to measured maturity values (e.g., vitrinite reflectance) and corrected borehole temperatures from wells [11.16]. For extensional basins, many simulations use McKenzie's thermal model of subsidence [11.43] or variations of this thermal model.

11.2.19 Petroleum Generation

Figure 11.7 shows the generalized evolution of organic matter during and after sedimentation. Hydrocarbon gas can be created at shallow depth (biogenic) or deeper (thermogenic), when associated with oil generation from kerogen or secondary cracking of oil. Gas generation does not continue indefinitely with depth, as depicted in earlier profiles [11.44, Fig. II.7.1], but ends when the kerogen is depleted. Many biomarkers survive diagenesis and catagenesis prior to complete destruction during late catagenesis and metagenesis [11.42]. The depth scale varies depending on different factors, such as the geothermal gradient or kinetics of petroleum generation. The scheme is generally applicable, particularly for marine source rocks, which dominate the geologic record [11.45].

Oil and gas generation depend on deposition of organic-rich fine-grained sediments, preservation, and thermal alteration, usually due to burial [11.46]. Three stages in the evolution of sedimentary organic matter (Fig. 11.7) include:

1. Diagenesis, i.e., transformations that occur prior to significant thermal alteration (e.g., generation of microbial methane)
2. Catagenesis or thermal transformation of kerogen to petroleum in the approximate range 50–200 °C
3. Metagenesis or thermal destruction of petroleum at approximately 200 °C or higher, but prior to greenschist metamorphism.

11.2.20 Diagenesis, Catagenesis, Metagenesis

Pure methane (dry gas) can be generated by methanogenic archaea in shallow sediments (< 1 km) in an optimum temperature range of ≈ 35 –45 °C [11.47, 48] (Fig. 11.7). Subsurface biodegradation is mainly an anaerobic microbial process that generates dry gas over geologic time by two different mechanisms. Primary biogenic methane originates by microbial reduction of acetate or carbon dioxide liberated from thermally immature dispersed organic matter in source rock or coal. The source rock commonly serves as a shallow unconventional reservoir, although short-distance migration to conventional reservoir rocks also occurs. Several factors control primary biogenic gas generation, including source-rock organic richness, herbaceous vegetation, fast sedimentation of juxtaposed source and reservoir rock intervals, and low temperature (< 80 °C).

Primary microbial methane was believed to account for up to 20% of worldwide commercial gas accumula-

Fig. 11.7a,b Schematic stratigraphic column (a) depicts the generalized evolution of organic matter during and after sedimentation. The depths for top and bottom of the oil window vary depending on geothermal gradient and kerogen kinetics. Preservation of organic matter, especially under anoxic conditions during diagenesis, can result in potential source rock, which undergoes burial and thermal maturation to become effective source rock for migrated petroleum. (b) Unconventional petroleum remains in the source rock, which effectively becomes reservoir rock (after [11.42], reprinted with permission by ChevronTexaco Exploration and Production Technology Company, a division of Chevron USA Inc.)

tions [11.47], although evidence for secondary microbial methane generated by degradation of crude oil suggests a considerably smaller contribution [11.49]. Measurements of gas wetness and stable carbon and deuterium isotope ratios of the methane, carbon dioxide, and other gases allow biogenic and thermogenic gases to be differentiated [11.49, 50]. Stable carbon isotope ratios can also be used to estimate abundances of end members in two-component mixtures, i. e., biogenic-thermogenic gas mixtures [11.51]. Secondary biogenic gas originates by microbial degradation of thermogenic gas in conventional reservoirs at the oil-water contact, where heavier hydrocarbons are converted to methane and a heavy oil residuum. This process likely involves syntrophic bacteria and methanogenic archaea that ferment alkanes to hydrogen and acetate, oxidize the acetate to carbon dioxide and hydrogen, and then reduce the carbon dioxide to methane [11.52]. There are at least three different carbon-flow pathways employed by different methanogens [11.50]:

1. Hydrogenotrophic
2. Acetotrophic
3. Methylotrophic.

In BPSM, microbial gas can be calculated by defining a Gaussian distribution of temperatures governing microbial activity. Burial history is important because reservoirs are effectively pasteurized above 80 °C. For example, burial to this temperature followed by uplift of the reservoir commonly results in no further biodegradation of the trapped oil [11.53]. Other criteria that control secondary biogenic gas generation [11.42] include access to petroleum and nutrients (e.g., nitrate, phosphate) at the oil-water contact, low water salinity (< 100–150 ppm) and little or no sulfate (sulfate reducers outcompete methanogens).

Catagenesis begins at ≈ 50 °C and ends at ≈ 200 °C, when oil generation from labile kerogen is complete [11.54]. Much of the initial petroleum generated from oil-prone source rock is liquid that con-

tains dissolved associated vapor or components that would be gaseous at surface conditions. Above 150 °C, the remaining hydrogen-poor kerogen generates mainly thermogenic hydrocarbon gas, which may initially be enriched in dissolved condensate, but becomes drier (proportionally more methane) as generation nears completion. In the Gulf of Mexico Smackover Formation, complete fractional conversion of oil to gas corresponds to ≈ 200 °C and vitrinite reflectance (R_o) of 2.0% [11.42]. In contrast, Tian et al. [11.55] used pyrolysis of Triassic oil from the Tarim Basin and analysis of the resulting gas and residual hydrocarbons to show that complete cracking of wet gases to methane requires $R_o > 2.4\%$.

The extent of transformation of kerogen to petroleum within organic-rich source rock is commonly quantified in BPSM by the transformation ratio (TR) or vitrinite reflectance (R_o). TR expresses the converted mass fraction of the initial reactant, i. e., the ratio of petroleum formed from kerogen in source rock to the total amount of petroleum that could be formed from that kerogen [11.44]. R_o is the calibrated percentage of light that is reflected from a polished coal maceral called vitrinite that originates from higher plants. Accurate R_o may be difficult to obtain in organic-rich marine sediments having little or no land plant input. For this reason, R_o is normally measured in organic-lean shales above and below the source rock. In BPSM, vitrinite reflectance is calculated (EASY% R_o) for comparison with measured R_o using kinetics established by Sweeney and Burnham [11.56]. Although commonly used interchangeably, R_o and TR have different kinetics. R_o kinetics start at an activation energy (E_a) of 36 kcal/mol, whereas most hydrocarbon generation kinetics start at least 10 kcal/mol later [11.57]. Because the frequency factors are nearly the same, the difference in E_a explains the significant difference between R_o and TR during early maturation, when R_o increases but TR remains near zero [11.57]. It is important to recognize that the TR kinetics vary with kerogen type, as discussed later.

In BPSM, TR and R_o can be examined through geologic time to identify the onset of oil generation, typically defined as 0.6% R_o or 10% TR [11.4]. The critical moment of the petroleum system is the time between 50 and 90% TR that best depicts the generation-migration-accumulation of petroleum [11.5]. Many workers use 10, 50, and 99% TR for the start, peak, and end of oil generation. The end of oil generation occurs at $\approx 2\%$ R_o .

11.2.21 Petroleum Generation Kinetics

Increased burial and/or paleoheat flow can result in sufficient temperatures to crack kerogen to oil and

gas [11.58]. The Arrhenius equation quantifies the relationship between temperature (T , K) and the rate of a chemical reaction (k)

$$k = Ae^{-\frac{E_a}{RT}}, \quad (11.9)$$

where E_a is the activation energy (kcal/mol), R is the universal gas constant, and A is the frequency factor or pre-exponential constant (s^{-1}), which largely depends on vibrational frequencies of the chemical bonds that are broken. Most workers assume that kerogen converts to petroleum in a complex series of sequential and parallel first-order reactions described by the above equation. First-order reactions depend solely on the concentrations of each reactant and the rate constant k .

Three general methods commonly used to quantify petroleum generation kinetics are:

1. Bulk kinetics (Fig. 11.8), which account only for conversion of kerogen to petroleum and do not distinguish between petroleum fractions
2. Oil-gas kinetics, which account for light hydrocarbons (e.g., C_1 to C_5 hydrocarbon gases) and oil (C_{6+})
3. Multicomponent or compositional kinetics, which consider more than two hydrocarbon components.

Many variations of multicomponent kinetics are used, such as four components [11.59] or 14 components [11.21] based on boiling-point classes, which can be used to predict phase properties in reservoirs, such as API gravity, GOR, or saturation pressure [11.1].

Predictions of oil composition cannot be made using routine published kinetic parameters. Computation models need to account not only for the chemistry of the generated petroleum, but must also include aspects of expulsion, retention, and secondary cracking. For example, a new SARA (saturate, aromatic, resin, asphaltene) kinetic modeling method can be used to improve predictions of oil quality in unconventional targets [11.7]. It accounts for 11 components (four bitumen, three hydrocarbon gas, two oil, CO_2 , and H_2S) and includes additional features such as complex secondary cracking through a multistage reaction network for bitumen to oil, oil to gas, and bitumen to gas conversions, as well as a special adsorption model for the bitumen components. The components are lumped according to physicochemical properties to minimize processing time. The method can be used to predict asphaltene flocculation and tar mats as well as formation of CO_2 and H_2S .

Most BPSM software provides a selection of default kinetic parameters that can be used when representative

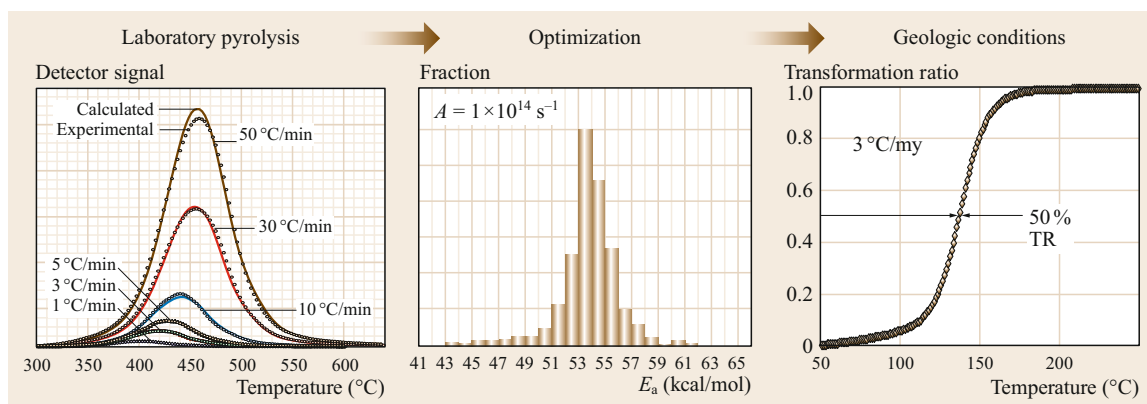

Fig. 11.8 A bulk kinetic model of a representative, thermally immature source-rock sample is obtained by optimizing (fitting) peaks from three or more programmed pyrolysis heating-rate experiments using software, such as Kinetics05 (after [11.60]). In the example, extrapolation to geologic conditions assumes a heating rate of 3 °C/my, but temperature history in the model may differ. TR = transformation ratio or extent of conversion of kerogen to petroleum

source-rock samples are unavailable [11.1]. However, default kinetics should be used cautiously. It is unwise to assume that kinetics for a specific source rock in the study area will be similar to default kinetics, unless both are from the same source rock at the same location. Kerogen type, as defined by Rock-Eval pyrolysis original HI, is not systematically related to kinetic response, and it is unwise to infer kerogen type or kinetics based on source-rock deposition environment [11.61]. Ideally, kinetic parameters should be determined on representative, organic-rich, unweathered source rock from the study area that has undergone diagenesis, but has yet to reach the early oil window (vitrinite reflectance equivalent ≈ 0.4 – 0.5%).

Various laboratory methods have been proposed to obtain E_a and A for conversion of source-rock kerogen to petroleum. These methods include closed-system isothermal pyrolysis, such as microscale sealed vessel pyrolysis (MSSV) [11.62], gold tube reactors [11.63], or hydrous pyrolysis [11.64, 65]. However, the most common approach is open-system programmed pyrolysis using Pyromat II, Rock-Eval VI, SRAnalyzer, Hawk, or similar systems and distributed reactivity kinetic modeling [11.66]. These calculations yield a range of E_a values that reflect the diversity of chemical bonds in the kerogen and an optimized value of A [11.67]. Pyrolyzate peaks for the conversion of kerogen to petroleum are optimized using standardized software, such as Kinetics05 (Fig. 11.8). Logarithms of E_a weighting factors and A are varied until the root mean squared discrepancy between observed and estimated rates of pyrolyzate yield reach a minimum [11.60]. Energy spacing of 1 kcal/mol through the E_a distribution is recommended because larger spacing (e.g., 2 kcal/mol) results in false minima [11.68].

Debate continues on the reliability of open- versus closed-system pyrolysis [11.65, 69–71]. Some consider that primary migration of petroleum through kerogen in the source rock is the rate-limiting step rather than cracking of carbon–carbon bonds [11.72]. More recently, some publications promote one-run open-system pyrolysis using a single heating rate and a fixed, universal A to determine petroleum generation kinetics [11.73]. However, based on analysis of 52 worldwide source rocks, Peters et al. [11.74] recommend at least three pyrolysis heating rates that span at least a 20-fold variation, where both E_a and A are optimized. Fast heating rates (e.g., 50 °C/min) may result in inaccurate temperatures due to the effects of thermal inertia. For these reasons, three or more heating rates in the range 1–30 °C (e.g., 1, 5, and 25 °C/min) are recommended, when the product of the heating rate and sample size is less than ≈ 100 mg °C/min.

The extrapolation of Arrhenius kinetic parameters determined in the laboratory to geologic time is based on three assumptions (Fig. 11.8):

1. The experimental data are accurate
2. The appropriate reaction model (e.g., distributed reactivity) is used to evaluate the data
3. The reaction mechanisms from experimental to geologic rates are similar [11.75].

Measured and predicted petroleum generation rate curves from open-system pyrolysis experiments are similar to those from natural maturation series, suggesting that laboratory experiments can be used to reliably predict maturation over geologic time [11.76]. However, distributed reactivity models fail for kerogens that have narrow activation energy distributions, and nucleation-growth models are necessary [11.74, 77].

11.2.22 Petroleum Migration and Accumulation

A key strength of BPSM simulators is the ability to model primary and secondary petroleum migration. Primary migration is expulsion of petroleum out of fine-grained, low-permeability source rocks, whereas secondary migration describes the transport of petroleum through coarser-grained, higher-permeability carrier beds and/or other conduits, such as faults, to the trap. Accurate modeling of primary and secondary migration efficiencies is needed to predict the volumes of petroleum in conventional accumulations and the amount that remains within the source rock. The latter capability is critical to evaluate unconventional resources.

Primary migration involves separate-phase transport of petroleum within the capillaries and pore throats of fine-grained, low-permeability source rocks. The driving force is internal pore fluid pressure during burial, but this also depends on source-rock richness and pore saturation. The initial expulsion is the release of generated petroleum from the kerogen into free pore space in the source rock. *Kelemen et al.* [11.78] used an extended Flory–Rehner regular solution theory to show that lower source-rock richness and cross-link density results in bitumen retention in the rock and enrichment of aliphatic components in the expelled fluid. Higher source-rock richness and cross-link density results in earlier fluid expulsion and enrichment of polar components. Two thresholds must be overcome before the petroleum becomes mobile: (1) the adsorption limit, and (2) the critical oil/gas saturation. Most light petroleum is first adsorbed onto the organic matter after generation, depending on TOC, temperature, and pressure. The excess amount is released as separate fluid phases of water, liquid petroleum, and gas, but must exceed the critical oil/gas and connate water saturation to allow fluid flow. These so-called saturation endpoints are lithologic parameters that are included in the relative permeability curves. Note that dissolved petroleum components can also be transported via diffusion within the phase, even if the phases remain immobile. Primary migration occurs over relatively short distances of less than 1 km [11.79].

Secondary migration is the subsequent transport of petroleum, driven by buoyancy, through coarser-grained, higher-permeability carrier beds or other conduits to the trap [11.44]. This may occur over tens or even hundreds of kilometers [11.79]. Finally, tertiary migration can occur when the trap for previous accumulations is reorganized, forcing the petroleum to move to another trap. Seeps can result from secondary or tertiary migration.

Petroleum migration is only relevant in 2-D and 3-D models. A limiting factor in migration modeling is that model paleoreconstructions may inadequately reflect the evolution of subsurface geometry or lithologic properties, i. e., the resolution of paleoreconstructions using available data seldom approaches that of nature.

A useful BPSM workflow is to first simulate without migration, for two main reasons: (1) this allows determination of the critical moment so that additional time steps can be added to the model if needed for better time resolution, and (2) because the model geometry is a reconstruction of the input basin geometry, it is prudent to check the reconstructed geometry before proceeding. Source-rock tracking allows the user to quantify the relative contribution of petroleum from different source rocks to a given accumulation. BPSM simulators also track the proportion of generated petroleum that seeps to the surface or beyond the edges of the model.

Depending on viscosity, rock permeability, and other factors, petroleum flows through permeable media at rates up to ≈ 100 m/yr and through fine-grained rocks at only 0.0001 m/yr [11.1]. This difference of seven orders of magnitude in flow rates suggests that different physics are required to model fluid flow. Because of the complexity of migration, several different modeling approaches are used, and no single method applies for all studies. The approaches include Darcy flow, flow-path (i. e., ray tracing), hybrid modeling and invasion percolation. Hybrid modeling combines two migration methods, as discussed below.

Darcy Flow Migration

Darcy flow migration is based on equations of flow through porous media where flow velocities are controlled by permeability and fluid viscosity (11.5). Like flow-path modeling, Darcy migration requires accurate definition of the carrier bed and seal rock in the model. Unlike flow-path modeling, Darcy migration accounts for complex transport processes, such as multiphase migration, gas diffusion, and the effects of pressure variations. Darcy migration balances all external forces within the petroleum system, i. e., capillary pressure, buoyancy, water pressure, and the viscous resisting force [11.1]. Accordingly, this method is especially suitable in BPSM when reservoir modeling, which also utilizes Darcy flow, will be employed.

Darcy migration modeling incorporates the full physics of the natural system and thus requires relatively long processing times, which limits use of detailed model geometries. Cell dimensions in complex models are commonly downscaled to allow the use of Darcy migration modeling, which entails loss of output resolution.

Typical analysis of a Darcy-flow BPSM model might involve visualizing the calculated vitrinite reflectance (EASY%R_o) or TR in the source rock and migration vectors and petroleum saturation in the reservoir rocks (Fig. 11.9). It may also be useful to examine the calculated pore pressure near faults to understand saturation behavior in those regions; faults can release pressure, thus focusing migration vectors toward them.

Flow-Path Migration

Flow-path migration modeling is the simplest of the migration methods to calculate and visualize in BPSM. The method is based on geometric analysis of the source-carrier-reservoir rock system: petroleum generated in source rock is expelled upward (only) into a carrier bed where fluid migrates by buoyancy to a geometric high below a seal rock [11.80]. Traps can fill with petroleum, which then spills to adjacent traps. Alternately, vertical leakage can take place through the seal or along faults. Within drainage areas, the uppermost portion of the carrier bed conducts petroleum to the reservoir rock. Thus, flow-path modeling encompasses migration path, drainage area, and accumulation analysis [11.1]. Flow-path modeling (and the flow-path domain in hybrid migration, below) does not account for the thickness of the carrier, reservoir, or non-reservoir rock between the pod of active source rock and trap. Petroleum is distributed below the top of the carrier bed or reservoir rock. Buoyancy pressure of the petroleum column and capillary pressure of the seal determine the volume of trapped petroleum, column height, and any loss through the seal.

Flow-path migration is rapid and highly focused using this approach. In effect, flow-path models produce inverted rivers of migrating petroleum (Fig. 11.10). BPSM flow-path output identifies discrete accumulations that are easily visualized and can be compared with maps of known oil and gas fields. It should be recognized that accumulations calculated in BPSM are approximations of existing fields and rarely match exactly. A typical output analysis might involve visualizing the flow paths and accumulations in carrier beds and some measurement of thermal maturity (e.g., saturations of residual petroleum) in the source rock.

Flow-path modeling has several advantages. The technique is most suitable where (1) petroleum is likely to occur in crestal structural traps that are well represented in the input basin geometry or (2) as an initial look at accumulation potential in frontier areas where little information about the subsurface exists. The method may be ideal where subsurface structure is imaged using high-resolution seismic data, which permit modeling of accurate reservoir geometries. Com-

puting times are short, thus allowing detailed model geometries, fine-scale model resolution (e.g., high accuracy of accumulation bodies, column heights, and seal losses), and rapid scenario testing of other model parameters. For this reason, it is also useful to employ flow-path modeling before other methods.

Flow-path modeling is generally unsuitable for study areas where petroleum occurs in stratigraphic traps or where subsurface structure is poorly known, e.g., some subsalt plays. However, when little subsurface data are available, flow-path modeling is commonly used to provide a quick look at potential accumulations. Flow-path modeling requires the user to predefine the carrier beds. Because geometric ray tracing is independent of any physical model of petroleum migration, it does not take into account interactions between the fluid and the layers between the source and reservoir rock. Physical processes that cannot be represented in flow-path modeling include overpressure generation, pressure-controlled petroleum migration, and pressure-driven downward expulsion [11.81]. Flow-path modeling also assumes instantaneous migration. Oil that arrives instantaneously in a trap based on flow-path modeling will experience a different thermal history than oil that migrates more slowly based on another migration method, resulting in predicted accumulations that may be compositionally distinct.

Hybrid Migration

Hybrid migration combines the two previously discussed methods, flow path and Darcy flow, into a hybrid scheme that distinguishes the mainly buoyancy-driven flow in carrier beds and reservoir rocks from pressure-dependent flow in the source and other non-reservoir rocks. In hybrid modeling, a predefined permeability threshold separates low-permeability (e.g., source rocks) from high-permeability lithofacies (carrier and reservoir rocks), which then are simulated by Darcy flow or flow-path migration, respectively. This so-called domain decomposition is applied throughout all model layers using the same grid size. However, the output can be sampled using grids of different size, i. e., Darcy flow and flow-path layers can be modeled at coarse and fine grid scales, respectively [11.1].

Hybrid migration modeling goes beyond domain decomposition to effectively handle each element of the petroleum system. Upward and downward expulsion from source rock is modeled using the Darcy equation. In the carrier bed leading to the reservoir rock, Darcy migration should be used for inefficient carriers, such as shale, when migration is slow. Flow-path migration is used for efficient carriers, such as sandstone. In the reservoir rock, the equilibrium state is treated with flow-path modeling, whereas breach of the seal and loss of

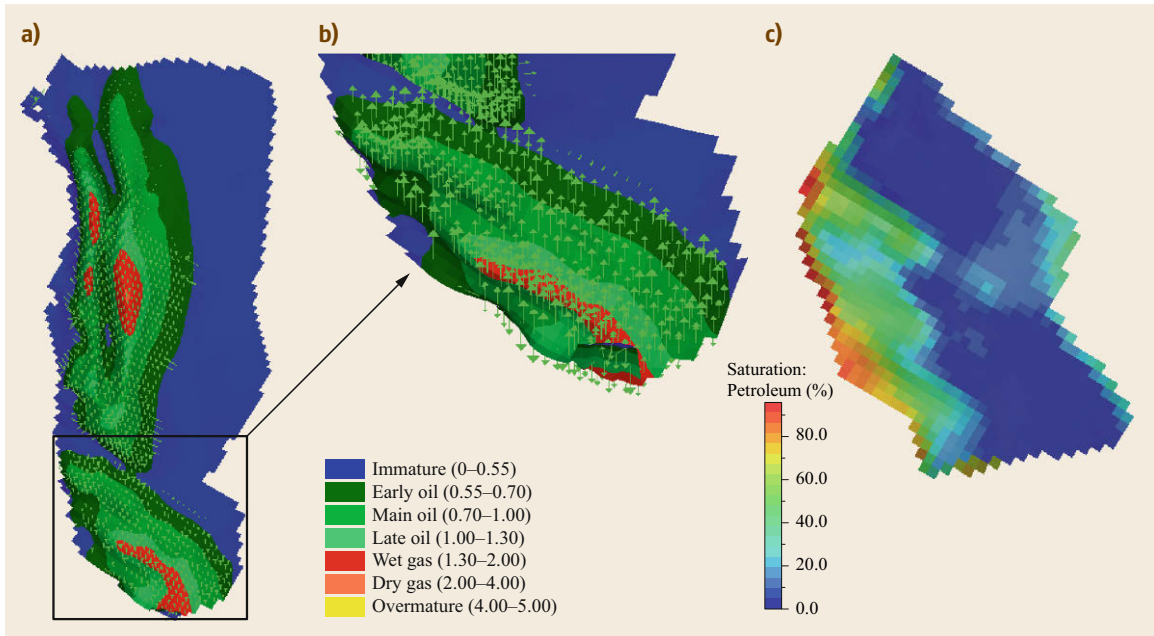

Fig. 11.9a-c Typical BPSM output based on Darcy migration showing EASY% R_o (after [11.56]) calculated in the source rock (a), migration vectors from the source rock to the overlying reservoir rock (b), and oil saturation in the reservoir rock (c). Note the coarse grid resolution in the reservoir rock (after [11.4])

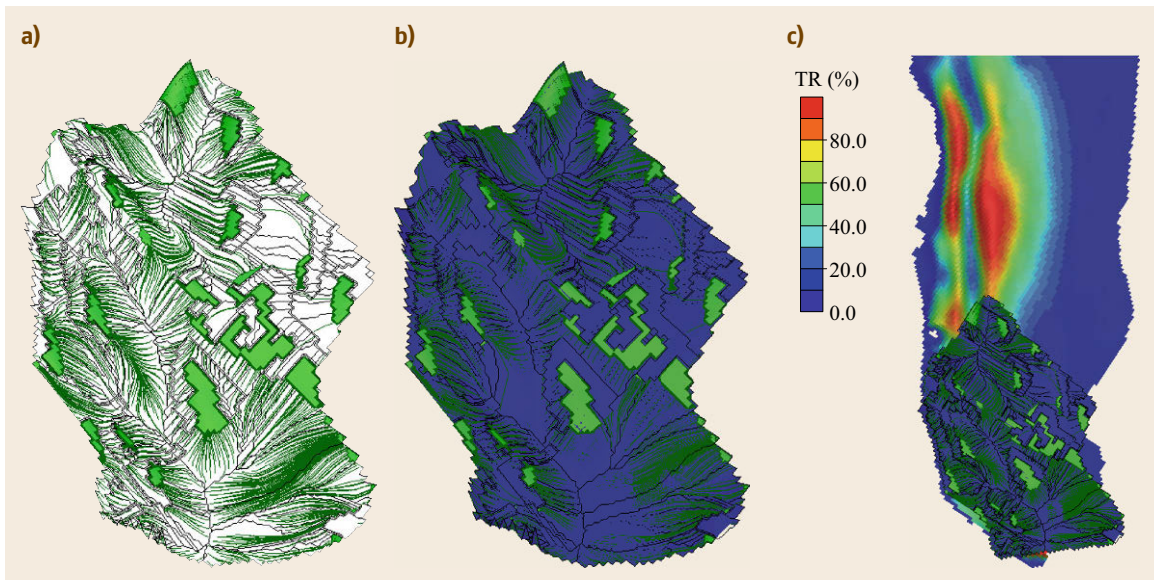

Fig. 11.10a-c Typical BPSM output based on flow-path migration showing drainage areas (*thin black lines*), migration pathways (*thin green lines*), and accumulations (*green polygons*) (a), the same view but with a superimposed reservoir rock depth map (b), and the same but with the source-rock depth map underlying the reservoir rock (c). The source rock is displayed as percent transformation ratio (after [11.4])

petroleum involves Darcy flow. Finally, flow velocities can be calculated using the Darcy equation in the overburden rock, depending on permeability.

As an example, a commonly used default value for the permeability threshold between the two domains is 10^{-2} mD at a porosity of 30% [11.1]. This threshold is

applied to model layers regardless of whether the porosity is 30% at a particular layer or event. In practice, the threshold that distinguishes Darcy from flow-path layers must be evaluated in context of the geology of each model unit. The 10^{-2} mD default means that only a few pure lithologies are treated as high-permeability layers (carrier beds and reservoir rocks). Once the user defines complex mixtures of lithologies for model layers, the consequent seal and reservoir layers may not behave as expected under the constraints of the domain decomposition. Thus, the user may need to adjust the threshold so layers that are known to be seals or reservoirs have permeabilities below or above the threshold respectively. In contrast, the user can also use in situ porosity to distinguish flow-path from the Darcy layers.

Invasion Percolation

Invasion percolation (IP) differs from the other migration mechanisms in that buoyancy is balanced against capillary entry pressure to determine where oil droplets move. The IP concept [11.81, 82], in which one fluid in a porous medium displaces the in situ fluid, was described earlier [11.83]. In petroleum migration, the invading fluid is petroleum, the in situ fluid is water, and the medium is a network of pores connected by narrow pore throats [11.84]. In IP calculations, the buoyancy force that drives migration is compared to the capillary entry pressure that retards it at these pore throats. Migration occurs as a front through the matrix of pore throats by accessing pores with the lowest threshold pressures. Initially, the choice of pathways by migrating petroleum is random, but later migration proceeds in preexisting pathways because the resisting force has already been reduced by petroleum saturations within the pore throats. In this way, the depth-dependent effect of gravity on the matrix concentrates the flow of the invading fluid into *stringers* within the porous medium. With increasing gravity gradient, stringers become confined and concentrated [11.85]. BPSM output for IP models consists of many stringers with physical properties that can be queried.

Determination of IP pathways relies on the relative distribution of permeability (i.e., capillary entry pressure) across the model domain. For IP to behave realistically in layers that are assigned homogeneous permeability in the model, heterogeneity is incorporated using a random distribution of permeability (noise) or by use of seismic attribute volumes to condition the flow pathways [11.84]. Some BPSM software permits capillary pressure variations (buoyancy forces for upward flow) and anisotropy (encourages lateral flow) to be specified. The challenge for the modeler is to choose the optimum combination of noise and

anisotropy to achieve the most realistic migration patterns.

As with flow-path modeling, IP compute times can be fast, allowing multiple charge scenarios to be tested quickly. Unlike flow-path migration, IP also allows consideration of fluid migration in non-reservoir layers, which do not need to be predefined by the model structure. However, IP can be slow to calculate when multicomponent kinetics and source-rock tracking are utilized in 3-D in conjunction with high-resolution seismic input.

BPSM output for models run with IP migration consists of hundreds to thousands of stringers with physical properties that can be queried. Stringer analysis, e.g., to query which pod of active source rock it derives from, is the reverse of flow-path analysis (Fig. 11.11). Accumulations in a model run with IP migration are actually probabilities of petroleum being present in a cell. Output is a series of discrete dots, but these can be displayed as bodies to determine column heights, as in flow-path modeling. It may be desirable to filter model output to reduce the many micro-accumulations that occur in low-permeability carriers.

Comparison of Migration Methods

Table 11.2 summarizes some features of the four main BPSM petroleum migration methods. The table is generalized, and comparisons may differ from model to model. Like flow-path modeling, IP assumes instantaneous flow and is suitable for modeling migration in high-resolution geometric models. Where charge timing is relevant, Darcy or hybrid flow methods are recommended over IP and flow path. For example, in cases where mixing or secondary oil cracking occur, time may be a relevant factor, so Darcy or hybrid migration should be used. In all methods except Darcy modeling, a high percentage of migrated petroleum is lost at the edges of the model if high-permeability layers are tilted to allow outflow [11.86]. Unlike flow-path modeling, IP is well suited for simulating complex migration paths and migration along faults in conjunction with seismic facies refinement. Compute times for IP migration can be as short as for flow-path modeling. However, if other numerically intensive routines are used, such as multicomponent kinetics and source-rock tracking, compute times for IP migration can be as long as those for Darcy flow modeling. Finally, all methods except flow-path migration can be used in areas of overpressure because capillary entry pressure can be modified by overpressure and the migration paths follow the direction of steepest ascent across the overpressure contours. In summary, no single migration modeling method is universally applicable. A useful approach for most BPSM studies is to compare results for

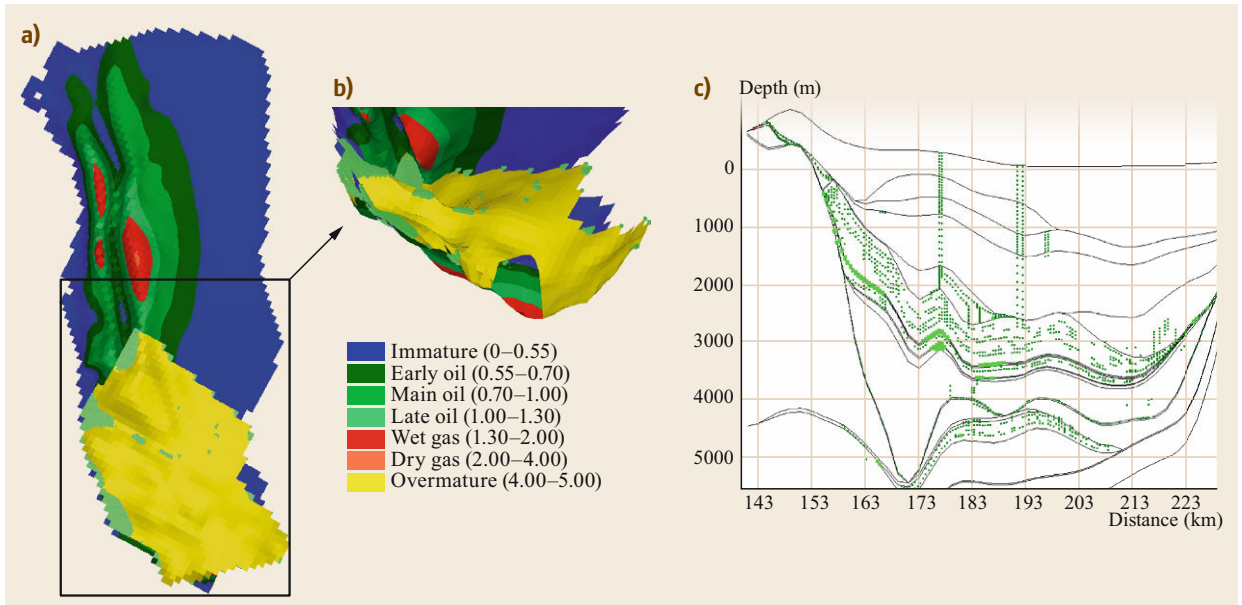

Fig. 11.11a-c Typical output from a BPSM model with IP migration showing EASY% R_o (after [11.56]) in the source rock overlain by IP accumulations in the reservoir rock (*green areas on yellow layer*) (a), discrete accumulation sites (*green areas*) in the reservoir rock (b), and a horizontal 2-D extraction from the 3-D model across the reservoir rock (c). *Smaller dark green dots* denote petroleum migration stringers and *larger green areas* denote accumulations (after [11.4])

Table 11.2 Comparison of features for Darcy flow, flow-path, hybrid migration, and invasion percolation modeling

	Darcy flow	Flow path	Hybrid migration	Invasion percolation
Compute time	Long	Short	Short/long	Short/long
Model resolution	Low	High	High (flow path) Low (Darcy)	High
Migration time	Timing of flow	Instantaneous	Instantaneous (flow path) Timing of flow (Darcy)	Instantaneous
Role of overpressure	Yes	No	Yes (Darcy) No (flow path)	Yes

all of the methods before focusing on the method that best addresses the study objectives [11.81].

11.2.23 Petroleum System Event Timing

Historically, most exploration was based on the simple play fairway concept in which the largest subsurface structures were drilled first. The petroleum system concept received little attention from industry until major exploration failures, such as the Mukluk wildcat well, Alaska [11.87], forced recognition of the need for a more systematic and comprehensive approach to exploration. A play consists of fields and prospects having similar trapping mechanisms (e.g., anticline, pinchout, or pinnacle reef plays). In play fairway exploration, previously discovered accumulations and their geology are used to risk undiscovered accumulations. For example, the Barrow Arch on the North Slope of Alaska contains

multiple structural-stratigraphic traps that were targeted for drilling mainly because of earlier discoveries in similar traps along the Arch, such as the Prudhoe Bay field. The spectacular and costly failure of the Mukluk well located along the Barrow Arch clearly demonstrated that play fairway maps are static present-day snapshots of subsurface geology that fail to account for the timing of petroleum system events. Unlike the play concept, modern BPSM is dynamic, accounts for the timing of petroleum system events, and can be used to better quantify the risk that traps are barren or the likelihood that they are filled with oil and gas.

The Alaska North Slope may contain much of the undiscovered oil and gas in the circum-Arctic [11.88]. A calibrated 3-D BPSM study of this area (Fig. 11.12) demonstrates the key role played by timing of petroleum expulsion from the source rock relative to trap formation [11.89].

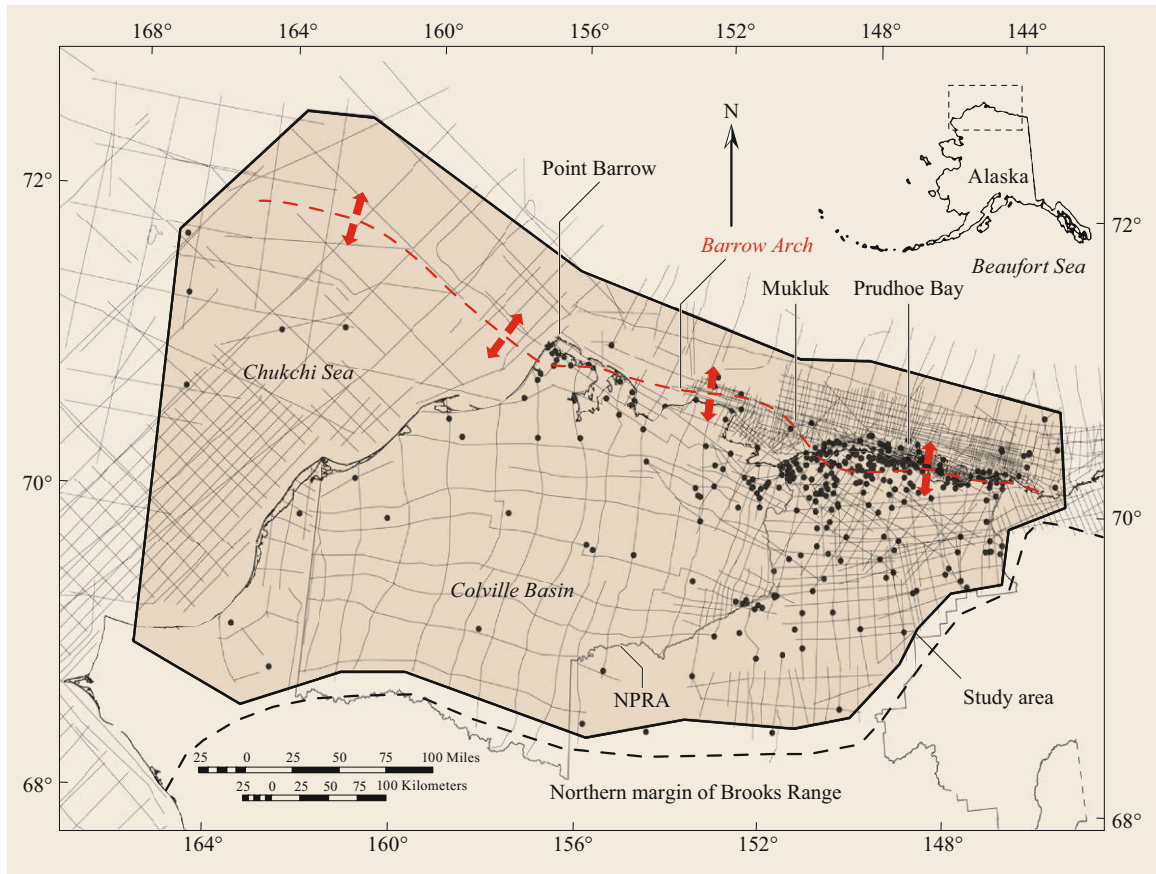

Fig. 11.12 A three-dimensional basin and petroleum system model of the Alaska North slope, which covers 275 000 km² (*polygon*) and is based on 48 000 km of seismic data (*gray lines*) in addition to stratigraphic and geochemical information from more than 400 wells. *Red dashed line* shows location of Barrow Arch (after [11.2], figure copyright Schlumberger, used with permission)

Trap formation at Prudhoe Bay preceded expulsion from the downdip thermally mature source rock, resulting in a giant accumulation. Chemometric (multivariate statistics) analysis of biomarker and stable isotope data shows that the Prudhoe Bay field contains a mixture of oil from the Triassic Shublik Formation and Cretaceous Hue-gamma ray zone (Hue-GRZ) with lesser input from the basal Jurassic Kingak Shale [11.90]. These results are consistent with the 3-D model, in which Shublik and Kingak source rocks started to expel petroleum during the Cretaceous, whereas the Hue-GRZ contributed later [11.89].

The reason for failure of the Mukluk wildcat well remains controversial. Prior to drilling, the Mukluk structure (Fig. 11.13) was estimated to contain 240 million m³ (\approx 1.5 billion bbl) of recoverable oil in a structural-stratigraphic trap, although permafrost impaired the quality of subsurface imaging and estimated seismic velocities. The 3-D model (Fig. 11.14) integrates the

hypothesis that so-called thief sands on the Lower Cretaceous unconformity (LCU) were responsible for remigration (tertiary migration) of hydrocarbons [11.91, 92]. Model results show that petroleum accumulated, but suggest significant risk of spillage from the structure through Kuparuk C-D thief sands overlying the LCU toward the Kuparuk River field to the southeast during Tertiary tilting (Fig. 11.15). A petroleum system event chart based on the 3-D model of the Mukluk area shows how the relative timing of these events impacted risk (Fig. 11.16). Drill cuttings from the completed well showed extensive oil stain in the target Ivishak Sandstone reservoir rock, but the well was uneconomic.

11.2.24 Modeling Unconventional Resources

BPSM software can be used to model both conventional and unconventional resources, and although there are differences (Table 11.3), they can be modeled simul-

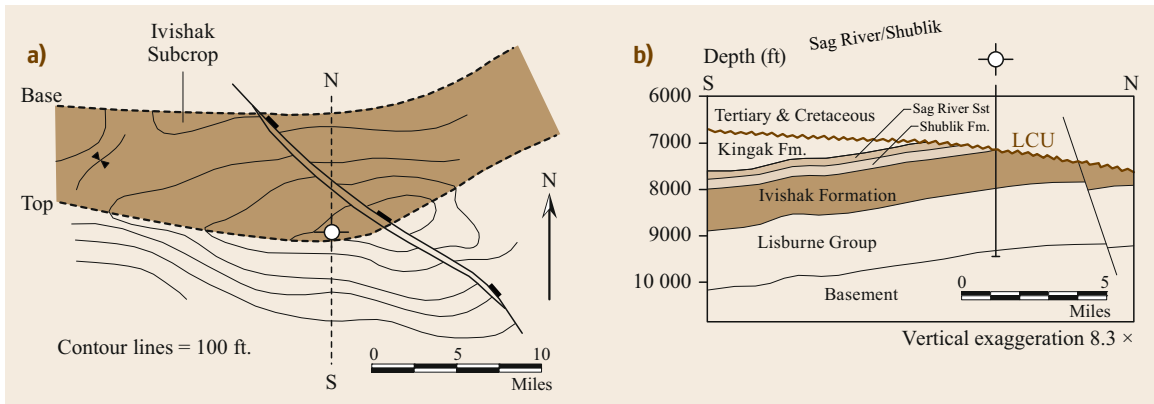

Fig. 11.13 (a) Seismic data indicated a four-way closure at the Mukluk prospect as depicted on the Ivishak Formation subcrop at the Lower Cretaceous unconformity (LCU; jagged line). The Mukluk structure is 32×14 km (≈ 20 mile long and 9 mile wide). The Ivishak Formation within the Permo-Triassic Sadlerochit Group is the main reservoir rock at Prudhoe Bay. (b) North-south cross-section through the well location shows the gentle Mukluk structure and truncation due to a normal fault to the north. The Sag River and Ivishak units contain carrier or reservoir facies, while the Shublik Formation is a major source rock on the North Slope (after [11.87], reprinted by permission of AAPG whose permission is required for further use)

Fig. 11.14 Present-day cross-section extracted from the 3-D model showing location of the hinge line for the section (red dashed line) used for Fig. 11.15. Inset shows the location of the section extracted from the 3-D model through the Mukluk prospect

taneously. Conventional exploration targets petroleum that migrated from the source rock to traps. A principal objective of BPSM for conventional systems is to establish the relative timing of petroleum generation-migration-accumulation and the timing of trap formation. Unconventional exploration targets petroleum that remains within the source rock. In unconventional shale plays, the source rock is a key element because

it includes the charge, reservoir, trap, and seal. Secondary cracking of oil to gas is generally unimportant in shallow conventional traps. However, oil that remains in the source rocks in the oil window can be more deeply buried where it cracks to hydrocarbon gas. Conventional BPSM focuses on the reduction in porosity that occurs during burial, whereas unconventional BPSM also tracks the increase in organoporosity

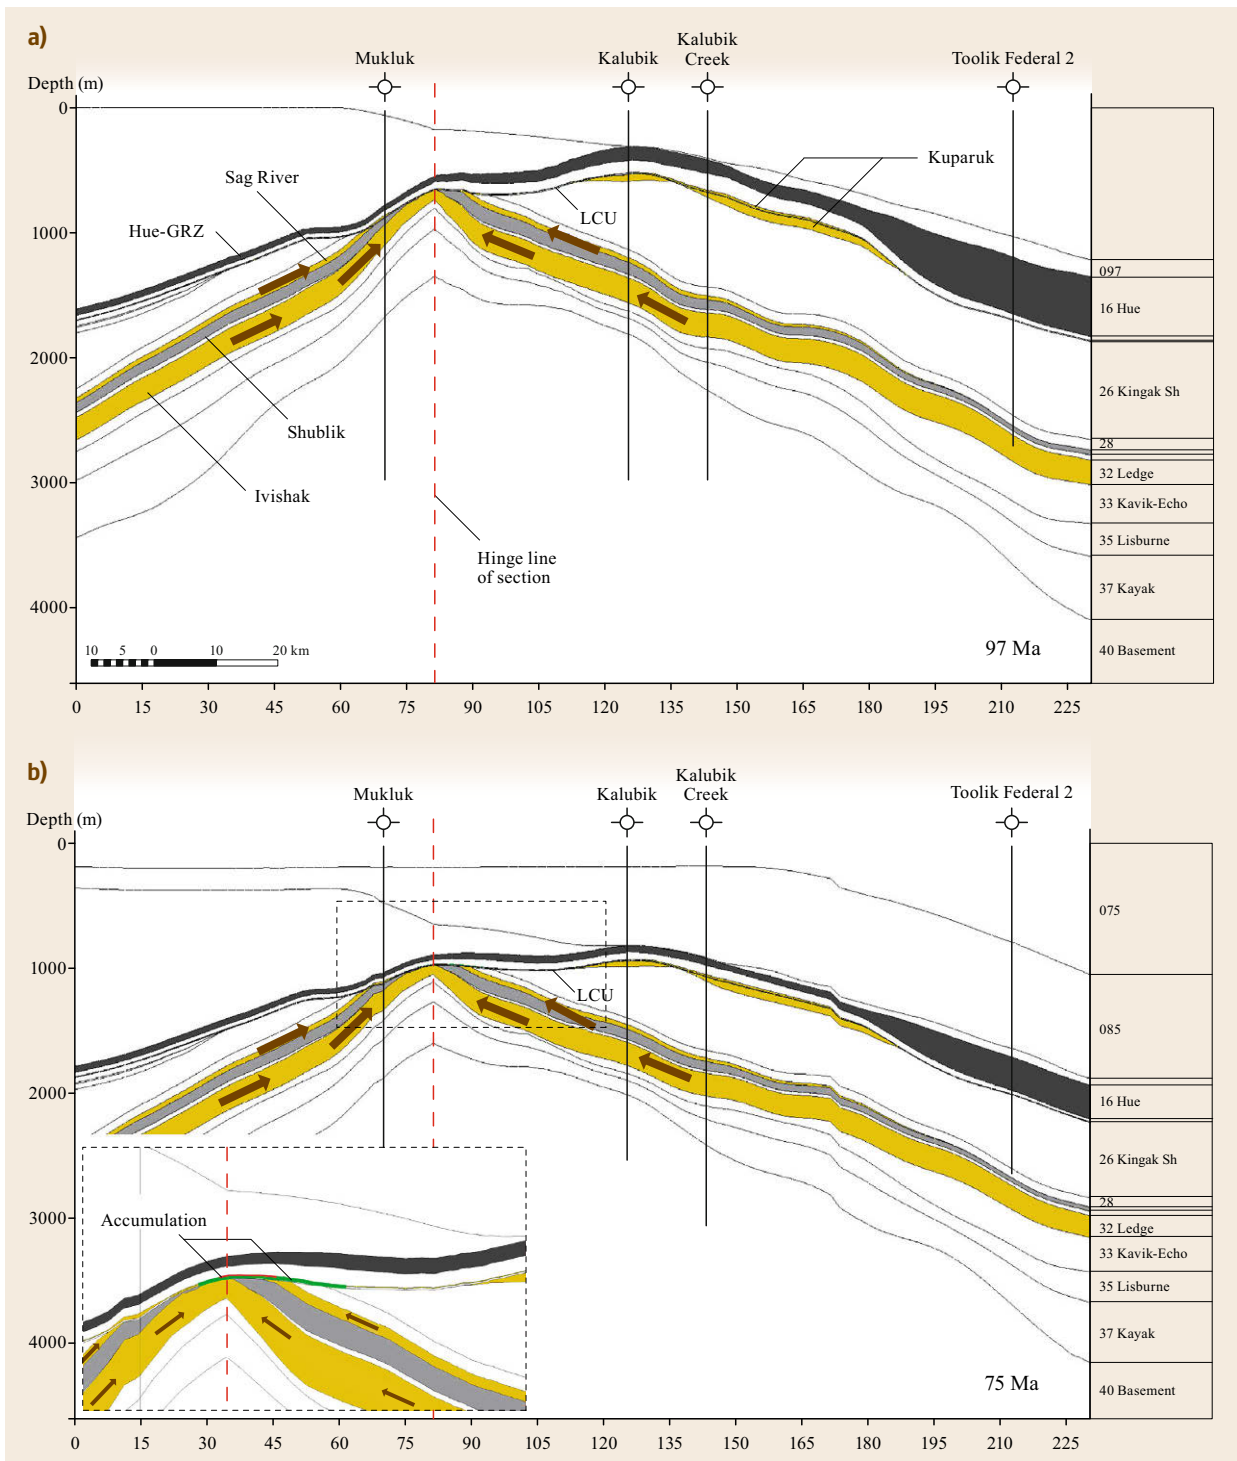

Fig. 11.15 (a) Cross-section from the 3-D model based on seismic data indicating four-way closure near the Mukluk prospect at 97 Ma. The section was opened to plane view along the hinge line from Fig. 11.14. (b) Cross-sections from the 3-D model showing closure at Mukluk at 75 Ma, although little oil accumulated due to erosion and early tilting (larger paleo-accumulations are predicted to the west of Mukluk along the Barrow Arch)

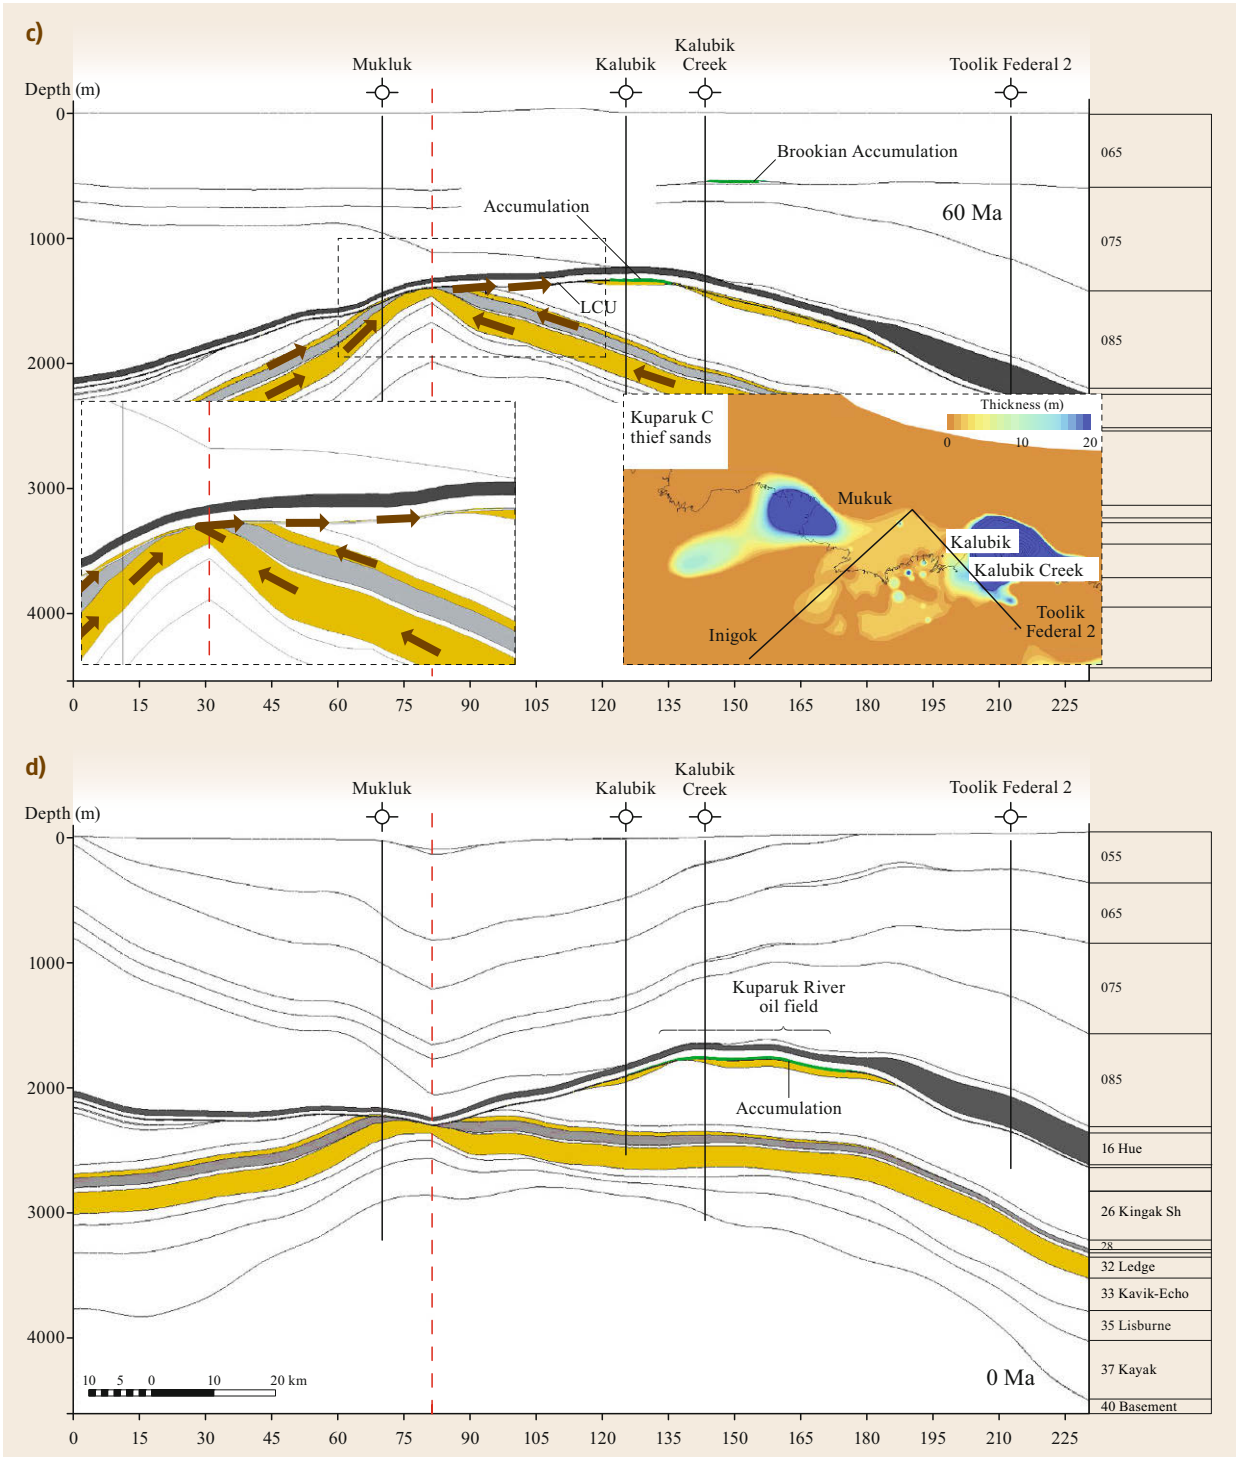

Fig. 11.15 (c) Continued Tertiary erosion at 60 Ma caused additional tilting and includes the possibility that Kuparuk C-D thief sands deposited on the LCU allowed remigration of oil to the southeast (*insets*) into small accumulations near the present-day Kalubik well at the LCU and in a sand lens in the shallower Brookian sequence. (d) Reversed tilting to present day (0 Ma) resulted in renewed closure at Mukluk, but most petroleum had already migrated toward the Kuparuk River field

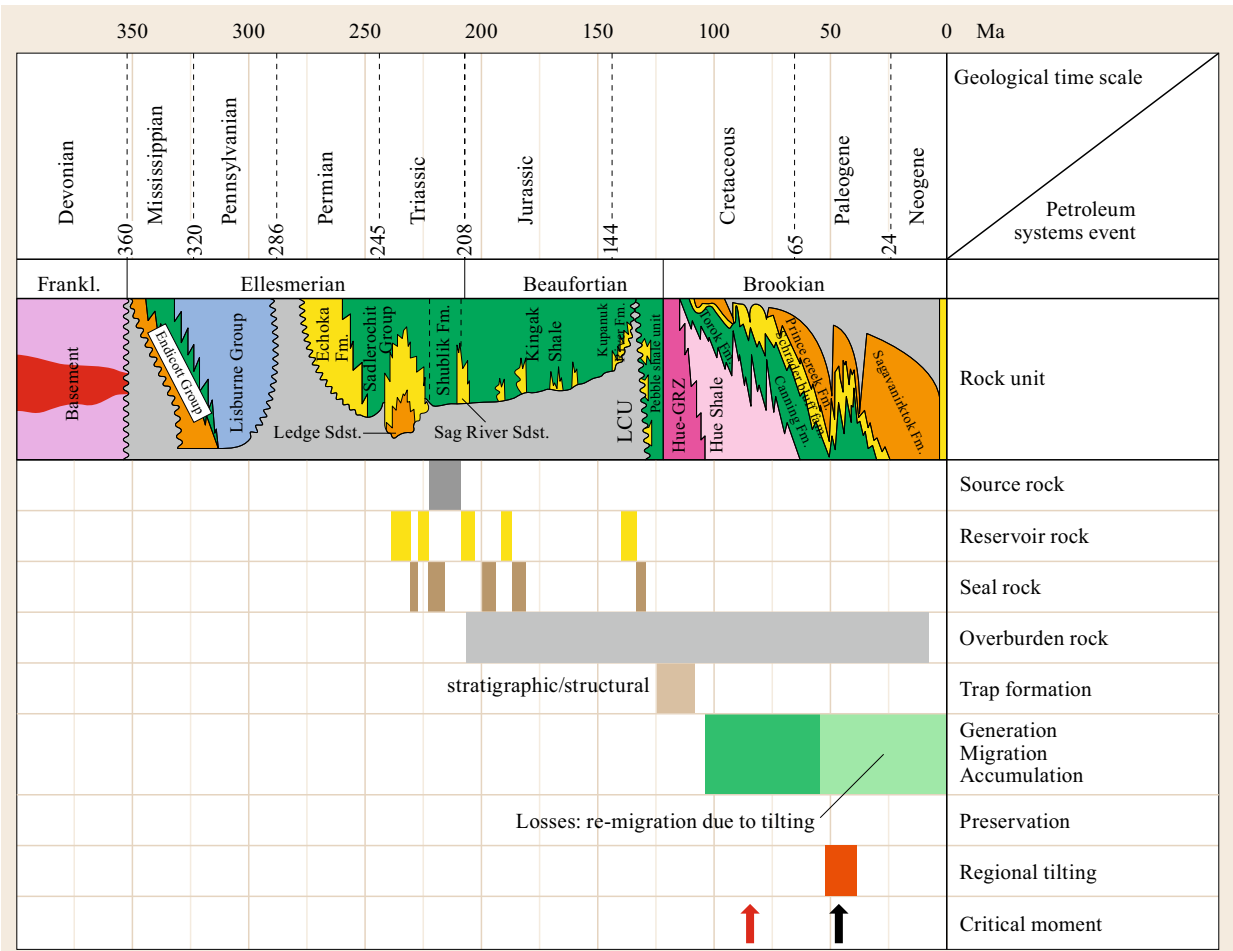

Fig. 11.16 Petroleum system event chart showing that tilting to a three-way closure during the Tertiary drained the Mukluk accumulation. *Light green part of bars* indicates estimated time of eastward migration of earlier trapped petroleum to traps in younger Cretaceous and Lower Tertiary reservoirs due to tilting. *Red arrow* points to the critical moment when the transformation ratio of the source rock in the adjacent depocenter is over 50%. *Black arrow* indicates the critical moment for the Mukluk well location in terms of geometry during regional tilting

Table 11.3 Some key differences between conventional and unconventional petroleum reservoirs

Conventional	Unconventional
Gas and oil migrate to the trap	Gas and oil remain in the source rock
Oil-to-gas cracking usually is unimportant	Oil-to-gas cracking is important
Reservoir storage in intragrain porosity	Conversion of kerogen creates reservoir porosity
Free gas is important	Proportions of free/adsorbed gas are important

that results from the conversion of kerogen to solid bitumen, oil and gas. Unlike conventional resources, which contain mainly free gas and oil in intragrain pore

spaces, production from unconventional resources depends on both free hydrocarbons in pore spaces and fractures and hydrocarbons adsorbed on the surface of the rock and trapped within the kerogen. An organic-rich source rock that contains 10 wt% TOC may have > 30 vol.% kerogen, which can provide substantial pore space for hydrocarbon gas and oil. As new porosity is created during kerogen cracking, hydrophobic hydrocarbons fill the pores in unconventional reservoirs.

Most unconventional petroleum systems have low porosity and permeability. Typically, these systems have at least 2 wt% TOC prior to thermal maturation, and some of the porosity occurs in pores that develop in the kerogen as it undergoes cracking to generate oil

and gas. *Jarvie* [11.93] divides organic-rich mudstones into:

1. Tight (no open fractures)
2. Fractured (open fractures)
3. Hybrid types (juxtaposed ductile organic-rich and brittle organic-lean facies).

Many tight shales show positive correlation between gas or oil saturation and TOC because much of the petroleum is trapped in pores that develop in the kerogen during cracking [11.94]. Organoporosity dominates the storage capacity of tight organic-rich mudstones, as in the Barnett (Texas) and Haynesville (Texas, Arkansas, Louisiana) formations. Clay minerals can also significantly contribute to the sorption capacity of shales [11.95].

Hybrid types of unconventional petroleum systems consist of intercalated fine- and coarse-grained units, so much of the generated oil and gas migrates short distances into the lean units, resulting in lack of correlation between gas or oil saturation and TOC. Hybrid types, such as the Bakken Formation in the Williston Basin, are generally the best-producing shale resource systems for two reasons: (1) matrix and fracture-related porosities are generally more significant in hybrid systems due to the juxtaposed organic-lean units, and (2) expulsion and short-distance migration from the organic-rich to the organic-lean units is favored.

Migration fractionation results in selective retention of heavy NSO compounds and asphaltenes in the tight organic-rich units and preferential migration of more mobile saturated and aromatic hydrocarbons to the organic-lean units, which increases their productivity. The Upper and Lower Members of the Bakken Formation are tight organic-rich mudstones with very low porosity and permeability and lack productivity, even when stimulated by hydraulic fracturing. However, the Middle Member of the Bakken Formation is organic-lean (low TOC), brittle (high carbonate content), and at the proper level of thermal maturity, and represents an excellent unconventional production target (Fig. 11.17).

A new play-based methodology provides a systematic approach to assess and explore for unconventional resources [11.96]. Use of this methodology with BPSM allows effective identification of *sweet spots* early in the exploration cycle. BPSM can be used to predict the amount and character of petroleum trapped in the mudstone. For example, BPSM can be used to assess high-grade portions of shale plays that contain oil or condensate in addition to hydrocarbon gas, which can differentiate commercial from noncommercial production. In addition, BPSM predicts the proportion of gas

adsorbed within kerogen pores or on mineral surfaces versus free gas in pore spaces or natural fractures. For example, implementation of a pressure-temperature-dependent Langmuir-type adsorption function allows reliable prediction of adsorbed gas in shale [11.95]. Ideally, Langmuir parameters should be measured on core or outcrop samples of the source rock.

In addition to the proportion of adsorbed hydrocarbons, geomechanical properties provide important information for unconventional resources, e.g., to differentiate between areas that are more or less likely to be naturally fractured as a result of stress-strain history. Three physical models are essential for BPSM: mechanical, thermal, and fluid flow. The mechanical model includes fluid pressure and rock stress predictions, which are closely coupled. Because the traditional Terzaghi model considers only the vertical stress component (discussed earlier), it is limited for predicting rock failure or fluid flow. Recent developments in BPSM simulators extend this concept to a 3-D rock stress model after *Biot* [11.24]. The 3-D rock stress model considers present-day geomechanical conditions and the evolution of basin-scale geomechanics through geologic time. Calculated stresses and strains can be used to improve evaluation of seal capacity and prediction of fracture orientations or fault properties, which are essential to assess unconventional resources.

Implementation of 3-D rock stress models in BPSM has the advantage that a complete data model can be directly used: the paleogeometries and cell grids; cell properties, such as porosity, compressibility and permeability; and physical values, such as temperature and fluid pressure. Pore fluid pressure is especially important because it is coupled with the solutions for rock stress.

11.2.25 Poroelasticity Rock Stress Modeling

BPSM can predict geomechanical properties that are key for hydraulic fracture stimulation of shale reservoirs. Geomechanical data are commonly combined with reservoir or borehole data to predict rock stress and strain for well completion design. Poroelasticity modeling of 3-D stress-strain can be used in BPSM to differentiate areas that are more or less likely to be naturally fractured due to stress-strain history. Hydraulic fracturing is likely to be more effective in previously naturally fractured unconventional targets.

The following poroelastic approach is based on Biot's effective stress equation, which relates stress to deformation of a porous and elastic medium. Stress and strain are bulk properties, i.e., stress is in equilibrium with boundary traction (tension or compression) and gravity load and strain represents deformation of the

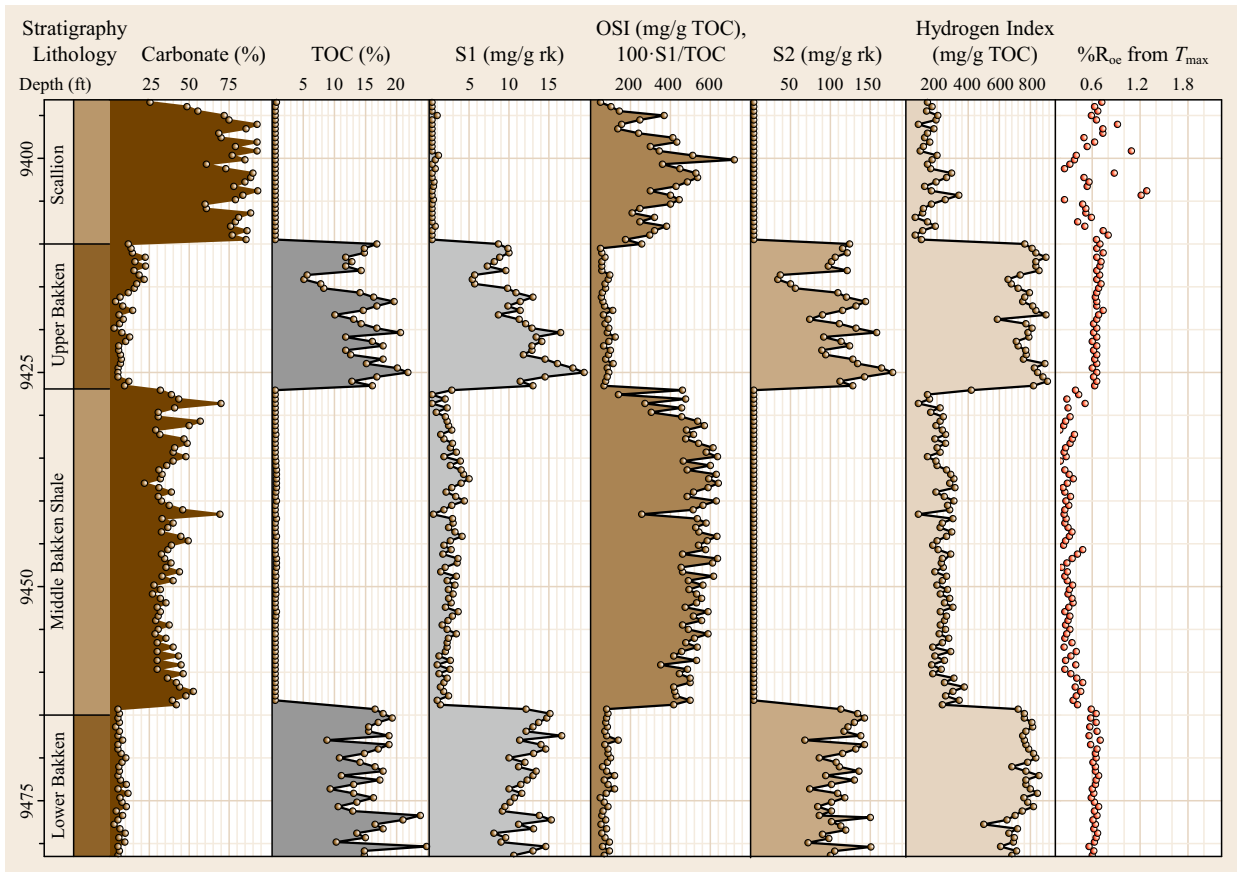

Fig. 11.17 Although the oil saturation index ($OSI = 100(S1/TOC)$) is apparently high for the Scallion Formation, both oil saturation (Rock-Eval pyrolysis $S1$ peak) and TOC are very low, resulting in unreliable OSI. $S1$ is high in the Upper and Lower Bakken, but the OSI is low. These zones do not produce petroleum, even when hydraulically stimulated, because $S2$ compensates for $S1$ and the kerogen adsorbs $S1$. However, the Bakken Middle Member in this well is productive because although $S1$ is lower than in the Upper and Lower Members, OSI is high (> 100 mg/g). Note that T_{max} (converted to vitrinite reflectance, R_o) is anomalously low in the Bakken Middle Member (after [11.93], reprinted by permission of AAPG whose permission is required for further use)

bulk volume

$$\sigma_{ij} - \alpha p \delta_{ij} = \sigma'_{ij} = \frac{E}{1 + \nu} \epsilon_{ij} - \frac{E\nu}{(1 - 2\nu)(1 + \nu)} \epsilon_{kk} \delta_{ij}, \tag{11.10}$$

where σ'_{ij} describes the effective stress tensor, σ_{ij} is the stress tensor, δ_{ij} is the Kronecker symbol, ν is Poisson's ratio, E is the bulk Young's elasticity modulus, and ϵ_{kk} is the strain. Poisson's ratio (ν) and the bulk elasticity modulus (E) can be derived from the Terzaghi compressibility (C_T) and simulation results using a traditional BPSM compaction law. Poisson's ratio is the negative ratio of transverse to axial strain, which describes how a rock that is compressed in one direction tends to expand perpendicular to this direction. Young's modulus, also called the elastic modulus, relates normal

stress to strain and measures stiffness of a rock (i. e., rock resistance to strain).

Commonly, boundary conditions include traction-free surfaces, fixed basin sides, and fixed basement. However, to handle compressional or extensional basins one can assign positive or negative displacements at the basin sides, respectively.

11.2.26 Rock Failure

The most common rock-failure models in BPSM are the Mohr–Coulomb [11.1] and Drucker–Prager [11.97] models in which differential stress or deviator stresses are the main controlling factors, respectively. Failure criteria are represented by envelopes that help to predict the stress conditions for rock failure and fracture type. The failure envelope is described by cohesion

and friction angle. Compaction can also be included when using a *cap* as an additional volumetric failure above the critical stress. Cap describes a strain regime that differs from brittle deformation. Increased normal stress beyond nonvolumetric plastic flow can result in compressive plastic flow and work hardening. In the Mohr diagram, this is described by an elliptical failure curve at high differential stress, e.g., see *Schutjens et al.* [11.98, Fig. 2].

The first step in failure analysis is to calculate failure risk, which is a measure of proximity of the stress to the failure envelope. The fracture directions and failure type (e.g., tensile, shear, or mixed-type fracture) can also be determined. The second step is a description of the effect of permeability increase on the stress-strain relationship. Implementation of these steps in forward modeling affects pore pressure and rock stress, and thus has implications for fluid flow. In addition, analysis of the basin-scale 3-D stress field allows prediction of fault transmissibility.

Failure analysis includes failure risk. The yield line distance (perpendicular distance between the failure envelope and the Mohr circle) is a measure of: (1) likelihood that fracturing will occur, and (2) the type of fracture. Rock failure depends on the fracture type and results in increased permeability. Implementation of failure analysis in BPSM results in pore-pressure variations and has implications for fluid flow. Finally, analysis of the basin-scale 3-D stress field allows prediction of the direction of fault planes. Note that alter-

native poroplastic solutions exist, such as the Cam–Clay model.

11.2.27 Example of the North Slope 3-D Model

The Alaska North Slope model provides a useful example of rock stress and failure analysis. Increasing awareness of unconventional shale gas and oil as a future long-term energy source has increased interest in its potential in northern Alaska. The Triassic Shublik Formation is a key source rock that contributes petroleum to the giant fields along the Barrow Arch (e.g., Kuparuk River and Prudhoe Bay). The Shublik Formation is considered to be a prime target for unconventional petroleum because of high organic carbon and carbonate (brittle) content, similar to the Eagle Ford Shale, which is a successful shale oil play in Texas. Key uncertainties for such unconventional systems include:

1. Rock properties and their vertical and lateral distribution
2. Geomechanical properties, such as brittleness
3. Organic content
4. Thermal maturity
5. Overpressure and its timing.

The distributions of horizontal stress tensors calculated in the Shublik Formation help to predict the directions of fractures (Fig. 11.18). Horizontal stress in

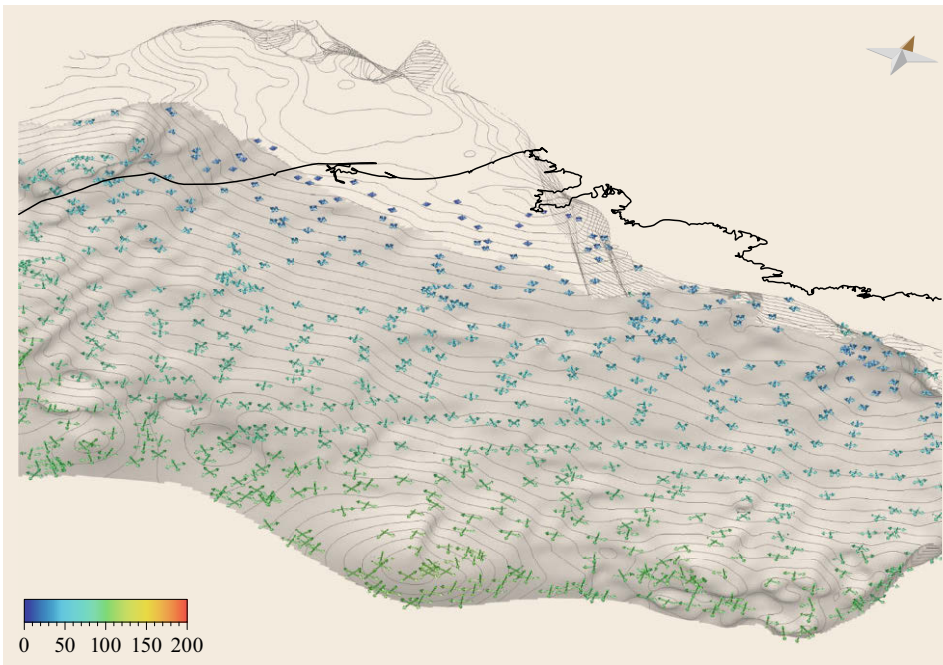

Fig. 11.18 Calculated horizontal total stress tensors (MPa) for the carbonate-rich, central portion of the Shublik Formation plotted on top of the basal unit of the Shublik Formation (gray). Length of tensors is scaled to total stress

the foothill region in the southern part of the model is higher than in shallow areas along the Barrow Arch. Different directions of the stress tensors indicate lateral variations of the stress pattern. Three-dimensional rock-stress modeling results indicate that there is less risk for brittle deformation in shallow regions along the Barrow Arch (Fig. 11.19). Mohr circle output is useful to compare the failure behavior of regions of interest. The first step in failure analysis is to examine whether the calculated Mohr circle for a specific location intersects the failure line. Figure 11.19 indicates that in the shallow region the Mohr circle fails to contact the failure envelope. However, farther downdip toward the center of the Colville Basin, the Mohr circle theoretically exceeds the failure envelope. Such a scenario is impossible in nature because when the Mohr circle touches the failure envelope, fracturing occurs and stress conditions shift the circle along the failure envelope toward the critical stress state to reach equilibrium conditions.

Once fracturing occurs, forward modeling in the second step of failure analysis considers the fracture-related permeability increase, which again influences

pore pressure, rock stress, and fluid flow. Figure 11.19 also shows the strong interrelationship of rock stress and pore fluid pressure. The horizontal red arrow points to an area where increased stress exceeds the failure line. This increased stress is related to Sag River Sandstone, which locally overlies the Shublik Formation. Elsewhere the Kingak Shale overlies the Shublik Formation. Because the compaction behavior of the Sag River Sandstone differs from that of the Kingak Shale, compaction of the underlying Shublik Formation is also affected, resulting in different pore pressures and rock stresses.

11.2.28 Continuing Developments

Continued advances in BPSM allow increasingly complex and accurate geologic studies. For example, the chemistry of migrating fluids affects the depth and temperature of silica phase transformations in biosiliceous rocks. These transformations change both the porosity and permeability of the rocks, which can influence the distribution of seals and traps. One recent advance in BPSM software is the ability to track the opal-

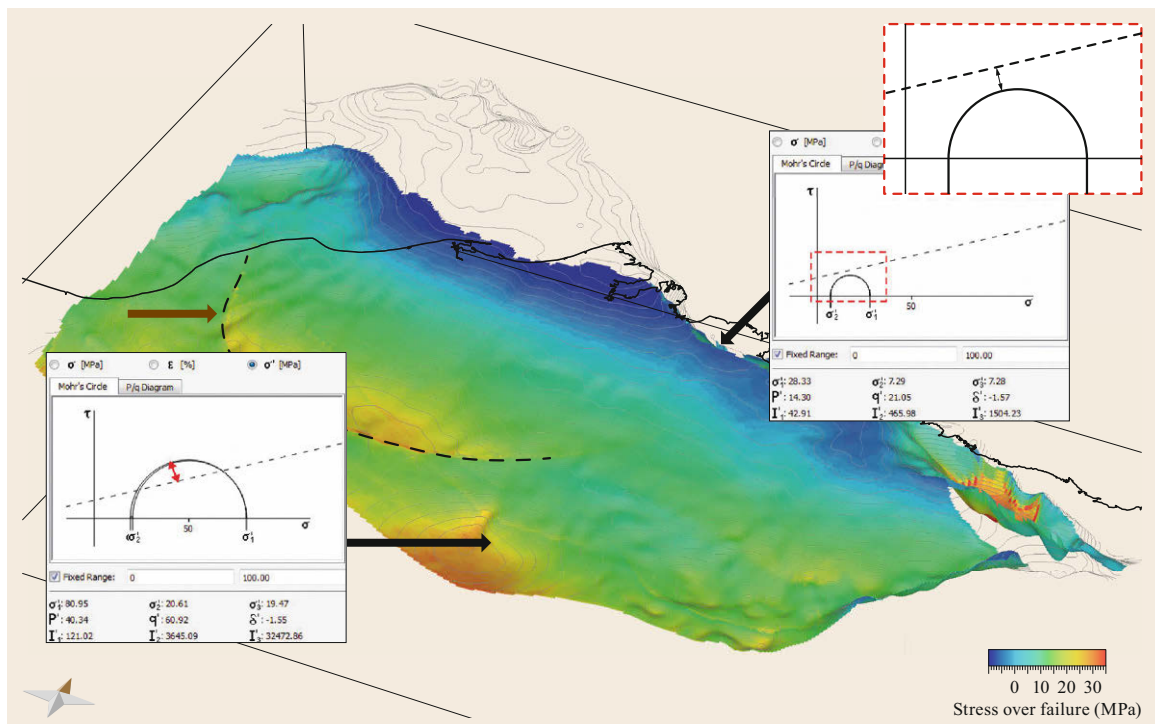

Fig. 11.19 Stress-over-failure overlay for the Shublik Formation showing Mohr circle output at two locations. *Insets* display the shortest distance from the Mohr circle to the dashed rock-failure line. Areas with negative values (*dark blue*) have little risk of natural fracture, whereas positive values (e.g., *red*; Mohr circle theoretically exceeds failure envelope) indicate high risk of fracture. *Horizontal red arrow* points to elevated stress-over-failure values that are related to the overlying Sag River Sandstone extending to the *black dashed line* (see text for details)

CT (cristobalite-tridymite) to quartz phase transition during burial history [11.99, 100]. This capability was used in a BPSM study of the Salinas Basin, California, to test the impact of silica diagenesis on generation timing due to differences in thermal properties of overburden rock and changes in bulk mechanical properties [11.40]. Some other examples of advances in BPSM focus on incorporating more sophisticated tec-

tonic histories. These include the role that structural thickening plays in the geologically rapid increase in overburden, the integration of strike-slip fault motion with 3-D BPSM [11.101], and the structural restoration of complex basin geometries due to thrusting via paleostep models [11.102]. Similar continued advances in BPSM software are vital to the success of petroleum exploration programs.

11.3 Conclusions

BPSM begins with a well-defined conceptual model based on discretized (gridded) input data to facilitate numerical simulation. Selection of 1-D, 2-D, or 3-D BPSM depends on available input data and the objectives and time constraints for each study. Recent advances in simulation software include 3-D poroelastic and poroplastic rock stress modeling, which are significant improvements over 1-D Terzaghi modeling. Because BPSM is forward deterministic modeling, organic richness and rock properties must be reconstructed to original values prior to burial. In geohistory analysis, each unit is decompacted to original thickness and corrected for paleobathymetry and eustasy. Boundary conditions for thermal evolution include heat flow and sediment-water interface temperature corrected for water depth through time. Measured petroleum generation kinetic parameters for representative, thermally immature equivalents of the effective source rock are generally superior to the default kinetics available in various software applications, which should be used only as a last resort. Calibration and risk analysis are vital parts of the modeling process. Because overpressure retards normal compaction, most calibrations start with the available pressure data, followed by thermal calibration using corrected borehole temperatures, vitrinite reflectance, or other maturity parameters, and calibration to other measurements, such as detailed compositions of petroleum in reservoirs.

The static play fairway concept uses a snapshot of the present-day geology of known accumulations

to risk undiscovered accumulations. Spectacular failures of the play fairway concept, such as the Mukluk wildcat well in Alaska, forced the industry to develop the quantitative petroleum system concept. Unlike the play fairway concept, the petroleum system concept is dynamic and can be used to reveal the relative timing of petroleum system elements and processes. Significant accumulations require trap formation prior to generation-migration-accumulation. Various processes, such as renewed tectonic activity, can result in remigration or destruction of accumulations and more than one critical moment. For unconventional resources, the source and reservoir rock are identical or closely associated, organoporosity is the container for much of the resource, and secondary cracking is particularly important. Hybrid systems, which juxtapose ductile, low permeability organic-rich with brittle and more permeable organic-lean intervals are typically the best producers. Finally, BPSM does not provide answers; it provides scenarios that can be tested or improved with more data to better understand and exploit each petroleum system.

Seismic Explorations

12. Seismic Explorations

Graham Ganssle

Geophysics is an extremely diverse subject including fields of study with backgrounds in chemistry, geology, biology, and physics. This chapter attempts to show the reader a broad cross section of the geophysics of petroleum exploration. Three fundamental steps exist in the workflow of geophysical petroleum exploration. First, there is the acquisition of seismic data by using initiating acoustic energy into the Earth's subsurface and recording the reflected energy. Second, this raw acoustic data is processed using the physical and mathematical principles of wave propagation and continuum mechanics. Finally the processed seismic data is interpreted. Interpretation endeavors

	References	431

to create a pseudo-geological model from the geophysical data for verification or update by purely geological data. The model is then iteratively updated by both geologists and geophysicists to form a complete risk assessment of a prospective drill location.

Seismic activity is an ongoing phenomenon. Earthquakes, caused by fault slip, are a recurring reminder of seismic activity in the Earth's subsurface. In reality, seismic activity is a result of the motion of any object. An object making contact with another object creates sound waves, especially when moving. These waves, in the case of earthquakes, can have very large amplitudes. Other seismic wave sources can create sound waves with quite small amplitudes. For example, every time a person walks down the street their footsteps on the pavement are creating very small seismic disturbances. The term *seismic* is used to describe the peak frequency of the resulting sound waves. Seismic waves are generally thought of as having low frequency (in the range of 5–8 Hz) and large amplitude. It is possible to measure seismic disturbances from earthquakes to footsteps on pavement using the right equipment. There are three major types of seismic waves. P-waves, also called primary or pressure waves, are familiar to everyone in the form of sound. Nearly all seismic exploration for petroleum uses p-waves. S-waves, also called secondary or shear waves, are slower and can only travel through solids. P-waves and s-waves are collectively called body waves because they pass through the Earth. Surface waves travel along the surface, similar to an ocean wave. Surface waves are not used for petroleum exploration, but they are extensively studied because

they cause most of the damage during earthquakes.

The velocity of body waves is related to the properties of the medium they pass through by the following equations

$$V_p = \sqrt{\frac{K + 4/3\mu}{\rho}} \quad V_s = \sqrt{\frac{\mu}{\rho}}, \quad (12.1)$$

where K is compressibility, μ is rigidity, and ρ is density. If we know both p-wave and s-wave velocities and can make some reasonable assumption about the density, we can determine the mechanical properties of the medium.

The measurement of seismic disturbances is carried out by measuring the motion of the ground for an extended period of time. This creates a record in time with each sample point being the magnitude of this motion. Recording from many locations arranged in a line or an array provides a record that approximates the local subsurface geology. When looking at a seismic data line the horizontal axis represents some spatial dimension, x , and the vertical axis represents the time dimension, t . At each (x, t) point the data is an amplitude. This amplitude is related to the reflection strength of the layer in the Earth's subsurface located at time t . In a perfect world, each reflection event on a seismic section would

represent one geologic bed, giving a perfect view of the Earth's subsurface.

Nowadays commercial seismic data is widely used in industry for the exploration of petroleum oil and gas. It is also used for the exploration of salt, certain hard-rock deposits, and engineering site investigation. The use of seismic data has proven to be so successful in petroleum exploration in the past 100 years that there are few prospects which have not had seismic shot over them at some point. Seismic data can be used in the exploration of new prospects, in the delineation of current targets, and in the classification of reservoirs. Therefore, it is extremely beneficial to use seismic data in any stage of target planning. However, the acquisition, processing, and interpretation of seismic data can be quite expensive. Because of this high cost, other techniques are employed. In large scale remote areas, gravity survey methods are often used to determine

where a seismic survey should be acquired. In areas with a large number of existing wells, the well data may be dense enough to eliminate the need for seismic data.

Inferring information about subsurface geology without going underground to take physical samples is a difficult task. Like all remote sensing problems, data is taken from a reference point far from the area of interest. There are many layers of interfering medium between the layer of interest and Earth's surface distorting the desired data. There are an incredibly large number of noise sources contaminating the data while it is being recorded. At the same time, the medium being recorded through is dispersing and absorbing the signal energy. These points demonstrate some of the reasons why a seismic survey is so expensive. They also fundamentally constrain the way seismic data must be acquired, processed, and interpreted after acquisition.

12.1 Seismic Data Acquisition

There are two major arenas of seismic geometry. The first is two-dimensional (2-D) seismic data. 2-D data is one line of data running in a direction of interest. The data looks like a panel of amplitudes, extending horizontally out in the direction of the line, and extending down in the direction of recording time. The second is three-dimensional (3-D) seismic data. 3-D data is a volume of data covering a lateral extent around the area of interest. The data looks like a 3-D volume of amplitudes, extending horizontally out in two directions, and extending down in the direction of recording time. 3-D data may be viewed on a computer in three dimensions or in cross section as a collection of 2-D lines. Seismic data specialists refer to increasing subsurface depth in terms of increasing recording time.

As with any specialty, the seismic industry has a wealth of nomenclature. In addition to 2-D and 3-D data there is four-dimensional (4-D) data. 4-D data does not implement a different recording geometry, like the difference between 2-D and 3-D, but is rather recorded repeatedly. 4-D data is recording a 3-D seismic survey, and then recording the same 3-D survey after some years to observe differences in the subsurface. The goal is to obtain information about the depletion of reservoirs and other time dependent processes. So, 4-D seismic is actually just two or more 3-D surveys acquired (preferentially in the same way) over the same area. There is also five-dimensional (5-D) terminology that is used in the seismic industry. 5-D is not a different recording geometry, but is a way of interpolating seismic data for special use in seismic data processing. By

means of these examples, it is realized that some of the nomenclature is overlapping and nonunique.

The initial requirement in recording seismic data is that there must be energy to record. Therefore, the acquisition of seismic data must start with a seismic source. In some cases, the seismic source is a natural one, as in the case of earthquakes. These scenarios are called passive seismic recording, as there is no operator controlled input energy. The acquisition of natural passive seismic activity is quite different than that of active seismic recording used in petroleum exploration. For example, the epicenter location of an earthquake is not known a priori, which creates a need for wide receiver spacing and continuous recording. After an earthquake has occurred, seismologists can look back in the seismic records from several stations to triangulate the signal to figure out the location of the epicenter.

Active seismic energy recording necessitates different acquisition parameters. In this case, the source position is known, so the receivers can be located according to signal requirements. The goal is to have a source that gives the best signal possible. A good seismic signal can be characterized by many features; several important ones are as follows. First, the source must transmit the bulk of its output energy into the ground. The energy that is not input into the ground is wasted for the purposes of subsurface imaging. Second, the source must input a signal of sufficient bandwidth to be used to image the strata in the exploration of petroleum. If the interpreters require a signal with a peak frequency of 40 Hz, for example, the source

may have to input a useable signal of up to 200 Hz depending on the geology. Third, the source must input enough energy into the ground that the signal is not degraded to the point of being undetectable. This parameter is a function of the absorption and dispersion characteristics of the local geology and the noise present in the area. There are many other constraints on sources, which in most cases can be controlled to an order of accuracy that is determined while planning the acquisition parameters.

There are three common ways to get the energy into the ground. These are dynamite, airgun, and vibroseis. If the survey is of an area on land, dynamite or vibroseis may be used. If the survey is over an area covered by water airguns are usually the preferred method, but in some shallow water instances dynamite may be used. Each of these three main types of sources has a huge variety of types, each meant for specific applications. Despite this large variety, dynamite, airgun, and vibroseis sources can be analyzed as groups with different signal characteristics.

Dynamite sources are used both on land and in shallow water surveys. The acquisition field crew drills holes into the ground where they place the dynamite. The holes are drilled to a depth sufficient to get the dynamite below the unconsolidated surface sediments, and into bedrock. This ensures good signal transmission from the dynamite into the ground. Unfortunately, dynamite does waste a good deal of energy in upward traveling waves going up into the air. However, dynamite is an excellent seismic source because of its desirable signal characteristics. The signal strength, or amplitude, can be very large. To get a larger signal amplitude, a larger charge or a combination of several charges can be used, or an array of charges can be laid out. Dynamite sources output an impulsive signal that has a large bandwidth. Short-duration, broadband inputs assist the seismic data processors in creating an accurate subsurface image.

Airguns are used in water surveys from shallow to ultra-deep water. The guns are towed behind a *shot boat* and are usually aligned in an array or linear pattern behind the boat. Airguns output less energy than dynamite, but can be very large in the case of deep water surveys. Because of the fluid coupling between the water and the seafloor, most of the energy the guns output is transferred into a usable signal. Some energy is lost to the atmosphere via transmission from the sea surface. Inputting more energy into the ground requires using a larger array of airguns, which can be costly. The signal from airguns is dependent on the design of the gun itself, the array design in which the guns are towed, and the timing of the individual guns. Just as dynamite, the signal is broadband impulsive.

The term Vibroseis came from an actual seismic acquisition company's brand name. Many other seismic acquisition companies now use similar designs, but the original name was so ubiquitous that it is generally used as a description of the process. The vibroseis method uses a heavy truck with a plate on the bottom attached to a vibrator driven by compressed air. The truck is moved into position, the plate is lowered to the ground and extended, lifting the truck off the ground. The plate then vibrates up and down in a specific pattern causing the ground to move as well. The vibration pattern is controlled by regulating the flow of compressed air with a servo. These trucks are usually lined up in arrays, and the vibrating pattern is decided very carefully to input a specific seismic signal. Of the three methods discussed, vibroseis inputs the smallest energy to the ground, making it ideal for use in populated areas where dynamite is not feasible. The signal obviously can be exactly specified, making it arguably the best signal shape of all of the seismic sources. The majority of vibroseis signals are called chirps. A chirp is a sinusoidal waveform that increases frequency as time increases. A simple chirp could be a sine wave with an argument of time squared; these signals sound a little like birds chirping to the human ear, hence the name. Chirps can be deconvolved with precision by the seismic processor, making vibroseis signals very useful.

Any of the three above mentioned sources inputs a seismic signal into the ground, where the signal is (among other things) reflected back to the Earth's surface. To gain any useful benefit from this system, receivers must be used to record the reflected signal. Two types of receivers are used: geophones and hydrophones. Geophones are used on land and hydrophones are used in water. Nowadays, geophones are sometimes used in the water as well. In deep water and ultra deep water plays, sometimes companies will use what are called ocean bottom nodes. Ocean bottom nodes are geophones placed on the seafloor by a remotely operated vehicle (ROV) robot. Airguns are used as a source in these instances. Ocean bottom node recording is extremely expensive, as thousands of geophones must be laid out by ROV operators and picked back up after recording is complete. The data quality however, is breathtaking.

Most geophones measure the vertical component of velocity only, although 3-component geophones are available. They record the motion at the Earth's surface as a function of time. Traditionally, only the vertical dimension of ground surface velocity is recorded to build a one-dimensional magnitude record. In some cases, all three dimensions are recorded separately to form what is called 3-component data. This data can be used to infer properties of the subsurface media by the motion of

shear waves. Geophones are laid out on the surface in groups, each of which is combined into a single trace. Each group may be an array or simply a cluster, and the groups may be laid out over an area for 3-D data or in a line for 2-D data. The location of each geophone group is recorded by a surveyor, or by a GPS unit attached to the geophone node.

Hydrophones are pressure vessels calibrated to record differences in the hydrodynamic pressure in the water in which they are towed. They are enclosed in long, flexible, oil-filled cables called streamers which are towed behind streamer boats at a depth of 5 to about 50 m. The streamers can be many miles long, so each streamer contains many hydrophones, several steering units capable of steering the streamer in depth and crosstrack (relative to the streamer boat's heading), and GPS units down the streamer to record position information. The streamer boats and the shot boats drive around in many different complicated patterns to accomplish an exact acquisition geometry decided in advance by a design team.

The geometry of the survey is of utmost importance. There is no point recording a seismic survey which does not most efficiently illuminate the subsurface area of interest so the geometry not only needs to be designed properly, but geometry also must be recorded in the field. The number one mishap in analyzing seismic data is incorrectly positioning the data relative to the original parameters. When seismic is recorded on land, the receivers and sources are laid out, their positions are recorded, and then the data recorded. In water, the shot boats and streamer boats both have GPS systems on the guns and the hydrophones to create a continuous record of position data along with the seismic data. During data processing, these positioning data are used to ensure that the final seismic section correctly indicates where to drill. The positioning data also constrains the way the seismic data must be handled during certain processing steps. If the recording locations for the seismic data are incorrect, not only will the resulting seismic section indicate incorrect locations to drill, it may also have erroneous structure and amplitude character as is demonstrated in Sect. 12.2.

When seismic data were first being recorded in the early twentieth century, the records were essentially the result of one source and one receiver being used at a time. This is called single density, or single-fold data. In modern seismic data, there are many receivers recording when a source goes off. The number of channels recording each subsurface location is the fold of the data. If the source and receiver spacings are equal, the fold will be one-half of the number of channels recorded from each shot. Today's seismic data is often recorded at up to 300-fold, an indication of why seismic

data sets are so large. In a typical land survey covering a 100 square mile area, you may have 10 000 sources with 300 records per source, for a total of three million records, also called traces. A typical sample interval is 2 ms, so if the trace lengths are (a typical) 8 s there would be 4000 samples per trace, for a total survey size of 12 billion sample points. This is hundreds of gigabytes of data even in a compressed format. The result is that it takes an incredible amount of computing power to deal with seismic data. Even still, the reason seismic data are recorded at such high fold is that data density is of paramount importance. As shown in Sect. 12.2, increasing the fold of the data input increases the quality of the data output.

In a hypothetical 3-D land survey, the recording acquisition geometry is a square. When shooting a source at the exact center of the square, which geophones should be recording? There are many answers to this question, depending on design parameters. One simple geometry, called split spread recording, would have 150 geophones recording in a line extending to the west of the source and a mirrored 150 geophones in a line to the east. This geometry would produce a fold of 300 if the shot spacing is one-half of the receiver spacing. This is very high fold and would hopefully produce a quality seismic section. The linear nature of this geometry however, means that there is only one direction, or azimuth, recorded. Azimuth is defined as a compass direction from source to receiver in the seismic survey.

The benefit of multiazimuthal acquisition geometries is to illuminate anisotropic properties of the rock. All subsurface beds are heterogeneous, meaning that they are inconsistent in lateral extent, for example, they have horizontally distributed inconsistencies. This is also true when looking in the vertical direction, as we have beds of varying rocks. Some rocks however exhibit anisotropy. Anisotropy is a change in seismic velocity as a function of direction. Nearly all sedimentary rocks have different seismic velocities in the vertical and horizontal directions. Fractured units often display azimuthal anisotropy. Multiazimuthal seismic data recording geometries can provide a characterization of the azimuthal anisotropy in subsurface beds. This happens because sound travels with different velocities through fractured and unfractured rock of the same composition. For example, imagine a shale with natural linear fracture planes oriented in the north-south direction. Sound waves would propagate with a certain speed through this shale in the north-south direction, but would be apparently slowed down in the east-west direction because of the interference created when propagating across the fractured layers. Because of this property, many modern acquisition geometries are laid out with a large azimuthal range.

Acquisition of seismic data is the first step in creating a seismic section that represents the subsurface geology. However, because of noise, waveform character, and geometrical considerations, a raw seismic record straight from the geophone does not look like a geologic section. It does look like a long record of

noise. Combining the large number of traces from the above hypothetical 3-D seismic example exhibits why the raw records of the full survey are incomprehensible. To get these noisy records to approximate anything resembling geology, seismic processing specialists must do an extremely large amount of number crunching.

12.2 Seismic Data Processing

Seismic data processing is more naturally accomplished in a different set of dimensions than that of the data acquisition dimensions. When acquiring seismic data, the directions to organize the data as it is streamed onto the hardware are the source, receiver, and time domains. This is because, as shown in Sect. 12.1, a source goes off while receivers are listening. The field crew records the live channels simultaneously as a function of time.

In many cases, it is more elegant mathematically to handle seismic data during processing in the offset, midpoint, and time domains. The offset domain is defined in terms of the linear distance between the source and the receiver. The midpoint domain is defined in terms of the imaginary distance halfway between source and receiver, at the surface. This domain is orthogonal to the offset domain. The time domain is the same as in the acquisition domains.

When the data comes in from the field it is often multiplexed, which means the bits from each channel are striped across one record. The seismic processor then must demultiplex the data, and sort it into midpoint, offset, time coordinates. This process is usually incorporated into the same steps as defining the geometry on the data. Each trace in a seismic data file includes a trace header which includes, among other information, the coordinates of the source and the receiver. Using the observer notes from the survey crew in the field, the data processor fills the geometry into each of these trace headers using any information available. This information may include the shotpoint, the record field ID number, or sometimes the actual GPS position of the stations themselves. Along with some other ancillary steps, these initial definitions and sorting are collectively named preprocessing.

There are many steps in the seismic data processing sequence that affect the data primarily in one of the three processing domains, midpoint, offset, and time. There are others that affect the data in more than one domain at a time, as they are intrinsically linked to the position of the data in both time and space. Each one of the dimensions can be discussed separately in many cases; however, the processing steps taken in an actual workflow can be in any order, and may be repet-

itive. A typical seismic data processing workflow can be thousands of steps long to get the data looking just right.

In the time domain among hundreds of processes that could be applied, there are three which stand out as being the categorical leaders. These are gaining, filtering, and deconvolution. All of these three processes affect the data only in the time domain, with no spatial effects in the midpoint or offset domains.

Gaining the data can be accomplished in many different ways. One of the first gain processes applied to seismic data is called geometrical spreading correction. Geometrical spreading correction gain is applied to correct for the natural absorptive effects of the Earth. As the acoustic waves propagate from the source to the receiver through rock, some of the energy is lost due to heat dissipation. The farther these waves must travel, the more energy is lost. Therefore, the late times on seismic records are always lower amplitude than the early times. Geometrical spreading correction gain is usually applied to the data as a time to the exponent gain. In many cases, a good starting guess for the exponent is two. Processors usually then scale the exponent up or down to make the records look even.

Filtering the data can be accomplished in thousands of ways. A common process uses a band-pass filter to allow a certain frequency spectrum of data to remain by eliminating everything else. For these types of filters, the data processor will apply Fourier transform to convert the data from the time domain to the temporal frequency domain, and then multiply some high and low frequency components by zero. The inverse Fourier transform is then applied, and the data is examined for content. Another filter is applied in frequency-wavenumber space, where a 2-D Fourier transform is applied and both dimensions are filtered. There are countless other 2-D filtering techniques, including methods in the time-space domain, the frequency-space domain, and the time-wavenumber domain.

Deconvolution of seismic data can be used to accomplish several things. Two major deconvolution processes are called spiking deconvolution and predictive error filtering. Spiking deconvolution aims to elimi-

nate the incoming signal waveform from the seismic source, called a wavelet, from the data. Spiking deconvolution generally tends to make the data appear to have sharper peaks and troughs on the waveform. Predictive error filtering deconvolution approximates and removes repetitive ringing from the waveform. This ringing could represent several things, but in many cases the ringing in a seismic record is produced by the propagation of multiple reflections, often simply called multiples. Multiples are caused by acoustic energy bouncing back and forth off a pair of reflectors, for example, the water bottom and the water surface in a marine seismic survey.

The offset domain is handled by many processes that affect the data only in the offset direction, but also some processes that also affect the data in the time and/or midpoint directions. The velocity of seismic wave propagation is of critical importance to the seismic data processor. The change in velocity and density between different regions in the Earth's subsurface is the cause of a seismic response. It is in the offset domain that seismic data processors estimate seismic wave propagation and correct for certain types of velocity changes.

When a source and a receiver are located at the same position, the acoustic energy measured propagates vertically. When we introduce a horizontal displacement, or offset, between the source and the receiver the acoustic energy measured has necessarily traveled not only in the vertical direction, but also in the direction of the offset. To see this, the seismic processor organizes the data traces into a group where all the energy has come from one source, and the traces increase in offset with respect to the horizontal axis. In many cases this offset is measured from the midpoint between the source and the receiver. In this case this group, or gather, of traces is called a common midpoint gather (CMP gather). CMP gathers are used to estimate the velocity with which acoustic energy propagates in the local media surrounding the midpoint in question.

Once the data is grouped into CMP gathers, the data processor begins to see a hyperbolic moveout response of the individual reflection events. Moveout is the increase in arrival time as a function of offset with each trace in a CMP (or other types of) gathers. The data processor can use the slope of the hyperbolas on the CMP gathers to estimate the velocity of the wave propagation. This is done by using a variable hyperbolic function as a function of time to sum, or stack, the traces in a CMP gather. The function's slope is varied many times and the semblance, or power average, is computed for each sample in time. Each semblance is then displayed as a function of velocity on a semblance panel. The data processor picks the highest semblance value,

which associates the velocity value at that time sample back to the data. The CMP gathers are then corrected in time according to the slope of each hyperbola so that the seismic events appear linear rather than hyperbolic. This process is called normal moveout (NMO) correction and is an integral part of seismic data processing.

Once the data has been corrected for normal moveout, the CMP gathers appear to have flat events. The traces in the gather are then summed and multiplied by some weighting function. This process is called stacking. Stacking a CMP gather creates one trace. This is done to reduce noise and increase signal quality. Every data trace in the seismic survey before this point has been sorted into CMP gathers. Each CMP gather is stacked, creating one trace per gather, and dramatically reducing the size of the data set.

The gathers in Fig. 12.2 correspond to the stacked section in Fig. 12.1. After normal moveout correction has been applied to a set of CMP gathers they are stacked. This means that every gather is summed into one trace on the stacked seismic section. In the example of Fig. 12.2, after stacking these six CMP gathers would become six traces in the stacked section of Fig. 12.1.

Assuming several other processes have been completed accurately, and that the geologic dips are not too steep, stacking the data approximates a zero offset section. Therefore the resulting seismic section after stack represents the subsurface geology. The data processor will output the data at this point, called a structure section, for a seismic data interpreter to look at to confirm whether or not the seismic data is on par with the subsurface model built from existing well data.

The midpoint domain processes are arguably the most interesting. There are several processes that affect the midpoint domain, but the most major of these is called migration. Migration processes strive to eliminate the effects of diffraction and sometimes refraction on the acoustic energy. There are a number of different migration algorithms, but all of them require a model of the seismic velocity throughout the survey area. Migration translates energy through the time, offset, and midpoint domains, although migration techniques are traditionally studied in the category of midpoint domain processes. Because of the movement of energy on the seismic section in the midpoint domain, the data processor must be very careful to apply the correct geometry before the migration inversion processes are implemented. Because the energy moves horizontally, the survey must extend a distance, called the migration aperture, beyond the area of interest. If the geologic dips are steep or lateral velocity variations are present, migration should be applied instead of the normal moveout correction before stacking. In the case of pre-stack migration inversion

Fig. 12.1 A 2-D seismic cross section (Reprinted with permission after [12.1])

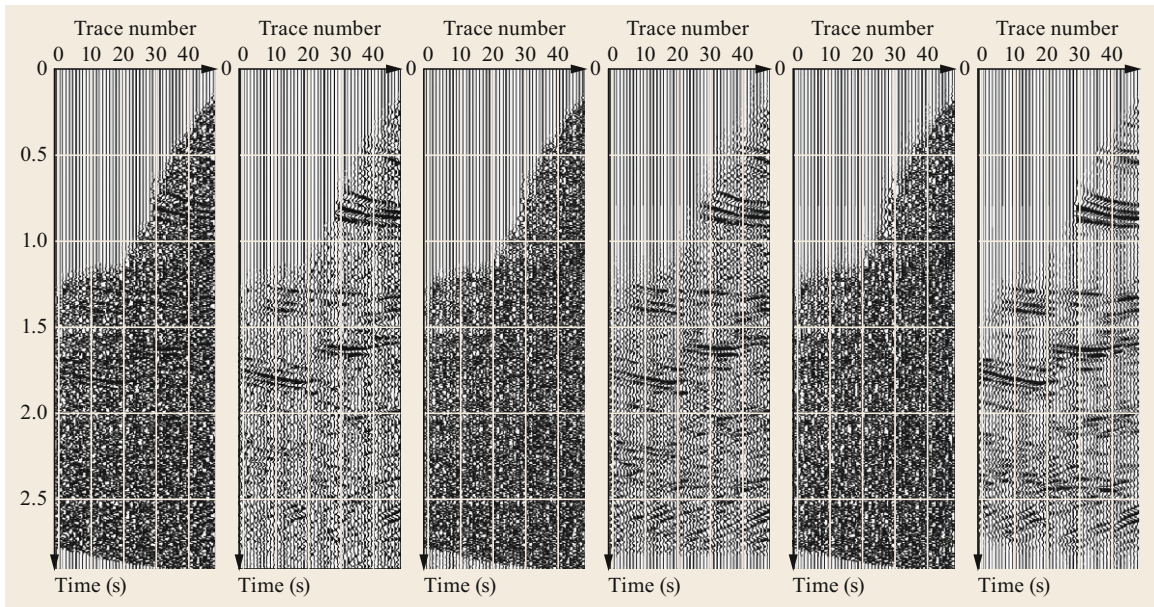

Fig. 12.2 A collection of CMP gathers corresponding to the seismic section in Fig. 12.1 (after [12.2])

techniques, the algorithm to complete the migration must in some cases apply geometry corrections to the trace headers.

Acoustic energy appears distorted on unmigrated seismic records. This distortion falls into several categories: first, approximate point reflectors in the subsurface cause acoustic energy to appear diffracted into hyperbolas, second, acoustic energy reflected off of dipping (sloped with respect to horizontal) reflectors appears to be translated in the down-dip direction with a smaller slope than reality, and third, all of this transla-

tion of energy creates an apparent change in amplitude of the seismic data. Migration processes work to fix all of these distortions. Migration is one of the largest subtopics of study in the seismic data processing arena, and as such there are many different approaches to implement migration. Before understanding how each of these processes works, a clear understanding of each distortion type is needed.

Diffraction of waves occurs in any wave dynamical system. The term diffraction describes the radial spreading of wave energy as it propagates away from

the spreading point. A simple analogy to the diffraction of seismic acoustic energy is a hole in a seawall off of a beach. Imagine there is a beach with a parallel seawall 100 m out from shore to stop waves. If there was a 1 m long section of seawall missing, when plane waves hit the seawall from the ocean side some of the waves would pass through the wall where the 1 m hole was. It is natural to automatically assume that beachgoers would see a flat sea with a wide wave hitting the shore. In point of fact, this is not the case. The energy from the incoming plane wave would be diffracted radially at the 1 m hole in the wall, causing a semicircular wavefront to propagate toward shore. If the beachgoers stood in a line down the beach and recorded the time at which the wavefront hit the shore in front of them, they would see a hyperbolic dependence in time with respect to their perpendicular distance from the hole in the seawall.

The same thing happens with seismic data. If there is a subsurface point diffractor the seismic receivers, which are laid out at even surface intervals extending away from the source, will record the diffracted energy with a hyperbolic dependence in time with respect to their offset from the diffractor. After stacking the data, the seismic section will show a hyperbola emanating from where the point diffractor is located in the subsurface. Assuming for the moment that the subsurface acoustic velocity is constant in the vertical and horizontal directions, the apex of the hyperbola will appear at the location of the diffractor.

The apparent shift in the location of seismic events along a dipping reflector is related to the diffraction response. The receivers only record acoustic energy as a function of time, therefore there is no directional component to their measurement. So the energy observed

after reflection from a dipping interface will appear skewed in the time and midpoint domains to be from a longer, less steep interface. This effect can also be accounted for by a process called dip moveout correction (DMO). DMO is similar to normal moveout correction with correction for dipping reflectors. Using DMO instead of normal moveout before stacking, followed by migration after stack, produces a result comparable to pre-stack migration if the lateral velocity variation is not too large. Because acoustic energy is diffracted and skewed in the subsurface, migration algorithms must also correct for an apparent loss of amplitude.

As was previously mentioned, there are many strategies for implementing migration algorithms. Some migration strategies use finite differencing methods, which can output a seismic section in depth or in time. Finite difference migration algorithms commonly use an approach to solving the wave equation by predicting the next sample point in the output section using the current sample point in the input section. Phase shift migration algorithms transform the input seismic section into frequency space to downward continue the wavefield by a specific interval for each step. After imaging has been completed, the output section is inverse transformed back into the time domain. Collapsing diffractions by a downward continuation and imaging strategy is analogous to using the focus ring on a camera. When the lenses are in the correct alignment the camera has focused the picture. When the continuation step in a migration algorithm has collapsed the diffractions to a point, the algorithm has imaged the data. While time migration corrects for diffraction, depth migration is necessary to correct for refraction effects such as the bending of seismic waves as they pass through an irregular salt body.

12.3 Seismic Data Interpretation

Once the data has been processed, a seismic data interpreter will analyze it to come up with recommendations on drilling target locations. The seismic data interpretation process is not as simple as point and shoot, however. There are six major subjects that fall under the umbrella of seismic data interpretation. These are: velocity profiling, structure interpretation, amplitude interpretation, well incorporation, attribute analysis, and analysis of amplitude variations with offset (AVO). Though there are many other subfields of work in the interpretation industry, it is essential to be familiar with these six.

Geophysicists have a litany of velocity definitions to deal with. In seismic data processing, there are stacking velocities, migration velocities, and many others. In

seismic data interpretation, there are sonic log velocities, checkshot velocities, and many others. Each type of velocity must be used in a particular circumstance. Stacking velocities are one measure of the acoustic velocity in the medium. Sonic logs use much higher frequencies than seismic surveys, typically thousands of hertz, and are not recorded all the way to the surface. Checkshot surveys approximate seismic acquisition in geometry and frequency and are thus the best velocity for depth conversion. If there are existing wells in the area, the first order of business when beginning interpretation of a new seismic survey is to vertically correlate the well data to the seismic data by creating a velocity function.

A velocity function in this case refers to a map from depth to time along a wellbore. The geophysicist must output a list of (time, depth) points increasing in depth down a well. This time–depth chart is discrete differentiated to come up with a set of velocity points with respect to depth in the well. These velocities are used by seismic data interpretation software to stretch or squeeze the projection of the wellbore on the seismic data to fit the geologic interpretation. When the velocity function for a well is correct the well should project on the seismic with the geologic interpretation in the same vertical position as known geophysical events.

In the simplest case, a geophysicist would create the time–depth chart by lining up geologic interpretation along the wellbore with known seismic events. For example, a geologist would provide the point at which a fault plane crosses the wellbore, so the geophysicist would find the fault plane on the seismic data. Now the depth (from the well data) and the time (from the seismic data) would be known at a single point. This would be done at several points along the wellbore to create the time–depth chart.

A sonic log is created by running an electric tool down the wellbore which creates acoustic energy at one end, and measures that energy at the other end. These tools can be very complicated, measuring different types of acoustic waves or directional acoustic energy, but overall the instrument simply measures the velocity (or slowness) of sound refracted in the borehole wall as the tool is passing through. Because of this dependence on the borehole wall, sonic logs produce questionable results in irregular boreholes as determined from the caliper log. The sonic log along with a formation density log is used to create a synthetic seismogram.

Acoustic impedance is the product of density and p-wave velocity. The reflection coefficient of a vertically incident p-wave is related to the difference in acoustic impedance across the reflecting interface by the following formula

$$RC = \frac{AI_1 - AI_2}{AI_1 + AI_2}, \quad (12.2)$$

where RC is the reflection coefficient, AI_1 is the acoustic impedance of the first medium and AI_2 is the acoustic impedance of the second medium. Reflection coefficients at non-normal incidence will be discussed later in the section on AVO. Because acoustic impedance contrasts are what cause variations in seismic waveforms, a simple synthetic waveform can be created in a clever way: first the density and sonic logs are multiplied to create a pseudo-acoustic impedance log. Next, an acoustic reflection coefficient series is generated

from the acoustic impedance. Then a seismic wavelet is created by either mathematical construct, or by approximation from real seismic data surrounding the wellbore. Finally, this wavelet is convolved with the reflection coefficient series to create the synthetic seismic trace (Fig. 12.3).

Once the synthetic data is created, it can be compared to the real data via the use of the time–depth chart. Recall that velocity is the derivative of the depth function with respect to time. By changing the velocity on individual intervals, the synthetic data can be stretched or squeezed vertically to match the real data. Usually a geophysicist will stretch/squeeze the synthetic data by eye next to the real data to correlate seismic events that look similar. The geophysicist will do this for many wells inside the area of the seismic survey. The benefit to all of this is that now the geologic interpretation will be qualitatively lined up to the seismic data via the projection of the wellbores on the seismic data. The next step in seismic data interpretation is to pick the seismic events that correspond to potential targets.

Picking seismic data is simply the process of selecting events in a seismic data volume by means of a colored marker so that a geophysical model can be built. There is no order in which the geophysicist must pick seismic data volumes, but there are some general guidelines to make orient the interpreter and build some structure into a large data set. When a seismic volume comes in from the processing shop, it can be overwhelmingly large. There are sometimes millions of data traces extending over many square miles of area. It is important to start picking a data set on the largest geophysical features and move toward the small scale.

First, the interpreter should pick major faults. Major faults are usually the easiest thing to see on seismic data, so beginning at one end of the data the interpreter picks a data line for the faults. Moving across the data set the interpreter picks seismic lines at some convenient interval. For a 100 square mile 3-D data set, a good gross fault picking interval may be every thirty lines. A computer program can be used to interpolate between picked lines, creating a full surface extending across the seismic data set which represents the fault scarp itself.

The next thing to pick on the seismic data should be important horizons of interest. A horizon is defined as a continuous, or discontinuous in some cases, seismic event extending in the lateral dimensions representing some geologic feature. If there is a large acoustic impedance contrast between, say, a dense limestone formation bottom and a porous sandstone bed top, the seismic data would have a large trough (or peak, depending on polarity) at the interface. This would be an

Fig. 12.3 A synthetic seismogram generated by convolution of the Ormsby wavelet shown on *right* with the reflection coefficient series shown on *left*

easy horizon of interest to pick as a starting point to make note of large scale geology–geophysical correlations.

After picking the major faults and horizons the interpreter will begin picking finer details in the data. The subtle structural features, geologic unconformities, and potential drilling target horizons should be picked at this point. In addition to these details, geobodies can

be picked during this step. A geobody is a 3-D seismic object of any construction picked in all three dimensions. Examples of geobodies can include erosional channels, fault blocks, or salt bodies. Software can be used to eliminate geobodies from a seismic volume, as to reconstitute a pseudo-stratigraphic section in time. Similar procedures to reconstruct stratigraphic slices from seismic data in time use flattening algorithms on

the horizons, which creates a (somewhat) geologically accurate image.

It is important when interpreting seismic data to recognize the difference between a seismic image and the subsurface reality. Seismic data is sometimes misunderstood as a picture of the subsurface. This could not be further from the truth. As was shown in the previous two chapters, seismic data not only undergoes many processes with apparent structure altering characteristics, but also acquired under noisy conditions miles away from target zones. Some seismic interpreters bet millions of dollars on seismic data alone. The reality is that the subsurface geologic interpretation is much more closely related to subsurface geologic reality. It is because of this fact that good seismic interpreters use geologic interpretations as a limiting case for the seismic interpretation. When interpreting, seismic always use real geologic data to test seismic-based hypotheses.

In any commercial software for seismic data interpretation, and in any other good interpretation software, there is the ability to input well data. These well data can be used in many ways. The above mentioned time–depth chart creation is one of the things seismic interpreters do with well data. Others include projecting geologic formation top interpretations on the seismic data to verify that the events being picked are close to geologic reality. The same thing can be done with well logs; an interpreter may use gamma ray, spontaneous potential, resistivity, neutron density, or many other well logs for geologic verification of geophysical picks. Well logs in some cases can also be used for qualitative comparison of areal coverage in a seismic data set.

The traces in a seismic data survey surrounding a wellbore are acoustic responses to the rocks surrounding that well. It follows then that seismic data anywhere in the survey bearing resemblance to the data around the well may be a response to similar rock characteristics. In this way, seismic data is used to create qualitative comparisons between well locations and prospective target locations. Well logs can be semi-quantitatively incorporated into this scheme by statistically analyzing the seismic response around many wells with similar log suites. Well logs can thereby be used to determine what causes seismic amplitude response.

In many introductions to geophysics courses, students are instructed to drill locations with bright spot seismic response. Bright spots, or isolated high amplitude anomalies within a low amplitude event, can be created due to the change in acoustic impedance of a formation because the pore spaces are filled with hydrocarbons rather than water. The bright spot phenomenon is certainly a good method to locate potential targets, but they are not necessarily always direct hydrocarbon indicators.

The amplitude of seismic data at a location is a function of a huge number of factors. Part of the interpretive geophysicist's job is to evaluate within each seismic survey what drives the amplitude response. In some areas, seismic amplitude may be very closely related to the presence of oil and gas. In these cases, the drilling company just puts the wells where the seismic data lights up!

Seismic amplitudes usually behave in a more complicated manner. In addition to hydrocarbons, seismic amplitudes can also respond to gross-to-net sand ratios, bed thickness, fracture orientation, etc. There are thousands of things that can cause seismic amplitudes to be artificially inflated or deflated in a location. When interpreting seismic amplitudes, one should always take a look at the processing sequence to be sure those amplitudes have been properly preserved. Statistically incorporating well logs into the seismic data can vastly improve the geophysicists' understanding of what is the greatest geologic contributor to seismic amplitude response. It is important to note that amplitude response may not have the same driving mechanisms throughout the entire seismic survey or from one target depth to another. Because of this, interpretation must be carried out separately from zone to zone and across the entire area.

Another type of seismic information that can help geophysicists understand potential drilling targets is called seismic attributes. A seismic attribute is anything represented at a point location in a seismic survey by a pair of spatial values, a time value, and the value of the attribute (x , y , time, attribute), for example, amplitude is a seismic attribute. Amplitude is one characteristic of a seismic waveform. Another characteristic, or attribute, of a seismic waveform would be velocity. In the seismic data processing chapter stacking velocities were defined. As was shown, every CMP gather location is analyzed and assigned a velocity for every time value in the stacked trace. Therefore, once this stacking procedure is complete the seismic data processor has a value of velocity at every point in the seismic survey. If desired the processor could output a seismic data volume of space, time, and velocity (x , y , time, velocity), this volume would be called the velocity attribute of the seismic survey.

As seismic attributes are derived from any mathematical operation on seismic data, there are an infinite number of attributes. Fortunately, due to the literature on the subject there are a finite number of categories into which these attributes fall. The major ones are geometrical, instantaneous, wavelet, and exotic attributes. The usefulness of seismic attributes varies with the geologic setting and the information, such as well data, available. The most important aspect to consider when deciding which attributes to use is that all attributes

come from recorded data. Performing mathematical operations on any data (seismic or otherwise) can provide a different view of that data, but once the data has been recorded no new information is available to that system. Seismic attributes do not create new information; they only bring out features of the data which are not accessible by the human eye in amplitude data.

The geometrical subset of seismic attributes includes several very useful attributes. They include curvature, dip characterizers, and coherence. Curvature attributes describe the shape of individual seismic events. Seismic interpreters can use attributes such as maximum curvature, Gaussian curvature, and most positive curvature to help tease out subtle structural details in seismic data or continuity in the bedding planes associated with their target prospects. The suite of dip characteristics includes dip azimuth, dip variance, and dip of maximum similarity. These attributes in areal cross section can help to delineate reservoirs or resolve geologically complex settings. Coherence, or similarity as it is also called, is an extremely helpful attribute which creates an image of the subsurface analogous to an MRI image. The discontinuities between seismic traces are assigned a low value of coherence, so continuous zones look blank. Coherence can be used in areal cross section or vertical cross section to delineate small faults or lineaments in the subsurface, for example, fluvial channels.

The instantaneous suite of seismic attributes is created using differential type operators which take only the surrounding samples into calculation, hence the name instantaneous rather than average. The major players in this category include instantaneous frequency, instantaneous phase, and relative acoustic impedance. The frequency and phase attributes are used to assist in quantifying geology–geophysical relationships. They can also be used to delineate the lateral extent of beds in some cases. Relative acoustic impedance is often touted as an attribute that shifts the seismic data from reflection coefficient amplitude data into a true geologic image. This is not quite the case, because there has not been any new information put into the system, but either way relative acoustic impedance gives the interpreter a phase shift and some scaling on the data which in some cases can, again, help delineate bedding.

In many cases the attributes of the wavelet attribute suite are used as intermediate products to create a final attribute based on several components. However, wavelet envelope and wavelet bandwidth can be used to assist in interpretation. These attributes can be viewed in vertical cross section to give the interpreter a better feel for the gross geologic structure under certain circumstances.

The term *exotic* attribute is used here to describe any attribute that does not appear in widespread use across the literature. As previously mentioned, there is an infinite number of attributes, so the exotic attribute category can include infinitely many attributes. One example that is used with great frequency is called sweetness. Sweetness is wavelet envelope over the square root of instantaneous frequency. Sweetness can be used to pick out areas of high net to gross sand ratio, which is important in in-field development projects and near-field exploration. If an interpreter recognizes which attributes work well in an area, he/she may be able to work together with a processor to create a custom exotic attribute. Just because this custom attribute works well in this one area does not mean it will work in any other setting.

Most beneficially, many seismic attributes will be used in concert with each other to create the best interpretation of the seismic data. One way to do this is by using a multivariate statistical approach. The seismic interpreter extracts traces of several seismic attribute volumes, including amplitude if valuable. The traces should be around wells that produce and wells that do not produce, as to build up a good sample set. Each of these trace data will be culled for samples around zones of interest. The interpreter then builds up a strong multivariate equation based on the attributes which seem to have clear response to the desired geological characteristic and builds a model zone for each real zone of interest. This can be done as a map-based (2-D) or volume based (3-D) process. When complete, the model zone should display a statistical likelihood of success for drilling as a function of time and/or space.

The last major tool in the interpretive geophysicist's toolbox is the analysis of amplitude with respect to offset. Amplitude versus offset (AVO) analysis can prove to be a powerful process for finding hydrocarbon rich target zones, and also for characterizing lithology in undeveloped regions. To perform AVO analysis, the interpretive geophysicist must have access to the processed CMP gathers from the processing geophysicist. The gathers may be processed to any point that the interpreter prefers, but should represent the final seismic section that is represented. All industry standard AVO analysis is done on NMO or, better yet, DMO corrected gathers, so that the interpreter can pick and observe flat events rather than hyperbolic events. Care must be taken at each pre-processing and processing step to preserve relative amplitudes. Amplitudes on land data are often affected by the near-surface, so surface-consistent amplitude balancing may be a necessary step. Pre-stack migration or DMO improves AVO response by moving energy between traces.

The interpreter will pick the gathers with a horizon of interest across an area of interest. This is usually performed with an autopicking software initialized with the normally incident traces in each gather. The picked event is analyzed by a simple algorithm on a per CMP basis and could output an AVO class for each. An AVO class (from class 1 to class 5) is an industry standard definition of the response characteristics in the gather. The Zoeppritz equations predict the amplitude of waves propagating away from an encounter with an interface with respect to angles from a normal. There are four Zoeppritz equations to give the amplitude of the reflected p-wave, the reflected s-wave, the transmitted p-wave, and the transmitted s-wave. All four equations use both p-wave and s-wave velocities, so the reflection amplitude behavior at non-normal

incidence contains information about mechanical properties such as compressibility of the formation that is not contained in the zero-offset trace. The presence of shallower interfaces means the transmission effects at each shallower interface must be modeled as well. There are a number of commercial AVO modeling packages available. The AVO characteristics can be displayed in a crossplot with the hopes of grouping outlying data. The outliers can be culled and their CMP locations displayed on a map. By way of example, if the interpreter knows that all CMP locations exhibiting an anomalously high Shuey three-term gradient to Shuey three-term curvature response are oil bearing, then this zone would be culled for this data response, and a possible location would present itself in areal cross section.

12.4 Summary

The seismic data interpretation procedures outlined above are used as a starting place for building a model. It is the interpreter's job to use the seismic data for verification of an Earth model. Sometimes the model only exists in the interpreter's head, but more explicit models are recommended. Seismic modeling software can create 3-D models from seismic interpretation. The interpreter will input his/her fault surfaces and horizon surfaces into the modeling software which will create 3-D volumes from this information. The 3-D models can be used to model reservoir drainage, to plan wells, or even to steer wells in real time as they are drilled.

The key to good modeling is iteration. The first model created will never be spot on, which is why the interpreter needs to rework the model as new information arrives. If for example a well is drilled on the initial model, the interpreter should have a new set of well logs to help quantify the seismic data. The iteration process continues from the initial model through the completion of the entire drilling program, and into any other projects of similar setting. Geophysicists also must iterate new geologic and engineering data into their models. Using all of the information at hand is crucial to continued success.

The initial and updated data must drive the model. It is a waste of money to come up with a hypothesis and then use the seismic data to prove that hypothesis. The correct order should be to look at the data and then come up with a hypothesis; if any new data comes in disproving that hypothesis, the hypothesis should be thrown out. A common mistake when building implicit Earth models that only exist in the head of the interpreter is following these incorrect hypotheses all the way to drilling a dry hole. In this way an explicit Earth model updated by the geophysicist, geologist, and engineer is the most accurate and successful way to complete a drilling program. The entire seismic data workflow is a procedure in risk mitigation. Any company can throw a dart at a map and drill that location, but the chance of success is low. Seismic data acquisition, processing, and interpretation reduce the risk of drilling to some point dependent on data and interpretation quality. If this reduced risk level is below whatever arbitrary threshold risk level the drilling company has decided on, then seismic exploration has done its job.

Acknowledgments. The author would like to acknowledge valuable comments from Dr. Greg Kroft and Professor Kent Pederson of the University of Calgary.

Formation Evaluation

Donald G. Hill

Petrophysicists utilize laboratory and borehole geophysical measurements as input into petrophysical models to estimate reservoir hydrocarbon resources and recoverable reserves. Unlike surface and airborne geophysicists, who work with one to three scientific disciplines, petrophysicists comfortably work with eight or more scientific disciplines on a daily basis.

One of the most exciting things that an exploration and producing (E&P) company can do is to drill a well. Prior to *spud-in*, the drilling target is some type of model: an explorationist's dream for a *wildcat well*, or a reservoir model for a delineation or development well. The act of drilling a well serves to either confirm or reject that model.

Figure 13.1 shows a schematic of a modern rotary well drilling system. The rotary drill bit at the bottom of a long *drill string*, grinds away to *make hole*. A *mud system*, consisting of mud supply tanks/pits, and pumps at the surface, forces drilling mud down the center of the drill string to cool the bit and clear *drill cuttings* from the face of the drill bit and return them

Fig. 13.1 Schematic drawing of a rotary well drilling system (courtesy of Petroleum Extension Service, The University of Texas, Austin)

to the surface, where they are removed, examined, and described. *Blowout preventers*, at the surface, can be closed to prevent high-pressure fluids and/or gases from escaping the well. The drill bit is rotated by a *down-hole drill motor, top drive, or rotary table* in the drill floor.

Heavy *drill collars*, above the bit and *bit subassembly*, provide weight on the bit to improve the *rate of penetration (ROP)*. The entire drill string is suspended by a *traveling block*, hung from a *crown block* at the top of the *derrick*. The crown block/traveling block assembly allows the driller to raise and lower the drill string

in the well and maintain the drill string under tension during the entire drilling process. The drill string must be maintained under tension to prevent it from twisting up, like so much wet spaghetti, during rotation.

The *drilling mud density (mud weight)* is maintained such that the borehole fluid pressure always slightly exceeds that of the formation pressure to prevent *blowouts*, which can be both dangerous and costly. Solids in the drilling mud form filter cake (*mudcake*) on the borehole walls opposite permeable formations, which protects the borehole prior to permanent protection via *casing and cement*.

13.1 What Is Formation Evaluation?

The terms, *formation evaluation, well log analysis, and petrophysics* are often used interchangeably, but do have slightly different meanings. Generally, however, they involve using core and fluid laboratory physical and chemical property measurements as well as wireline and logging while drilling (LWD) well logs to evaluate wells for potential hydrocarbon reservoir rocks and economic hydrocarbon accumulations, as well as mechanical properties of the rocks penetrated by a drilling well. The following types of information are all used to conduct formation evaluation (FE):

- Laboratory fluid property measurements
- Laboratory (rock) core physical property measurements
- Drill cuttings descriptions (strip log)
- Mud logs
- Wireline log measurements
- Measurements while drilling (MWD)
- Logging while drilling (LWD)
- Formation flow tests.

13.2 The Need and Purpose of Formation Evaluation

Without FE an oil or gas well is simply an expensive hole in the ground. Formation evaluation is used to establish the presence of potential reservoir rock, evaluate those reservoirs for potential hydrocarbons and to determine the value of those hydrocarbon reserves. It is also used to develop reservoir mechanical properties models for the drilling and producing departments. Figure 13.2 illustrates the interrelationships between FE and other disciplines within a petroleum exploration and production (E&P) operation.

To appreciate the economic role of formation evaluation in the operations of a modern petroleum company, look no further than the formula for calculating original oil (reserves) in place.

$$STOOIP = \frac{7758Ah\phi(1 - S_w)}{B_{oi}}, \tag{13.1}$$

where STOOIP is stock tank original oil in place (bbls), *A* is the reservoir closure area (ac), *h* is the average reservoir (net) thickness (ft), ϕ is the average reservoir decimal porosity, *S_w* is the average reservoir decimal

water saturation, *B_{oi}* is the initial oil formation volume factor, 7758 is the ac/ft to bbls conversion factor (different conversion constants will be required, for other units).

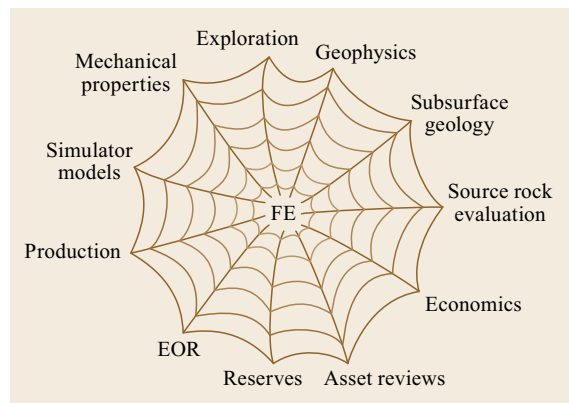

Fig. 13.2 Formation evaluation (FE) relationships in petroleum exploration and production (E&P)

A similar relationship also exists for gas reserves.

$$\text{SCFOGIP} = \frac{43\,560Ah\varphi(1 - S_w)}{B_{gi}}, \quad (13.2)$$

where:

- SCFOGIP is standard (temperature and pressure) ft³ original gas in place.
- A is the reservoir closure area (ac).
- h is the average reservoir (net) thickness (ft).
- φ is the average reservoir decimal porosity.
- S_w is the average reservoir decimal water saturation.
- B_{gi} is the initial gas formation volume factor.
- 43 560 is the ac/ft to SCF conversion factor (different conversion constants will be required, for other units).

Three of the five variables in (13.1) and (13.2), (h , φ , and S_w), are obtained from well logs via FE, well

13.3 Well Logs

To most people in the exploration and production (E&P), or *upstream* petroleum industry, *formation evaluation* means *well log analysis*. A good place to start, therefore, is to explain just what is meant by the term *well logs*.

13.3.1 What Are Well Logs?

Well logs are some record, as a function of depth, of what a well penetrates in the subsurface. They are endemic to the petroleum industry. The following quote says it all [13.1]:

Petroleum geologists as a whole spend much more of their time working on problems that arise after drilling has started than they do in finding structures and locating wildcat wells.

Most of this effort involves collection of data, preparation, and interpretation of well logs of various types.

The origin of the term *well log* seems to be lost in the antiquity of the petroleum industry. The most probable version, however, appears to be related to out of work whaler seamen after petroleum kerosene displaced whale oil for lighting.

13.3.2 Driller's Logs

Discussions with *E.C. Thomas* [13.2] and *Richard Bate-man* [13.3], at a recent Society of Petrophysicists and Well Log Analysts (SPWLA) meeting, however, provided some insight on this issue. According to Richard and E. C, the fallout from the Drake Well, in Pennsyl-

log analysis, or petrophysics. The closure area A comes from seismic mapping and/or subsurface geology. The formation volume factor B_{gi} comes from an analysis of rock and fluid measurements, by a *Qualified Reserves Engineer*.

In practice the terms h , φ and $(1 - S_w)$ in (13.1) and (13.2) are replaced by

$$\sum_{i=1}^n h_i \varphi_i (1 - S_{wi}), \quad (13.3)$$

where h_i can be as small as the sampling interval on the well logs. Obviously, because of the large values possible for A , small changes in φ_i and S_{wi} can result in very large changes in the reserves values. The remainder of this chapter will discuss how a petrophysicist uses FE to arrive at quantitative estimates of reservoir porosities and saturations, as well as estimates of permeabilities.

vania, decimated the previously lucrative whale oil industry, and displaced the crews of the whaling vessels. These unemployed seamen found work in the new Pennsylvania oil fields and, as a result, brought their seafaring vocabulary, including the use of *logs*, with them.

Most of us are familiar with the term *ship's log*, the diary, usually kept by the captain and/or first mate, of a ship's movement and activities when out of port. Just as the ship logs helped owners keep track of their property, *driller's logs* helped the owners of drilling rigs and developers drilling wells keep track of activities on a *drilling well*. Driller's logs are so common that most government agencies require *driller's logs* to be submitted for every oil, gas, geothermal and water injection, or environmental well drilled within their jurisdictions. Note that the driller's log examples, shown in Figs. 13.3 and 13.4 were submitted on a California Division of Oil and Gas form.

Driller's logs are considered to be *public domain* and unless the operator designates them to be *tight hole* (confidential), they are available to the general public as soon as they are received and recorded by the government agency. The driller's log header, shown in Fig. 13.3 details how the well was completed. Figure 13.4 shows the driller's account of what was encountered while drilling the well.

13.3.3 Wellsite Geologist's Sample Description Strip Logs

The science of stratigraphy, pioneered by English canal digger *William Smith* [13.4], showed that geological

formations could be correlated between outcrops, road cuts, quarries, canal cuts, and building excavations. The specialty of subsurface geology took this tech-

nique down hole to materials encountered in drilling wells. The initial vehicles for subsurface correlation were driller's logs.

Fig. 13.5 Graphic drill cuttings sample description (*strip*) log ▶

Some drillers are very conscientious and, while not trained as geologists, their driller's logs can be used for subsurface correlation. Other driller's logs have been constructed from memory, after a well had been completed, and/or are not very descriptive of the material being drilled. These latter driller's logs are essentially useless for subsurface geology. They satisfied the legal requirement that a report be filed and that is about all.

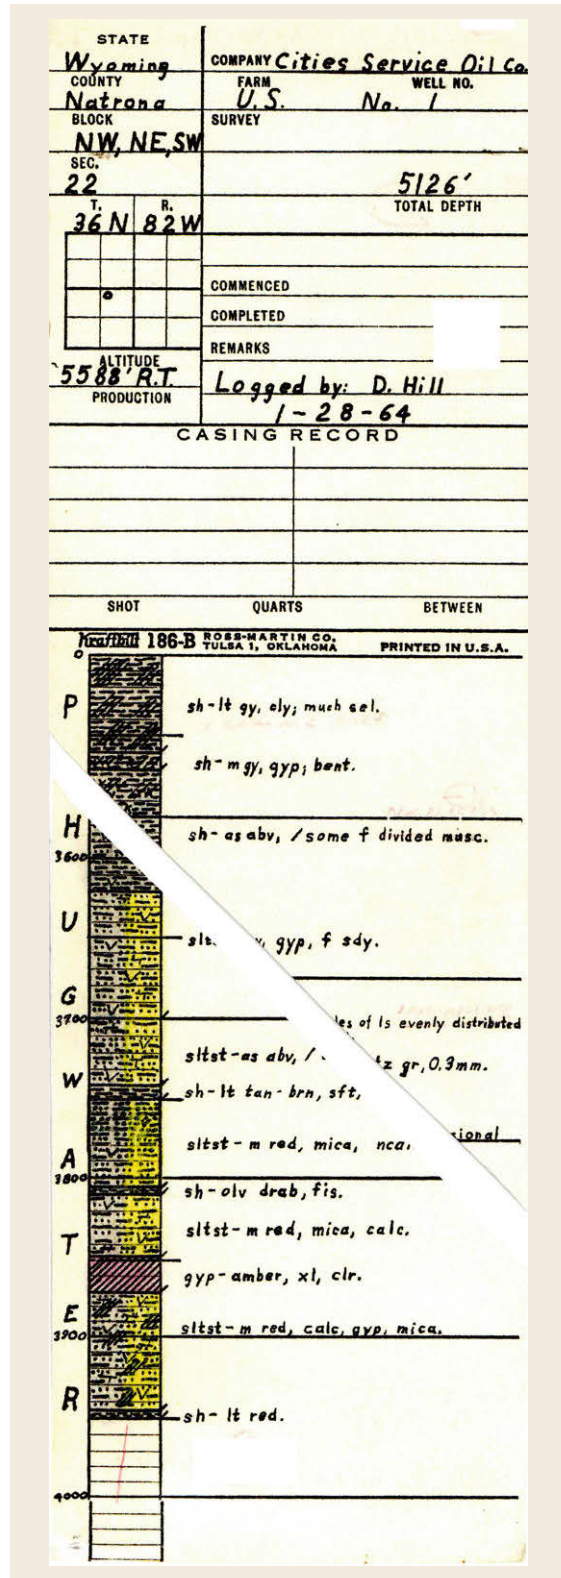

As soon as it became obvious that driller's logs were not that reliable, geologists became involved. The drill-site geologist's sample log initially consisted of descriptions of drill cuttings and/or cores cut as the well was drilled. Some operators (e.g., Standard Oil of California, now Chevron) required small drill cutting samples on their geologist's sample logs. Geologist's sample/core logs gradually evolved into a stylized graphical display, at standardized depth scales, with shorthand notations of the cuttings lithology. These records were often called *strip logs*, because the original preferred medium was 2" = 100 ft, depth scale, rolled card stock. Figure 13.5 is an example of a hand-drafted sample cuttings log.

13.3.4 Mud Logs

Mud logs incorporate simplified versions of geologist's sample logs, along with various drilling parameters. They are often used in lieu of geologist's sample description logs (contractors are cheaper than your own employees). They also provide an early warning of *pay zones*, as well as potential *blowouts*, *lost circulation*, as well as noxious and/or poisonous gases. Drillers utilize them to optimize their drilling operations. Mud logs were the first *real-time* logs available, as they are acquired as the well is being drilled.

13.3.5 Wireline Logs

Wireline logs are records of the physical and/or chemical properties of the materials penetrated by a drilling well. Open-hole wireline logs are acquired by suspending in instrument package (*sonde*) on a cable to make the measurements and are acquired after the well has been drilled (at least to a *casing point* depth), but before casing has been set to protect the well bore. They have evolved from simple station measurements, utilizing a jury-rigged surface electrical survey electrode array, to the current sophisticated system of continuously recorded multiple parameters, including quality control information available today. Figure 13.6 shows an open-hole wireline log through a sand-shale (clastic) section, with an initial geologic interpretation.

Fig. 13.6 Western Australia wireline log

Note that the different log curves not only have different colors, but also different curve types. This is so that the curves can still be differentiated, if the colored log display is sent via fax or copied in grayscale.

Cased-hole wireline logs are made after casing has been run. They are often used to evaluate the casing condition and effectiveness of cementation, monitor production operations and to identify remaining, or bypassed, reserves of producing fields.

13.3.6 MWD/LWD Logs

Measurements while drilling (MWD) and logging while drilling (LWD) logs utilize specialized drill collars and data telemetry systems that allow most (but not all) wireline measurements to be made as the well is being drilled. Because MWD/LWD systems use mud-pulse or electromagnetic (EM) telemetry, they are real time measurements, compared to wireline measurements, which are made only at casing points, or total depth (TD). They were developed for use in high-risk wells and for high angle deviated or horizontal wells, which are difficult to log with wireline methods.

The first vendors to offer MWD measurements were drilling and mud logging vendors and the measurements were unique to directionally drilled wells, where they were used for well steering control. With time, geological and formation evaluation measurements were added to the MWD subassemblies. The LWD designation was initially unique to a single vendor that used the term to distinguish its drill string measurements from those of other vendors. For a time, the two terms were used almost interchangeably.

Currently, MWD usually designates those measurements used to control directional drilling while LWD is used for those measurements that parallel wireline measurements. All of the major wireline vendors also now offer MWD/LWD services. In addition to duplicating most of the wireline measurements, there are also some FE measurements unique to MWD/LWD systems.

13.3.7 Who Uses Well Logs?

Petroleum E&P professionals can expect to encounter well logs and petrophysical analyses many times in the course of their careers:

- Completion Engineers utilize petrophysical results to establish completion intervals.
- Qualified Reserves Engineers utilize petrophysical results to establish recoverable reserves.
- Asset Review teams use petrophysical results to establish property values for property disposal and/or acquisition.
- Reservoir Engineers utilize petrophysical results to build simulator models and for depletion planning.
- Production Engineers utilize petrophysical results to help develop and operate fields.
- Enhanced Oil Recovery (EOR) Engineers utilize petrophysical results to plan EOR operations.
- Production Superintendents will decide budgets including petrophysical programs.

The most common users of well logs, however, are none of the above. *Geologists and geophysicists* are the petroleum E&P professionals that utilize well logs the most, to obtain seismic velocity information (geophysicists) and to make stratigraphic and structural correlations between wells (Fig. 13.7).

13.3.8 What Is Desired Versus What Can Be Measured

While three of the five variables in (13.1) and (13.2) are obtained from well logs, two of these three:

- Porosity φ
- Saturations:
 - Water saturation (S_w)
 - Oil saturation (S_o)
 - Gas saturation (S_g)

are not measured directly. Instead, well logs measure such things as:

- Acoustic interval transit time (Δt)
- Neutron porosity (φ_N)
- Bulk density (ρ_B), which depend upon:
 - Porosity (φ)
 - Water saturation (S_w)
 - Lithology
- Natural gamma radiation:
 - Total γ -ray
 - Potassium-Uranium-Thorium (K-U-T) spectral γ -ray
 - Photoelectric factor (PEF), which depend upon lithology
- Spontaneous polarization (SP), which depends upon:
 - Mud filtrate/formation water salinity contrast
 - Lithology
- Apparent resistivity R , which depends upon:
 - Porosity (φ)
 - Lithology
 - Water salinity
 - Water saturation (S_w)
- Nuclear Magnetic Resonance (NMR), which depends upon:
 - Porosity (φ)

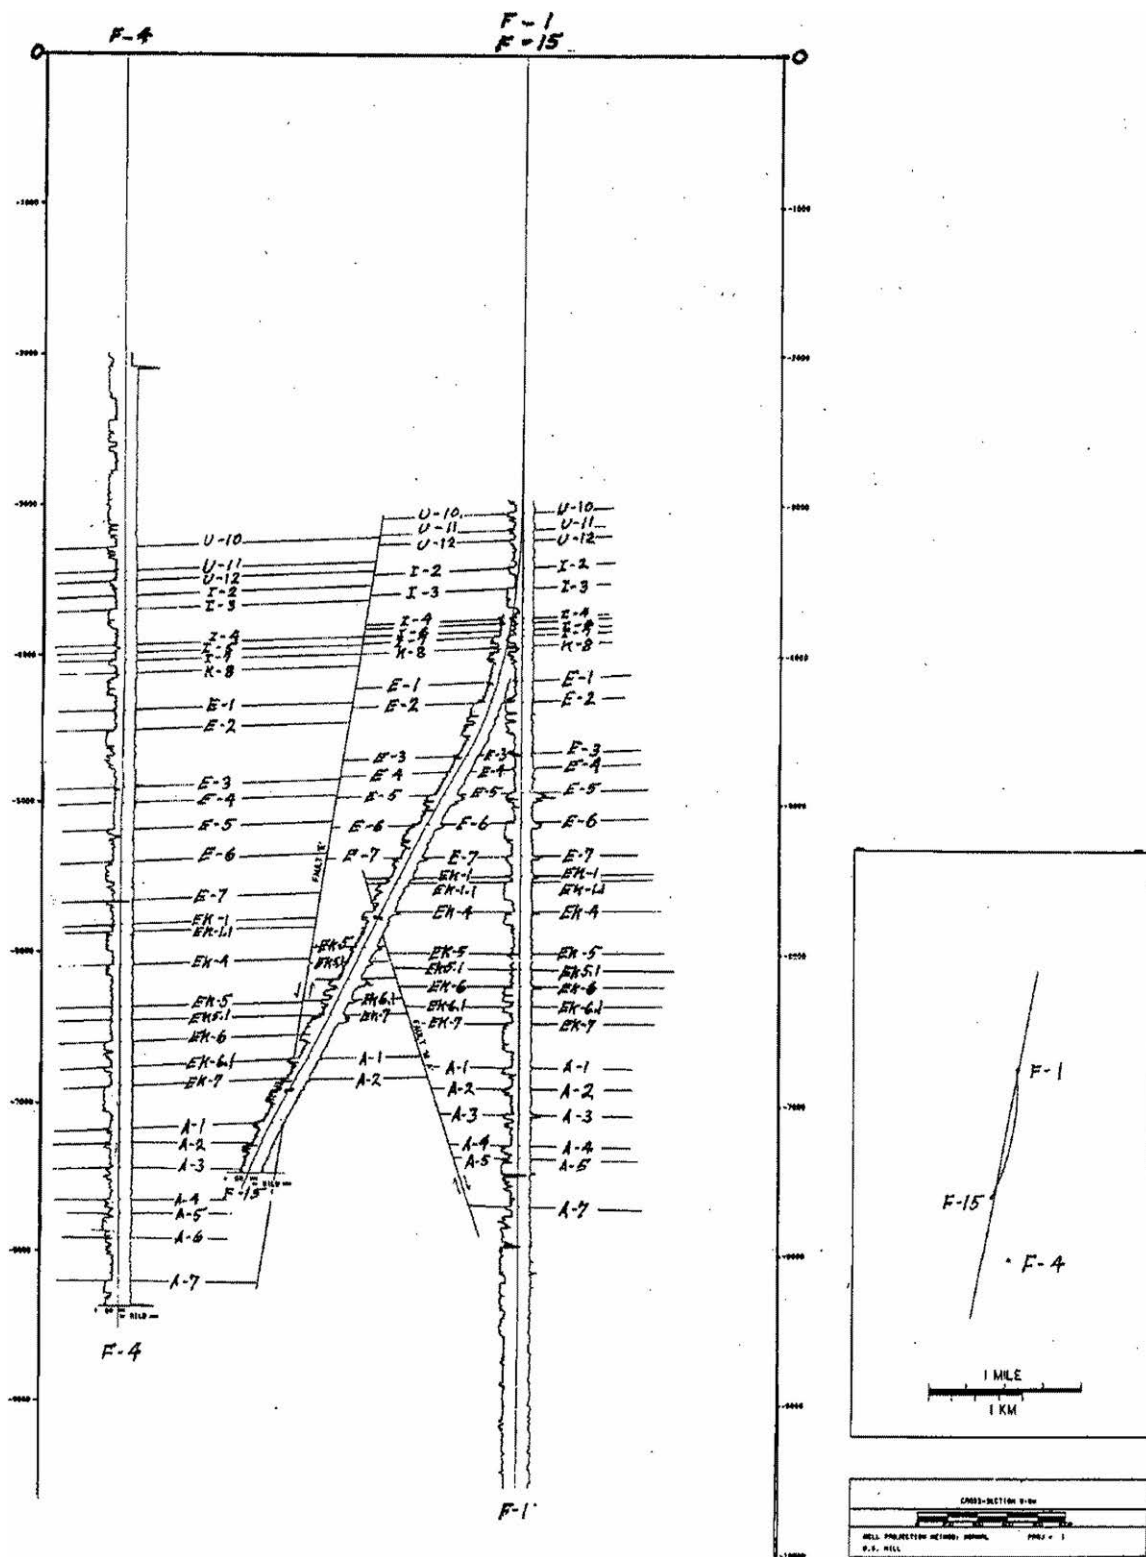

Fig. 13.7 Use of a well log cross-section to explain complex structure

Table 13.1 Open hole logging tools and techniques, with Schlumberger mnemonics (compiled from a variety of sources)

Primary purpose	Tool or technique
Lithology	Spontaneous potential (SP) Gamma ray (GR) Side wall cores (SWCs) Photoelectric factor (PEF) Tri-mineral, MID, and MN plots
Porosity	Density (RHOB) Nuclear magnetic resonance (NMR) Neutron (NPHI) Acoustic (ΔT) Cross-plots
Salinity/water resistivity	Spontaneous polarization (SP) R_{wa} analyses Hingle plots Pickett plots
Saturation	Resistivity (ES) Induction (IES, DIL) Laterolog (LL, LL3, DLL) Array induction (AIT)
Flushed zone saturation	Microspherically focused log (MSFL) Microlaterolog (MLL) Dielectric constant (EPT, DPT) Nuclear magnetic resonance (MRL)
Permeability	Nuclear magnetic resonance (MRL) Formation testers (FTs, RFT, MDT)
Fluid identification	Formation testers Density/neutron overplot FID plot S_w tools
Structural/stratigraphic information	Dipmeter (HDT, SHDT) Borehole televiewer (BHTV) Resistivity microscanners (FMS/FMI) Nuclear magnetic imagers (NMIs)
Borehole imaging	Borehole televiewer (BHTV) Resistivity microscanners (FMS/FMI) Nuclear magnetic imagers (NMI)
Borehole temperature	Temperature (TEMP)
Formation pressure	Formation testers (FT, RFT, MDT)
Borehole shape	Caliper (CAL)

- Fluid types
- Permeability
- Pore wall lining.

The desired porosities and saturations must be inferred from well-log measurements, using FE/petrophysical models and techniques. The petrophysical/FE models and techniques used to do this inference will be the subject of this chapter.

In spite of the overlapping responses of the various wireline and MWD/LWD tools, most of them are identified with specific applications. Table 13.1 lists some of the more common tools and interpretation techniques, by their primary purpose. Some tools and techniques (e.g., caliper) do have a single primary purpose. Many, however, really have multiple primary purposes. Almost all of them are used as components in various multiparameter petrophysical analysis techniques.

13.4 Who Are Petrophysicists and How Do They Work?

Petrophysicists may have formal training in any of several fields, including chemistry, physics, geophysics,

mechanical, electrical and petroleum engineering, geology, sedimentology, and stratigraphy. Regardless of

their formal training, good petrophysicists also have several years of experience, working with FE problems from a variety of geological settings throughout the world. Some specialize in specific techniques, specific geologic environments, and/or specific geologic basins. Some are generalists. Some have been practicing logging engineers. Others have gravitated to the field from research laboratories, or E&P operations.

The common characteristics among petrophysicists (if you can say there are such things) are curiosity, imagination, creativity, and a desire to make the best estimates of volumetric parameters given the information at hand. In short, a petrophysicist works much like a physician or detective, analyzing incomplete evidence to develop a logical analysis. Paul Worthington, former Petrophysics Director at the British Petroleum Sunbury E&P Research Laboratory, may have said it best [13.5]:

A petrophysicist is someone who, on a daily basis, is required to attempt the impossible and who almost pulls it off every time.

While this may be a little self-serving, it is not far off the mark. I know of few traditional scientists and engineers who would be willing to do what petrophysicists are asked to do, every day, given the sparse amount of information they usually have at their disposal.

Often (e.g., for discovery and older wells), not all of the information needed for a solid petrophysical interpretation is available. In these cases, the petrophysicist must make his/her best estimate of the missing information. Later, if the missing information becomes available, the petrophysical interpretation can be modified, using the new information. In a sense, *all petrophysical interpretations are preliminary*, subject to later revision as additional information becomes available.

13.5 How Wireline and MWD/LWD Logs Are Acquired

Table 13.1 lists common objectives for well log measurements, and the logging tools and/or petrophysical analysis techniques used to obtain them. The most effective approach to estimating the desired petrophysical parameters is to use multiple measurements and analysis techniques.

Figure 13.8 is a schematic drawing of a wireline logging system in operation. A measurement instrument package (sonde) is lowered to the bottom of the well to be logged and chemical/physical properties of the immediate borehole environment are measured as the sonde is slowly (1500–3600 ft/hr) retrieved from the well. A large winch, located in the (surface) logging unit, raises and lowers the sonde in the well via 1-9 conductor, double steel armor (also a conductor) wrapped cable. The logging cable also supplies power to the sonde and serves as the communications link between the measurement instruments in the sonde and the recording devices at the surface.

An alternative configuration (MWD/LWD) utilizes special instrument packages, contained in drill bit sub-assemblies, which make the log measurements, encode them, save them to downhole memory and/or transmit them to the surface via coded pressure pulses in the mud column or EM signals.

Fig. 13.8 Wireline logging system

13.6 Uses of Well Logs

The initial uses of wireline measurements were to correlate formations between boreholes. *William Smith* established that geologic formations could be correlated over great distances [13.4], by observing the character of the rocks and included fossils exposed in outcrops and in road cuts, canal cuts, quarries, and building excavations. Subsurface geologists carried this approach into the subsurface, by describing drill cuttings and cores.

The Schlumberger brothers established that wireline physical property measurements could be used for the same purpose. If the correlations are relative to (hung on) a specific formation, the results are called *stratigraphic cross-sections*. If the correlations are hung on subsurface depth, the result is called a *structural cross-section* (Fig. 13.7).

These (stratigraphic and structural) correlation uses of well logs are still the largest single use of wireline and MWD/LWD products.

Figure 13.7 shows a structural cross-section from a West African oil field. This cross-section was used to solve a perplexing field development problem. The F-15 (side-track) well was programmed *not* to cross Fault E. The well, however crossed the previously unknown Fault A, truncating the EK-4 Sand, and *floatated*, crossing Fault E in the A-3 Sand, bottoming out in the *hanging wall* of the fault structure, repeating the A-1 and A-2 Sands. The operator recognized that the well cut two faults, but interpreted the second fault to be antithetic, like Fault A, which would result in a missing section, and erroneously correlated the sands below the fault to deeper pay sands in the section of the horst, containing the oil field. The sands below the fault in the F-15 well were wet because they were off the structure containing the oil field. The structural cross-section of Fig. 13.7 shows the correct structural relationship of the F-15 well sands, to the F Structure and its pay sands.

Quantitative wireline measurement tools and laboratory measurements on core material led to the development of formation evaluation, well log analysis, or petrophysics (nearly interchangeable designations). Initially wireline measurements were calibrated using core measurements as standards. Current wireline and LWD tools, however, are sufficiently reliable and well calibrated that they can often identify core measurements, which are in error, and/or are biased by inhomogeneities (nugget effect).

Wireline measurement suites are now routinely used to scan wells to search for potential hydrocarbon-bearing intervals. Once hydrocarbon indications have been found, wireline measurements are used to quantify the reservoir thickness (net pay), pore space (porosity), and the type and amounts of fluids occupying that pore space (water, gas, and oil saturations). This basic reservoir information (net pay, porosity, and saturation) is used with structural and stratigraphic information to develop stock tank original oil in place (STOOIP) and standard cubic feet original gas in place (SCFOGIP) values for reserves estimates and depletion management ((13.1) and (13.2)).

In addition to volumetric measurements, modern wireline and MWD measurements also provide information on:

- Borehole volume
- Mechanical properties of the rocks penetrated by wells
- Temperatures and pressures of the subsurface
- Subsurface borehole path
- Images of the borehole wall
- Structural and stratigraphic information about the subsurface.

13.7 Petrophysics and Well Logging: Historical Development

Old well logs never die. They reside in records storage or well files and are repeatedly used by explorationists and engineers over time. The measurements currently being made, however, are much different from those that were done in the past. Because of this, it is worth a short history lesson. *Bateman* [13.6] and *Hill* [13.7] have more detailed historical reviews.

It is difficult to discuss the historical development of well logging without sounding like a promotion for Schlumberger, as the development of the industry and Schlumberger are so intertwined and this multinational integrated corporation so dominates the industry. While

exact figures are difficult to obtain, Schlumberger controls approximately 80%± of the world wireline, LWD and core laboratory industry. They do, however, have strong, though much smaller, competitors.

Schlumberger has not always been the first to introduce a new technology. Partially, this is because new technology introduction costs are generally much less for their smaller competitors, as vendors generally want to be able to offer any new services system-wide. Once a market has been established, however, Schlumberger has generally quickly covered the new (competitor) product and rapidly advanced the new technology, to

maintain their control of the market. In the few cases where Schlumberger did not have its own competing technology it has, in recent years, bought out startups with innovative technologies.

Tables 13.2–13.8 highlight some of the milestones in the logging/petrophysical industry. It has been com-

plied from a variety of sources, not all of which agreed upon the dates of when specific events happened. Most of the nonelectrical new technologies were introduced by organizations other than Schlumberger. Many of the significant improvements of these new technologies, however, did come from Schlumberger.

Table 13.2 Prelogging petrophysical milestones (from a variety of sources)

Date	Event
1830	First attempts to measure spontaneous polarization generated by metallic sulfide deposits
1900	Gamma ray discovered
1911	Conrad Schlumberger begins research in electrical prospecting techniques at Ecol des Mines, Paris Initial equipotential mapping field work by Conrad Schlumberger, at the family's Val-Richer estate, Normandy
1912	First observation of induced polarization First Schlumberger electrical prospecting patent filed
1913	First successful use of Mes a la Mass technique to outline a buried conductive ore body Conrad Schlumberger observed SP signals over buried sulfide ore bodies
1919	Paul Schlumberger underwrites Conrad Schlumberger's electrical prospecting research Brother Marcel joins the efforts Earl P. Halliburton founded New Method Well Cementing Co.
1923	Formation of Societe de Prospection Electrique, Precedes Schlumberger (Pros) Surface electrical surveys in Belgian Congo, Canada, Romania, Serbia and Union of South Africa

Table 13.3 Petrophysical milestones: 1927–1942 (from a variety of sources)

Date	Event
1927	First electric log (station measurements) at Pechelbronn Field, France
1928	Introduction of three-conductor logging cable
1929	<i>Electrical coring</i> paper presented at A.I.M.E meetings Electrical logging introduced to California, USSR, and Venezuela
1930	Introduction of SP log Electrical logging introduced to Indonesia
1931	Introduction of manual (hand-cranked) continuous pen recording
1932	Introduction of the normal electrode array resistivity log Introduction of directional surveys Introduction of temperature logs Introduction of bullet perforation Bill Land and Walt Wells form Lane-Wells Bullet Perforation Company Chadwick discovers the neutron
1933	First neutron log evaluation
1934	Schlumberger Well Surveying Corporation formed Introduction of automatic (galvanometer) recording
1935	Introduction of sidewall cores Introduction of photographic recording
1936	Introduction of dual galvanometer recording
1937	Introduction of three-galvanometer recording
1938	Introduction of four-conductor cable Introduction of neutron log Nuclear magnetic resonance discovered
1939	First gamma ray log publication
1940	Introduction of armored cable Introduction of gamma ray logs Jess Hall Sr. founded Weatherford Spring Co.
1941	Introduction of three-arm (SP) dipmeter
1942	Publication of Archie equations
1941	Introduction of three-arm (SP) dipmeter
1942	Publication of Archie equations

Table 13.4 Petrophysical milestones: 1945–1960 (from a variety of sources)

Date	Event
1945	Introduction of focused electrical logs Introduction of the R_{xo}/R_t (Rocky Mountain) Interpretation Technique
1946	Introduction of three-arm dipmeter with short (micro) resistivity pads and caliper logs
1947	Introduction of induction log Introduction of nine-pen galvanometers
1948	Schlumberger opens research center (later renamed Schlumberger-Doll Research Center) in Ridgefield, Connecticut Transistor invented
1949	Introduction of microlog, with caliper
1950	Introduction of guard resistivity logs, or Laterolog-3 (LL3). Introduction of gamma ray logs Introduction of gamma ray neutron log (GNT)–gamma ray log combination
1951	Introduction of continuous recording three-arm dipmeters, with microresistivity pads Introduction of microlaterolog
1954	Introduction of continuous velocity logs, later called acoustic or sonic logs. Introduction of powered downhole caliper arms Introduction of nuclear magnetic resonance (proton precession) magnetometer
1955	Introduction of wireline formation testing Introduction of compensated (dual detector) neutron log
1956	Introduction of five-coil induction Publication of Wyllie time-average equation Introduction of (single detector) density logs Establishment of American Petroleum Institute (API) calibration pits Publication of first nuclear magnetic resonance (NMR) logging paper
1957	Introduction of FORTRAN programming language Publication of first density logging paper
1958	Introduction of Laterolog-8 Introduction of cased-hole density logs for determining top of cement Sputnik launched Integrated circuits invented
1959	Introduction of six-coil induction logs Introduction of compensated (dual detector) density logs
1960	Introduction of chlorine logs

The first oil well was logged, using wireline techniques, in 1927, at Pechelbronn Field, Alsace-Lorraine, France (Fig. 13.9). The story, however, actually starts much earlier. R. W. Fox, a British scientist attempted to map spontaneous polarization (SP) anomalies generated by metallic sulfide deposits in Cornwall in 1830. Carl Barus, an American, utilized SP to study Nevada mines in 1880.

In 1900, Paul Schlumberger sold his interests in the family textile firm, Nicolas Schlumberger et Compagnie, to his brothers and emigrated from Alsace-Lorraine to Paris to be near his children. Two sons, Conrad and Marcel, became involved in minerals exploration and later started the first wireline company. Modern formation evaluation owes its heritage to these two men and the financial backing of their father.

13.7.1 The Schlumberger Brothers and Pros.

Conrad Schlumberger was a physics professor at l'École des Mines. He began experimenting with sur-

face electrical measurements to map geologic targets about 1911, commandeering his daughter's copper baby bathtub for his laboratory experiments [13.8]. Marcel Schumberger was a graduate mechanical engineer from l'École Centrale des Arts et Manufactures. He worked as a consulting mining engineer, based in Paris.

Conrad's first fieldwork involved surface equipotential mapping to locate buried inhomogeneities. Between 1912 and 1914, Conrad was able to successfully demonstrate his equipotential mapping techniques over several buried metallic ore bodies throughout Europe. Demonstrations, by Conrad and other geophysicists, utilized surface apparent resistivity profiling using centralized four-electrode current and potential arrays, also to identify buried subsurface features, such as shown in Fig. 13.10. These demonstrations had to be sandwiched in between his teaching and research at l'École des Mines.

In 1919, Paul Schlumberger pledged up to 500 000 Fr of his personal fortune to support his sons' *research study in view of determining the nature of*

the subsurface [13.8]. This, together with dowries from both of the brothers' wives, freed the Schlumberger brothers from the details of earning a living and allowed them to concentrate full time on commercializing Conrad's ideas of geoelectrical exploration techniques.

The Schlumberger brothers were ideally matched. Conrad was the dreamer and theoretician who developed conceptual techniques. Marcel was the practical engineer, who made these techniques work. In 1926, they felt confident enough in what they were doing to found l'Société de Prospection Électrique, Procèdes Schlumberger (Pros.).

Pros. offered surface electrical mapping services to the world. Electrical techniques were not utilized for petroleum exploration until 1923. Pros. would not attempt borehole measurements until the Pechelbronn well, in 1927. During this period (1919–1927) the Schlumberger brothers managed to exhaust most of their initial financial stake, without much return on their investment. They did, however, enjoy several technical, if not financial, successes.

13.7.2 The Pechelbronn Well

On 5 September 1927, Conrad Schlumberger's son-in-law Henry Doll, Roger Dost, and Charles Scheibli (all employees of Pros.) recorded the first well log, by dropping a surface electrical resistivity profiling electrode array down a well at Pechelbronn Field, Alsace-Lorraine, measured a resistivity profile of the formations intersected by the well [13.8]. This log (Fig. 13.11) was obtained with stationary readings, every 5 m. The purpose of the Pechelbronn well logging operation was to see if the Schlumberger brothers' surface resistivity profiling technique, dropped down a borehole, could be used to correlate subsurface geological formations between wells. While the resulting log (Fig. 13.11) does not look very impressive, compared to modern logging vendor products, it did demonstrate the concept that wireline measurements could be used for subsurface correlation.

The Schlumberger brothers were unlikely entrepreneurs. Pros. certainly had not been a money-making enterprise. While neither of them could have predicted it, at the time, that day at the Pechelbronn well allowed them to establish what would become one of the world's largest oilfield service companies. They only knew that someone was willing to pay them to run their resistivity profiling technique in a borehole. The Pechelbronn well logging operation allowed the Schlumberger brothers to rescue an intriguing, but struggling operation and turn it into a profitable one. Within three years, *Schlumberger electrical coring trucks* (Fig. 13.12) were logging wells throughout the world.

Fig. 13.9 First well logging operations: Pechelbronn Field, Alsace-Lorraine, France. Note multiple winches (from [13.10], courtesy of SPWLA)

In 1929, *E. G. Leonardon*, manager of Schlumberger Electrical Prospecting Methods, New York, convinced the Schlumberger brothers to publicize their well logging techniques via technical publications. The first wireline paper, *Electrical Coring: A Method of Determining Bottom-Hole Data*, presented in 1929 and published as A.I.M.E. Technical Publication 462, in 1932, established a tradition of stimulating technical disclosure via publication (if not complete) by Schlumberger, which has been followed by other wireline vendors [13.11].

Through the Great Depression, the logging arm of Pros., now named Schlumberger, grew steadily [13.10]. By WW-II Schlumberger could safely make the claim: *Where ever the oil bit goes, Schlumberger will follow.*

In 1931, the surface exploration arm of Pros. joined with another firm, l'Société Géophysique de Recherches Minières (specializing in electromagnetic and seismic refraction methods) to form *Compagnie Général de Géophysique (CGG)*. After World War II, CGG became a surface geophysical contractor, semi-independent of Schlumberger. Schlumberger Well Logging Services concentrated entirely on wireline measurements. There remained a rather loose connection between CGG and Schlumberger until Schlumberger

Fig. 13.10 Surface resistivity profile over a limestone fault block and a shear zone. The positions of current electrodes (C_i) and potential electrodes (P_i) are indicated (after [13.9])

acquired the geophysical contractors Western-GECO and PRAKLA-SEISMOS, while CGG acquired Davis Great Guns Wireline Services.

Conrad Schlumberger first observed spontaneous polarization (*polarisation spontanée*), over a buried pyrite ore body, in 1913. By 1931, SP (often called *porosity Log*) was being included with resistivity as part of the Schlumberger electrical logs (E-Logs) or electrical surveys (ES). The desire to obtain structural information stimulated the development of dipmeters. The desire to obtain rock samples (larger than cuttings) from wells, which had not been cored, led to sidewall core guns and, much later, rotary sidewall coring bits.

Through the end of World War II, wireline logging meant electrical logging and also meant Schlumberger. Logs were not often used quantitatively, but rather for correlation. After the war, other techniques and other vendors began to appear. Wireline measurements also began to be used in more quantitative ways. Early logging units (Fig. 13.12) looked much different from current models.

13.7.3 Archie's Equations

In 1942 and 1950, *G.E. Archie*, of Shell Oil Co., described the formation factor/porosity and resistivity index/water saturation relationships we now know as

Archie's equations [13.12, 13]

$$F = \frac{R_o}{R_w} = a\varphi^{-m} \quad (13.4)$$

$$F = \frac{R_t}{R_o} = S_w^{-n}, \quad (13.5)$$

where:

- F is the (dimensionless) formation factor.
- R_o is the electrical resistivity of a brine-saturated rock.
- R_w is the electrical resistivity of the brine saturating the rock.
- φ is the (decimal) porosity of the rock.
- a and m are coefficients determined by the data.
- I is the (dimensionless) resistivity index.
- S_w is the (decimal) water saturation of the rock.
- n is a coefficient determined by the data.

The empirical coefficient m is sometimes called the cementation exponent. The empirical coefficient a is sometimes called the tortuosity coefficient. The empirical coefficient n is sometimes called the saturation exponent.

Archie's equations ((13.4) and (13.5)) offered the opportunity to obtain quantitative reservoir information from wireline measurements. To do this, however, required wireline porosity tools. The failure of these (Archie) relationships, under certain circumstances, re-

quired the development of more complex petrophysical models.

The need for saturation tools for use in wells drilled with air and/or oil-based mud, led to the development of induction logs. Interest in uranium exploration stimulated the use of natural gamma radiation logging tools. The recently declassified nuclear technology (and

unemployed nuclear engineers, following the end of World War II) led to the development of density and neutron logs. The need for deep penetration, high-resolution resistivity information led to the development of guarded, or focused, laterologs. The need for detailed seismic velocity information led to the development of acoustic, or sonic, logs.

Fig. 13.11 First well log: Pechelbronn Field, Alsace-Lorraine, France (courtesy of SPWLA)

Fig. 13.12 Early Schlumberger logging unit in the California Desert (from [13.10], courtesy of SPWLA)

13.7.4 Continuous Velocity Logs and Jesse Wyllie's Relationship

Interest in better seismic velocity information led to the development of acoustic logs. The California Research Company (now part of Chevron Energy Technology Company, or ETC), Magnolia Petroleum (now part of EXXON-Mobil Exploration & Production Research, or EPR), and Shell Development (now part of Shell Upstream Technology) all developed operational acoustic tools in a dead heat. In 1956, *M.R.J. Wyllie* and associates, at Gulf Research and Development Company (now part of Chevron ETC), developed what we know as Wyllie's time-average equation [13.14]

$$\varphi_s = \frac{\Delta t - \Delta t_{ma}}{\Delta t_f - \Delta t_{ma}} \frac{1}{c}, \quad (13.6)$$

where:

- φ_s is the (Wyllie) sonic porosity.
- Δt is the observed rock interval acoustic transit time ($\mu\text{s}/\text{ft}$).
- Δt_{ma} is the rock matrix interval acoustic transit time ($\mu\text{s}/\text{ft}$).
- Δt_f is the fluid interval acoustic transit time ($\mu\text{s}/\text{ft}$).
- c is a coefficient, determined by the data.

The empirical coefficient c is sometimes called a compaction correction.

Most new logging techniques based upon applications of different branches of physics had occurred by the late 1960s. The development since then has been primarily in the areas of increased measurement accuracy, equipment reliability, data transmission and data processing techniques. In many ways, these last technological advances have been even more impressive than the initial technique developments.

13.7.5 Improvements in Recording the Results

The first logs were acquired as station measurements, like the Pechelbronn well. The logging array (or *sonde*) was suspended at the measurement depth, while instruments were adjusted and measurements recorded. Lore and legend has it that the first continuous logs were

obtained by using small boys who adjusted the instrumentation and called out the readings, as the sonde was slowly retrieved from the bottom of the well. A circa 1930s promotional movie, however, now called the *Schlumberger Melodrama* shows Schlumberger Engineers frantically balancing potentiometers, gang-linked to chart drive (linked to the logging cable winch) pen recorders as a well is logged (Fig. 13.12). The development of unbalanced bridge circuitry and pen chart recorders allowed faster continuous logging operations. The use of photographic film and light lever cameras with depth markers allowed the development of reproducible hard copy logs.

Manually adjusted bridges and other instrumentation were replaced by hand-wired (breadboard) analog computers. These, in turn, were replaced by specialized analog computer modules, called function formers, and standardized mounting racks, called NIM (for nuclear instrument module) BINS.

Initially, well logs were recorded only in hard copy mode (pen recorder charts and photographic film). At one point, the largest customer of Kodak continuous 8 in film was claimed to be Schlumberger. Film log prints made duplication easy, but if different instrument settings were desired the well had to be relogged.

Dresser Industries attempted, in the 1960s, to utilize multichannel FM magnetic tapes, similar to those used for recording seismic data. This soft copy data recording allowed playback with different function former settings, eliminating the need to relog the well. While technically successful, the system was so difficult and cumbersome to operate that it was never accepted by the petroleum industry and was eventually abandoned.

Schlumberger attempted to use paper Teletype tape. This recording system, however, proved to be not only overwhelmingly noisy, but the paper tape was often damaged by the elements under which wells were logged [13.6].

By the 1970s, fast and reliable multichannel analog to digital (A/D) systems and nine-track tapes were being used to record data in the field. Wireline vendors and several large petroleum companies began to utilize these field recordings as input to complex mainframe computer petrophysical analysis systems.

Gearhart Industries introduced the first use of a general-purpose minicomputer in a field logging system in the mid 1970s [13.15]. The use of an on-board minicomputer allowed not only digital recording of the data, but also some processing and analysis in the field. Other major wireline vendors quickly followed suit. Rumor has it that the Digital Electronics Co. (DEC) salesman that closed the deal for Schlumberger to install two DEC PDP-11 minicomputers in each logging unit was immediately promoted to Vice President, Marketing.

The final piece of the digital revolution involved replacing downhole analog electronics in the logging sonde, with miniaturized A/D and microprocessor chips. This advance was stimulated by two developments:

- Miniaturization was stimulated by the space program.
- Sandia National Laboratory sponsored a high-temperature/high-pressure logging tool component development program in the early 1980s, which completed the transition [13.16].

Downhole A/D sampling, storage and transmission meant more stable logging sondes and greater data transmission (i. e., broadband) speed and volumes to the surface. This allowed the development of more complex sondes, such as microresistivity borehole scanning tools, array acoustic, induction, and laterolog sondes, as well as shorter multitool stacks. Table 13.9 summarizes common wireline service mnemonics, by vendor.

A recent major technological development has been the introduction of specialized drill collars, with instrumentation packages, recording, and/or telemetry, which allow formation evaluation measurements during the drilling operation. Since the introduction of the first MWD (measurements while drilling) sub-assemblies in 1979, many wireline measurement capabilities have been duplicated by MWD (now called

logging while drilling or LWD). Table 13.10 summarizes the several MWD/LWD vendors and their services.

13.7.6 Development of Formation Evaluation

Formation evaluation, or well log analysis, sophistication has kept pace with wireline and MWD hardware developments. Before calculators were readily available, log analysts utilized slide rules, such as shown in Fig. 13.13, *chart book* nomographs [13.17] and precalculated tables, such as Table 13.11. Worksheets were utilized to organize the process. Programmable calculators simplified this process and made more complex petrophysical models practical. Microcomputer spreadsheet calculations increased the speed and accuracy of

the process, once the log values were entered into the spreadsheet. Specialized formation evaluation software for mainframe and minicomputers (Fig. 13.14) made detailed well log analysis possible. Microcomputer FE software (Fig. 13.15) made it portable.

Wireline vendors can now telemeter data, via satellite, from the wellsite to processing centers or to client offices worldwide. This capability allows detailed digital well log analysis within hours of running the logs. Wireline vendors can also utilize on-board microcomputers to do complete log analysis, *in the cab* and will also download well log data, at the wellsite, to floppy disks or USB flash drives. This allows petrophysicists to conduct detailed digital well log analysis on laptop microcomputers at the wellsite utilizing the software similar to that available in vendor and client offices.

13.8 The Schlumberger Legacy

Many people and organizations have been responsible for the formation evaluation developments highlighted in the preceding section. The overwhelming contributors to these developments, however, have been the Schlumberger brothers and the organization they founded.

With their 1929 A.I.M.E. presentation, the Schlumberger brothers established an industry standard of using technical publications as a means of publicizing their capabilities. Much of the most valuable FE literature is from technical papers published by Schlumberger and their competitors.

Schlumberger developed an outstanding internal training program. The father of Russian and Soviet well logging, V.N. Dakhnov, was trained by Schlumberger in the 1930s. Many logging engineers currently working for competitors were originally trained by Schlumberger. Petroleum companies have eagerly hired Schlumberger-trained logging engineers as formation evaluation specialists.

Schlumberger has established the industry standard for client training. The rationale for this was that an informed client was more apt to purchase logging services than an uninformed one. Most petroleum explorationists and engineers have attended at least one Schlumberger-sponsored school.

Schlumberger's client publications provide excellent formation evaluation references. Most petroleum explorationists and engineers have at least one Schlumberger manual or chart book. Keeping up with modern technology, most of these documents are now available on CD, or as downloadable PDF files from Schlumberger and other vendor websites cited after the reference list.

Schlumberger has established industry standards for tool calibration, quality control, data recording, and

product presentation. The Schlumberger employees' technical pride is hard to match anywhere. Essentially all other wireline vendors have attempted to succeed by *looking like Schlumberger*.

In spite of this legacy, Schlumberger is not always the vendor of choice. Many of the petrophysical milestones, listed in Tables 13.2–13.8, were not introduced by Schlumberger. Whenever a competitor has introduced a new service, which appeared to be economically viable, however, Schlumberger has always been quick to introduce their own version of the service. Often, the new Schlumberger service has included significant technical improvements over the initial service offered by a competitor.

However, all vendors, shown in Tables 13.9 and 13.10, as well as several others, can deliver excellent products. The final criterion for wireline vendor selection is equipment availability, service, and competitive pricing.

All long-term logging service contracts should be written with performance clauses, which can, with cause, be exercised. No logging crew wants to be replaced by a competitor's unit, *in relief*.

13.9 Laboratory Measurements

All of the physical and chemical wireline and/or MWD/LWD measurements have their origin in laboratory measurements. In fact, most log measurements were originally calibrated by laboratory measurements on reservoir fluid samples and rock cores acquired from the wells, in which the logs were run. While modern log measurements and interpretation techniques are much more sophisticated than their ancestral versions, laboratory measurements still play a very important role in defining the petrophysical model parameters used in FE to convert what is measured via well logs into what is desired to evaluate petroleum reservoirs.

13.9.1 Fluid Measurements

In the simplest terms, petroleum reservoir rocks consist of fluid-filled pores, or *porosity* (ϕ) and solid rock, or *matrix* ($1 - \phi$). The pores, in turn, can be filled with air, hydrocarbon gases, other gases, liquid hydrocarbons, and/or water (*brine*) of various salinities and compositions. In typical FE fashion, we will start with the noneconomic (i. e., nonhydrocarbon) fluids, and then progress to what is desired (hydrocarbons).

Air and other gases, like (gaseous and liquid) hydrocarbons, are electrical insulators. As a result, oil-

and gas-filled porosity will have very high electrical resistivities. Like gaseous hydrocarbons, air and nonhydrocarbon gases will have very low density (i. e., close to zero gm/cc), resulting in very high apparent density porosities and low hydrogen indexes (density of hydrogen ion concentration), resulting in very low apparent neutron log porosities, and slow acoustic velocity, resulting in high apparent sonic porosities. Also, all gases absorb acoustic energy, resulting in sonic log *cycle skipping*. Unlike gaseous hydrocarbons and most other gases, however, air-filled porosity does not occur below the local water table. As a result, except for those areas with very shallow petroleum reservoirs, such as the US Appalachian Mountains and Mid continent, and/or with deep water tables, such as the California San Joaquin Valley, air-filled porosity is not a major concern for FE. Other nonhydrocarbon gases, such as nitrogen and CO₂, however can be a concern.

The chemical and physical properties of oil and gas field brines (waters) are critical to FE. This is because both oil and gas almost always coexist with brines in hydrocarbon reservoirs. Most quantitative volumetric hydrocarbon measures utilize the electrical resistivity contrast between the insulator hydrocarbons and con-

Part B | 13.9

Fig. 13.16 Arps empirical nomograph and equations. The nomograph allows a hands-on solution of the equations, as indicated by the *dotted line* (courtesy of Baker-Atlas)

ducting brines. As a result, laboratory measurements on reservoir brines are very common in FE.

J.J. Arps, of the British-American Oil Producing Co. (now Gulf Oil, Canada) conducted a series of experiments on the effects of salinity and temperature on the electrical resistivity of sodium chloride solutions [13.18]. Figure 13.16 shows empirical relationships and a nomograph for solving them, based on the Arps studies.

The Arps relationships of Fig. 13.16 are extremely useful for FE. Given the water resistivity R_w at one temperature T_1 it is very easy to estimate:

1. The apparent NaCl concentration
2. The water resistivity at any other temperature, T_2 .

The *fly in the ointment* of using the Arps relationships is that Na^+ and Cl^- are not the only ions in petroleum reservoir brines. Other cations and anions can and do behave differently from Na^+ and Cl^- . Several investigators [13.19–24] have investigated the electrical behavior of non-NaCl petroleum reservoir brines. Figure 13.17 is an empirical nomograph for multipliers to estimate *NaCl equivalent concentrations* of petroleum reservoir brines containing more than just Na^+ and Cl^- ions.

The concentration relationships, shown in Fig. 13.17, are very useful for two purposes:

1. They show which ions act much differently than Na^+ and Cl^- and how these effects change with total brine salinity.
2. They allow estimation of *equivalent NaCl salinity* from a chemical analysis of an unknown brine, by using the weighting factors from Fig. 13.17.

Fig. 13.17 Empirical equivalent NaCl salinity multipliers, for common petroleum reservoir anions and cations [13.25]

Fortunately, the relationships of Fig. 13.17 are not often needed. Most petroleum reservoir brines can usually be considered to be NaCl brines, without introducing significant error. Also, most modern brine chemical analyses usually include R_w measurements, which render the use of the Fig. 13.17 corrections unnecessary.

The density of water at standard temperature and pressure (STP) ranges from 1.00 gm/cc for distilled water to 1.146 gm/cc, for 200 000 ppm NaCl [13.21]. A good approximation for NaCl brine density ρ_w is a linear interpolation, i. e.,

$$\rho_w = 1 + 0.73 \frac{C}{1\,000\,000}, \quad (13.7)$$

where C is (NaCl) concentration, in ppm.

The most common hydrocarbon laboratory measurements are *pressure, volume, temperature* (PVT) measurements and are used to relate hydrocarbon volumes in place to their volumes at surface conditions. PVT measurements are the source of the formation volume factors, B_{oi} and B_{gi} , of (13.1) and (13.2).

The reported density of gaseous hydrocarbons is 0.4 g/cc, or less [13.26]. Oils and condensate densities range from 0.6–1.00 gm/cc [13.26]. Guerard [13.27] reports California heavy crude densities from 0.938 gm/cc (Wilmington Field, 19.4° API) to 0.982 gm/cc (Kern River Field, 12.6° API).

13.9.2 Rock (Core) Measurements

The original laboratory petrophysical measurements were conducted on cores, cut during drilling operations, and used to estimate reservoir properties. The cost of properly acquisition, preservation, transport, storage, and laboratory measurements on cores, compared to the relatively rapid (near real-time) wireline and MWD/LWD measurements have made core measurements less common. However, almost all major petroleum reservoir formation analyses include at least some core measurements.

Core acquisition can be accomplished via:

1. Percussion side wall cores (SWC)
2. Rotary sidewall coring devices
3. Rotary whole cores.

SWC are the simplest to obtain because they can be obtained, after the well has been drilled, using wireline SWC guns. Core material from SWC, however, is most appropriate for visual examination chemical analysis and grain density determinations only. The percussion coring operation shatters and/or compresses the rock fabric, making the resulting cores unsuitable for any physical measurements involving electrical or fluid flow and porosity.

Core material obtained via the other two methods can be used for all rock physical and/or chemical measurements.

Routine Core Analysis Measurements

Essentially all whole core (plugs) and rotary cores cut are subject to routine core analysis or permeability, porosity, and saturation (KPS) measurements:

1. Dean-Stark core (solvent) cleaning, and summation of recovered fluids, for estimation of porosity and *residual* (oil and water) saturations
2. *Ambient condition* helium Boyle's Law, or Archimedes, *effective* porosity ϕ_e measurement
3. *Ambient condition horizontal* (i. e., parallel to bedding) air permeability K_{ha} measurement.

The following are often also done at the same time as KPS measurements:

1. Whole core natural gamma ray, γ -ray, profile scan measurement
2. Whole core slabbing and *normal and ultraviolet light* core photography
3. Core *stratigraphic, mineralogical, and structural* description
4. Grain density ρ_g measurement
5. *Restored net effective overburden* air permeability and helium porosity measurements.

Because these additional services are at additional cost, they are not always done.

Whole core γ -ray scans allow proof positive depth matching between the core and wireline measurements. Core depths can, and often are, as much as 1–2 drill pipe joints different from the wireline measurement depth. Matching the whole core γ -ray scan and wireline γ -ray curves allow exact depth matching of the core and wireline measurements.

Whole core slabbing, photography and descriptions provide much more detailed information than available from either core measurement plugs or wireline measurements. The core photographs will last much longer than even preserved core. If the whole cores are to be slabbed and photographed, best practice is to do so *after* the core measurement plugs have been taken, as this provides a permanent record of the measurement plug locations.

Grain density measurements are the least expensive additional plug or rotary core measurements, as they usually constitute only an additional computation from the measurements made to calculate routine porosities.

Restored net effective overburden (NEO) ϕ and K_a values can be compared to wireline measurement estimates, which are taken at depth. Figure 13.18 shows a NEO transform for a Western Australia field.

Cross plots of core porosities have often been used to calibrate wireline porosity tools. Modern wireline porosity tools, however, are calibrated well enough that they can often be utilized to identify problems in laboratory core measurements, as shown in Fig. 13.19.

Special Core Analysis Laboratory (SCAL) Measurements

Special core analysis laboratory (SCAL) measurements are much more complex and time consuming and

Fig. 13.18 Cross plot of surface versus restored net effective overburden (NEO) porosities and NEO model transform, from Western Australia field

Fig. 13.19 Cross plot of core versus wireline log porosities, from Congo Basin field, illustrating the effects of small, interconnected vugs on core porosity

Fig. 13.20 Archie formation factor (1833 sample database) model for clean recent sandstones [13.28]

consequently much more expensive than routine core analysis measurements. As a result, while routine core analysis measurements may be taken every foot, or closer, SCAL measurements are usually conducted on a few locations within a cored interval, with these locations based on the routine measurements.

SCAL measurements include:

1. Single-phase liquid permeability k_l measurements
2. Dual-phase relative permeability k_r measurements
3. Capillary pressure P_c measurements
4. Formation factor F (see (13.4), Archie's first equation) measurements
5. Resistivity index I (see (13.5), Archie's second equation) measurements.

The most significant SCAL measurements for FE are the two responsible for the Archie equations ((13.4) and (13.5)).

In 1940, Gus Archie, a Petrophysicist with Shell Oil published a paper [13.12] based on his studies of the resistivities of water saturated rocks, their measured porosities, and the resistivity of the saturating brines (13.4), which is known as *Archie's first equation*.

Archie's initial values for the (13.1) constants a and m were 1.00 and 2.00 respectively [13.12]. As more and more formation factor measurements were made, it became clear that the a and m coefficients would vary from reservoir to reservoir. Figure 13.20 shows

Fig. 13.21 Archie resistivity index for Congo Basin field reservoir

Fig. 13.22 Capillary pressure at atmospheric pressure (P_a) the indices indicate wetting (P_w) and nonwetting (P_{nw}) conditions (after [13.29])

a statistical analysis of 1833 sets of formation factor measurements collected from most of the major multinational and national oil companies, as well as research laboratories, of the time. This analysis returned values of $a = 1.13$ and $m = 1.73$, which are probably good default values for clean (i. e., low shale) recent (unconsolidated) sandstone reservoirs.

Archie also published a second paper [13.13] summarizing his studies of the resistivities of reservoir rocks with partial water saturations, which formed the basis of *Archie's second equation* (13.5).

Archie's initial value for the n coefficient was $n = 2.00$ [13.13]. As was the case for the Archie formation factor model, the n resistivity index coefficient is reservoir specific. Figure 13.21 shows the resistivity index for a Congo Basin reservoir. The reservoir, shown in Fig. 13.21 has at least two distinct reservoir n values: one (1.73) less than 2.00 and a second greater than 2.00. FE, in cases such as these, requires that the reser-

voir interval be first divided into those depth samples that satisfy each resistivity index model, prior to estimating water saturation S_w .

The third SCAL measurement most significant for formation evaluation is *capillary pressure* P_c the differential invasion of the wetting and nonwetting fluids into a pore throat or capillary (Fig. 13.22). Resistivity index measurements are conducted making repeat resistivity measurements on a core initially completely saturated ($S_w = 1.00$) with water, as the water is decreased by introduction of a nonwetting fluid. Since this is the same technique used to measure *capillary pressure*, the two measurements are often combined.

Capillary pressure data is often converted to the following normalized dimensionless quantity

$$J_{sw} = \frac{P_c}{\sigma \cos \theta} \sqrt{\frac{k}{\varphi}}, \quad (13.8)$$

where:

- J_{sw} is called the *Leverett J-function* [13.30]

Fig. 13.23 Leverett J-functions for Danish North Sea field reservoirs

- P_c is (measured) capillary pressure
- σ is interfacial tension between the two fluids
- θ is the contact angle of the wetting phase
- k is the permeability of the sample
- φ is the porosity of the sample.

As was the case for the Archie equation a , m , and n coefficients and Leverett J-function models are reservoir specific (Fig. 13.23).

Once a Leverett-J function has been developed for a given reservoir, it can be used to independently verify wireline and MWD/LWD saturation results, as it is based entirely upon core measurements and height above a fluid contact. The Leverett J-function, shown in Fig. 13.24 was developed from capillary pressure measurements on core from a high-porosity, high-permeability Niger Delta field reservoir. Reservoir engineers responsible for developing this field did not believe the very low ($\approx 5\%$) wireline irreducible water saturation S_{wir} estimates obtained for this reservoir. The Leverett J-function for the reservoir (Fig. 13.24) confirmed the low wireline S_{wir} estimates.

Leverett J-function saturations can also be used to independently verify wireline and/or MWD/LWD S_w estimates through a transition zone between reservoir fluid phases. The P_c above a fluid contact is given by

$$P_c = \Delta\rho gh, \quad (13.9)$$

where:

- $\Delta\rho$ is fluid density difference
- g is gravitational acceleration
- h is height above the fluid contact.

Fig. 13.24 Niger Delta field Leverett J-function illustrating very low S_{wir}

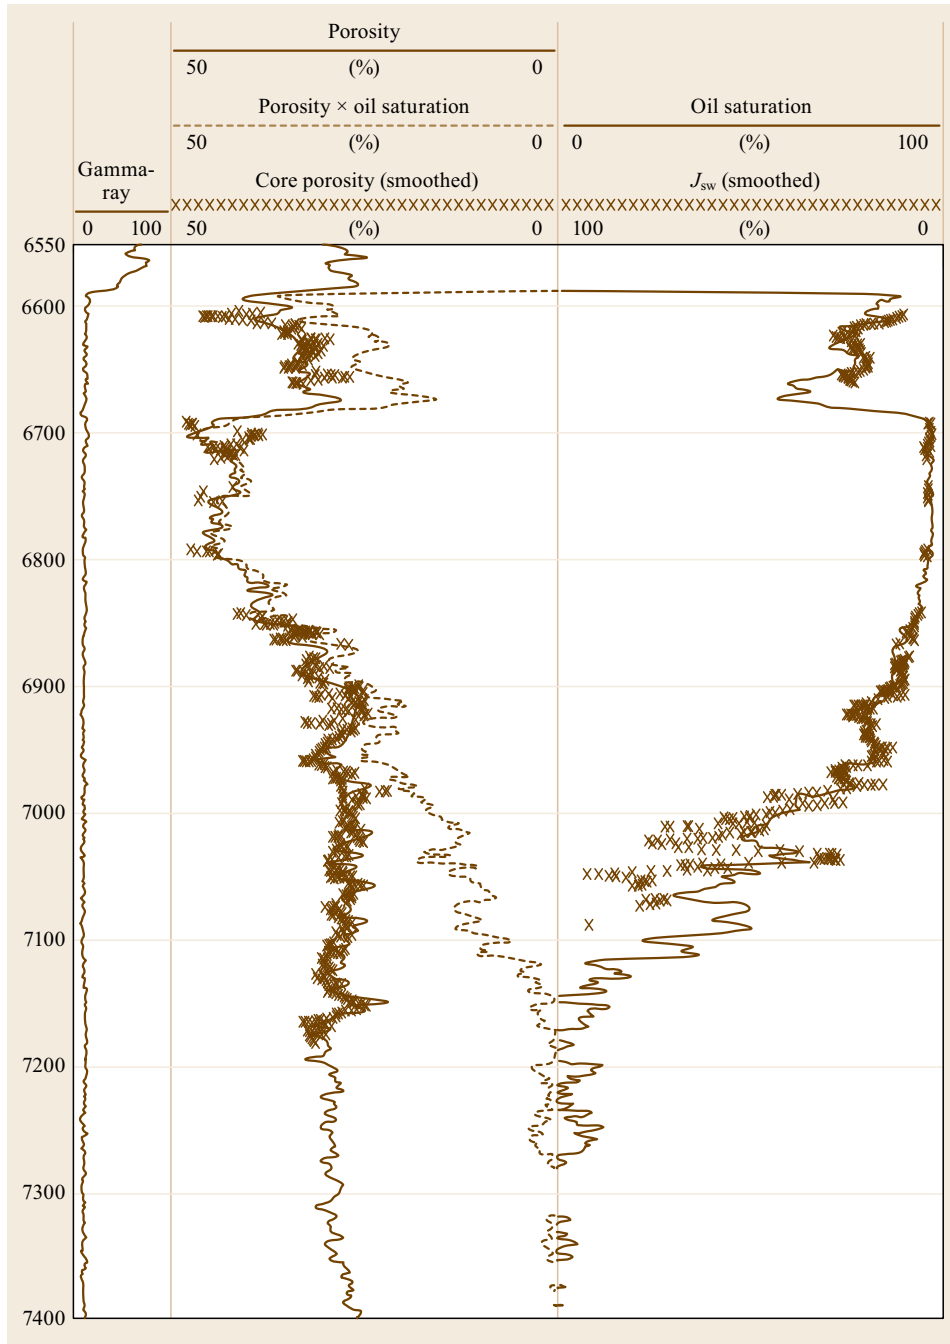

Fig. 13.25 Comparison of Leverett J-function J_{sw} (smoothed) and wireline s_w estimates for a Danish North Sea field well

Figure 13.25 shows a comparison between wireline and Leverett J-function saturation estimates for a Danish North Sea chalk reservoir. Considering that the J-function S_w are based on one-inch core plug measurements, at one foot sampling, while the wireline S_w are based upon 2–3ft average measurements sampled at 0.5 ft intervals, there is very close agreement.

Finally, Leverett J-functions, wireline porosity data, and O/W contact information can also be used in lieu of wireline saturation data, as was recently done for a major review of a world-class heavy oil resource in a third world country [13.31]. In this case, the reason for this approach was unreliable saturation log data.

13.10 Well Logging Environment

13.10.1 Wellsite

Most wireline and MWD/LWD quantitative measurements attempt to duplicate the results of similar laboratory measurements. In the laboratory, the sample measurement environment can be strictly controlled. All of this control changes when the measurements are taken from the laboratory to the wellsite.

The laboratory measurement sample (usually a 1 in \times 1 in core plug), is replaced by the earth and the laboratory sample holder is now the well. The measurement conditions, which can be strictly controlled in the laboratory, are now at whim of the downhole temperature, pressure and brine chemistry. The climate controlled laboratory recording instrument environment is replaced by the weather (dust, rain, mud, wind, snow, etc.) at the surface. In addition, getting the logging equipment to the wellsite can be an adventure in itself.

Figure 13.7 is a schematic of a modern wireline logging operation. The logging tool, or *sonde*, is suspended in the well by a multiconductor double steel armored cable, which passes over sheaves hung from the traveling blocks in the drill rig tower, and under a sheave anchored to the rig floor to the logging (truck or skid) unit. The wireline power and recording equipment are located at the surface. The multichannel double wrapped armored cable provides the means of delivering power to the sonde, serves as the strength member to retrieve the sonde, and the data transmission link from the sonde measurement, A/D sampling, preprocessing system and encoding systems are now on the sonde.

MWD/LWD systems *look* much like the schematic shown in Fig. 13.1, with the following exceptions:

1. The logging instrument package is part of a specialized bit subassembly (Item No. 2 of Fig. 13.1), which also includes a mud turbine that provides power to the measurement instrumentation, A/D sampling, preprocessing system and encoding systems.
2. The drill pipe and drill collars provide not only the weight on the bit, but also the strength to raise and lower the MWD/LWD instrument package.
3. Communication between the MWD/LWD instrument package and the surface is provided by a mud-pulse system in the bit subassembly (EM and drill pipe transmission systems are under development at time of writing, but are not yet fully commercial).
4. Sparse sampled log information is transmitted to the surface, during the drilling operation, via the mud-pulse system. Detailed logging data is recorded on

random access memory (RAM) storage in the logging instrument package and downloaded at the surface during bit change trips.

MWD/LWD data is acquired during the drilling operation. As a result the *sparse sampled* MWD/LWD data can be true *real-time* data preceding even mud log data to the surface, as the latter must wait for the mud to be circulated from the bit to the surface. Invasion and mud-borehole wall reactions should be at a minimum for all MWD/LWD data, as the sensors lag the bit by only a few feet. By contrast wireline data is acquired after the well has reached either total depth (TD), or a casing point, and the well has been circulated (*conditioned*) for the logging operation, which usually takes several hours. Consequently, wireline measurements are acquired a few hours to days after the bit has passed the measurement depths, allowing considerable invasion and mud-borehole reactions to occur. *Detailed* MW/LWD data does not usually reach the surface until the bit is retrieved, but the data acquisition occurs at the same time as the *sparse sampled* data.

Wireline data is normally acquired as the sonde is retrieved from the bottom of the well, so that the cable will be under tension. Exceptions to this protocol are temperature and pressure logs, which should be acquired with minimal disturbance to the mud column and to avoid hysteresis in the measurement sensors. MWD/LWD measurements can be acquired either during drilling or as the bit is retrieved from the borehole. The former protocol is preferred for the reasons given above.

Both wireline and MWD/LWD systems are subject to extreme temperature, pressure, chemical, and vibration conditions during data acquisition. At the surface the wireline and/or *sparse sampled* MWD/LWD data is retrieved via slip rings in the cable reel (wireline) or mud-pulse decoder (MWD/LWD). The *detailed* MWD/LWD data is retrieved from the bit subassembly RAM after they have been retrieved at the surface. The slip-ring or mud-pulse decoder systems may be noisy and/or fail. The RAM system can also fail due to the extreme operational conditions encountered in drilling super deep wells.

The logging crew is operating in a rather hostile environment. They may also be operating on little rest. The logging unit is office, workshop, mess hall, and sometimes even bunkhouse for the engineer and crew. The drillsite is usually remote from any support facilities. The drilling crew is openly suspicious that the logging vendor may *damage their hole*. Downtime while waiting for replacement equipment is simply not

tolerated by the client. That excellent physical measurements can, and usually are, obtained is a testimony to the ingenuity and dedication of the wireline and MWD/LWD tool designers, logging vendor crews, and operations base support shops.

13.10.2 Logging Operations

Table 13.13 summarizes the steps that *should* occur for all wireline and/or MWD/LWD logging operations. All logging tools, both wireline and MWD/LWD, must be calibrated according to vendor *shop calibration* standards at the vendor operations base prior to being delivered to the wellsite. *Shop calibrations* are a normal part of the logging vendor services and must not be negotiated away in return for reduced charges. There is an oft-quoted saying in the industry, attributed to an old time logging engineer: *If it wiggles, I can sell it.*

Poorly calibrated or uncalibrated logs are little more than *wiggly lines* and *are of no value* for quantitative, or even qualitative measurements.

Shop calibrations should be repeated at least monthly. With modern digital downhole circuitry, many logging vendors claim that that *shop calibrations* are good for 90 days. There is a significant problem with this reasoning. Even modern logging tools *do* fail and/or drift out of specifications.

If a logging tool fails to meet shop calibration standards, without significant adjustment, all logs run since the tool's last successful shop calibration are called into question.

For this reason, a good practice is to require successful shop calibration of all tools delivered to a wellsite *immediately* prior to leaving the vendor's operations base. Since logging vendors are continually running shop calibrations, *there should be no surcharge* for this service. Remote offshore and/or helicopter-accessed land drillsites do pose special problems. However, some operators address this situation by requiring the logging vendor to provide shop calibration facilities at these remote drillsites. This service may incur additional cost. However, it should be minor in light of the

Table 13.13 Typical wireline and MWD/LWD logging operations

overall cost of a well costing several US\$ millions to drill.

Failure of a logging vendor to meet the above conditions should be cause for calling out another vendor, in relief, or cancellation of an extended logging contract. This only needs to happen once to get the attention of the logging vendor's upper management.

Delivery of logging tools with proper *shop calibrations* to the drillsite is only the first step in log quality assurance. The logging vendor must demonstrate that the tools can pass standard *prelog calibration checks*, referenced back to the most recent *shop calibration*, prior to putting them into the well. If the logging tools fail the *prelog calibration check*, they should be replaced by *backup tools*, which can pass the *prelog calibration check*. For this reason the logging vendor should *always* have sufficient *backup tools* at the drillsite to meet this contingency, without significant loss of rig time.

The logging witness must verify that the equipment used for the logging job is the same equipment used for the most recent shop calibration. Otherwise, the resulting logs are uncalibrated.

At the completion of the logging operation the logging vendor *must* perform *postlog calibration checks* to provide proof that the tool did not fail or undergo calibration drift during the logging job. While rare, this type of tool failure can happen. It took considerable persuasion to get the logging engineer to perform the *postlog calibration check* shown in Fig. 13.26. His shock was matched only by his chagrin when he learned that his supposedly stable tool had drifted 61 API units during a 2500 ft logging job.

13.10.3 Well Logs

Log Header

Figure 13.27 shows a typical well log header, which summarizes considerable information about the well and logging job. The logging vendor's logo and the log type (1) are always displayed across the top of the first page of the header. Below this, are: information about the well (2), consisting of operator name, well name, field name, country, state/province, location, and elevation. Information about the logging job, consisting of bit and casing size (3), logged interval (4), mud information (5), well bottom hole temperature and temperature buildup information (6), and who logged and

Fig. 13.28 Well log scales [13.26]

witnessed the logging job (7) are displayed on the lower half of the first page, and sometimes on the second page. Equipment data (8) and engineer's comments about the logging job (9) are located on succeeding pages of the header. Tool calibration records are also displayed below the header on detailed (1 : 200 or 5 in = 100 ft depth scale) log print headers and below the log. All detailed log prints should also contain a 200–300 ft *repeat section*, which documents the fact that the measurements can be repeated. This display standard was established by the American Petroleum Institute (API) over seventy years ago and survives to this day.

The *logging witness* is an extremely important part of the log documentation. Whoever signed the logging vendor's work order certifies that:

- The vendor's equipment was working properly.
- All logging sondes were properly calibrated.
- The shop calibrations were for the tools actually used for the job.
- The logging job was performed to the client's specifications.

From the client's standpoint, the *logging witness* is the most important person in the logging operation.

Logging witness *should not be an assignment for the most junior member of the office, or anyone else with little knowledge of proper logging protocol and calibration standards.*

Measurement Tracks

The API well log standard log display consists of three measurement tracks with a *depth track* between tracks one and two, as shown in Fig. 13.28. Linear scaled tracks usually have ten divisions per track and logarithmic scaled tracks usually have two or four logarithmic cycles per track (note that each cycle starts at deciles of two). Tracks 2 and 3 are often combined to give an expanded presentation (sometimes called *track 4*). This standard is followed even for complex tool stacks consisting of several measurements, resulting in multiple displays for all measurements taken at the same time. Wellsite and off-well computer analysis displays may have more log tracks than the API standard and the depth track may be moved to the left of track 1 or included on one of the display tracks.

Tool Stacks, Trips, Runs, and Suites

Wireline logs are run at well TD and at other intermediate depths where casing is set to protect the well bore. Detailed MWD/LWD are commonly organized along the same depth intervals. Depending upon the sophistication of the wireline vendor, not all log measurements may be made at the same time. Not all log measurements are conducted at each logging depth. All of these situations have resulted in some confusing nomenclature. Most large companies should have their own internal notations. The following nomenclature,

Fig. 13.29 Borehole model (courtesy of Baker-Atlas)

developed by Chevron, can serve as a good example:

- Tool stack: A combination of sondes capable of multiple types of measurements (e.g., density, neutron, gamma ray, and caliper all on a single combination tool stack)
- Trip: A single (tool stack) set of measurements (e.g., induction/sonic, on one trip, density/neutron on a second trip, borehole imager on a third trip)
- Run: Number of logging depths at which a single tool stack is run
- Suite: All logs run at a given depth.

Calibration Records and Logging Program Data

Detail (5 in = 100 ft, or 1 : 200 depth scale) log displays will have calibration records. Modern computer-driven log displays and Library ASCII Standard (LAS) files will also have several pages of information about the computer program input parameters and changes during the logging job and subsequent analysis. Three types of calibrations are documented on the detailed log displays:

1. Master, or shop calibrations
2. Prelog calibration checks
3. Postlog calibration checks.

It is critical that all three of these calibration records be attached to the detail log images and that the equipment serial numbers be the same. Calibration is the *only* time that anyone knows, for certain, that the tools are actually working properly.

13.10.4 Borehole Model

Figure 13.29 shows a generalized borehole model used for interpretation of wells drilled normal (*straight* or *vertical holes*) to formation bedding (satisfactory similar models for highly deviated and *horizontal wells* have yet to be developed) annotated with common FE notation.

Borehole Diameter

Bit and casing programs used for any given well will vary considerably. The actual bit and casing program used will depend drilling target depths, formation pressures, prior knowledge of the area, drilling costs, rate of penetration, borehole conditions, safety, and operational or casing and cement efficiency.

Each casing string represents a considerable investment. Because of this, well programs have bit and casing programs minimizing intermediate casing strings, consistent with safety and drilling target depth.

Bit and casing programs are extremely important to FE. The largest wireline sondes have 5.25 in diam-

eters and should not be run in boreholes drilled with ≤ 6.25 in bits, unless the rock is extremely competent.

Quantitative FE requires physical and chemical property measurements of the borehole rock. Logging tool measurements respond not only to the rock properties but also to the properties of the drilling fluid (*mud*) in the borehole, and *mudcake* lining the inside of the borehole, or casing and cement encasing the casing, for cased holes. The effects of the mud and mudcake or casing and cement between the sonde and borehole wall must be removed before quantitative FE parameters can be estimated.

Most wireline tools are calibrated for 8.5 in diameter boreholes, filled with freshwater (≈ 8.5 lb/gal) mud. MWD/LWD tools are calibrated for borehole sizes consistent with the bit size used with the individual MWD/LWD tools. If either type of tool is used in boreholes with conditions other than the design conditions, the measured results must be *corrected* to the design conditions. These corrections are called *environmental* or *borehole corrections*. Even borehole corrected log data is not very reliable for boreholes much larger than 6–12 in greater than the tool diameter.

Borehole Fluids

The primary purposes of drilling fluids are to:

1. Cool the drill bit
2. Lubricate the moving parts of a drill bit
3. Remove cuttings from the cutting face of the drill bit
4. Suspend the drill cuttings in the drilling fluid
5. Return the drill cuttings to the surface
6. Prevent well blowouts
7. Protect the borehole
8. Protect potential reservoirs.

Drilling engineers have a variety of drilling fluids and additives that help accomplish these goals. Many of these drilling fluid types and additives can effect log measurements and interpretation results. These drilling fluid effects must be accommodated for quantitative FE.

The final choice of drilling fluid types used is usually based upon drilling costs, drilling efficiency and anticipated drilling hazards.

Slightly *overbalanced* (i. e., pressure at a permeable bed slightly greater than the formation pressure) is often considered to be optimum, as this condition usually results in high rates of penetration (ROP), reduced formation damage, and boreholes closer to gage than those with highly overbalanced mud systems. Underbalanced muds risk blowouts. Dispersive mud additives (e.g., lignosulfonate) should not be used if expansive clays (e.g., montmorillonite) are prevalent in the formations to be

drilled. Tool sticking and borehole collapse is likely to occur in these situations. If swelling clays are expected, KCl-based and/or oil-based muds are preferred. Each of these mud types, however, must be accommodated during FE.

Heavy mud (e.g., mud weight greater than 16 lb/gal) used to contain deep high-pressure formations may result in severely overbalanced conditions at shallow permeable formations causing differential sticking of logging tools and drill pipe. Heavily overbalanced muds also risk driving mud additive chemicals deep into formations and causing unwanted reactions.

Mudcake

Mud weight additives are used in petroleum well drilling fluids to ensure that the pressure in the borehole, opposite permeable formations, is greater than that of the formation pressure. Fluid loss additives in the drilling fluid build up opposite permeable formations to stop the loss of drilling fluid into these formations, and also to protect the integrity of the borehole. The resulting solids buildup is called *mudcake*. Mudcake reduces the borehole diameter and displaces pad-type logging tools from the borehole wall. The resulting pad-type log data must be corrected for the effects of the mudcake. Mudcake buildup is usually greater for wireline tools than for MWD/LWD tools because the latter pass the formation to be logged within minutes of the drill bit and the mudcake does not have much time to form.

Flushed Zone

During the process of mudcake formation, drilling *mud filtrate* (liquor) is forced into the formation, flushing out most of the formation fluids. The resulting roughly cylindrical shell about the borehole is called the *flushed zone*. This mud filtrate invasion will alter logging tool responses. These invasion effects must be corrected before any quantitative FE is attempted.

Invaded Zone

Beyond the flushed zone is another roughly cylindrical shell of partially invaded formation, called the *invaded zone*. The flushed and invaded zone diameters, commonly called *invasion diameters* d_i will depend upon the mud/formation differential pressure, drilling and formation fluid viscosities and formation permeability.

Uninvaded Zone

The outermost portion of the Fig. 13.29 borehole model is called the *uninvaded zone*. It is the portion of the formation beyond any mud filtrate invasion. Usually only the deepest reading (induction or laterolog) resistivity

logs actually receive a significant response from beyond the invaded zone. The use of multiple resistivity tools with different investigation depths (the latest incarnations are the array induction and laterolog array tools) allow inversion of the measured values to a cylindrical shell resistivity model, defining the flushed, invaded, and uninvaded zones, which allows an estimate of true formation resistivity R_t .

13.10.5 Subsurface Temperatures

Geothermal Models

Knowledge of formation temperatures is very useful for FE and reservoir engineering. Electrical resistivities are highly temperature dependent. Temperature also figures heavily in reserve determination. Borehole temperatures are measured with temperature-sensitive devices attached to logging sondes. These can be maximum recording thermometers (MRTs) or continuously recording devices. Borehole temperatures, however, are generally *not* the same as the formation temperature at the same depth.

As a rule, subsurface temperatures increase with depth. Typical regional petroleum province geothermal gradients range from 1.0 to 3.0 °C/100 m (0.55 to 1.92 °F/100 ft). Detailed subsurface temperature gradients, however, are seldom linear. Rocks with low thermal transmissibility, such as dense impermeable rocks, have high geothermal gradients. Rocks with high thermal transmissibility, such as porous and permeable sands, have low geothermal gradients.

13.11 Well Logging Tools

The applications of well logging tools have greatly expanded, from the simple resistivity profiling used for the Pechelbronn well, to multiple specialized tools and tool stacks for measuring subsurface geology and physical properties.

13.11.1 Porosity Tools

What Are Porosity Tools?

In the simplest terms, a reservoir rock may be considered to be made up of two components:

- A solid (*matrix*)
- Void space (*porosity*).

Knowledge of porosity is extremely important for FE because without porosity, there would be no place to put liquid or gaseous hydrocarbons. Archie's equations

Fault zones often form permeable pathways, allowing deep, high-temperature fluids to circulate closer to the surface. A well encountering such a fault will exhibit shallow temperature highs and gradient reversals.

Heavy annual rainfall with outcropping permeable formations often result in deep flushing of reservoir rocks. Wells encountering such reservoirs may show low temperature excursions from the otherwise smooth geothermal gradient profiles.

Thermal Disturbances Due to Drilling

The act of drilling a well disturbs the local geothermal gradient. Abrasion at the bit face heats the rocks, while circulating drilling fluids cool the rocks at the bit face. The temperature of drilling mud pumped down the drill pipe is generally cooler than the mud returns coming back out of the well.

Temperature disturbances due to drilling can be predicted using a simple thermal model. This physical heat transfer problem was initially solved by the English Geophysicist, E.C. Bullard. Undisturbed temperatures can be estimated using semilogarithmic extrapolations of measured temperatures based on functions of the circulation and buildup times.

In 1951, D.R. Horner, a reservoir engineer with Shell Development, correctly recognized that the mathematical physics of transient pressure tests were the same as that of Bullard's drilling temperature disturbance problem. As a result, the petroleum industry usually refers to Bullard temperature buildup extrapolations as *Horner Plots*.

((13.1) and (13.2)) required knowledge of porosity to be able to estimate reserves. *Porosity tools* are borehole measurements that respond primarily to the porosity (void space) in the rock. Four established borehole measurements, *resistivity (conductivity)*, *density*, *acoustic (sonic) transit time*, and *hydrogen index (neutron porosity)*, as well as an emerging measurement, *nuclear magnetic resonance (NMR)*, all respond strongly to formation porosity.

Resistivity (Conductivity) Logs

Resistivity and induction (conductivity) logs are commonly known as *saturation logs* because formation resistivity (conductivity) is dependent upon both porosity and saturation. *Archie's equations* ((13.4) and (13.5)) relate formation resistivity to porosity and water saturation S_w . In the absence of hydrocarbons, $S_w = 1.00$, and Archie's first equation (13.4) can be solved for poros-

ity if the water resistivity R_w and Archie coefficients a and m are known. In these cases, Archie's first equation can be used to evaluate the reservoir qualities of water sands when only resistivity or induction logs are available. Resistivity (conductivity) logs were the first porosity tools available, when other porosity tools were yet to be developed.

Acoustic (Sonic) Logs

Measurement of Acoustic Interval Transit Time. An acoustic impulse will travel through a material at the speed of sound, characteristic of that material. The interval transit time Δt is the inverse of the acoustic velocity. Knowledge of Δt is useful, not only for estimating formation porosity, but also for estimation of seismic velocities for inversion of seismic data.

Acoustic (Sonic) Logging (Sonde) Tool. Figure 13.30 is a schematic drawing of a generalized borehole compensated (BHC) wireline acoustic logging tool. The measurement principle is analogous to a reversed seismic refraction profile. Two acoustic receivers, located beyond the critical refraction distance from an acoustic source, record the arrival time of an acoustic impulse, which has been refracted along the borehole wall.

To compensate for the effects of borehole diameter irregularities (rugosity) and sonde inclination, the process is reversed and the two arrival times averaged. The interval transit time Δt is this average divided by the dual receiver separation distance.

Different wireline and MWD/LWD vendors offer slight variations of the measurement concept shown in Fig. 13.30. Modern digital equipment allows specialized sources rich in compressive (longitudinal, or P) and/or flexural (shear or S) wave motion, as well as receiver arrays with automatic semblance picking logic to identify rock P and S wave inverse velocities. In all cases, however, the basic measurement concept is seismic refraction, as shown in Fig. 13.30.

Acoustic (Sonic) Porosity. Jesse Wyllie and associates at Gulf Research and Development Co. [13.14], Louis Raymer and associates at Schlumberger [13.32], and Jean Raiga-Clemenceau and associates at TOTAL [13.33] all developed empirical porosity/acoustic transit time relationships for sedimentary rocks. None of these relationships have any physical basis but do appear to fit observed data (some better than others).

Acoustic logs do not seem to be as severely affected by borehole washouts as some of the other porosity tools. For this reason, they are often preferred in rugose borehole situations. Acoustic logs are, however, affected by clay minerals and gaseous hydrocarbons and must be corrected for these effects.

Fig. 13.30 Compensated acoustic sonde with transmitters (T) and receivers (R)

Density Logs

Borehole Measurement of Bulk Density. High-energy (1.17–662 KeV) γ -rays collide with electrons within the rock losing part of their energy to the electrons. The incident γ -ray does not disappear, but changes directions and does lose energy. This process is called *Compton scattering* and is the physical principle upon which γ - γ density logging is based. Eventually, after several collisions, the scattered γ -ray loses enough energy that it drops below the Compton scattering energy window. Lower density rocks will yield higher Compton energy window γ -ray count rates (*fluxes*) at the density sonde γ -ray detectors, than higher density rocks. This decrease in γ -ray flux is proportional to the *electron density* of the material through which the γ -rays pass. For most sedimentary rocks the *electron density* is proportional to the *bulk density*. *Compton scattering γ -ray flux* occurs for both rock solids (*matrix*) materials and (water and hydrocarbon) liquids, but much less so in gases.

γ - γ Density Logging (Sonde) Tool. The density logging sonde is a borehole wall contact tool. Figure 13.31 shows the progression of density log sondes over time.

Because γ -ray energies are attenuated with collisions with any electron, it is essential that the source and

Fig. 13.31a–d Density sonde progression: (a) Original (single detector) sonde. (b) Compensated (dual detector) sonde. (c) Spectral (Compton scattering and photoelectric effect) sonde. (d) Three detector spectral sonde

detector(s) are placed in close contact with the borehole wall.

First-generation density log sondes (Fig. 13.31a) utilized a chemical γ -ray source and a single detector, encased in shielding material with columnating windows to the exterior of the source. The entire assembly was pressed against the borehole wall via a bowspring on the back of the tool. The tool actually measured the Compton scattering energy window γ -ray flux at a fixed distance from the source. Borehole wall density was estimated via calibration graticules, using mud weight and mudcake thickness from bit size and caliper measurements. Results of this sonde design were extremely susceptible to borehole rugosity and variations in mudcake thickness. These shortcomings almost doomed the technology before it even got started.

Addition of a second detector (Fig. 13.31b), however, made the density tool so reliable that it became the primary porosity tool, second only to the density-neutron combination. The dual detector compensated density log sonde mudcake correction was achieved by cross plotting the near and far detector fluxes, based upon empirically developed analogue borehole models (Fig. 13.32).

Modern density log sondes (Fig. 13.31c) record not only Compton scattering γ -rays, but also those within a lower, *photoelectric effect factor* (PEF), energy window. This latter measurement is useful for lithology identification, because *photoelectric effect* energy win-

dow γ -ray attenuation is nearly independent of porosity. Mudcake corrections for these sondes are based upon multivariable inversions of the Compton scattering and PEF window fluxes at the two detector distances. Unfortunately, *PEF* energy window γ -rays are highly attenuated by barite-weighted muds.

The most recent density log sondes (Fig. 13.31d) utilize a third spectral γ -ray detector adjacent to the γ -ray source. Information from the third detector helps stabilize the effects of barite-weighted mud and extend the utility of PEF measurements.

Compton energy window γ -ray attenuation is proportional to electron density, which for most sedimentary rocks, saturated with either water or oil, is roughly proportional to bulk density. PEF γ -ray energy window attenuation is less susceptible to porosity variations and thus more sensitive to variations in matrix types.

Different wireline and MWD/LWD vendors offer slight variations of the Fig. 13.31 sonde designs. Current MWD/LWD density tools use source-detector sets on four quadrants of the MWD/LWD subassembly to ensure that at least one of them is in wall contact as the drill string is rotated. In all cases, however, the basic measurement concept is based upon γ -ray attenuation physics.

Density Porosity. Unlike the sonic log, there is a theoretical basis for density log porosity estimates: mass balance. For a simple reservoir rock, consisting of

Fig. 13.32 Generalized rib and spine mudcake correction

a solid (matrix) of average density ρ_{ma} and porosity φ filled with a fluid of average density ρ_f , the bulk density ρ_B , is given by

$$\rho_B = \varphi \rho_f + (1 - \varphi) \rho_{ma} \quad (13.10)$$

which can be solved for φ as

$$\varphi_D = \frac{\rho_B - \rho_f}{\rho_{ma} - \rho_f} \quad (13.11)$$

Density logs are severely affected by borehole washouts, mudcake buildup, barite-weighted muds, clay minerals, and gas. Density log measurements must be corrected for these effects before (13.11) can be used for quantitative φ_D estimates. Severe borehole washouts may render density log data unusable.

Neutron Porosity Logs

Neutron logs were the first logging tool developed primarily to measure formation porosity.

Measurement of Hydrogen Index. When fast ($> 1.0 \text{ MeV}$) neutrons collide with nuclei within a rock

Fig. 13.33 Generalized compensated neutron sonde (after [13.34])

they are scattered (change trajectory direction) and lose part of their energy to the target nucleus. The amount of the energy loss is related to the relative masses of the neutron and the target nucleus. The greatest (i. e., near total) energy loss occurs when the mass of the target is close to that of the incident neutron (i. e., the hydrogen nucleus).

Within a few microseconds of introduction to a rock, fast neutrons are moderated (i. e., lose energy) to thermal ($< 0.1 \text{ eV}$) energy levels and the resulting moderated neutrons drift randomly until they are captured by chlorine, bromine, silicon, or hydrogen atoms. The capturing nucleus then becomes excited and emits a high-energy γ -ray of capture, whose energy is diagnostic of the capturing nucleus.

The hydrogen density of a material (often called the hydrogen index) can be estimated by counting either the thermal neutron or capture γ -ray flux at some distance from the fast neutron source. Both of these techniques have been used in neutron porosity tools.

Neutron Porosity (Sonde) Tool. Figure 13.33 is a schematic rendering of neutron porosity tool measurement principles [13.34]. The measurement principle is analogous to that of the density tool. A source of fast neutrons is introduced into the borehole wall, where they are scattered and the resulting moderated thermal

neutron and/or capture γ -ray flux is monitored at some distance from the neutron source.

The earliest neutron porosity tools (generically called GNT) used only a single detector, which measured the γ -ray of capture flux at a fixed distance from the source. This measurement was converted to apparent formation porosity via calibration gratitudes, which also utilized mud and borehole diameter information. The GNT results were extremely sensitive to borehole size, and usually had to be calibrated by core measurements on a field-by-field basis; a process which could be extremely time consuming, as each different sonde had to be calibrated for every borehole diameter in which it was run. *Swulius* [13.35] described the massive effort involved in calibrating over 70 GNT-type tools for the Kelly Snyder Field, West Texas, SACROC Unit Reservoir Description Project, which resulted in over 600 different core calibration neutron porosity transforms.

Modern Compensated Neutron Logs (CNL or CNT) utilize dual detectors and are much less sensitive to borehole variations. CNL porosity is empirically referenced to thermal neutron flux (detector count) ratios of prototype tools recorded in the American Petroleum Institute (API) limestone calibration pits, located on the University of Houston campus [13.36]. Each vendor has its own sandstone and dolomite calibration curves based on tests in their own calibration pits as shown in Fig. 13.34. *Ellis* [13.37] and *Ellis and Singer* [13.26] advocated a more basic calibration standard, based upon *slowing down length* for epithermal (0.1–100 eV) neutrons, and *moderation length* for thermal neutrons. While this approach has merit, the lithology-based calibrations appear to be too deeply entrenched in the industry for this change to happen.

Different wireline and MWD/LWD vendors offer slight variations of the measurement concept shown in Fig. 13.33. Current MWD/LWD neutron logs use source-detector sets on four quadrants of the MWD/LWD subassembly (i. e., similar to density subassemblies), to ensure that at least one of them is in wall contact as the drill string is rotated. In all cases, however, the basic measurement concept is the neutron attenuation physics, as shown in Fig. 13.33.

Neutron Porosity. Neutron porosity φ_N is based on the bulk *hydrogen index* (HI) HI_B (a fictitious parameter introduced by Schlumberger, specifically for neutron log interpretation), which is the ratio of hydrogen ions present in a rock to the number of hydrogen ions present in an equal volume of water. The bulk *hydrogen index* HI_B , for a simple reservoir rock, consisting of a solid (matrix) of average HI_{ma} , and porosity φ filled with

Fig. 13.34 Compensated neutron tool lithology based porosities (courtesy of Baker Atlas)

a fluid of average hydrogen index HI_f is given by

$$HI_B = \varphi HI_f + (1 - \varphi) HI_{ma} , \quad (13.12)$$

which is similar in form to (13.10), for bulk density. Because of the definition of HI, its value for water is $HI_w = 1.00$. The HI for most oils is usually assumed to be $HI_o \approx 1.00$. For most reservoir rocks, the average $HI_{ma} \approx 0.00$. With these assumptions and the HI definition, (13.12) can be simplified to

$$\varphi \approx HI_B . \quad (13.13)$$

The neutron empirical calibration standard is the API limestone test pits in Houston [13.36]. For this reason, neutron logs are often presented as limestone porosity, even if the dominant lithology penetrated by a well is not limestone. In these cases, transforms based on models such as that shown in Fig. 13.34 are used to convert the measured φ_{Nls} , to the appropriate lithology porosity. Cross-plot porosities and lithology analyses, such as that shown in Fig. 13.35, are all based on neutron data in limestone units.

Neutron logs are severely affected by borehole washouts, mudcake buildup, chlorine, boron, clay minerals, and gas. Neutron log measurements must be corrected for these effects before (13.13) or cross plots can be used for quantitative φ_D estimates. Severe borehole washouts may make neutron porosities unusable.

Fig. 13.35 Density-neutron cross-plot grid annotated for lithology and porosity

Advantages and Liabilities of Radioactive Porosity Tools

Since the introduction of compensated density and neutron tools, the combination of these two porosity tools has become the industry standard for both wireline and MWD/LWD porosity measurement. Not only do they provide excellent porosity measurements, they also provide information about reservoir rock lithology. In addition, the gas and clay mineral effects on these two measurements work in opposition:

- The effects of clay minerals increases apparent φ_N , but tend to decrease apparent φ_D .
- Conversely, the effects of gas increases apparent φ_D , but decreases apparent φ_N .

Consequently, if both density and neutron logs are available, good estimates of total porosity φ_T are

$$\varphi_T \approx \frac{\varphi_D + \varphi_N}{2}$$

or

$$\varphi_T \approx \sqrt{\frac{\varphi_D^2 + \varphi_N^2}{2}} \quad (13.14)$$

A second approach to estimating both φ_T is to use a *cross-plot* grid, such as Fig. 13.35.

Both the density and neutron tools are considered to be *radioactive porosity tools*, because they each use chemical radioactive sources. These chemical sources require special care and handling, because of health and safety (H&S) considerations. Density logs use either ^{60}Co or ^{137}Cs chemical radioactive sources. Neutron logs use either AmBe or ^{252}Cf chemical sources, or ^2H - ^3H neutron generators. All of these sources, including the tritium (^3H) target for the neutron generators, are considered to be hazardous materials and must be used under the direct supervision of a licensed radiological engineer.

Because of H&S, as well as environmental concerns, logging vendors using radioactive logging tools must provide secure storage and transport facilities, as well as keep extensive records of when and where the sources are taken. Sources lost must be recovered and, if abandoned in wells, must follow abandonment and notification protocols approved by the Nuclear Regulatory Commission (NRC) in the US or similar governmental agencies elsewhere. A recent breached density source accident in California's San Joaquin Valley resulted

in the well owner immediately instituting wellsite decontamination, hazardous waste disposal, shutting in wells within a defined exclusion zone with the loss of an estimated 60–100 BOPD production, and signing a Consent Order to monitor the field for 300 yr (10 half-lives) because of ^{137}Cs contamination.

Recent concerns about international terrorist activities have raised concerns about the security of all (medical, scientific, engineering and well logging) radioactive sources. US Homeland Security-commissioned studies have resulted in doomsday scenarios, such as the one depicted in Fig. 13.36. While Gilchrist et al. [13.38] stress that 3500 Ci of ^{137}Cs (used for the Fig. 13.36 scenario) would constitute close to the total of all density logging sources in the world, simulation maps, such that of Fig. 13.36, make it difficult to hold logical discussions of the costs and benefits of radioactive logging sources. The US National Academy Sciences (NAS) has recommended the phasing out of current well logging radioactive source technology, but has offered no timetable or alternatives. Two West African countries have also recommended phase-outs, but have not announced alternatives or timetables. The papers by Badruzzaman et al. [13.39] and Gilchrist et al. [13.38] provide very good summaries of the dilemma facing the industry.

Nuclear Magnetic Resonance (NMR) Logs

The utility of measuring NMR in reservoir rocks was recognized in the 1950s [13.40] and a prototype tool was developed the same decade [13.41, 42]. A reliable NMR logging tool was not developed, however, until the late 1980s [13.43]. It took 30 yr for the technology required to build a reliable MNR logging tool to catch up with the promise provided by scientific insight and laboratory measurements.

Measurement of Nuclear Magnetic Resonance (NMR). One of the subatomic particle quantum numbers is called *spin*, which generates a magnetic moment. The particle spin has two values $\pm\frac{1}{2}$ indicating parallel and antiparallel to the local magnetic field. Protons, neutrons, and electrons all have quantum spin numbers. Protons, however, have the largest NMR response [13.43].

For ions with multiple protons (i. e., $Z > 1$), protons pair up with protons of the opposite (spin) quantum number. Ions with odd atomic numbers have one unpaired proton and, thus, have greater NMR responses than those with even quantum numbers. The ion with the greatest NMR response is the hydrogen ion, with only one proton and no neutrons or electrons. Oxygen and carbon, by contrast, have only paired protons and a very low NMR response. Consequently, the primary

Fig. 13.36 Simulation of potential radiological contamination due to the hypothetical detonation of a radiological dispersion device (RDD, or dirty bomb) containing 50 lb explosive and 3500 Ci of ^{137}Cs , at the lower tip of Manhattan Island (after [13.38], courtesy of SPWLA)

source of NMR in reservoir rocks is due to the hydrogen ions in reservoir rocks, or to the hydrogen ions in water and hydrocarbon molecules. Unlike HI, the NMR response to clay minerals is negligible compared to that of water.

In the absence of any external magnetic field, proton spins have random orientations. In the presence of an external magnetic field, the proton spin moment will orient either parallel or antiparallel to the external field. If a larger (local) magnetic field is imposed, the proton spins will reorient, with their moments precessing (rotating) around the new net magnetic field, much like the gyroscope inertial field vector precessing around the Earth's gravitational field. This proton spin precession about the net external magnetic field vector is called *proton precession*, or (in the presence of a pulsed local field) *nuclear magnetic resonance (NMR)*. The frequency of the rotation is proportional to the magnetic field strength. The length of time for the precession to decay is related to the energy interaction between the spinning protons and material in the walls of vessels containing the water and/or hydrocarbons. The precession decay time for vessels of similar composition is thus the size of the vessels (i. e., pore sizes for reservoir rocks) and the composition of the vessel wall material (i. e., the pore throat lining).

In the mid 1960s, Varian Associates utilized the NMR phenomenon to develop a *proton precession magnetometer (PPM)*, which monitored the precession frequency of a fixed volume of water in a sealed container to measure spatial variations in the Earth's magnetic field [13.44].

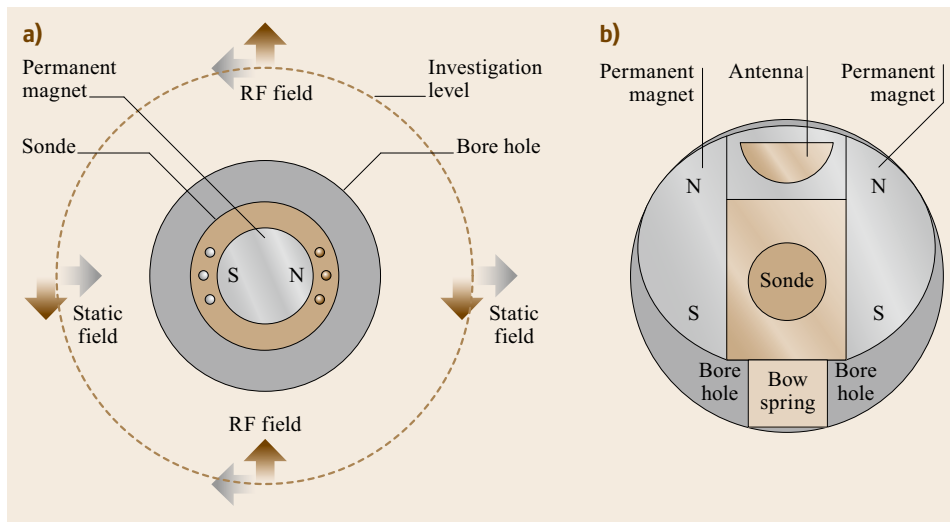

Fig. 13.37a,b Modern NMR logging sonde design cross-sections ((a) centralized sonde design, (b) eccentered sonde design)

Brown and Fatt [13.40] and Seevers [13.45] demonstrated that NMR precession times could be utilized to estimate volumes of *free fluid*, and consequently the pore space sizes in a reservoir rock. Brown and Gamson [13.41] used these concepts to design a prototype NMR logging tool.

Nuclear Magnetic Resonance Logging (NML) (Sonde) Tool. The first (NMR) logging tool was designed by Byron Jackson to Chevron specifications [13.41]. It used the Earth's magnetic field as the external field and Electromagnets for the locally imposed field. This tool was a technical success in that it did demonstrate that borehole NMR measurements were feasible. The original tool, however, was a prototype tool and subject to frequent failures. At the insistence of Chevron, Exxon, Mobil and Shell, Schlumberger and Dresser-Atlas (now Baker-Atlas) introduced their own NMR logging tools, which were also prototype tools. Because of the crude analog measurement circuitry used in all of these tools, the drilling mud had to be *poisoned* with steel filings to rapidly attenuate the borehole signals.

The initial target NMR log situations, for Chevron, Exxon, Mobil and Shell, were freshwater, heavy oil reservoirs, like those of California's San Joaquin Valley. This was just too small a potential market to justify the massive R&D effort needed to develop reliable NMR logging tools.

The NMR log situation remained at this level until the 1980s. By then new technologies (e.g., high temperature and pressure programmable microprocessors, and powerful new ferrite permanent magnets) had developed, which were favorable toward designing sophisticated and reliable NMR logging tools. NU-

MAR Corporation, a small Israeli startup, lured several NMR researchers and tool-design engineers from the major logging vendors and designed their own NMR tool, called *Magnetic Resonance Imaging Log (MRIL)* [13.46].

The NUMAR NMR tool incorporated:

- State-of-the-art ferrite technology
- Downhole high temperature and pressure digital circuitry, with microprocessors for A/D sampling, data processing, encoding and transmission
- Uphole data processing and interpretation.

NUMAR also worked closely with those oil companies requesting NMR logging services to ensure that their needs were met with the NUMAR tool. In less than 15 yr, NUMAR established NMR logging as a viable commercial market and themselves as a viable NMR logging vendor. With the NMR logging market established, Schlumberger introduced its own version of new NMR tools and Halliburton acquired NUMAR Corporation. All four major logging vendors now offer wireline NMR logs and three offer LWD versions. Two distinct designs have emerged: centralized and eccentered versions, as shown in Fig. 13.37. All current NMR sondes utilize *pulse echo magnetic resonance imaging*.

Nuclear Magnetic Resonance Porosity and Permeability. The original application of NMR logs was to estimate porosity and saturations in freshwater, heavy oil reservoirs. A second application was to estimate reservoir rock pore-size distributions, and thereby permeability. Figure 13.38 shows a comparison of laboratory core and NMR permeability analyses.

Fig. 13.38 Comparison of measured and NMR relaxation time predicted core permeabilities [13.45]

Figure 13.39 shows a comparison of wireline NMR and laboratory core porosity analyses.

Once major logging vendors had introduced reliable NMR tools, new applications were developed. Coates et al. [13.46] listed the following NMR log applications:

- Presence and quantities of different fluids (water, oil, and gas)
- Porosity and pore size distributions
- Bound and free water saturations
- Effective porosity and permeability
- Flushed zone saturation S_{xo} for wells drilled with oil-based mud (OBM).

Figure 13.40 shows a relationship between NMR T_2 relaxation time and light oil viscosity. Allen et al. [13.47] shows other examples of NMR Log versus core measurement comparisons.

Nuclear Magnetic Resonance and Lithology. Most NMR log vendors claim that NMR is independent of lithology, which is not completely true. While the NMR response to reservoir rock matrix material is not as strong as for the traditional porosity (acoustic, density and neutron) tools, the precession decay time, as indicated above, is related not only to the pore sizes, but also to the material lining the pore throats. To get the most reliable NMR log interpretations, an independent source of reservoir lithology is required. Kenyon [13.50] provides a very good summary of the

Fig. 13.39 Comparison of measured core porosities to those predicted from NMR Logs. The red line is a RMA fit to the data, while the blue line is the 1 : 1 correspondence (after [13.48])

Fig. 13.40 Light and heavy oil have different viscosity versus NMR T_2 trends (after [13.49])

petrophysical principles behind NMR log applications, including the lithology aspects.

NMR Versus Conventional Porosity Logs. NMR logs are not simply the specialized tool for a limited (e.g., heavy oils and freshwaters) market, as was once thought. They are also not, however, the *magic bullet* or *Swiss army knife*, that many vendors claim. NMR logs are less sensitive to matrix lithology than conventional (acoustic, density, and neutron) tools. However,

they do require a good independent source of lithology and porosity information for best results. They also provide permeability estimates, which definitely fill a gap in the conventional porosity log tool kit.

NMR logs, however, are more expensive to run than conventional porosity tools, both in terms of logging charges and rig time. For best NMR log analysis results, conventional porosity tools also must be run, which makes them a luxury for many small oil and gas fields, as well as independent operators.

NMR logs do not require radioactive sources, like density and neutron logs. As indicated above, however, NMR logs are not a replacement for conventional porosity tools. Because of this, the petroleum industry (both operators and logging vendors) is mounting intense efforts to develop alternatives to chemical neutron and gamma-ray sources. These efforts have not been successful to date. As a result, the petroleum industry has been requesting extensions for using chemical density and neutron radioactive sources.

13.11.2 Lithology Tools

What Are Lithology Tools?

Essentially all wireline and MWD/LWD measurements respond to lithological changes in the borehole wall rock. *Lithology tools* are those tools, or combinations of tools, which have strong responses to these changes.

Single-Tool Methods

Single-tool methods utilize a single tool whose lithology response is unique enough that it can be used alone to determine the dominant lithology.

Natural Gamma-Ray Logs. There are three natural sources of γ -ray radiation as shown in Fig. 13.41:

- Potassium 40 (^{40}K)
- Thorium (^{232}Th) decay series
- Uranium (^{238}U) decay series.

Of these three sources, ^{40}K is the major contributor to sedimentary rock natural γ radiation, because potassium is a major constituent of feldspars, sylvite, micas and clay minerals.

Micas and clay minerals are major constituents in shales and contain large amounts of potassium: potassium 40 (^{40}K) is radioactive. Because potassium is not a constituent of quartz, calcite, or dolomite, the natural γ -ray log is often used as a shale indicator. Uranium and thorium salts are also often precipitated in reducing environments, such as organic shales (e.g., the Antrim Shale of the Michigan Basin).

Sand-shale lithologies are estimated by establishing a low- γ -ray *sand line* (100% sand) and a high- γ -ray

shale line (100% shale), for the interval of interest. Intermediate γ -ray values are assigned a shale volume V_{sh} by a variety of empirical γ -ray V_{sh} models. Similar V_{sh} estimates can be made for carbonate reservoir rocks.

The γ -ray log is not an infallible V_{sh} indicator. Arkosic sands contain large amounts of orthoclase and microcline (K-feldspars), which will generate high γ -ray responses. Zircon and sphene, often found in high-permeability, clean beach sand (good quality reservoir rock) deposits, commonly have thorium as contaminants, which will generate high γ -ray log responses. Apatite-rich sands often contain ^{212}Pb and/or ^{214}Pb , which are two of the radioactive daughter products of the uranium and thorium decay series, making them radioactive. Monazite sands are often mined for their thorium content, which makes them radioactive. Fractured carbonates and volcanics often have uranium and thorium contamination along fractures, which will also generate high γ -ray log responses. Sylvite and other potash minerals contain large amounts of potassium, which can generate high γ -ray log responses in evaporite sequences.

The γ -ray log works as a *shale* indicator often enough, however, it is commonly used to estimate V_{sh} .

Spontaneous Polarization (SP). Spontaneous polarization (SP) is an electrochemical phenomenon that occurs when the salinity of the drilling mud filtrate is different from that of the formation waters and high permeability rocks are bounded by low permeability shales (which form cation-selective membranes). When the formation waters and mud filtrate are not the same salinity, anions (negatively charged ions) and cations (positively charged ions) will migrate from the higher concentration fluid to the lower concentration fluid, in an attempt to equalize the salinities.

Shales act as cation-selective membranes, passing only cations and blocking anions, leaving a cation deficiency on the upstream (high permeability) and a cation surplus on the downstream (low permeability) fluid interfaces. The resulting electrical charge variations can be monitored by measuring the electrical potential, with respect to some fixed point, as a function of depth.

A *normal* SP occurs when the formation waters are more saline than the mud filtrate waters. In these cases, the SP opposite sands will be negative, compared to that opposite shales. A *reversed* SP occurs for the opposite situation.

Because the SP opposite (high-permeability) sands is different from that opposite (low-permeability) shales, the SP is often used as a sand-shale indicator. An SP *sand line* (100% sand) and a *shale line* (100% shale) are established for the interval of interest and the intermediate SP values are scaled linearly between 0 and 100% V_{sh} .

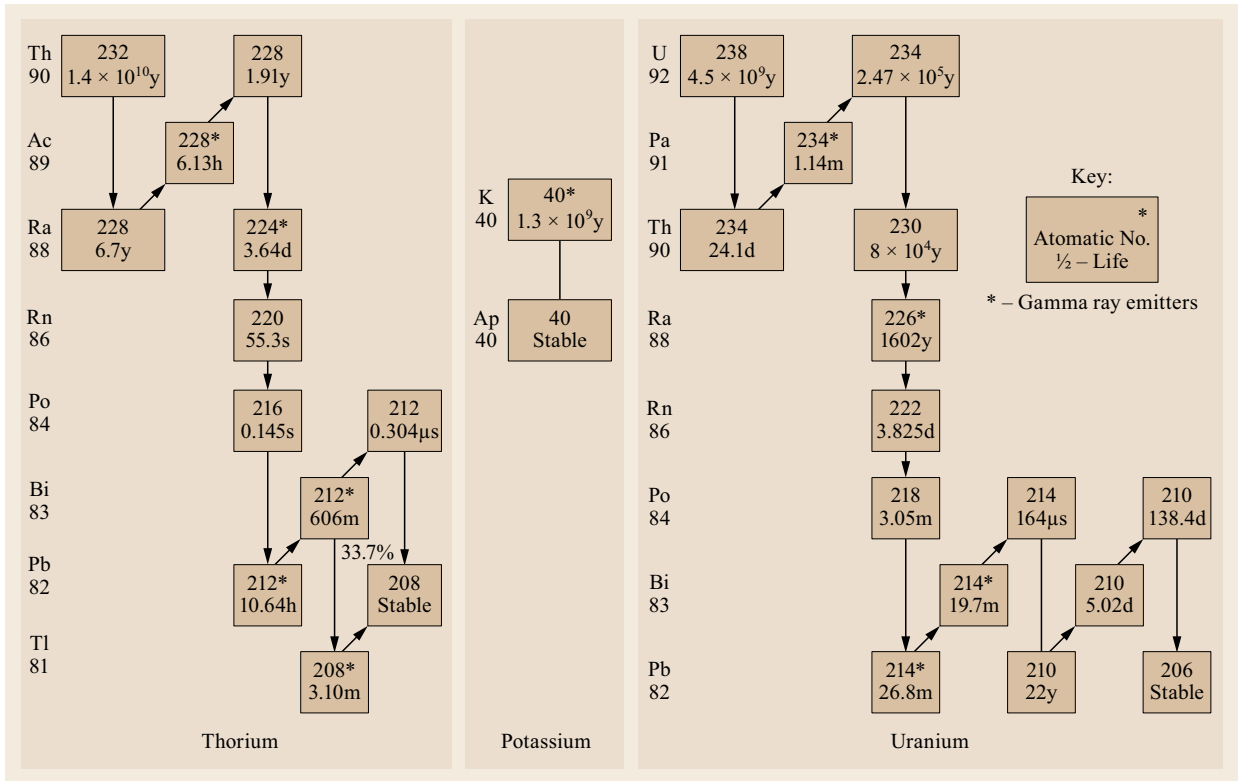

Fig. 13.41 Radionuclide decay for ⁴⁰K, ²³²Th series and ²³⁸U series (after [13.51])

There are many problems with using the SP as a quantitative V_{sh} indicator. If there is little or no salinity contrast between the mud filtrate and formation waters the SP will be flat and of little value. Because of formation water salinity variations, the SP can be reversed, flat, and normal, all in the same well. Clay minerals in sands will depress the SP sand deflections.

Photoelectric Factor (PEF). Low-energy (< 0.2 MeV) γ -rays are adsorbed by electrons within the rock increasing their energy level and releasing a photoelectron on impact. This process is called *photoelectric adsorption* and is the principal upon which the Z, or PEF, curve of modern density log tools is based.

Photoelectric absorption is dependent upon the atomic number (Z) of the target atom. Lithodensity, spectral density, or Z-logs use the near detector ratio of γ -ray flux in the Compton scattering and photoelectric absorption windows to estimate bulk photoelectric factor, PEF, which is largely independent of porosity. Because of this, the PEF curve can be an excellent lithology indicator.

The accepted matrix PEF values for common reservoir dominant minerals are:

- Calcite: 5.1
- Dolomite: 3.1
- Quartz: 1.8.

which provides sufficient separation for lithology identification in complex lithology environments, such as the Pinda Formation of the Congo Basin.

Less well known and appreciated is the fact that the accepted PEF values for common potassium feldspars are:

- Anorthoclase: 3.1
- Microcline: 2.8
- Orthoclase: 2.9.

which are all around the dolomite value. The reason this is significant is that arkosic sands, which have high potassium feldspar content, generally do not occur in carbonate environments. As a result, high- γ -ray responses in a clastic (sand and shale) environment, such as California's San Joaquin Valley, with PEF values near 3.0 may indicate arkosic sands, not shale or dolomite.

The PEF values for micas and clay minerals, the principal components of shales, range from 1.8 to 6.3,

which means that the PEF alone is not a good clay and mica mineral identifier. Because the PEF curves are based on low-energy γ -rays, they are very sensitive to barite mud additives and may not be useful for lithology identification in heavy mud situations.

Multiple Tool Methods

Multiple tool lithology determination methods utilize two or more measurements in either direct cross-plots, such as that of Fig. 13.35, or in computed parameter cross-plots, such as that of Fig. 13.42 or Fig. 13.43.

The techniques utilized to perform this type of analysis are collectively known as cross-plot techniques. There are many types of cross-plot techniques and their derivation can get rather tedious.

Single Versus Multiple Porosity Tools. Conventional (acoustic, density, and neutron) porosity tools work very well for estimating porosity if the dominant lithology is known and in the absence of gas or clay minerals. In cases of uncertain lithologies, clay minerals and/or gas, single porosity tools are not sufficient. Two, and often all three porosity tools are required to identify the lithology, as well as estimate porosity, in these cases.

Probably the most commonly used cross-plot technique is the density-neutron cross-plot, shown in Fig. 13.35. The Fig. 13.35 grid is actually a graphical nonlinear coordinate transform from neutron log limestone porosity $\varphi_{N_{ls}}$ versus density log bulk density ρ_B space to lithology-porosity space. Sandstone, limestone and dolomite (100% lithology) porosity curves are superimposed on a $\varphi_{N_{ls}} - \rho_B$ grid. Measured log values are plotted on the background ($\varphi_{N_{ls}} - \rho_B$) grid and the lithology and total porosity φ_T are interpolated between the matrix-porosity grid lines. Figure 13.35 also indicates the effect of gas. While not shown on the Fig. 13.35 grid, clays generally plot well below the dolomite line, toward high $\varphi_{N_{ls}}$ values. Similar grids exist for acoustic (sonic)-neutron and density-acoustic (sonic) cross-plot analyses.

Matrix Identification (MID) Plots. Figure 13.42 shows the metric matrix identification (MID) plot grid, which requires all three conventional (acoustic, density and neutron) porosity tools. Using the Fig. 13.42 MID grid is not as simple as the dual porosity grids. Use of this cross-plot analysis technique is a three-step process:

1. Plot the measured values from the three porosity tools on density-neutron and acoustic (sonic)-neutron dual porosity grids to obtain apparent (total) cross plot porosities for each pair.

Fig. 13.42 Metric apparent matrix interval transit time t_{maa} versus apparent matrix density ρ_{maa} in a MID plot grid

2. Using the apparent total porosities, cross plot them and the measured density and acoustic (sonic) values on specialized cross-plot grids to obtain apparent matrix interval transit times, t_{maa} , and apparent matrix densities ρ_{maa} .
3. The resulting t_{maa} , and ρ_{maa} are then cross plotted on the MID grid of Fig. 13.42. Points falling between matrix points on Fig. 13.42 can be scaled linearly to obtain approximate mixture percentages (i. e., the quartz-calcite-dolomite triangle).

Manually, this is very tedious. Fortunately, however, most FE software will take care of the intermediate steps and plot the results on a grid, such as Fig. 13.42.

Lithodensity Matrix Identification (LID) Trimineral Plots. Figure 13.43 shows the lithodensity identification (LID) plot grid, which requires only lithodensity, spectral density, or Z-density ρ_B and PEF curves, along with neutron log $\varphi_{N_{ls}}$. Like the Fig. 13.42 MID grid, using the Fig. 13.43 LID analysis technique is a three-step process:

1. Plot the measured density and neutron porosity values on a density-neutron dual porosity grid to obtain

Fig. 13.43 Lithodensity matrix identification plot (LID) grid

apparent (total) cross-plot porosity ϕ_t and apparent matrix density ρ_{maa} .

2. Cross plot the PEF, bulk density, and total cross-plot porosity on a special nomograph to estimate the apparent volumetric photoelectric absorption factor U_{maa} .
3. Cross plot the resulting ρ_{maa} and U_{maa} on the Fig. 13.43 nomograph. Points plotting between the individual matrix points can be estimated as percentage mixtures.

Like the MID plot, this is very tedious to do manually. Again, most FE software will take care of the intermediate steps and plot the results on a grid, such as Fig. 13.43.

13.11.3 Saturation Tools

Saturation tools are those logging tools that are very sensitive to (gas, oil and water) saturation variations. Formation resistivity R_t estimated from these tools is used to estimate the uninvaded formation water saturation S_w . The hydrocarbon saturation, S_o or S_g , is then $1 - S_w$. There are four types of open-hole saturation tools:

- Resistivity tools, which use electrodes (e.g., laterologs)
- Resistivity tools, which use coils (e.g., induction Logs)
- Resistivity tools, which use antennas (e.g., dielectric or electromagnetic wave propagation logs)
- Nuclear magnetic resonance logs.

While three of these tools measure formation resistivity, they each interact with the formation differently.

Electrode Tools

Electrode tools utilize galvanic coupling between the sonde and the formation, so they require conductive fluid in the borehole.

Electrode tools should not be used in wells drilled with air, foam, mist, or oil-based mud (OBM).

Formation resistivity was the first borehole measurement that the Schlumberger brothers made. The Pechelbronn well was logged by dropping the then current Schlumberger surface resistivity electrode array down the borehole and making a series of (station) measurements at different depths similar to what had been previously been done on the surface, with a technique called resistivity profiling.

It soon became apparent that there were better borehole electrode array designs than those that had been used on the surface. As a result, several different electrode array designs have appeared over the years. The major purposes of the successive electrode designs were twofold:

- Enhance thin-bed resolution and quantitative measurement
- Decrease the influence of borehole fluids, mudcake, and invasion.

These two goals are essentially mutually exclusive. The initial response to this dilemma, continued to the present, has been to use multiple electrode arrays on the same sonde.

The current electrode tools of choice are array laterolog tools (ALTs). Schlumberger was the first vendor to offer this type of service, but most major vendors now offer it. The Schlumberger version, introduced in 1990, uses downhole microprocessors, multiple electrode arrays, all current electrodes on the sonde, multiple frequencies, and records both amplitudes (impedance), and phase shifts to provide six apparent resistivities, which can be inverted to provide two-dimensional (cylindrical) resistivity models (Fig. 13.44a). The Atlas Wireline version (Fig. 13.44b), introduced in 1995, uses downhole microprocessors, multiple guard or LL3 electrode arrays, multiple frequencies, and records both amplitudes (impedance), and phase shifts to provide six apparent resistivities, which can be inverted to provide two-dimensional (cylindrical) models [13.52].

Figure 13.45 shows the invasion effects for a Schlumberger HRLA tool in an 8 in borehole filled with conductive mud [13.53]. Laterolog-type tools work best when the borehole fluid resistivity R_m is less than that of the formation R_t . They are calibrated for 8 in boreholes filled with nominal (e.g.,

Fig. 13.44a,b Array laterologs: Atlas Wireline Multilaterolog with various antennas (A) and points of measurement (M). R_m represents the resistivity of the mud, R_t the (true) formation resistivity (after [13.52], courtesy of SPWLA)

15 000–25 000 ppm NaCl salinity mud. Significant departures from these conditions require borehole or environmental corrections before quantitative water saturation S_w estimates can be made. Array laterolog tool results are not measured resistivities, but ring resistivity model inversion results, and need no further environmental corrections. Figure 13.45 compares the Schlumberger array laterolog curve responses to other electrode tools.

Laterologs should not be used in air, mist, or oil-based mud filled boreholes.

Microelectrode Tools

Microelectrode tools are contact devices designed to provide flushed zone resistivities R_{xo} . In permeable formations there is usually significant flushing of formation fluids by the mud filtrate. This flushing, or invasion, is observable by separation of the micro- and deep resistivity curves and provides a qualitative indication of permeability. The resulting flushed zone water saturation S_{xo} is estimated from R_{xo} . The movable hydrocarbons (i.e., hydrocarbons that can be produced) are then estimated by $S_{xo} - S_w$.

Ballengee [13.54] describes several microresistivity pad designs, as shown in Fig. 13.46. The common goal of these different designs was to reduce the effects of the borehole mud and mudcake, while emphasizing the flushed zone resistivity measurement. The current microresistivity tools of choice are either the microspherically focused log (MSFL), shown in Fig. 13.46 or the microcylindrically focused tool (MCFT), shown in Fig. 13.47. Microelectrode tools are very sensitive to

Fig. 13.45 Comparison of various high resolution laterolog array tool apparent resistivities (of five laterolog arrays RLA) versus invasion, for an 8 in borehole containing conductive mud (after [13.53])

mudcake thickness and must be corrected for it if accurate flushed zone resistivities are desired.

Microelectrode tools should never used in air, mist, or oil-based mud filled boreholes.

Coil Tools

Coil, or induction, resistivity tools were developed to be able to make formation resistivity measurements in air, mist, foam, or oil-based mud (OBM) filled bore-

Fig. 13.46
Microresistivity sonde pads [13.54]

holes. They can also be used with freshwater mud-filled holes and modest formation resistivities, such as in the US Gulf of Mexico and Niger Delta. Induction tools really measure formation conductivity (the inverse of resistivity). The resolution of analogue induction tools is 5 Mho/m, which means that Induction resistivity values over $200 \Omega \text{ m}$ are highly suspect. Modern digital system induction tools, with downhole A/D conversion and microprocessors, can accommodate slightly higher formation resistivities, but are still not as reliable as laterolog tools for the highest formation resistivities.

Induction tools should not be used for situations with saline muds and/or high resistivity formations.

Figure 13.48 shows the operational principals of induction logging. A high-frequency (kHz) oscillating current is passed through a transmitter coil, which generates a primary oscillating dipole magnetic field. This primary magnetic field generates secondary oscillating currents in the formation surrounding the borehole (and in the borehole fluids), which generate secondary oscillating dipole magnetic fields. A receiver coil, coaxial with, but distanced from, the transmitting coil detects the combined primary and secondary magnetic fields and feeds this signal to software, which separates the primary and secondary signals and inverts them to apparent formation resistivity (conductivity). Analog induction tools only measured impedance, because the mutual induction in the long logging cables swamped the small signal phase shifts between the closely spaced transmitter and receiver coils. Modern digital system induction tools, with downhole A/D conversion and microprocessors, can measure both impedance and phase, providing more precise formation models [13.55].

Fig. 13.47 Microcylindrically focused tool (MCFL) array with three electrodes (E) and operational schematic [13.26]

The original induction tools utilized only a single transmitter, emitting a single frequency signal and only one or two receiver coils. The current induction tools of choice are array induction tools, first introduced by BPB Oilfield Services (now Weatherford) [13.56]. Figure 13.49 shows two versions of array induction tools.

Recent AIT innovations involve tri-axial transmitter and receiver coils recording both amplitude and

Fig. 13.48
Induction log
operational
schematic [13.26]

phase, which are inverted to define principal components of the formation resistivity tensors of anisotropic formations [13.57]. This configuration is very useful for dipping formations, deviated boreholes and/or horizontal wells.

Antenna (Dielectric) Tools

Antenna, or dielectric, resistivity tools were developed for use in situations with heavy, viscous, oils and very fresh waters. Water is one of the very few naturally occurring electrically polar molecules. As a result, freshwater has a very high (≈ 80) dielectric constant. Even saline waters have dielectric constants between 40 and 60 [13.58], depending upon salinity, temperature and signal frequency. By contrast oils and most reservoir rocks have dielectric constants less than nine (i. e., a factor of approximately ten or more below freshwaters) and oils have dielectric constants between 2–5.5 [13.58].

Dielectric constant logging measurements involve transmission of high (MHz–GHz) frequency electromagnetic (EM) waves through the borehole wall rock. At one time, all major logging vendors and some operating companies had versions of dielectric tools. The various tools fell into two the distinct styles, shown in Fig. 13.50. Low (MHz) mandrel-type tools had coils attached to nonconducting sondes and were centered in the borehole, while high (GHz) pad-type tools used slot antennas, pressed up against the borehole wall [13.60].

The original dielectric tools were so successful that they may have delayed development of NMR tools for

Fig. 13.49a,b Two array induction tool configurations. (a) An array of one transmitter and ten receiver units, (b) A single receiver with four transmitters (after [13.59])

Fig. 13.50 Generic dielectric logging tools (after [13.60])

the heavy oil, freshwaters market. With the advent of the NUMAR MRIL tool and its successors, NMR tools displaced dielectric tools, because they were so versatile. As recently as early 2010, only a handful of operational dielectric tools remained, primarily in the San Joaquin Valley of California.

In late 2010 and early 2011, Schlumberger and Halliburton both introduced new-generation digital dielectric tools, which appear to be gaining market share. Discussions with several San Joaquin Valley operators indicate that the new generation dielectric tools are displacing NMR tools for freshwater, heavy oil reservoirs, leaving saline water, heavy oil reservoir and/or more complex situations to the NMR tools. The market for these new dielectric tools, however, appears to remain with heavy oils with fresh formation waters.

Modern dielectric constant tools utilize multiple transmitters, receivers, and frequencies to map dielectric dispersion [13.61, 62].

Nuclear Magnetic Resonance Logging Saturation

The original NMR logs were considered to be shallow measurement tools, useful only for flushed zone saturations, as well as porosity and permeability, and

could not distinguish between different fluid types. Current-generation NMR tools, however, with strong permanent magnets, utilizing magnetic pumping, and downhole digital circuitry, can discriminate between different fluid types, even though their depth of investigations is still very shallow [13.61, 62]. NMR logs can discriminate between clay-bound water, capillary-bound water, free water, and heavy oil. For best results, however, these NMR interpretations require supporting information from other porosity, lithology and saturation tools. Because of this and the additional costs of NMR, many operators still prefer to use traditional porosity tools.

13.11.4 Environmental Corrections

Petrophysical models are based on *true* formation physical properties. Unfortunately essentially all logging tool measurements, with the possible exception of acoustic measurements, include the effects of the borehole fluids, mudcake, and invaded zone. As a result, environmental or borehole corrections are required before the logging tool measurements can be used in petrophysical measurements. Petrophysical evaluations without first making environmental corrections risk sometimes expensive erroneous results.

Manual evaluation, using environmental corrections is tedious. As a result, experienced petrophysicists will often evaluate whether or not the borehole corrections are needed (i.e., will they make a significant difference), before applying them.

Petrophysical evaluations using FE software are relatively simple because the software does all of the tedious calculations and the analyst only needs to supply the correct input. For this reason petrophysicists will nearly always apply environmental corrections when using software. Then if questioned about whether or not environmental corrections were used, the simple answer is, *yes*.

The exceptions to universal environmental corrections are:

- Compensated acoustic log results
- Array laterologs
- Array induction logs.

Compensated acoustic logs only measure the acoustic transit time along the borehole wall. The transit times through the mud column and mudcake are canceled out by the measurement technique, so no correction is needed. The array laterolog and induction log curves are not measurements, but model inversions of the measured data. As a result, environmental corrections have effectively already been applied to these curves during inversion before they are presented.

13.11.5 Salinity (R_w) Tools

What Are Salinity Tools?

Archie's equations require porosity (from porosity tools), resistivity (from resistivity saturation tools) and formation water resistivity. Salinity tools provide the last element.

Wet Chemistry

If a formation water sample is available, its resistivity can be measured directly. Sometimes, particularly in older wet chemistry analyses, direct R_w measurements are not available. In those cases, equivalent NaCl salinities and R_w can be estimated from the individual ionic and total dissolved solids (TDS) concentrations [13.18–24]. Figure 13.17 is a nomogram based upon these empirical studies.

Spontaneous Polarization (SP)

The effects of cation-selective membranes in low permeability shales, adjacent to high permeability reservoir rocks, was described earlier in the *Lithology Tools* section. The potential differences created can be used to estimate formation water R_w , via the Nernst equation [13.63]

$$E = -\frac{RT}{F} \sqrt{\frac{a_w}{a_{mf}}}, \quad (13.15)$$

where E is the relative (i.e., from clay to sand) SP anomaly (mV), R is the universal gas constant, F is the Faraday constant, T is the absolute temperature ($^{\circ}\text{K}$). a_w and a_{mf} are the formation water and mud filtrate electrochemical activities, respectively.

The electrochemical activities are thermodynamic quantities independent of temperature, but not easily obtained. However, Doll [13.64] used a slightly different version of (13.14)

$$E = -\frac{RT}{F} \sqrt{\frac{R_{mf}}{R_{we}}}, \quad (13.16)$$

where R_{mf} and R_{we} are *equivalent* water resistivities, related to R_{mf} and R_w via laboratory determined empirical relationships. A good approximations for these relationships at 75°F are

$$R_{mf} = -0.032R_{mf}^2 + 1.069R_{mf} - 0.031$$

and (13.17)

$$R_w = -0.03R_{we}^2 + 0.0936R_{we} - 0.029,$$

which were obtained by fitting second-order polynomials to published nomograms. Equations (13.16)–(13.17) are presented in the normal R_{mf}/R_w order of usage. The terms R_w and R_{mf} are interchangeable.

A strong SP will develop opposite clean sands, bounded by clays, if the formation water salinity is significantly different than the mud filtrate salinity. In those cases, R_w can be estimated from the mud filtrate resistivity R_{mf} and the SP. Weak R_w/R_{mf} contrasts yield anemic SP deflections. The presence of clay minerals in the sand will also depress the SP deflection.

Spontaneous polarization (SP)-based R_w estimates tend to be less reliable than other estimates. As a result SP is often the R_w estimator of last resort. The SP, however, can be used to estimate R_w in oil and gas sands, with no water leg; something that other log-based R_w estimators cannot do.

Apparent Water Resistivity R_{wa}

In clean water sands, Archie’s equations can be solved for R_w , as $S_w = 1$. The resulting R_w estimate is called R_{wa} , or *apparent water resistivity*. This technique is extremely fast and may be one of the most commonly used means of estimating R_w . This technique will work only with environmentally corrected deep resistivity data and requires knowledge of the Archie a and m coefficients. It will not work, however, in the presence of clay minerals and/or hydrocarbons. It also requires the assumption that the same brine is present in the hydrocarbon zone as the water zone.

Cross-Plot Ratio R_w Estimators

Cross-plots of R_t versus porosity on various grids are also commonly used to estimate R_w . These techniques can also be used to estimate S_w . The Hingle plot (Fig. 13.51) requires prior knowledge of the a and m Archie coefficients to estimate R_w and also n to estimate S_w . Hingle plots require special grids unique to each a and m pair. The Pickett plot (Fig. 13.52) requires prior knowledge of the Archie a coefficient to estimate m and R_w and n to estimate S_w . Pickett plots use log-log grids. However, to be most effective, the x - and y -axes logarithmic cycles should be of equal lengths, as in Fig. 13.53. Then, not only is R_w , given by the 100% porosity, but the slope of the water line is the m exponent in Archie’s first equation.

13.11.6 Borehole Imagers

What Are Borehole Imagers?

Borehole imagers provide detailed (mm–cm scale) images of the borehole walls. Prior to the development of borehole imagers subsurface structural and stratigraphic information was obtained from four sources:

- Seismic reflection time and migrated depth sections, which provided both horizontal and vertical detail on a scale of tens of feet.

- Well-to-well log correlation, which provided vertical detail on a scale of feet, but very poor (well spacing scale) horizontal scale detail.
- Whole-core examination, which provided mm-scale vertical detail, but only over the interval of the core.
- Dipmeter interpretation, which provided inch-scale vertical resolution at the wells, but was clouded by the need to use statistical methods to make the determination. The geologic interpreter was distanced from the original data.

Borehole imagers provided whole-well mm–cm scale images of the borehole wall, which could be virtually manipulated and examined much like whole cores, but without the time and expense involved in obtaining oriented whole cores.

The two most successful borehole imagers have been:

- Acoustic borehole viewers (BHTV)
- Microresistivity scanners (MRSs).

Each of these imagers has its advantages and limitations. The real game changer for borehole imagers has been the image workstations. These are powerful mini- and/or microcomputer-based systems that allow the interpreter to manipulate and measure features on the borehole images, much like he/she would do with physical whole cores, and generate tables of dip and

Part B | 13.11

Fig. 13.51 Carbonate sequence Hingle plot example

strike information to present alongside other log data. While considerable creative software supports the data manipulation, analysis, and storage systems, the actual interpretation is done by the geologist or geophysicist manning the work station.

Acoustic Borehole Imagers

Acoustic borehole televiwers (BHTV), are really SONAR devices that emit ultrasonic (500 KHz–2 MHz) acoustic pulses into the mud column and measure the *reflected* amplitudes and (time-of-flight) reflection times. The first BHTV tools were developed by Mobil Field Research Laboratory (now EXXON-

Fig. 13.52 Carbonate sequence Pickett plot example

Fig. 13.53 (a) Circumferential acoustic scanning tool (CAST) and (b) Three-dimensional pseudocore image of an openhole log (courtesy of Halliburton)

Mobil), in the late 1960s [13.65]. Early attempts to commercialize this tool, by Halliburton, Dresser-Atlas (now Baker-Atlas), and Schlumberger were plagued by poor performance (tool failures and poor resolution). The first truly successful commercialization was a re-engineered tool by Gearhart (now Halliburton), in the late 1980s [13.66], designated the circumferential acoustic scanning tool (CAST). Figure 13.53 shows the current CAST tool specifications and an example of a CAST pseudocore image.

Acoustic borehole televiwers require liquid-filled boreholes, but operate better in OBM than do microresistivity scanners, provide full 360° image coverage of the borehole walls, which microresistivity scanners generally do not, and operate better in rugose boreholes than do microresistivity scanners. The time-of-flight data also provide three-dimensional information about the borehole wall. Figure 13.54 shows four rotated pseudocore images of the same depth interval, from a Congo Basin well. The protrusions from the pseudocore are mud-filled vugs in the borehole wall, which were not measured in routine core analyses by two different laboratories, but which did effect the density and neutron logs run in the wells from this field.

Baker-Atlas, Halliburton, and Schlumberger now all offer modern digital system versions of BHTV.

Microresistivity Scanners

Microresistivity scanners were logical evolutions of dipmeters and were originally developed to overcome some of the shortcomings of early BHTV tools. Multiple button electrode arrays were added to dipmeter pads. The problem introduced with this approach is

Fig. 13.54 Rotated CAST pseudocore images of the same depth interval, from a Congo Basin well, showing mud-invaded vugs in the borehole wall

that, as the borehole diameter increases, gaps in circumferential coverage between the dipmeter pads expand. The dilemma faced by logging vendors was how to distribute this loss in circumferential coverage to best describe the stratigraphy and structural patterns displayed on the borehole wall. Schlumberger uses four pads, Baker-Atlas and Halliburton use six and Weatherford uses eight.

The larger the number of pads, the smaller the circumferential coverage gap between each pad, but also the smaller the circumferential area covered by each pad. The smaller the number of pads, the larger the circumferential coverage on each pad, but also the larger the gap in coverage between pads.

Schlumberger, with only four pads, added side flaps to each of its pads to increase the circumferential coverage of each pad arm. While Schlumberger denies that this is a problem, there is always speculation that the pad flap may not have the same pressure against the borehole wall as the main pad, particularly with continued usage. Because all pads must be in good contact with the borehole wall, this can be a serious concern. Figure 13.55 shows an example of the Schlumberger FMI image, through vuggy carbonate [13.66]. The dark

portions indicated mud-filled vugs, while the bright yellow portions indicate hard carbonate. While Fig. 13.55 appears to show eight pad strips, there actually only four pads with their flap electrodes, making the appearance of two separate strips. The wide gaps indicate the separation between the pad/flap combos.

Baker-Atlas and Halliburton, with six pads, and Weatherford, with eight pads, staggered their pads into two slightly displaced rows of outsized pads, to maximize circumferential coverage on each pad and minimize the gaps between pad coverage. Figure 13.56 illustrates the Halliburton EMI pad arrangement [13.67]. Figure 13.57 shows a Weatherford CMI display.

Acoustic Versus Microresistivity Imaging Tools

Both imaging tools offer only images and neither deliver quantitative measurements. Acoustic imaging tools were developed, primarily, for fault and fracture identification. Microresistivity scanners were developed, primarily, for detailed stratigraphic evaluation.

The microresistivity scanners offer mm- to cm-scale image resolution, while the acoustic images offer only 2–3 cm scale resolution. The acoustic imagers gen-

Fig. 13.55 Schlumberger fullbore formation microimager (FMI) images of a vuggy carbonate (from [13.65], courtesy of SPWLA)

Fig. 13.56 Halliburton electrical microimaging (EMI) tool (courtesy of Halliburton)

erally work better in OBM-filled boreholes than do the microresistivity scanners, and offer full 360° borehole wall coverage, which the microresistivity scanners generally do not. Acoustic imagers also offer three-dimensional depth resolution, which the microresistivity scanners do not, and work better in rugose boreholes than the microresistivity scanners. Microresistivity scanners may work better in horizontal boreholes, because of the need for the acoustic imagers to be centered in the borehole. Acoustic imagers must be run at slower (1200 ft/hr) logging speeds than microresistivity scanners. Each tool has its niche market and the tools are not interchangeable.

13.11.7 Wireline Formation Testing

Wireline formation testers are special wireline tools, which allow one or more formation pressure measurement(s) and collection of one or more formation fluid sample(s), without having to conduct open-hole or cased-hole drill-stem tests. Modern versions of these tools include the ability to purge the sample chamber and to perform preliminary analysis of the sample fluid, to ensure that it is formation fluid and not mud filtrate. These tools are different from most wireline tools, in that they are used in fixed, or station logging, mode. Figure 13.58 shows one such tool. All major logging vendors offer similar services, for both wireline and LWD applications.

Fig. 13.57 Weatherford compact microimager (CMI) display

Wireline Formation Tester Applications

The principle applications for wireline formation testers are:

- Collecting formation-fluid samples for analysis
- Monitoring mud column and formation pressures
- Identification of formation-fluid pressure gradients and contacts

without having to run open-hole or cased-hole drill stem tests. Figure 13.59 shows a formation tester Pressure-depth plot for a Papua New Guinea well. Two gas

Fig. 13.58 Schematic of a wireline formation tester (after [13.68])

Fig. 13.59 Formation tester pressure-depth plot for a Papua New Guinea well, showing mud column and formation-fluid pressure gradients

gradients have been identified indicating isolated reservoirs, as well as an oil and water gradient in the second reservoir, which allows identification of the G/O and O/W contacts in this reservoir. Identification of fluid contacts from gradient intersections is critical for long

transition zones such as the Danish North Sea chalk reservoir, shown in Fig. 13.25. Formation tester pressure data have also been used to identify severely overbalanced mud situations, which could cause differential sticking.

13.12 Putting It All Together

To this point, we have covered the major pieces that make up formation evaluation. This section shows how they all fit together.

13.12.1 Western Australia Well

Figure 13.60 shows the dual laterolog/microspherically focused log (DLL/MSFL), with SP, gamma ray and caliper log display, for the pay interval of a Western Australia well. The well was the second, or confirmation well, for an off shore discovery. Track 1 of the log display contains the caliper, SP, gamma ray, and cable tension curves. Track 4 (combined tracks 2 and 3) displays the deep R_{LLD} and shallow R_{LLS} laterolog and micro-spherically focused log (MSFL) resistivity R_{xo} curves on logarithmic scales, with a four-cycle grid. The gross pay interval is from 1109.75–1130.0 m in depth. There appear to be shale breaks (nonreservoir rock) at 1122.50–1126.00 and 1130.00–1137.75 m depths.

Figure 13.60 shows the dual induction laterolog-3/borehole compensated sonic log (DIL/BCS), with SP, gamma ray and caliper log display, for the interval shown in Fig. 13.61. Track 1 contains caliper, SP, gamma ray, and cable tension curves, on linear scales. Track 3 contains the sonic interval transit time Δt and deep induction conductivity C_{ILD} curves on linear scales. Track 4 (combined tracks 2 and 3) contains the deep R_{ILD} and medium R_{ILM} induction and laterolog-3 R_{LL} resistivity curves on logarithmic scales, *even though the two-cycle logarithmic grid is only in track 2*. This DIL/BCS display is not typical for DIL/sonic (acoustic) log displays. The more common display is to use a two-cycle grid in track 2, with a 1 : 1 backup, for values over 20 Ω m.

Figure 13.62 shows the compensated neutron log/compensated density log (CNL/CDL), with gamma ray caliper and cable tension log display, for the interval shown in Fig. 13.61. Track 1 contains density caliper, neutron caliper gamma ray and cable tension curves on linear scales. Track 4 (combined track 2 and 3) contains density ρ_B and neutron limestone porosity φ_{CNS} curves on linear scales. Track 3 contains the density correction curve $\Delta\rho$ on a linear display.

The log displays in Figs. 13.60–13.62 were obtained on separate logging trips. Even though there is dupli-

cation of the SP, gamma ray, caliper, and cable tension curves, each curve is unique to the logging trip on which it was run.

13.12.2 Manual Analysis

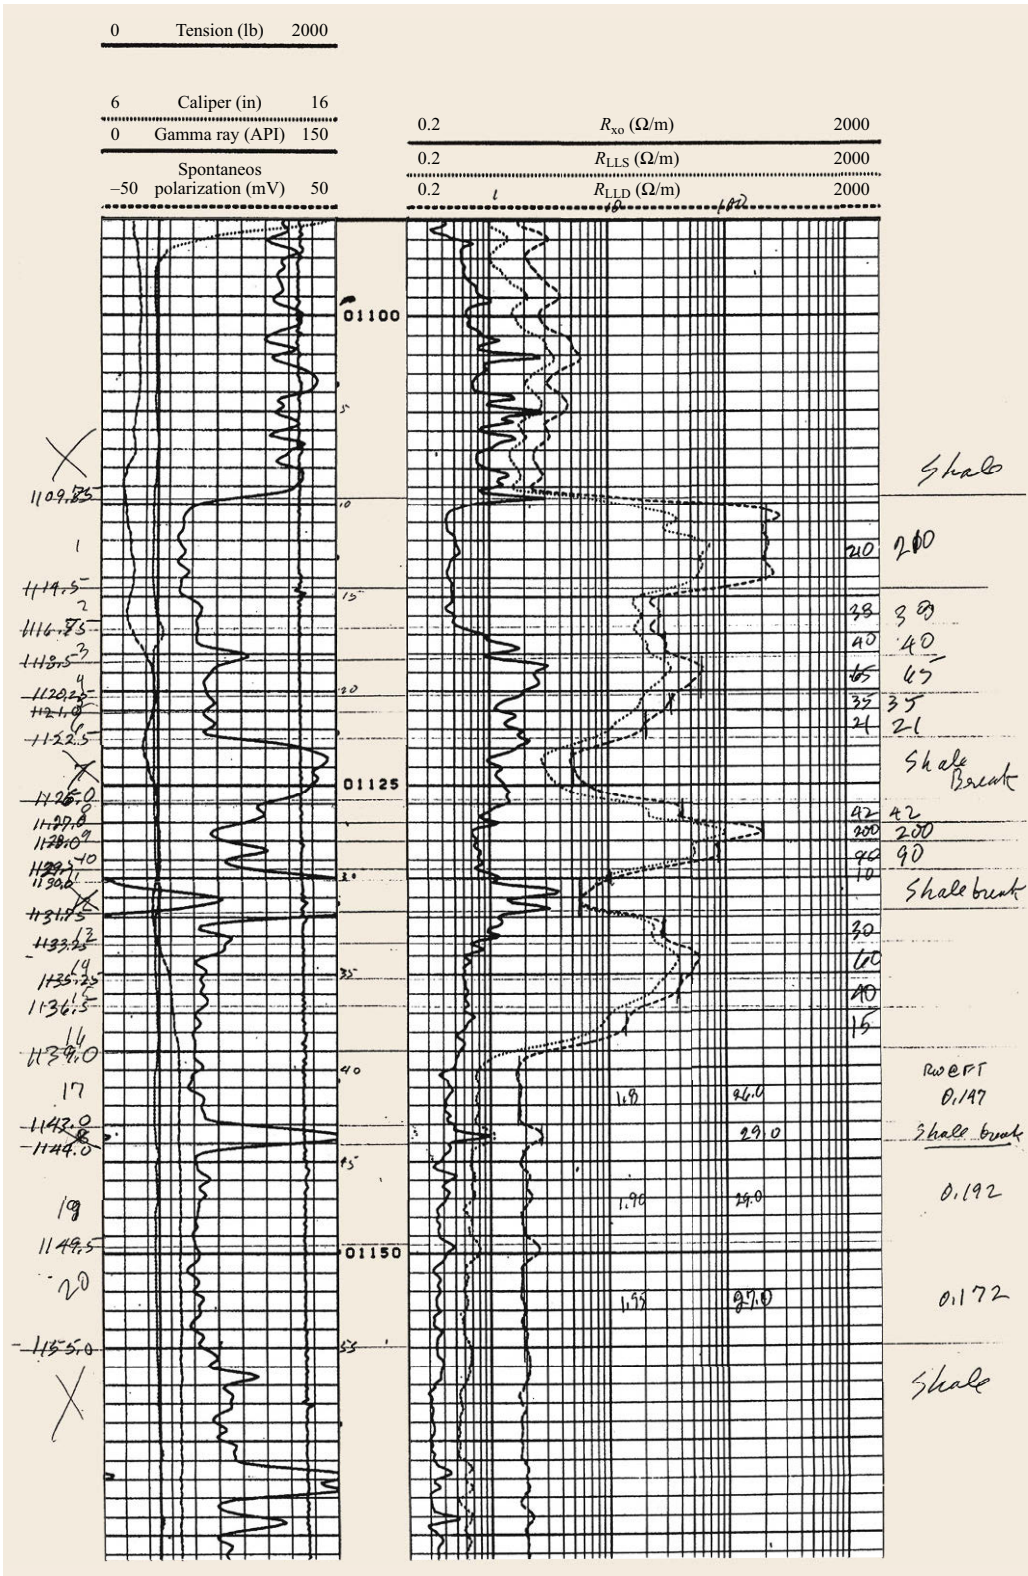

The pay zone in Figs. 13.60–13.62 has been broken into 14 separate analysis levels of essentially constant log values for manual analysis. Three additional analysis levels in the water leg, below the pay zone, are also included for estimating R_w . The deep laterolog resistivities have been annotated on Fig. 13.60, the acoustic interval transit times have been annotated on Fig. 13.61, and the bulk density and neutron porosities have been annotated on Fig. 13.62. Figure 13.63 shows the density-neutron cross-plot of the Fig. 13.63 density and neutron data and is used to obtain cross-plot porosities.

Table 13.14 shows R_{wa} estimate results for the 1139.00–1143.00, 1144.00–1149.00, and 1149.50–1155.00 m depth intervals in the water leg. Porosities are taken from the Fig. 13.63 density-neutron cross-plot. Raymer–Hunt–Gardner (RHG) porosities are also estimated from the sonic log data, as a check on the density-neutron cross-plot porosities. Archie a and m coefficients are from special core analysis laboratory (SCAL) results. Formation temperatures are estimated from a field-wide temperature-depth model. Formation water apparent NaCl salinities for the three R_{wa} estimates are also estimated as a check on the R_{wa} estimation.

Table 13.15 shows Archie S_w estimates for the 14 analysis intervals. Archie S_w is also estimated for the uppermost water leg analysis level, as a check on the S_w estimation. Density/neutron cross-plot porosities are used with RHG porosities estimated for verification. Deep laterolog resistivities (R_{LLD}) are used instead of the deep induction log resistivities because the well was drilled with high salinity (KCl) mud. The reservoir summary for this manual analysis is shown in the lower left-hand corner of Fig. 13.64, as:

- Gross pay: 29.25 m
- Net pay: 24.00 m
- Average porosity: 26.9%
- Average S_w : 17.0%.

13.12.3 Computer-Aided Analysis

For comparison, Fig. 13.64 shows a computer-aided detailed log analysis for the Western Australia well. This

detailed evaluation utilized environmentally corrected log data, with more complex porosity and S_w models than the above manual analysis. Because of this, the results, though similar, are slightly different.

13.13 Summary

Wireline measurements have evolved from simple surface resistivity profiling arrays dropped down boreholes for well-to-well correlation to complex multimeasurement tool stacks, used to provide data for estimating reserves. Along the way specialized drill collars have been developed to duplicate wireline measurements and specialized tools developed for other useful downhole measurements.

Acknowledgments. This chapter is based on a one-day petrophysics review I developed for Chevron Overseas Petroleum, Inc. management and updated several times since. Anyone who attempts to do such a review stands on the shoulders of everyone who has gone before. In preparing this chapter, information has been collected from several sources. While many of the graphics and tabulations are my own, many oth-

ers have come from published sources, from in-house courses taught at Chevron, or from student presentations in classes taught at the University of Southern California, as well as the cited sources in the text and references. I would particularly like to express my gratitude to the Society of Petrophysicists and Well Log Analysts and the Petroleum Extension Service of the University of Texas, for permission to use graphics from their publications, as well as Baker-Atlas, Halliburton and Weatherford for permission to use some of their graphics. In many cases, these three vendors offered better examples than the graphics I originally asked to use. Finally, I appreciate the patience of Hsu Chang, the editor of this publication, for his patience while I tracked down permissions to use the third-party graphics I wanted to use to illustrate my thoughts.

Petroleum Production Engineering

Shengnan Chen

Petroleum production engineering focuses on producing hydrocarbons from well bottom-hole to surface through the wellbore. In this chapter, the terms inflow performance relationship, tubing performance relationship and choke performance relationship are firstly introduced, which relate the production rates with the in situ pressure along the flow path of the reservoir fluids in the wellbore. Different artificial lift techniques are then discussed to either resume production from a well where no flow is occurring or to achieve a higher production rate by lowering the well flowing bottom-hole pressure. Well stimulation methods, including matrix acidizing and hydraulic fracturing, are finally presented, which enhance the well production rate either by removing the skin from the well, or creating high conductive flow paths for the reservoir fluids to flow to the bottom-hole of the producers.

The goal of petroleum production engineering is to maximize oil and gas production in a cost effective manner. It involves a series of techniques to ensure the inflow of oil and gas to the wellbore, to lift the fluids to the surface efficiently, and to separate produced oil, gas

and water on the surface. As an important subsystem of oilfield development engineering, petroleum production engineering is closely related to reservoir engineering and the storage and transportation engineering of oil and gas.

14.1 Flowing Wells and Gas Lift

Initial reservoir pressure and economic cost analysis determines what methods can be used to extract oil out of the reservoirs. In petroleum production engineering, engineers are concerned with transporting reservoir fluids from the well bottom-hole to the wellhead at surface. There are mainly two categories of production methods:

- Natural flow: reservoir fluids can flow to the surface naturally due to pressure in the formation.
- Artificial lifting: reservoir fluids must be lifted when there is insufficient pressure in the reservoir to lift the produced fluids to the surface.

Schlumberger claims that of the approximately one million oil and gas wells producing in the world, roughly 5% flow naturally – leaving nearly all of the world's oil and gas production reliant on efficient artificial lift operations.

14.1.1 Inflow Performance Relationship

The inflow performance relationship (IPR) is one of the most important methods for analyzing well production. IPR reflects the ability of fluids to flow from a reservoir to a well by quantifying interactions between well

production rate, well bottom-hole flowing pressure and reservoir pressure.

According to Darcy's law (14.1), well production rate can be expressed as

$$q_o = J (P_e - P_{wf}) , \quad (14.1)$$

where:

- q_o Well production rate (m^3/s)
- P_e Reservoir pressure (Pa)
- P_{wf} Well flowing bottom-hole pressure (Pa)
- J The productivity index ($\text{m}^3/(\text{Pa s})$).

The productivity index J , reflects the relationship of reservoir parameters, fluid properties, completion conditions, drainage area, and production rates.

IPR for Single-Phase Reservoirs

At initial reservoir conditions, the pressure of a reservoir may be above the bubble-point pressure of the hydrocarbon fluids. If so, it is referred as an undersaturated reservoir. Bubble-point pressure refers to the pressure (at a given temperature) at which the natural gas begins to come out of the oil and form bubbles. If well flowing bottom-hole pressure is also above the bubble-point pressure, then the reservoir only has single phase (hydrocarbon liquid) flow. For single-phase flow in the reservoir, the productivity index can be analytically calculated for different flow regimes.

Flow in a reservoir is often characterized as being one of two types: transient flow or boundary-dominated flow. The transient flow regime exists before the pressure wave created by well production has reached any reservoir boundary yet. Once the pressure wave reaches the boundary, steady-state or pseudosteady-state flow may appear in the reservoir, depending on the pressure condition at the boundary.

Transient Flow. Transient flow refers to a flow regime where the pressure wave has not reached the reservoir boundary. For a well located in the center of a circular reservoir, the productivity index equation for transient flow can be expressed as

$$J = \frac{q_o}{P_i - P_{wf}} = \frac{4\pi k_o h}{\mu_o B_o \ln \left(\frac{4k_o t}{\gamma \phi \mu_o c_t r_w^2} + S \right)} , \quad (14.2)$$

where:

- P_i Initial reservoir pressure (Pa)
- k_o Effective permeability (m^2)
- B_o Oil volume factor (m^3/sm^3)
- h Effective height (m)
- μ_o Oil viscosity (Pa s)
- r_w Wellbore radius (m)

- t Time (s)
- γ Euler's constant = 1.78
- ϕ Porosity
- c_t Total compressibility factor ($1/\text{Pa}$)
- S Skin factor, influenced by well completion, down-hole damage or well stimulation and obtained from build-up curve.

The flow time required for the pressure wave to reach a circular reservoir boundary can be expressed as

$$t_{\text{pss}} = 1200 \frac{\phi \mu_o c_t r_e^2}{k_o} , \quad (14.3)$$

where r_e is the radius of the drainage area (m).

Steady-State Flow. A steady-state flow regime may appear once the pressure wave reaches the boundary. In steady-state flow, all parameters including pressure, temperature and flow rate at any single point of the system do not change over time. Pressure at the boundary for steady-state flow is constant and could be maintained by a water injection well or an aquifer.

For a well located in the center of the circular reservoir with a constant pressure boundary, the productivity index of the production equation can be expressed as

$$J = \frac{q_o}{P_e - P_{wf}} = a \frac{2\pi k_o h}{\mu_o B_o \left(\ln \frac{r_e}{r_w} + S \right)} , \quad (14.4)$$

where a = unit conversion factor, which is $a = 1$ Darcy in SI units; $a = 86.4$ when units of measure are q (m^3/d), k (μm^2), μ (mPa s), h (m), p (MPa). If the unit of pressure is kPa, $a = 0.0864$.

Pseudosteady-State Flow. Pseudosteady-state flow may appear once the pressure wave reaches the boundary. In pseudosteady state flow, the pressure at any point in the reservoir declines at the same constant rate over time. For circular closed reservoirs, where there is no liquid flow at the boundary, the productivity index in the production equation at pseudosteady state can be expressed as

$$J = \frac{q_o}{\bar{P}_r - P_{wf}} = \frac{2\pi k_o h}{\mu_o B_o \left(\ln \frac{r_e}{r_w} - \frac{3}{4} + S \right)} , \quad (14.5)$$

where \bar{P}_r is the average reservoir pressure (Pa).

A shape factor needs to be used if the close drainage area is noncircular. Values of the shape factor for different shapes can be found elsewhere.

IPR Curves for Single-Phase Reservoirs. An IPR curve is a graphical presentation of the relationship between well production rate and well flowing bottom-hole pressure. IPR curves for single-phase reservoirs

are straight lines as shown in Fig. 14.1. The slope of the IPR curve is the productivity index, J , which is constant in a single-phase reservoir.

IPR for Two-Phase Reservoirs

Productivity index, J , presented in the previous section, is valid for reservoir pressure and well flowing bottom-hole pressure values as low as the bubble-point pressure, when single-phase flow exists in the reservoir. When the reservoir pressure drops below the bubble-point pressure, the dissolved gas escapes from the oil and becomes free gas. Both oil and gas will be flowing in the formation.

Vogel [14.1] proposed a dimensionless IPR equation for dissolved gas drive reservoirs

$$q_o = q_{o \max} \left[1 - 0.2 \frac{P_{wf}}{P_r} - 0.8 \left(\frac{P_{wf}}{P_r} \right)^2 \right], \quad (14.6)$$

$$q_{o \max} = \frac{J^* \bar{P}}{1.8}, \quad (14.7)$$

where J^* is the productivity index when reservoir pressure is above the bubble-point pressure.

IPR Curves for Two-Phase Reservoirs. An IPR curve for a two-phase reservoir is shown in Fig. 14.2. The productivity index, J , is not constant, but keeps decreasing as well flowing bottom-hole pressure decreases in a two-phase reservoir.

IPR for Partial Two-Phase Oil Reservoirs

Partial two-phase reservoirs refer to the cases where the reservoir pressure is above the bubble-point pressure,

Fig. 14.1 A typical IPR curve for an oil well in a single-phase reservoir

Fig. 14.2 A typical IPR curve for an oil well in a two-phase reservoir

while the well flowing bottom-hole pressure is below the bubble-point pressure. A generalized IPR model needs to be applied under such circumstance

$$q = J^* (\bar{P} - P_b) + \frac{J^* P_b}{1.8} \left[1 - 0.2 \left(\frac{P_{wf}}{P_b} \right) - 0.8 \left(\frac{P_{wf}}{P_b} \right)^2 \right], \quad (14.8)$$

where P_b is the bubble-point pressure of the reservoir fluids (Pa).

IPR Curves for Partial Two-Phase Reservoirs. An IPR curve for a partial two-phase reservoir is shown in Fig. 14.3. The productivity index, J is constant when well flowing bottom-hole pressure is larger than bubble-point pressure in a two-phase reservoir. When well flowing bottom-hole pressure is lower than bubble-point pressure, J is not constant, but decreases as well flowing bottom-hole pressure decreases.

Fig. 14.3 A typical IPR curve for an oil well in a partial two-phase reservoir

14.1.2 Tubing Performance Relationship (TPR)

Flow Regimes

In the wellbore, the pressure of the reservoir fluid decreases as it flows from the well bottom-hole to the wellhead. If the pressure drops below the bubble point in the wellbore, the following four flow patterns may occur in a vertical wellbore (Fig. 14.4):

1. Bubble flow
2. Slug flow
3. Annular flow
4. Mist flow.

In bubble flow, small gas bubbles are dispersed in the liquid phase. Gas is the dispersed phase and liquid is a continuous phase. In slug flow, with expanding gas bubbles, small bubbles merge into large bubbles until

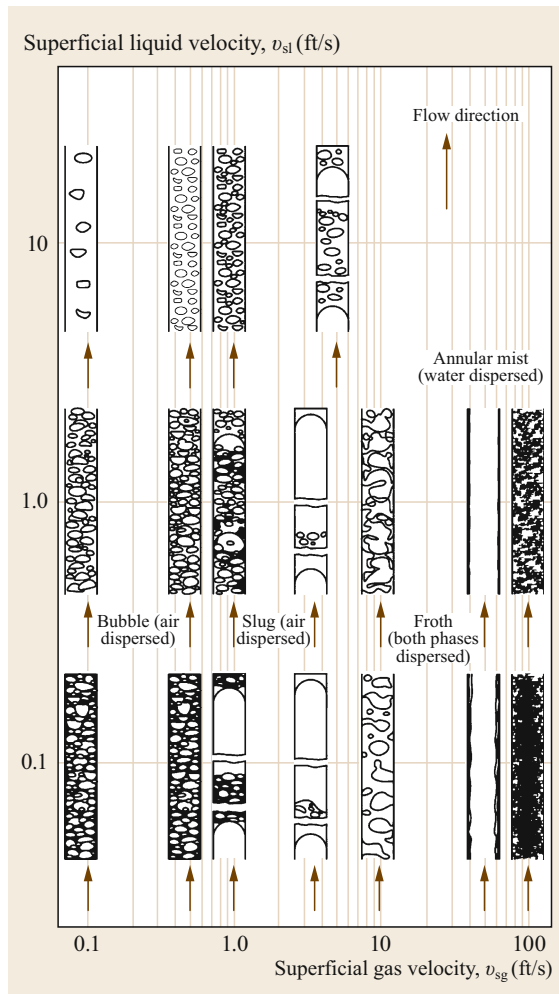

Fig. 14.4 Flow regimes in gas-liquid flow (after [14.2])

the entire cross-section is occupied by the gas phase. In annular flow, as the gas volume further increases, the continuous gas phase occupies the center of the tubing and the liquid phase appears as a ring flowing along the wall of the tubing. Gas and liquid phase are both continuous in annular flow. In mist flow, liquid exists as liquid droplets, which are dispersed in gas flow. The gas is the continuous phase and the liquid is dispersed phase.

Liquid Holdup

Due to the density difference between liquid and gas, and the low mixture flow rate, the gas phase rises faster than the liquid phase when oil and gas flow upward simultaneously in the wellbore. This phenomenon is called gas slippage. As a result of the slippage, the density of the in situ gas-liquid mixture will increase. The denser liquid phase is held up in the wellbore relative to the lighter gas phase. Thereby the hydrostatic head of the mixture, which is a function of gravity, also increases. Additional energy loss arising from slippage is called slippage loss.

TPR Models

Based on energy balance equations, the pressure gradient of multiphase flow along the vertical wellbore can be expressed as

$$\frac{dP}{dz} = \rho g + \rho v \frac{dv}{dz} + f \frac{\rho v^2}{2D}, \quad (14.9)$$

where:

P Pressure (Pa)

z Height of the fluid mixture calculated from the midpoint of pay zone (m)

ρ Fluid density (density of the mixture) (kg/m^3)

g Gravity acceleration (m/s^2)

v Mixture velocity (m/s)

f Darcy-Weisbach friction factor of mixture flow, which can be determined by Fig. 14.5

D Tubing diameter (m)

It can be seen from Fig. 14.5 that the friction factor is a function of Reynolds number and relative pipe roughness. Reynolds number is a dimensionless quantity in fluid mechanics used to determine whether a fluid flow pattern is laminar or turbulent flow. The relative pipe roughness is its absolute roughness divided by the internal diameter of the pipe.

Homogeneous Model. In 1952, *F.H. Poettmann* and *P.G. Carpenter* proposed a method to calculate a friction loss coefficient (or energy loss coefficient) for the pressure gradient of the gas-liquid vertical flow [14.4]. The features of this method are as follows:

Fig. 14.5 Moody friction factor diagram (after [14.3])

1. The acceleration term is ignored in the pressure gradient equation, which is the second term on the right-hand side of (14.9)
2. No specific flow pattern description is used
3. Density calculations are done without considering slippage
4. Friction loss coefficients are calculated from the relationship curve of $f \approx Dv\rho$ based on the field data.

Because the curves of f are obtained from the field data, the impacts of the friction, slippage and acceleration are all taken into consideration. The calculation method for the loss resulting from these factors is similar to that of calculating friction loss. Obviously, the fluid viscosity and the liquid holdup are not considered in the homogeneous models.

Separated Flow Model. Separated flow models are more realistic than the homogeneous flow models. In situ density of the fluid mixture along the wellbore is calculated by determining the liquid holdup, and different flow regimes are also considered in the separated flow models. Many separated models are available for TPR calculations, and they all include empirical correlations in different models.

In 1967, *Orkiszewski* proposed a new method based on the analysis of previously published methods [14.5]. *Orkiszewski* compared previous methods with measured data and found that the *Griffith* and *Wallis* method [14.6] and the *Duns* and *Ros* method [14.7] were relatively accurate. The *Griffith* and *Wallis* method was more reliable in the low flow-rate range of slug flow, but it was not accurate at the high flow-rate range. The *Duns* and *Ros* method also shared a similar problem. *Orkiszewski* improved the *Griffith* equation of slug flow by extending it to the high-rate range, which increased the application range. When dealing with transitional flow patterns, *Orkiszewski* used the same approach with the *Duns* and *Ros* interpolation method. In *Orkiszewski*'s model, the retention rate (the ratio of one-phase volume to total volume in a pipe interval) was determined based on observed physical phenomena. The distribution pattern of gas and liquid phases should also be considered in calculating the pressure gradient of slug flow. Thus, calculation methods of retention rate and friction loss for each flow pattern (bubble flow, slug flow, transition flow and mist flow) were proposed in *Orkiszewski*'s model.

The method of calculating pressure gradients was similar to that of calculating friction loss coefficients

based on different flow patterns. The only difference was that the flow pattern needed to be determined in advance based on flow pattern boundaries before calculating mixture density and friction gradient.

14.1.3 Choke Performance

Once reservoir fluid reaches the surface of a flowing well, it will then pass through a choke, which is located on the wellhead. A wellhead choke controls the surface pressure and production rate from a flowing well. Chokes usually are selected so that fluctuations in the line pressure downstream of the choke have no effect on the production rate.

As shown in Fig. 14.6, the pressure difference through a choke is calculated based on the pressure before the choke (P_1) and the pressure after the choke (P_2). Due to the low tubing head pressure, gas expands at the wellhead and the gas flow rate increases significantly. The diameter of the wellhead choke is relatively small, and thus the flow rate of the mixture through the choke is extremely high and may reach the critical flow velocity. Critical flow occurs when the fluid flow rate reaches the propagation velocity of the pressure wave in the fluid media.

At this point, we can regard the gas–oil flow through the choke as nozzle flow at critical conditions. Under such conditions, the relationship between the mass flow through the choke and the pressure difference of the choke is shown in Fig. 14.6.

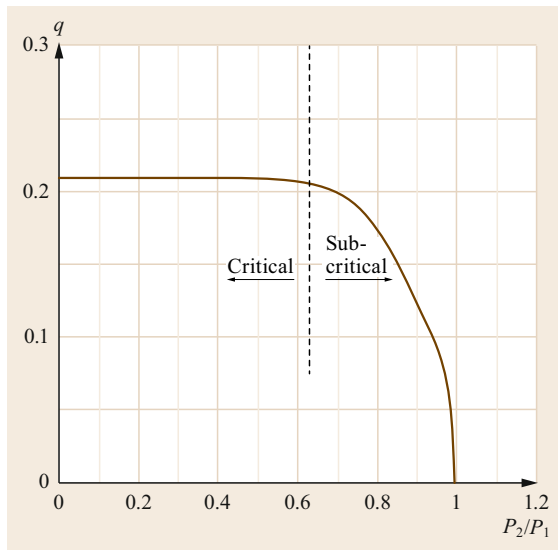

Fig. 14.6 Dependence of flow rate through a choke on the ratio of the upstream to the downstream pressure (after [14.8])

The critical pressure ratio is the pressure ratio P_c/P_1 at the maximum flow rate. Based on the thermodynamic calculation, the critical pressure ratio is

$$\frac{P_c}{P_1} = \left(\frac{k}{k+1} \right)^{\frac{k}{k-1}}, \quad (14.10)$$

where k = gas adiabatic exponent – for natural gas, k is 0.546.

The critical pressure ratio when air flows through the nozzle is

$$\frac{P_c}{P_1} \approx 0.528. \quad (14.11)$$

Based on (14.11), when the pressure ratio is equal to or less than 0.528, the flow rate is about equal to the speed of sound. Under the critical flow condition, that is, $P_2/P_1 = P_c/P_1 \leq 0.528$, the flow rate change is only affected by P_1 , i. e., the pressure before the choke.

The pressure before the choke is the tubing head pressure, which can be calculated by

$$P_t = \frac{cR^n q}{d^m}, \quad (14.12)$$

where:

- P_t Tubing pressure (Pa)
- R Oil gas ratio
- q Oil production
- d Choke diameter
- c, m, n Constant.

Due to the difference of fluid properties and mixture types of oil and gas, the constants c , m , and n may take different values, which are shown in Table 14.1.

14.1.4 Gas Lift

An oil well cannot flow naturally if the formation pressure is not high enough to push the reservoir fluids up to the surface. In order to maintain or increase the oil production rate, high-pressure compressed natural gas or air is injected into the lower section of the wellbore to propel the reservoir fluids to the surface. This is called gas lift. Besides pushing the liquid by its expansion energy, the high-pressure compressed gas aerates the liquid to reduce its effective density, thus facilitating the liquid reaching the surface.

Table 14.1 A summary of c , m , and n values given by different researchers

Correlation	c	m	n
Gilbert [14.9]	10.0	0.546	1.89
Ros [14.10]	17.4	0.5	2.0
Baxendell [14.11]	9.56	0.546	1.93
Achong [14.12]	3.82	0.65	1.88
Pilehviri [14.13]	46.67	0.313	2.11

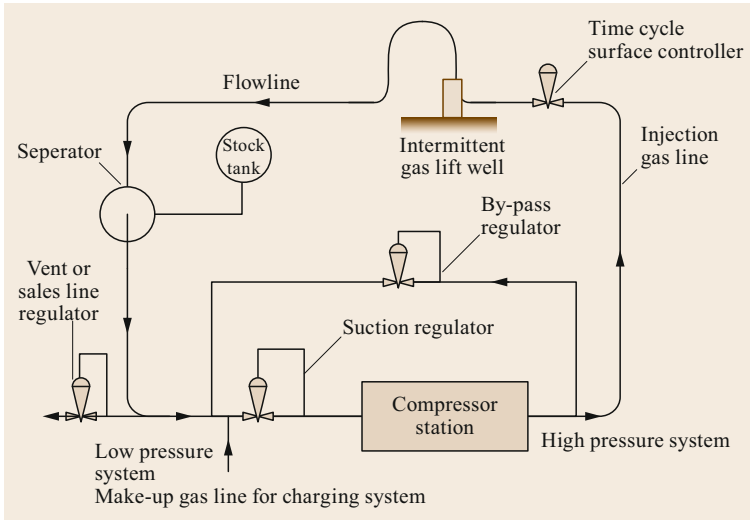

Fig. 14.7 A simplified flow diagram of a closed rotary gas lift system for a single intermittent well (after [14.8])

Fig. 14.8 Gas-lift concept (after [14.14])

Gas lift can be widely applied to high-productive and deep wells from which the fluids contain small

amount of sands, water, corrosive substances, and which have large gas-oil ratios. However, sufficient gas

sources, usually natural gas produced from nearby gas and oil wells, are the prerequisites to applying the gas lift method.

Based on the injecting operations, gas lift can be classified as continuous or intermittent. In continuous gas lift, high-pressure gas is continuously injected. Continuous gas lift is especially applicable to high-production wells with reasonable reservoir pressures. In intermittent gas lift, gas is injected periodically to lift the fluid plugs that form during injection intervals. Figure 14.7 depicts a simplified flow diagram of a closed rotary gas lift system for a single intermittent well. Intermittent gas lift operations have a start-and-stop gas

injection pattern, which is regulated by the time cycle surface controller. It is mainly used for low-production wells with low reservoir pressures.

Figure 14.8 illustrates the subsurface configuration of a gas lift well. Injected high pressure gas flows in the annulus and enters the tubing through the operating valve and gets mixed with the reservoir fluids. Multiple valves may be installed in a well during a gas lift operation. To obtain the maximum efficiency, the tubing end should reach the middle of the pay zone to produce fluids at the maximum submergence depth. Thus, even if reservoir pressure drops after a period of time, high efficiency gas lift can still be maintained.

14.2 Artificial Lift

Artificial lift increases production rates from a producing well. Generally this is achieved by the use of a mechanical device (e.g., pump) inside the well.

During development of oil fields, producing wells cannot always flow naturally. For some wells, natural flows can significantly reduce and eventually stop when there is insufficient pressure in the reservoir. For some other wells, natural flows cannot occur initially due to low formation pressure or high viscosity reservoir fluids. In these situations, artificial lift is required. Artificial lift may also be applied in naturally flowing wells to increase the oil production rate above what would flow naturally.

Artificial lift methods can be classified as gas lift and pumping. Commonly used well pumps include sucker rod pumps, hydraulic pumps, electrical submersible pumps, progressive cavity pumps, and plunger pumps. Although recent technology has facilitated the use of more and more electrical submersible pumps and hydraulic pumps, especially in deep wells, the majority of artificial lift pumps are still sucker rod pumps.

14.2.1 Sucker Rod Pumping

Sucker rod pumping (also known as beam pumping) consists of a pumping unit, a pumping rod and a downhole plunger pump. Figure 14.9 shows the schematic diagram of a working sucker rod pumping unit.

Pumping Unit

Pumping unit refers to the surface equipment. A beam pumping unit mainly includes a horsehead, polished rod, walking beam, crank arm, gear box, power, and assistive devices. When it is working, the speed rotary motions of the power machine are transferred to a crank shaft through a belt and a reducing gear box, in order to rotate the crank slowly. Such rotary motions are then

converted into the reciprocally up and down motions of the horsehead by the walking beam and a pitman. As a result, the horsehead drives the polished rod up and down to lift reservoir fluids.

Downhole Plunger Pump

A plunger pump is a downhole device used with a sucker rod pumping unit in the well. Normally, besides oil, the pumped reservoir fluids also contain sand, wax, gas, water and corrosive substances. As it usually works at hundreds or thousands of meters deep, the pump has to tolerate pressure of more than 20 MPa. The efficiency of the pump directly affects the production rate of the producing well.

The bottom of the pump barrel is installed with a sucking valve (also known as standing valve), which can only open in upwards movements. Using a polished rod, a plunger is put down into the pump barrel. A discharge valve (also known as traveling valve), which only opens in upwards movements, is installed on the plunger.

A stroke process includes an upstroke and a downstroke. In one cycle, reservoir fluids flow into plunger, and then into the tubing above the plunger. The maximum moving distance of polished rod in a cycle is called polished rod stroke.

Upstroke. In this process, the pumping rod drives the upward movement of the plunger and the traveling valve, as shown in Fig. 14.10. The traveling valve on the plunger is closed due to fluid pressure in the tubing. Meanwhile, the pressure below the plunger is reduced, and the standing valve is opened because of the pressure difference between fluid pressure and the pressure in the pump. The reservoir fluids pass the standing valve and enter the cylinder. If the tubing is filled with reservoir fluids, the produced fluid volume from the

Fig. 14.9 Rod-pumped well (after [14.15])

Fig. 14.10 Working principle of the plunger lift (after [14.16])

wellhead is equal to the volume corresponding with stroke length. Therefore, during the upstroke process, the plunger pump sucks in fluids, while the wellhead discharges fluids. To suck fluids into the pump, the pressure in the pump should be lower than a submergence pressure.

Downstroke. During this motion, the pumping rod drives the plunger and traveling valve downward, as shown in Fig. 14.10. The standing valve is closed. The traveling valve is opened once the pressure in the pump exceeds the pressure exerted by the liquid column above. As a result, liquids below the plunger flow upward into the tubing through the traveling valve. Fluids are discharged into the tubing from the plunger pump. To discharge fluids, the pressure in the plunger pump should be larger than the pressure of the liquid column above.

14.2.2 Other Artificial Lift Methods

In addition to sucker rod pumping and gas lift systems, other artificial lift systems are used in the oil field, including electrical submersible pumping, hydraulic jet pumping, hydraulic piston pumping, progressive cavity pumping and plunger lift systems.

Electrical Submersible Pump

As shown in Fig. 14.11, an electrical submersible pump (ESP) system consists of a motor, a protection box,

Fig. 14.11 Electrical submersible pump completion (after [14.17])

a gas-liquid separator, multistage centrifugal pumps, cables, junction boxes, a control panel, and transformers. In addition, some other small components are installed in this system, including single-direction flow valves, drain valves, centralizers, downhole pressure measuring instruments, and variable speed drive devices. ESPs used in the field are multistage centrifugal

pumps operating in a vertical position and utilizing centrifugal force to lift hydrocarbons to the surface, enabling high flow and enhanced production. Electrical power is transmitted to the downhole motor by cables to drive multistage centrifugal impeller and converted into kinetic energy via the downhole pump. Produced liquids, after being subjected to great centrifugal forces

caused by the high rotational speed of the impeller, lose their kinetic energy in the diffuser where a conversion of kinetic energy to pressure takes place, and are lifted up to the surface. ESPs are considered as a high-volume pump and are adaptable to highly deviated wells, up to horizontal, but must be set in straight sections. There are more than 130 000 ESPs installed globally.

Hydraulic Piston Pumping

A hydraulic piston pump is a device without rods. High-speed fluids are injected into the tubing to drive a motor up and down reciprocally. The fluids flow through the driven cylinder and valve to assist pumping. Hydraulic piston pumping is applicable to wells of high gas-oil ratio in which the oil has a high pour point, is sand-rich and/or waxy. It also is applicable to deep and inclined wells. It consists of a surface power tank, high pressure triplex pumps, a control manifold, wellhead control valves, and a downhole pump. The downhole pump is the core component in the system, which is typically double acting. All the surface pumps are high-pressure piston pumps. There are two operational types.

Open power fluid operation is a single-tubing structure using low-viscosity oil as the power fluid. Friction loss in the pipe is low for the power fluids. In addition, the fluids can reduce the viscosity of reservoir crudes by mixing them with the low-viscosity oil.

Closed power fluid operation utilizes light oil or water as power fluids. The power fluids are self-circulating, and do not mix with reservoir crudes. The power fluids can be recycled efficiently. Therefore, limited amounts of power fluids are required.

Hydraulic Jet Pumping

Hydraulic jet pumping is a special kind of hydraulic pumping. It injects high-pressure power fluid into the well through a nozzle-throat Venturi combination, mixes with produced fluids and by the Venturi effect creates a high pressure at the discharge side of the pump. Similar to a hydraulic pumping system, a jet pumping system consists of a surface tank, a high-pressure surface pump and a downhole jet pump.

Figure 14.12 demonstrates the working mechanism of a downhole jet pump. High-pressure power fluid is ejected at high speed from the nozzle, creating a low-pressure area that sucks reservoir fluids into the throat. Then, power fluids and reservoir fluids are mixed and exchange momentum. The kinetic energy of the reservoir fluid is increased, and converted to pressure energy through a diffuser.

Jet pumping does not have moving parts in the downhole. It is applicable to high-temperature, deep,

Fig. 14.12 Sketch of a hydraulic jet pump installation (after [14.8])

high-production wells, and to crudes that contain sand, corrosive substances and are viscous, and have a high gas-liquid ratio.

Progressing Cavity Pump

A progressing cavity pump is the fastest-evolving artificial lift technology in the petroleum industry. It consists of a stator with a double helix cavity and a rotor in the sleeve cavity, which can be engaged with the stator, as shown in Fig. 14.13. When the rotor moves around the stator in the cavity, the seal chamber between the rotor and the stator moves along the tubing axially to

Fig. 14.13 Rod-driven PCP completion (after [14.18])

discharge fluids uniformly, continuously and steadily to the outlet. Progressive cavity pumps are advantageous because they are flexible, reliable, anti-abrasive and have high volumetric efficiency. With the develop-

ment of synthetic rubber and adhesive technology, the progressive cavity pump has become the major artificial lift method for cold heavy oil production with sand (CHOPS), as well as for polymer flooding.

14.3 Well Stimulation

Well stimulation refers to any well intervention performed on a production or injection well to enhance production or injection rates by improving the flow of the reservoir fluids from the drainage area into the well bore. Common well stimulation techniques include matrix acidizing and hydraulic fracturing.

14.3.1 Matrix Acidizing

Acidizing increases permeability of the formation matrix and removes skin near the wellbore. Matrix acidizing can be combined with hydraulic fractur-

ing procedures to further improve the flow capacity of the hydraulic fractures. In sandstone reservoirs, acid solution is injected into the formation to dissolve the cements in the matrix, and also to dissolve *skin* materials clogging the fractures. Such materials include clays, drilling muds and contamination of the formation during well completion. In carbonate reservoirs, acidizing is not used to recover the permeability of a damaged zone, but to create wormholes, which serve as low-resistance pathways for reservoir fluid to flow towards the production well.

Acidizing in Sandstone Formations

As with matrix acidizing, acidizing in sandstone formations dissolves the cements between sand grains and removes the damage near the wellbore. Acidizing can also dissolve materials clogging the pores or other scale to recover and improve formation permeability in the stimulated zone.

In sandstone formations, there is more argillaceous sandstone with less carbonate content. Ordinary hydrochloric acid (HCl) treatment can't achieve the desired performance improvement. For this application, the acid mixture includes 10–15% HCl, 3–8% hydrofluoric acid (HF) and additives. This mixed acid is usually referred as hydrofluoric-hydrochloric or mud acid.

The HF in mud acid is a strong acid and can dissolve all kinds of components in the sandstone (such as quartz, clay and carbonate). However, the HF cannot be used alone. The main role of HCl in the mud acid is to dissolve the carbonate and maintain a low-pH environment in the acid solution. This treatment will considerably recover and improve the permeability of the formation near the wellbore.

Acidizing in Carbonate Formations

Acidizing in carbonate reservoirs is used to create wormholes, through which reservoir fluids can flow after stimulation. Minerals in carbonate reservoirs mainly include calcite (CaCO_3) and dolomite ($\text{Mg}(\text{CO}_3)_2$). When the calcite content is more than 50%, the carbonate reservoirs are classified as limestone formations. On the other hand, when the dolomite content in the reservoirs is more than half, the carbonate reservoirs are classified as dolomite formations. In carbonate reservoirs, pores and fractures comprise the dominant pore space for the reservoir crude. Based on the type of pores and seepage channels, carbonate reservoirs can be classified into three categories:

1. Porous-type carbonate reservoirs
2. Fracture-porous carbonate reservoirs
3. Fractured carbonate reservoirs.

In the porous-type carbonate reservoirs, pores provide the primary crude storage space and seepage channels. In fracture-porous carbonate reservoirs, the main

seepage channels are fractures. However, the reservoir fluid storage space and seepage channels are different in fractured reservoirs. It is generally accepted that for a naturally fractured carbonated reservoir with high matrix porosity and low matrix permeability, matrix provides the dominant fluid storage space and fractures provide the seepage channels [14.19]. Acidizing in carbonate reservoirs mainly deals with the contaminations in the pores and fractures. In addition, it also can increase the intrinsic permeability by expanding the original fractures and pores.

Hydrochloric acid (HCl) plays an important role in acidizing treatment in carbonate reservoirs. When the HCl is injected into the reservoir pores or fractures, it will react with the fracture surface. HCl reacts with CaCO_3 to form CaCl_2 , CO_2 and H_2O . The acidizing parameters between the HCl and CaCO_3 at different concentrations of HCl are summarized in Table 14.2 [14.8].

Using appropriate acids and additives in matrix acidizing treatments is of crucial importance in enhancing oil production. The most commonly used acid for carbonate formations is HCl. Mixtures are used, including the formic acid, acetic acid, and multicomponent acid, which is a mixture of HCl, formic acid and acetic acid. Sulfamic acid can also be used in carbonate reservoir acidizing treatment. A wide variety of acids, such as oleic acid emulsions, concentrated HCl solutions and foamy HCl, are used to control reaction rates.

HCl is a strong acid, which can react with lots of metals, metal oxides, salts and other alkaline materials. When HCl reacts with carbonates, it produces highly soluble chlorides, such as CaCl_2 and MgCl_2 , leaving behind a residual acid solution without any precipitation. In the acidizing process, the higher extent of heterogeneous dissolution on the fracture face, the higher the fracture conductivity. In addition, the low cost of HCl makes it the most popular acidizing agent for stimulation treatment.

The advantages of high-concentration HCl treatment are:

1. When high-concentration HCl solutions are used for matrix acidizing, the reaction rate between acid and

Table 14.2 Acidizing parameters between HCl and CaCO_3 at different HCl concentration

HCl concentration (%)	5	10	15	20	28
HCl specific gravity	1.025	1.05	1.075	1.1	1.14
HCl content in 1 m ³ HCl solution (kg)	51	105	161	220	320
CaCO_3 corrosion ^a by 1 m ³ HCl solution (m ³)	0.026	0.053	0.081	0.111	0.162
Standard volume of generated CO_2/m^3	15.8	32	49.5	68	98
Weight percent of CaCl_2 solution (%)	7.3	14.1	20	26.3	35
Acid solution volume to dissolve 1 m ³ CaCO_3/m^3	38.4	18.9	12.4	9	6

^a The specific gravity of CaCO_3 is 2.71

rock matrix is relatively slow, which can increase the effective radius of acidizing.

2. The matrix acidizing process with HCl generates CO₂ gas, which leaves the formation and does not contribute to sludge formation. Hence, the amount of sludge is relatively low, which reduces sludge acid flow-back.
3. Usually, there is more calcium than magnesium in carbonate rocks. Therefore, acidizing will generate more calcium chloride and magnesium chloride. These chlorides increase the viscosity of sludge acid. Also, as chloride concentrations increase, they moderate the reaction rate between unreacted acid and the rock matrix. In addition, the higher viscosity improves the ability of the sludge acid to suspend solid particles and carry them out of the formation.
4. At high concentrations, HCl is less likely to be affected by reservoir water dilution. The disadvantage of HCl acidizing is that the initial reaction rate between the acid and limestone can be too fast, especially in deep wells with high temperature. As a result, acidizing mainly takes place near the wellbore. In addition, HCl will cause a lot of metal pitting, and even lead to severe corrosion. In wells with high H₂S content, HCl acidizing can lead to hydrogen embrittlement of steel.

14.3.2 Hydraulic Fracturing

Hydraulic fracturing uses a fracturing fluid (e.g., water) to transmit pressure to the formation around the well. A high pressure and large discharge pump is used on the surface. As large amounts of fracturing fluid are injected into the well, the well bottom-hole pressure increases. One or several fractures will be created near the wellbore once the well bottom-hole pressure exceeds the formation fracture threshold pressure. Fractures extend deep into the reservoir until the injection rate is equal to the rate at which the fracturing fluid seeps away. Proppants (such as sand) are added to the fracturing fluid to prevent the fracture from closing after stimulation, leaving behind multistage proppant-packed fractures with high flow conductivity.

Production after hydraulic fracturing stimulation is enhanced due to the following reasons:

1. *The flow resistance is decreased.* Before fracturing, the flow from the reservoir to well bottom-hole follows the rule of radial fluid flow. Pressure is mainly consumed in overcoming the flow resistance near the wellbore. The flow conductivity of the fractures is much higher than that of the unfractured matrix, and the flow area becomes larger too.
2. *Fractures break through near wellbore contamination.* Over time, various impurities accumulate near

the wellbore and form a blocked (contaminated) area, which reduces the well production rate. Fracturing breaks through the blocked area, allowing the reservoir fluids to flow through the blockages.

3. Fracturing expands the natural microfractures in the reservoir and connects them. This increases the effective reservoir volume, which significantly boosts the well productivity.

Fracturing Fluids

Commonly used fracturing fluids include water-based fluids, oil-based fluids, and emulsion-based fluids. Foam-based fracturing fluids are also used in the field.

Water-based fracturing fluid is a water-based solution with different chemical additives. Water-soluble polymers can improve the solution viscosity after dissolving in the water. Other commonly used additives include: demulsifiers, emulsion breakers, preservatives, antileaking agents, friction reducers, fungicides and stabilizers. Water-based fracturing fluid has high viscosity, can carry abundant proppants, and has good thermal stability and good rheological properties. But it may leak off to the formation and cause formation damage.

Oil-based fracturing fluids are usually crude oil or thickened crude oil acid-based fluids. Thickened crude oil will automatically break once encountering the formation brine. Oil-based fracturing fluid can prevent the swelling of the formation clay, which minimizes formation damage. However, oil-based fluids have low viscosity, poor thermal stability, low proppant carrying capability and low fracturing efficiency.

Emulsion fracturing fluids usually consist of oil and gelled water. The combination has the advantages of both constituents. Because the continuous phase is water, the friction of the emulsion is low, the viscosity is high, and the thermal stability is good. Also, the emulsion has high proppant carrying capability and low leak-off velocity. And it can prevent the swelling of clay.

Foam fracturing fluids are a mixture of liquid (e.g., water), gas (e.g., nitrogen) and chemical additives. Formation damage caused by such fluids is less due to the low leak-off rate into the formation.

Proppants

Currently, the mostly used proppants include ceramic proppants, resin-coated sands, and natural sands.

Natural sands have been widely used in shallow formations (less than 1500 m) and have a high success rate. Natural sands have high quartz contents, uniform particle sizes and high sphericity. In addition, natural sands are abundant and costs are lower compared to other proppant types. The main component of natural sand is coarse quartz without crystal cleavage. It will break into small pieces under high pressure, leading to lower

fracture conductivity. The highest stress quartz sand can stand is in the range of 21 and 35 MPa.

Ceramics are the most commonly used artificial proppants. The mineral constituents are alumina, silicates and iron-titanium oxide. Ceramic proppants have irregular shapes, with sphericities of around 0.65. Importantly, they have high strength. Ceramic proppants are suitable for deep reservoirs with high fracturing closure stress. Under 70 MPa fracturing closure stress, the permeability of ceramic pack is one order of magnitude higher than that of natural sand pack. The high density of the ceramic proppants requires high quality fracturing fluid, especially in deep high-temperature wells.

Resin-coated proppant has moderate strength, and can stand a fracture closure stress of between 56.0 and 70.0 MPa. Resin-coated proppant is produced by wrapping resin film on sand; the thickness of the resin film is about 0.0254 mm, accounting for about 5% of the weight or less.

Fracture Initiation and Propagation

Initiation pressure is the pressure at which fracture initiation starts in the formation rock. When the well bottom-hole pressure reaches initiation pressure, the fracture begins to propagate. This can be identified by a sudden pressure drop, shown as the breakdown pressure in Fig. 14.14. Figure 14.14 depicts the pressure change during fracturing operation of one stage. ISIP refers to the instantaneous shut-in pressure which equals the final injection pressure minus the pressure drop due to friction. Fracture closure pressure is equal to the minimum in-situ stress. Fracture will be closed once the pressure in the fracture is less than the fracture closure pressure. The fracture will continue to propagate into the formation if more fluid is injected. When the injection rate equals the leak-off rate, the propagation of fractures stops.

Fig. 14.14 Typical stress test pump-in/shut-in (after [14.20])

Fracture Model

There is still controversy about whether a single fracture or multiple fractures are created in a hydraulic fracturing job. The Perkins–Kern–Nordgren (PKN) model is one of the widely used models to predict the geometry of the fracture. It was developed by Perkins and Kern in 1961 [14.21]. In 1972, Nordgren [14.22] modified the Perkins and Kern model by adding terms for leak-off and storage within the fracture to the solution, thus, the model is commonly called PKN model. The PKN model assumes that fracture has a constant height and propagates along the horizontal direction. It can be used when the fracture length is much larger than the fracture height. A schematic view of the fracture geometry is shown in Fig. 14.15. In this figure, h_f is the fracture height, $w(x, t)$ is the fracture width, x_f is the fracture half length. $u(x)$ is the fluid flow rate within the fracture.

$$\bar{w} = 0.3 \left[\frac{2q_i \mu (1 - \nu)^2 x_f}{E} \right]^{\frac{1}{4}} \left(\frac{\pi}{4} \gamma \right), \quad (14.13)$$

where:

- \bar{w} Average width (in)
- q_i Pump rate (bpm)
- ν Poisson's ratio
- x_f Fracture half length (ft)
- E Young's Modulus (psi)
- μ Viscosity of the fracture fluid (cp)
- γ Constant ≈ 0.75 .

Fig. 14.15 The PKN fracture geometry (after [14.14])

Offshore Production

15. Offshore Production

Ekaterina V. Maksimova, Cortis K. Cooper

About 71% of the Earth's surface is under water. It is not surprising that exploration companies pay attention to the bedrock below oceans, treating it as a source of oil and gas. This chapter presents a brief overview of offshore drilling from oceanographic-meteorological, engineering, geological, legal, and historical perspectives. Some topics discussed are the types of rigs and platforms used for offshore drilling and effects of metocean conditions (such as currents, waves, and winds) on these structures and operations; the factors influencing the regions of hydrocarbon potential, and how the coastal state's ownership is defined; and finally, the history of offshore drilling, its current state, and prospects for the future are touched upon.

So-called offshore drilling is nothing new – the first substantial offshore commercial production started in the 1960s. Figure 15.1 demonstrates that about one-third of the world's oil supply is currently produced

offshore – in shallow (< 500 m) or deep waters. Not only is the gap between onshore and offshore oil production increasing, but there is one distinct trend gaining steam in the offshore oil industry: compa-

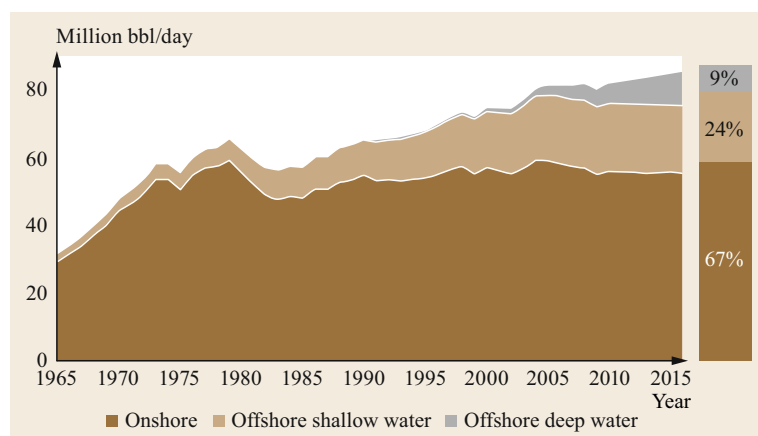

Fig. 15.1 Onshore versus offshore oil production (courtesy of Infield Systems, London)

nies are now forced to drill deeper than ever before. Total offshore oil production accounted for 22% of global production in 2000 – 1% of which (< 2 million bbl a day) was from deep water. In 2010 these figures rose to 33 and 7%, respectively. The

deep water production increased to 10 million bbl a day in 2014 and currently accounts for approximately 10% of the world's total production. Ultra-deep water (> 1500 m) production is gaining strength as well [15.1].

15.1 Historical Overview

How did it all begin? The oil production history can be divided into five main periods: pre-oil period (early history–1900), early onshore period (1900–1930), early offshore period (1930–1960), boom and bust (1960–1990), and deep water and reorganization period (1990–present).

In 1847, the first *onshore* oil well in the world was drilled using a primitive percussion drilling mechanism in Azerbaijan's Bibi-Heybet oil field under the direction and initiation of the Russian engineer V.N. Semenov. It was not until eleven years later that the first *onshore* oil well was drilled in Pennsylvania, US [15.4].

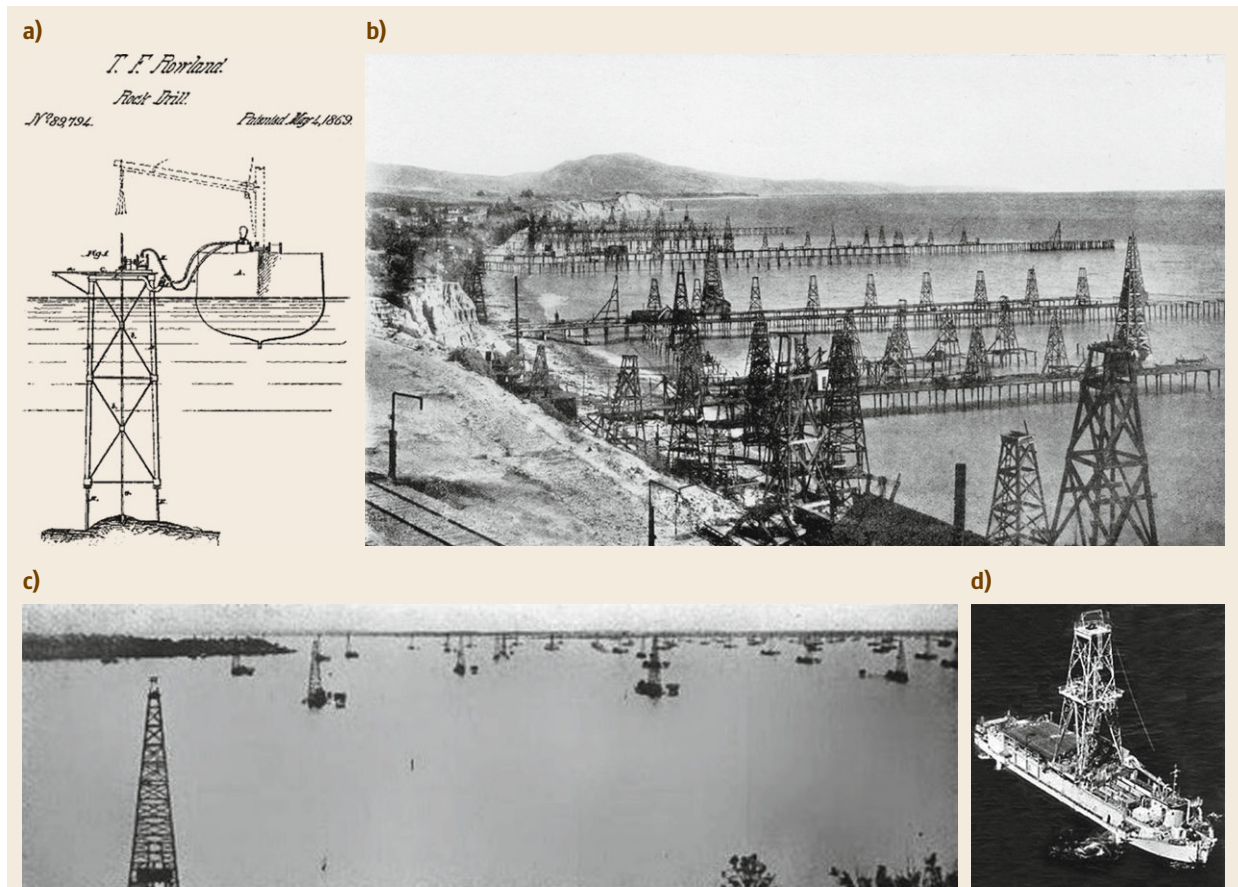

Fig. 15.2 (a) Although never built, Thomas Rowland's design for an offshore platform was far ahead of its time (US, 1869). (b) The people of Summerland, once a pleasure resort in California, are now successfully pumping oil out of the adjacent ocean bed (US, c. 1900s). (c) Cable-tool derricks on Louisiana's Caddo Lake (US, c. 1911). (d) CUSS I was one of the first vessels in the world capable of drilling in water depths up to 3600 m, while maintaining a position within a radius of 180 m (US, 1961) (after [15.2, 3], courtesy of US National Oceanic and Atmospheric Administration and US National Science Foundation)

Fig. 15.3 Worldwide progression of water depth capabilities for offshore drilling and production as of March 2015 (courtesy of WoodGroup Mustang)

Oil and natural gas from the oceans and lakes have also been used for quite some time. Primitive methods of *offshore* oil collection existed in the 19th century in Azerbaijan (Caspian sea), US (California's coast), and Japan. Some historians say that the true beginning of the modern *offshore* industry can be traced to 1869, when Thomas Fitch Rowland of Greenpoint, New York, patented a *submarine drilling apparatus*. Rowland's design (Fig. 15.2a) included a fixed platform for drilling offshore to a depth of 15 m. The anchored four-legged tower resembled modern offshore platforms, but was never built.

Offshore petroleum production started in the US two decades later. The first *offshore* oil platform constructed from piles was done in *fresh* waters of Ohio's Grand Lake (St. Marys) in 1891. Small local companies produced oil there during the 1890s, ushering in the modern era of sea drilling [15.5]. The first offshore oil wells in *salt* water were drilled in the portion of the Summerland field extending under the Santa Barbara Channel off California in 1896. Closely resembling boardwalks in appearance (Fig. 15.2b), rows of narrow wooden piers extended up to 410 m from the shoreline with their piles reaching 11 m down to the floor of the Pacific. Using the same techniques as were used then on land, steel pipes were pounded 138 m below the seabed [15.6]. The Summerland ocean field pro-

duced for 25 years, fueling the growth of California's economy.

Other notable early offshore drilling activities occurred on the Canadian side of Lake Erie in the 1900s and Louisiana's Caddo Lake in the 1910s. The Caddo Lake wells – completed over water without a pier connection to shore (Fig. 15.2c) – have frequently been called America's first true offshore drilling [15.7]. Shortly thereafter, wells started to be drilled in tidal zones along the Texas and Louisiana coasts in the Gulf of Mexico. In the 1920s, drilling activities occurred from concrete platforms in Venezuela's Lake Maracaibo. One of the well-known offshore structures was a well in Azerbaijan, which came on stream in 1923 and was located on an artificial island in a shallow portion of the Bibi-Heybet bay in the Caspian Sea. Later, a solid milestone was achieved in 1947, when a productive well was first built beyond the sight of land – 17 km off the Louisiana coast in the Gulf of Mexico – but still in waters of only 5.5 m deep.

Rapid growth of the offshore oil and gas production began in the 1960s (Fig. 15.1). The process accelerated in 1970–1980s, as indicated by the number of countries that produced oil and natural gas on the continental shelf: in 1970, there were only about 20 countries, but more than 50 in the early 1990s [15.8]. The growth of offshore oil production was due to several factors.

First, the energy crisis of the mid-1970s brought a sharp rise in oil prices, which provided a financial incentive to take on the increased cost of drilling offshore. Second, large onshore fields started to decline – or were controlled by the Organization of the Petroleum Exporting Countries (OPEC). These factors drove innovation in offshore technology: the first mobile drilling ship, CUSS I, was developed under funding from the National Science Foundation’s Mohole Project in 1961 (Fig. 15.2d).

By the early 1990s, there were more than 40 000 offshore wells drilled [15.9], and the drilling depth was

steadily increasing (Fig. 15.3). In the early 1980s, 85% of offshore oil was produced at depths of less than 100 m, but already by the mid-1990s, developments from 200–400 m depths were no longer rare. The maximum production depth increased dramatically from 300 m in 1984 to 1000 m just ten years later, and to 2934 m in 2010 (Fig. 15.3). The offshore production also became more remote – in 1970, the installation location of the production platforms was only 10 km offshore. At present, the farthest installation – Husky’s SeaRose FPSO in Canada – is located 350 km away from the coast.

15.2 Ownership

How deep and far offshore can a country drill? The concept *freedom of the seas* was designed by the Dutch jurist Cornelius van Bynkershoek in 1702 and existed virtually unchanged for 300 years. According to this principle, the territorial waters of coastal states were limited by 3 nmi (5.6 km), which corresponded to the distance of a cannon shot, the state’s capacity of exercising an effective control over the offshore territory at that time. All waters beyond that distance were considered international waters and governed by the principle

of *mare liberum*, introduced by the Dutch jurist Hugo Grotius in 1609: free to all nations, but belonging to none of them.

In the early 20th century, most countries proposed updating the law of the sea and to define national waters with a broader interpretation – namely, to enable the use of mineral resources, create instruments for the protection of national fish stocks, and prohibit uncontrolled release of waste into the open sea. As a result, the United Nations held its first (1956), second (1960),

Fig. 15.4 Ocean zones near the coastline. Continental shelf delineation criteria (courtesy of GRID-Arendal)

and third (1967) conferences on the law of the sea. Currently, virtually all oil and gas offshore development is based on the use of United Nations Convention on Law of the Sea (UNCLOS) [15.10], and the possession issues are mostly resolved. The two main regions of disputes nowadays are the Arctic and the southern oceans. Under the UNCLOS article 76, the *legal continental shelf* is the part of the seabed (but not the water column itself) over which a coastal state exercises sovereign rights with regard to the exploration and exploitation of natural resources, including oil and gas deposits. The legal continental shelf (Fig. 15.4) extends as a natu-

ral prolongation of the land territory to the continental margin's outer edge, or 200 nmi (370 km; this zone is usually referred to as EEZ, or exclusive economic zone) from the coastal state's baseline, whichever is greater. The definition of the *legal* continental shelf should be distinguished from the *scientific* definition [15.11]: the continental shelf is the sea bed surrounding a continent at depths of up to 130–200 m, at the edge of which the continental slope drops steeply to the ocean floor (as also shown in Fig. 15.4). The UNCLOS article 76 gives further details of defining the borders of the *extended legal* continental shelf.

15.3 Major Offshore Fields

Would the continental shelf (UNCLOS definition) normally include any important coastal state locations with offshore hydrocarbon potential? Substantial oil and gas reservoirs typically require an organic-rich sediment layer, which is at least 1 km thick and overlaid by a geological *trap*. Common traps for hydrocarbons include shales, salt domes (evaporates), and anticlinal folds of permeable and nonpermeable strata. Continental shelves and rises (scientific definition in Fig. 15.4) usually contain the largest accumulations of sediments – often in excess of 10 km – with a high probability of including organic-rich source rocks deposited, when the

proto-ocean basins were narrow and had restricted circulation [15.13]. The abyssal plains probably contain insufficient thickness of sediments (< 1 km) to yield hydrocarbon accumulations. Parts of the deep trenches may be more favorable, as some foundered remnants of continental blocks may have broken off during early rifting processes [15.14].

Areas that contain wide legal continental shelves with thick sediments deposited in regions favorable for hydrocarbon formation are shown in Fig. 15.5 [15.12]. These occur throughout the Arctic Ocean (coasts of Greenland, Norway, Alaska, northern Canada, and Rus-

Fig. 15.5 Map showing conventional hydrocarbon potential based on sediment thickness and crustal age and type. High potential is represented by increasingly *darker grays* (qualitative and relative only), the extended legal continental shelf regions outlined in *black*, while the 200 nmi exclusive economic zone areas are outlined by *thin curved gray lines* (after [15.12])

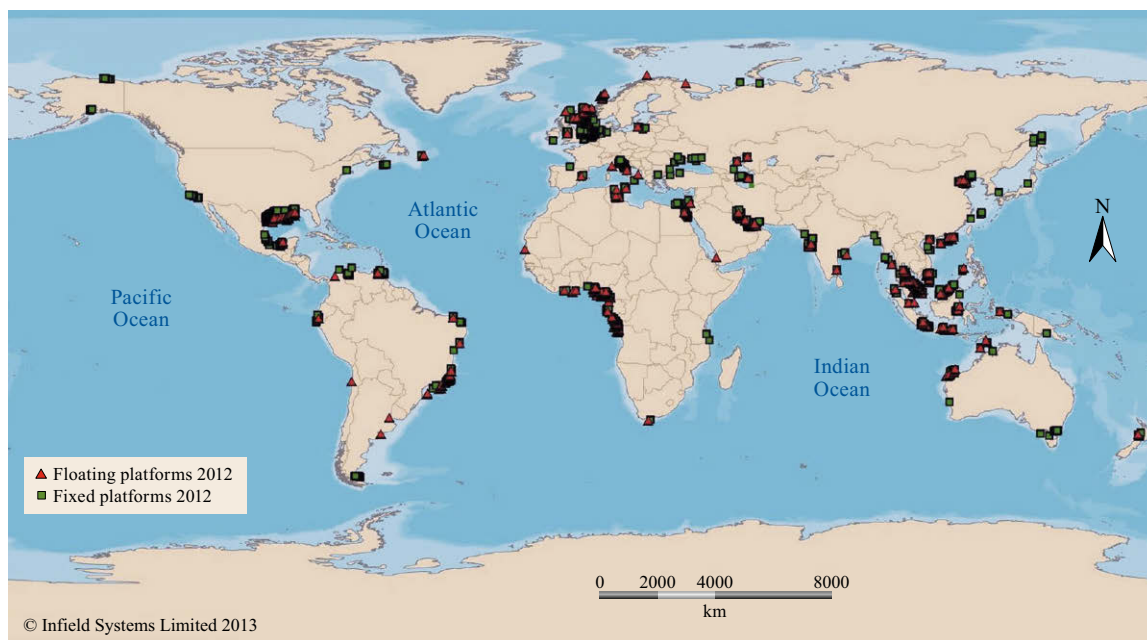

Fig. 15.6 Main offshore oil production regions as of 2012. *Triangles* and *squares* represent floating and fixed platforms, respectively (courtesy of Infield Systems Limited, London)

sia) and much of the continental margin of Antarctica. Favorable offshore conditions also occur along the Atlantic shores of North, Central, and South America (including Mexico, Trinidad-Tobago, Venezuela, Guyana, Suriname, French Guiana, Brazil, Uruguay, and Argentina), western Europe, around much of Africa, the northern margin of the Indian Ocean, Indonesia, and around Australia, New Zealand, off mainland China, Korea, Taiwan, and the Pacific shore of Russia (Sea of Okhotsk). Smaller basins include the Gulf of Mexico and the Caribbean Sea (2–6 km thickness), the Mediterranean Sea (up to 8 km), the Black Sea and the Caspian Sea (4 km), the Bering Sea, the Sea of Okhotsk, the Sea

of Japan, the South China Sea, and the seas within the Indonesian Archipelago (all 2–4 km). However, several of these favorable areas have water depths of as much as 5500 m and extend 1500 km or more from the shore, making hydrocarbon production there difficult. Out of these areas, ten shelves with the largest potential are off Antarctica, Canada, Brazil, US, Sri Lanka, India, Argentina, Madagascar, Russia, and Morocco. Figure 15.6 displays the actual global offshore production regions, which nowadays include the Persian Gulf, the Gulf of Mexico, Western Central Africa, Brazil’s coast, the North Sea, the Caspian Sea, and Southeast Asia [15.1].

15.4 Offshore Oil and Gas Platforms

As of 2014, there were roughly 9000 offshore production platforms [15.15] and 1020 mobile offshore drilling units (MODUs) [15.16] in service worldwide (approximate locations are as in Fig. 15.6). Figure 15.7 shows the major types of production platforms, while Fig. 15.8 is a montage of modern MODUs. MODUs drill exploratory (*wildcat*) wells and, in deeper water, are frequently used to drill development (production) wells prior to, but sometimes even after, the production facility is installed.

The choice of the type of production platform or MODU for a given field development depends on many

factors including water depth, ice coverage, soil conditions, and storminess. For production platforms, other important factors are production flow rate, hydrocarbon characteristics, and existing pipeline infrastructure.

15.4.1 Jackets and Jack-Ups

By far, the most prolific production platform is the *fixed platform* or *jacket* (left-most structure in Fig. 15.7), composed of a lattice of tubular steel held to the sea floor with long piles, also typically composed of steel

Fig. 15.7 Major types of offshore production systems (courtesy of US Bureau of Safety and Environmental Enforcement)

Fig. 15.8a–c Major types of offshore drilling systems. (a) Jack-up, (b) semi, (c) drillship (courtesy of Noble Corporation)

pipe pounded into the sea floor up to 50 m. Its analog for mobile drilling, known as a *jack-up*, is shown in Fig. 15.8a. Jack-ups are floated into place, and then the topsides are raised by extending the legs through a *jack-ing* mechanism.

The early precursor of modern jackets was first deployed off California in the 1930s, but it wasn't until the early 1950s that they began to proliferate in the Gulf of Mexico. Today there are 8000–8500 jackets in use around the world, the majority in the Gulf of

Mexico [15.15]. They are versatile and robust structures that can be easily scaled to the needed hydrocarbon production volume and built in many fabrication yards around the world. In shallower water regions with mild climates, a jacket might consist of just four legs and cost a few million US dollars. In deeper water, with a large number of producing wells, they can cost upwards of US \$100 million. Jackets have been deployed in many different environments, including mild low-latitudes like West Africa or Malaysia, more severe mid-latitudes affected by tropical cyclones (hurricanes), higher latitudes affected by frequent and severe extratropical storms, and even Arctic conditions with heavy first-year ice.

The chief constraint for jackets and jack-ups is water depth. At around 100–150 m, in harsh weather environments, a jacket's natural resonance period approaches the period of surface waves. In essence, the jacket begins swaying in rhythm with the wave forcing, resulting in metal fatigue, especially at the joints of the structure. The obvious solution is to stiffen the jacket with additional steel, but this, of course, increases cost. In milder climates, the economic cutoff is a bit deeper, but still only about 200 m. Designers have also tried extending the depth limit of the basic jacket design by purposely designing it to be more flexible, thus increasing the resonant period above the dominant waves. A few of these so-called *compliant towers*, or CTs (Fig. 15.7), have been built, but they are only economic in special circumstances.

15.4.2 Gravity-Based Structures (GBSs)

Another type of a fixed structure used for production is the so-called *gravity-based structure*, or GBS (not shown in Fig. 15.7). First deployed in the 1970s, almost all of the nearly 50 GBSs have been installed in the North Sea and were constructed of reinforced concrete. These are massive structures weighing up to one million tons and deployed in water up to 300 m, though most have been installed in 100–150 m. GBSs are well suited to stormy weather or heavy ice loads because of their mass, stiffness, resistance to overturning, and low foundation stresses. Their biggest weakness is that they must be built in a fjord; hence, they have only been used off Norway and the east coast of Canada.

15.4.3 Tension-Leg Platforms (TLPs)

One of the earliest floating production platforms was the *tension-leg platform*, or TLP (Fig. 15.7), which consists of a floating hull, usually composed of two large parallel pontoons, whose motion is constrained

by tendons made of tubular steel attached to the sea floor. As suggested by the name, the tendons remain in tension, essentially *pulling down* on the floating hull, and thus restraining its horizontal and vertical motions. A TLP experiences acceptable movement even in severe storms, yet is competitive with other alternatives in water depths ranging from roughly 500 m to at least 1500 m. As of 2015, there are 23 TLPs [15.17] in operation – all but eight in the Gulf of Mexico. Some of these are the so-called *mini-TLPs* (Fig. 15.7), which are inexpensive production-only platforms with no drilling capability.

15.4.4 Semisubmersibles (Semis)

By far, the most numerous deep water production and drilling platform is the *semisubmersible* (Fig. 15.8; a subtype of a semi, FPS, is shown in Fig. 15.7 as well). *Semis* are generally composed of two large sub-surface parallel pontoons connected to the upper deck by 4–6 columns, although triangular three-column versions have appeared more recently. Restrained by catenary moorings, semis were first used for drilling in the 1960s, but after about 20 years of stellar performance in the most severe ocean environments, the first purpose-built production semi was put into service in the North Sea. Semis are distributed widely, but primarily in the northeast Atlantic, Brazil, and the Gulf of Mexico. The deepest deployment is in the Gulf of Mexico at just over 2400 m. Semis are by far the most numerous floating drilling systems, with 273 in service in 2015 [15.17].

15.4.5 Spars

A *spar* (Fig. 15.7) is one of the more recently developed floating platforms, consisting of a long, large diameter cylinder (e.g., 30 m in diameter and 200 m in length) held vertically by heavy ballast at the base of the cylinder coupled with catenary mooring lines. Ballast and mooring lines keep the resonant period of the spar well above the period of wind waves. Hence, even in severe climates, spars deliver acceptable movement. As of 2015, 22 spars [15.17] had been installed in water depths ranging from 600 to 2400 m – all but two in the Gulf of Mexico.

15.4.6 Floating Production, Storage and Offloading (FPSO) Units

The prize for the most versatile floating production facility goes, without doubt, to the *floating production, storage and offloading* (FPSO, see Fig. 15.7) platform. First deployed in the 1970s using surplus oil tankers,

FPSOs are now purpose-built vessels with about 161 in service worldwide in 2015 [15.18]. They come in many different configurations, but are typically ship-shaped. In mild weather environments, they are simply spread moored with catenary lines in a fixed heading, but in moderate to severe climates, the FPSO is connected to a large buoy or a *turret* in the bow of the ship, which allows it to weather vane into heavy weather. FPSOs are economical in virtually any water depth, with systems having been installed in shallow water all the way out to 2500 m (Fig. 15.3). As the name implies, FPSOs include an offloading and storage capability, often making them the obvious choice for stranded fields where there is no existing pipeline infrastructure. FPSOs store oil, typically about one million barrels, and offload that oil to a tanker (also shown in Fig. 15.7), which is moored directly to the FPSO or from a nearby offloading buoy. Because the liquids ship directly, FPSOs are typically fitted with extensive onboard separation and processing equipment.

FPSOs are rarely equipped with the capability to drill or maintain wells and are frequently paired with subsea developments, the latter consisting of automated wellheads interconnected through flowlines and a flexible riser to the FPSO. Well expansion and maintenance must be done with a MODU.

There are many variants of FPSOs including floating storage and offloading systems (FSOs), floating production systems (FPSs), floating storage units (FSUs), and, most recently, floating liquid natural gas (FLNGs) units.

15.4.7 Drillships

As the name implies, *drillship* are ship-shaped MODUs, numbering 87 in operation worldwide [15.16] as of 2014. Typically used in very deep water, drillships (Fig. 15.8) are *dynamically positioned* by using thrusters or propellers. Thanks to the lack of moorings, drillships are capable of drilling to 3500 m (Fig. 15.3) and can quickly decouple from a well to avoid the most severe storms.

15.5 Metocean Impacts on the Offshore Industry

Metocean is an acronym for *meteorology and oceanography*, and is a term used in the offshore oil and gas industry to describe topics involving the quantification of winds, waves, currents, and related physical phenomena in the ocean and atmosphere. When engineers design a major facility or vessel to operate and survive in the sea, they must consider the loads, and other risks that may affect the facility. If the risks are under-

15.4.8 Subsea Systems

The fastest growing deep water offshore production system is the so-called *subsea system* (Fig. 15.7), consisting of wellheads, manifolds, and flowlines, placed on the sea floor and *tied back* to one of the surface-piercing systems described earlier. Subsea systems don't have to worry about severe weather, collisions, or ice, although these advantages are offset by the difficulty of maintaining equipment and a limited range of processing options. Nevertheless, subsea systems allow economic development of reservoirs that are thin but wide, meaning development of small uneconomic reservoirs that may be tens of kilometers away from an existing surface production or coastal facility.

The main component of a subsea system is a wellhead, which sits on the sea bed directly over the well. Wellheads are nicknamed *trees* because they contain many *branches* of pipes. Their complexity is partially a result of the many functions that they must execute, such as fluid monitoring, chemical injection for well maintenance, pressure boosting in the case of underpressurized reservoirs, and chemical injection to ensure unrestricted flow during the often long transit to the surface. Since most subsea systems are installed in deeper water (Fig. 15.3), they are generally serviced using remote operated vehicles (ROVs), further complicating their design.

Several hundred subsea systems have been installed [15.19], and many will follow in the future, as various constraints are removed with new technology. Arguably, the most serious constraint is the distance between the wellhead and the surface-piercing facility, the so-called *tieback*. As of 2015, the longest tieback was 150 km (Nobel Energy's Tamar gas field), but the average is closer to 20 km [15.17, 19]. The tieback constraints are driven largely by the difficulty in pumping a multiphase fluid (oil/gas/water) at low temperatures with high pressure drops and with limited available power. The discipline of *flow assurance* has become increasingly important in dealing with hydrate formation, slugging, wax deposition, and corrosion.

estimated, then damage can result, and lives may be lost. Conversely, if risks are overestimated, the costs may be too high, perhaps, to the point that the project cannot pass the financial hurdles and is never built. For instance, overestimating a design wave height for deep water floating production platforms could result in adding too many mooring lines. At several million US dollars per mooring, this is a substantial penalty.

But it doesn't stop there, since these additional lines would add hundreds of tons of static load, so a larger, more buoyant facility will be needed, thus, generating additional capital cost – well beyond the cost of the excess mooring lines. In short, an accurate quantification of air and sea parameters can have far-reaching effects on the safety and profitability of offshore facilities. For this reason, metocean risks are usually specified and described in a separate chapter in the project design documents.

In 2005, the American Petroleum Institute (API) recognized the influence of metocean criteria and began publishing a standalone set of recommended practices for the offshore industry [15.20]. Typical procedures include quantifying the so-called ambient air and sea *climatologies* on different time scales – hourly, daily, monthly, seasonally, annually, decadal, and so on. These include average and extreme statistics, exceedance probabilities and joint probability distributions, persistence information, and so on. The ultimate goal for offshore operations is to have accurate forecasts for the atmosphere and ocean states at any given time.

Metocean criteria are typically broken into two categories: operating and extreme. During *operating* conditions, the facility or vessel should be capable of achieving routine functions of its primary purpose, for example: drilling, pumping oil and gas, generating wind energy. Typical products used to quantify operational conditions are cumulative probability distributions of wave height, tables of wind speed persistence, average air and water temperatures, air moisture and pressure, water salinity, tidal amplitudes, and so on. These products are used in estimating the fatigue lives for structure components and operation down time. In contrast, *extreme* conditions are generated by episodic and, sometimes, poorly predictable events (e.g., storms, earthquakes, resonances in the basins) that occur *rarely*. During extreme conditions, normal operations are suspended – the vessel is slowed, oil or gas production is stopped, wind turbines are feathered, and so on. A common example of an often used extreme metocean parameter is the 100-year wave height – the largest wave expected over a 3 h period once in 100 years. Since both extreme and operating conditions are heavily affected by winds, waves, and currents, these phenomena are briefly discussed below, along with the processes that commonly control them and the impacts they can have on offshore facilities and operations.

15.5.1 Winds

In terms of raw speeds the most powerful storm in the marine environment is the *tropical storm*, commonly referred to as a hurricane, typhoon, or tropical

cyclone, depending on what part of the world they are in. These storms are *convective*, i.e., they are fundamentally driven by vertical movement of energy and humid air. Since they require warm, humid air and warm surface waters, tropical storms are creatures of summer and early fall. They can generate sustained winds around 200 km/h with horizontal scales of order 200 km. Because they move fairly fast, tropical storms pass over a site in a matter of hours. Tropical cyclones are strongest in latitudes of $30 \pm 10^\circ$ and most numerous in the eastern North Pacific, southern North Atlantic, and western Pacific.

Extratropical storms are large scale storms, sometimes affecting a 1000 km wide swath. They occur during the hemisphere's fall-winter-spring season, when strong horizontal temperature gradients are found in the mid- to higher-latitudes. Despite somewhat weaker wind speeds, extratropicals can still generate sustained winds of 120 km/h and do so over distances of order 500 km for a day or more. Because of their longer space and time scales, extratropicals hold the record for generating extreme waves. Figure 15.9 shows satellite images of Hurricane Katrina overlaid on the large extratropical storm. Note the circular, smaller scale of the hurricane in relation to the sprawling, more chaotic shape of the extratropical storm.

There are several types of other severe storms with small length scales that can generate strong winds. *Thunderstorms* (often called squalls) can generate winds up to 120 km/h, but individual cells have horizontal length scales of only a few km, so they affect a site for just a few minutes. *Water spouts* are small scale phenomena observed over water and are generally no stronger than a moderate squall, but tornadic water spouts can be generated by mesocyclones in a manner similar to terrestrial tornadoes. Another intense, small scale storm, known as the *polar low*, is only found at high latitudes in the presence of strong horizontal temperature gradients [15.21]. Because of their small size and isolated range, there are few direct wind measurements in polar lows. Indeed, they were not even fully recognized by meteorologists until the advent of satellite imagery in the mid-1960s.

When referring to the wind speed, it is always important to reference the time over which the speed is averaged. A wind *gust* is typically averaged over 3 s. For more sustained winds, typical averaging periods are 1 min and 1 h. The differences between averaging intervals can be substantial. For example the 3 s wind is typically about 300% less than the 1 min wind. Another important detail is the height of the wind above the mean sea level. The standard height is 10 m, but the most important winds for many platforms are at the level of the main decks, which can be 30–50 m above

Fig. 15.9 Overlay of the so-called *storm of the century*, an extratropical storm affecting the Northeast US in March 1993, and hurricane Katrina as it approached New Orleans in August 2005 (courtesy of US National Oceanic and Atmospheric Administration)

the sea level. There, the winds will be of order 15% higher than at 10 m.

Strong winds impact the offshore industry in many ways: by making it difficult or impossible to perform certain operations, such as off- or on-loading of cargo using the on-board crane and installing or repairing facilities. Extreme wind loads dominate the environmental loads in several of the production and drilling concepts including TLPs, FPSOs, semis, and drillships. That is because these platforms have a relatively large portion of the structure above the sea, or because the platform has been carefully designed to minimize wave loads.

15.5.2 Waves Observed at the Ocean Surface

All motions in the ocean, just like in the atmosphere, can be ordered in terms of their periods space scales, as well as responsible generation mechanisms. Most readers are familiar with waves observed at the surface that are generated whenever the wind blows over open water. The longer the wind blows, the higher and the longer the period are the waves, all else being equal. Similarly, the longer the open-water distance over which the wind blows (*fetch*), the higher and longer period are the waves. *Storm surges* are massive waves with heights of up to 30 m that have periods shorter than those of the tides and are considered to be of a large scale external inertia-gravity wave type. They can flood the coastal areas when they surge onto the shore. The largest wave heights are generated by strong extratropical storms, where the winds can blow over a fetch of hundreds of km for several days. The small scale winds can generate waves with shorter periods. When dominated by gravity, they are called *surface gravity waves*; even smaller scale waves with periods

shorter than 0.25 s are affected by surface tension and are called *capillary waves*.

Surface gravity waves travel at speeds that are dependent on their period; though, in *shallow water* (compared to the half wavelength), the water depth also affects the wave speed. When the wind blowing in the direction of the surface gravity wave is faster than the wave speed, the wave is called the *wind wave*, and its height and period will continue to grow. If the wind drops below the wave speed, the waves are referred to as *swell*. Swell can travel for over 1000 km in the open ocean with little decay in energy. *Tides*, *tsunamis*, and *seiches* are other familiar types of waves that can propagate long distances. They originate independently of the wind forcing by predictable gravitational pull of other planets, intermittent earthquakes, and resonances in the basins respectively. Tsunamis and seiches typically have periods shorter than tides, and all show largest effects in shallower water.

Thus, waves in the ocean rarely have a single period but are composed of a spectrum of periods and are best quantified using statistical measures [15.22]. For example, the most common measure of surface gravity wave height is the so-called *significant wave height*, which is proportional to the total energy in the wave spectra, and for a typical wave field it can be shown to equal the average of the highest one-third of the waves. Significant wave height also corresponds to a wave height that a trained observer would notice when viewing a typical sea state during an interval of several minutes. The maximum wave height expected during a given period of time (e.g., an hour) can be calculated with a Forristall distribution [15.23], which shows that the largest wave expected during a 1 h time interval in a tropical or extratropical storm will be roughly 1.6–2.0 times the significant wave height depending on the wave period

Fig. 15.10 Schematic summary of the characteristic duration and peak velocity of various types of deep water ocean currents

and how peaked the wave spectrum is. However, this distribution has no upper limit, which means that many of the so-called *rogue* or *freak* waves reported in the literature are, in fact, expected, as they lie well within the confidence limits of the Forristall distribution.

The large wave disturbances that one can easily observe at the ocean surface are often the dominant environmental loads on most offshore facilities, especially jackets, jack-ups, and GBSs. Waves, of course, also have a big effect on operations, including transferring of cargo, offloading of oil, installation, and repair.

15.5.3 Ocean Currents

The notion of *current* is usually used as a *common wisdom* term for either low-frequency (compared to tidal frequency) flow or higher frequency waves that appear to happen within the water column (e.g., tides in the deep water). Figure 15.10 shows the characteristic duration and maximum velocity scales of different types of energetic deep water ocean currents. For example, the figure shows that storm-generated currents have a broad range of magnitudes and periods, the latter being strongly related to the time scale of the generating atmospheric process. The strongest storm-driven currents with peaks of 4–5 kn (7.4–9.2 km/h) are driven by *tropical cyclones*. Cyclones are especially efficient generators of strong near-surface currents, in part because the storms typically translate at near-resonance to the inertial period of the ocean. Another factor is that tropical cyclones occur over regions of the ocean, topped by a relatively thin (30–60 m) layer of warmer water, which serves to concentrate the wind energy. *Ex-*

tratropical storms are the other type of atmospheric disturbance that generate substantial currents but of much longer time scales and lower magnitude – hence, the downward sloping trend of the curve in Fig. 15.10.

Other types of currents may include *internal tides* and *solitons* (internal inertia-gravity waves), *mud flows* (density-driven turbidity currents near the ocean bottom), *shelf waves* (also known as *coastally trapped waves*: large-scale waves due to the presence of the coast, density stratification, and bottom slope), and *boundary currents* and *eddies* (large scale ocean circulation patterns at mesoscale, subbasin, and basin scales). In an analog to Fig. 15.10 for shallower water of a continental shelf, the tidal curve would appear much higher, reaching something like 6 kn (11.1 km/h). Thus, the reader is reminded that a given site rarely, if ever, would be affected to the same extent by all the processes schematically depicted in Fig. 15.10, nor would the peak magnitude always reach the levels shown [15.24].

In the early years of offshore development, currents were completely neglected in the load calculations because the dominant structure types – jackets and jack-ups – have a small drag cross-section beneath the water level, and, hence, are dominated by wave and wind loads. However, as the industry expanded into deeper waters, currents have become much more important. That is due, in part, to the shift towards floating platforms, which are much more influenced by strong currents than jackets. For instance, in the case of a TLP, the current can push the TLP downstream, but, since the TLP is restrained vertically, this movement *knocks down* the TLP – lowers it in the water, bringing the deck closer to the waves. This, of

course, can be corrected in many different ways, but the bottom line is that currents are important to the TLP design. Ocean currents have similarly important impacts on spars and FPSOs, though for different reasons. Regardless of the surface platform type, ocean currents affect important subcomponents, such as drilling and

production risers. The former contain the drill string/mud, while the latter convey hydrocarbons from the sea floor to the surface platform. Ocean currents impose a drag load on the riser and can cause fatigue through *vortex-induced vibration* and other mechanisms.

15.6 Future Offshore Production and Drilling

What will the offshore oil and gas field of the future look like? There are at least two major unknowns that affect the outlook: the potential for a carbon tax on fossil fuels and the volume of production from onshore shale. If both are substantial, the demand for relatively costly production in the Arctic and ultra-deep water will be reduced. While these uncertainties will affect the pace of development, it probably won't affect the general direction. That direction is toward more subsea production in deeper water and in the Arctic. Such trend is driven by economics: the less expensive way is to install production equipment on the sea floor and to bring it ashore, if possible, or connect it to a preexisting surface facility. Such arrangements allow the development of relatively small reservoirs, which would not be economic if they required a new surface facility. In any case, the future of the offshore production, with no doubt, relies on the improved theoretical understanding of the ocean circulation and metocean criteria through physical observations, theory, and modeling efforts.

Because of the innate advantages of subsea production, major investments in engineering research are also underway to expand its capability. These efforts are focused on increasing tieback distances between the subsea wellheads and existing surface platforms, and putting more and more of the production activities on

the sea floor. Ultimately, the goal is to be able to develop reservoirs without any surface facility. This is a daunting challenge, since it requires new technology for subsea separation, well and flow line maintenance, and compression. Before these can become reality, progress will have to be made in generating large amounts of power (of the order 1 MW) on the sea floor [15.19]. In terms of new producing regions, it is likely that activity will continue to extend into deeper water. The main deep water play is in the Gulf of Mexico, but the US portion of this basin may be fully explored in another decade. Subsequently, deep water activity will likely increase in the deep waters off of Africa, Australia, and South America.

The Arctic is the last great region that may hold large reserves of hydrocarbons (Fig. 15.5), yet has not been much exploited (Fig. 15.6) because of high costs and environmental concerns. Decreasing ice cover will reduce costs and, to some degree, the environmental risks, so this could further spur production. That said, forecasts of increased offshore Arctic production have been made for at least four decades and yet have failed to materialize, because cheaper sources of hydrocarbons were discovered in the interim. Shale production may prove to be the next spoiler to advocates of Arctic drilling.

Petroleum Distillation

Chang Samuel Hsu, Paul R. Robinson

Crude oils are complex mixtures of numerous molecules with different boiling points. After removing solid particulates and salts by a desalting process, fractional distillation is the primary means for refineries to separate the molecules into fractions (cuts) continuously. A crude distillation unit includes an atmospheric distillation tower, a vacuum distillation tower, and associated equipment. The cuts can be further processed or upgraded in downstream units – hydrotreaters, catalytic reformers, fluid catalytic cracking units etc. The products of upgrading units often require further separations, usually by distillation for lighter cuts and extraction for heavy cuts.

16.1 Overview

There are many phases of petroleum from gas to solid, including natural gas, condensates, crude oils, tar etc. Separating complex crude oils that contain thousands or millions of components is based on volatility by boiling point and solubility by various solvents. Fractional distillation is the primary means of separation of crude oils at refineries into fractions of different boiling ranges. The fractions are subsequently upgraded or converted into useful products in other units. For very heavy fractions, extraction becomes the method of choice for further separation. However, the crude oil distillation unit (CDU) is the first processing unit in virtually all petroleum refineries.

Crude oils are complex mixtures of numerous molecules with different boiling points. Refineries separate the molecules into fractions (cuts) primarily by continuous fractional distillation. Distillation separates mixtures of two or more substances, usually liquids, with the application of heat. The vapor over a boiling mixture is richer in components with lower boiling points. When this vapor is drawn away and condensed by cooling, the condensate will contain more of the more-volatile components. At the same time, the remaining liquid will contain more of the less-volatile components.

Distillation has an interesting history [16.1]. Aristotle wrote about the recovery of ethanol from wine, stating that *ordinary wine possesses a kind of exhalation, and that is why it gives out a flame* [16.2]. Recovering turpentine from tree sap is another example of ancient distillation [16.3]. In Alexandria, during in the first century AD, Greek alchemists used distillation to separate volatile spirits from many substances, including obtaining naphtha from bitumen. In China, distillation probably began during the Eastern Han 東漢 Dynasty (25–220 AD). Evidence indicates that distilled beverages were being consumed during the Jin 金 and Song 宋 Dynasties (907–1279 AD). A twelfth-century still was uncovered in Qinglong, Hebei province.

In 1500 AD, Hieronymus Braunschweig, a German alchemist, published the first comprehensive book on distillation [16.4]. The book is divided into three parts:

1. The first part describes the equipment and techniques used in batch distillation.
2. The second part is a list of plants and methods for distilling *spirits* from them.
3. The third part describes the medicinal uses for various spirits.

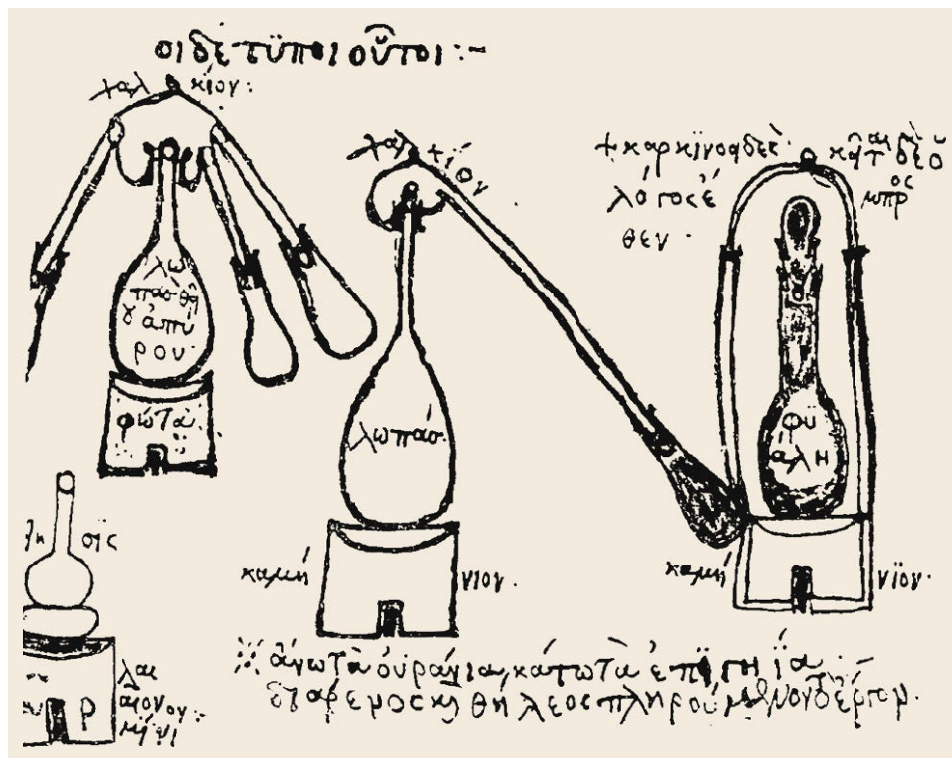

Fig. 16.1 Drawing of alembics by Zosimos of Paniplos (after [16.5])

Early batch-distillation gear included alembics and retorts, which are glass or ceramic flasks with long necks that point downward and to one side. Figure 16.1 presents drawings by Zosimos of Panopolis, a third-fourth century Greek alchemist and Gnostic scholar who was born in Egypt and may have traveled throughout the Middle East [16.6]. Figure 16.2 shows a retort assembly with a water-cooled receiver. As a mixture inside the main flask is heated, vapors rise and flow through the air-cooled neck. At the cooler temperature in the neck, the vapors condense and flow into a receiver, which collects the distillate. To improve separation (increase purity), the distillate is redistilled, usually in a different apparatus and sometimes several times.

Pot stills (Fig. 16.3) were fashioned from copper. Some included coiled water coolers, which improved separation efficiency. Today, pot stills are employed to produce cognac, Scotch whiskey, and tequila. The goal in distilling these products is not to achieve maximum purification of alcohol, but to prepare beverages with characteristic flavors.

Preheating and reflux emerged in the early nineteenth century. In reflux, cooled condensate is returned to the top of a column, from whence it flows downwards, pulling with it heavier molecules entrained in the upcoming vapor. Eventually, it reaches

Fig. 16.2 Retort with water-cooled receiver (after [16.7])

a zone corresponding to its boiling point and vaporizes again.

Aeneas Coffey patented a single-column still in 1830, enhancing a previous design developed by Robert Stein in 1826. The *Coffey still*, also called the *Patent still*, operated continuously, producing spirits with more than 60 vol.% ethanol. The limit on alcohol purity is 95.6 vol.%, where ethanol and water form an azeotrope. An azeotrope is a constant-boiling mixture. The composition of the vapor is the same as the composition of the unboiled mixture. Further separation cannot be achieved by distillation alone.

Fig. 16.3 A pot still for recovering alcohol-containing distillate from fermented mash. The condenser is a water-cooled coil. Cold water is added and hot water is removed to keep the condenser temperature constant

In 1877, Ernest Solvay obtained a US Patent for tray-column distillation, which he used to separate ammonia from water in his process for making sodium carbonate from limestone and brine.

Figure 16.4 shows a simple schematic for continuous fractional distillation, which is the primary separation method in oil refineries. Additional details are provided in subsequent sections. The preheated feed is a mixture of light and heavy liquids. It enters the column from the side.

In crude oil distillation, steam is injected into near bottom of the tower to improve separation. It does so by reducing the partial pressures of the hydrocarbon components while providing heat for vaporization. Steam is a key feature of crude distillation, but it may or may not be featured in other refinery distillation units.

Light components vaporize and flow up through several trays toward the top. Unvaporized feed flows down toward the bottom. At the top, vapors go to a cooler (condenser) into a reflux drum. Part of the light condensate is withdrawn as a product; the rest is returned to the top of the column as reflux to provide cooling. Reflux plays a major role in controlling temperature and enhancing separation at the top of the tower, where it shifts the mixture closer to vapor-liquid equilibrium and recovers more liquid products from vapor. The reflux ratio is the amount of liquid returning to the tower divided by the amount of liquid withdrawn

as product. With a higher reflux ratio, fewer theoretical plates are required.

At the bottom of the tower, the liquid residue goes through a reboiler. Part of the reboiled residue becomes product; the rest is returned to the tower to provide heating.

This combination of cooling at the top and heating at the bottom imposes a temperature gradient. One or more intermediate streams (middle distillates) are drawn as side cuts from the tower and cooled. The trays (plates) improve separation. At each tray, some of the vapor condenses and flows back down the column. When the condensed liquid reaches a zone that is hotter than its boiling point, it re-vaporizes. Temperatures are controlled by flow rates, and flows are adjusted with control valves (CVs).

Early distillation trays were perforated plates, which were relatively inefficient and very sensitive to deviation from horizontal; a tilt of just a few degrees could flood one side of the tray. With modern designs, separation efficiency has improved tremendously. Figure 16.5 illustrates a bubble-cap tray with downcomers. Condensed liquid flows down through a pipe (downcomer) to the hotter tray below, where the higher temperature causes re-evaporation of the lighter components. Ascending vapor flows up through the base of the cap, down through the lip, and into the liquid. The liquid level on the tray is set by the height of the

Fig. 16.4 Continuous distillation in a trayed column (tower)

Fig. 16.5 Bubble caps and downcomers on distillation trays. The side-draw comes from a product tray (after [16.8])

downcomers. The level must be high enough to cover the outer lip of the bubble cap. A given molecule evaporates and condenses many times before finally leaving the tower. Bubble-cap trays provide good contact be-

tween downflowing liquid and upflowing vapor, which knocks heavy material out of the vapor.

Several other kinds of trays are available. On valve trays, bubble caps are replaced with chimneys topped

with a valve. When vapor flows up the chimney, the valve opens and vapor flows into the liquid on top of the tray. The direction of flow is horizontal, which provides superior mixing. If the vapor flow is too low, the valve closes, preventing *weeping* – the flow of liquid down the chimney.

Occasionally, refiners install inert packing, either structured or random, to improve liquid–vapor contact with minimal pressure drop. Adding packing can be equivalent to adding several trays. One type of random packing comprises unconnected metal rings. Figure 16.6 shows an example of structured packing.

Packing is bothersome during maintenance, because it can be hard to remove, especially if it is fouled or corroded.

16.2 Distillation Theory

Distillation separates mixtures of two or more liquids with the application of heat. When heated, individual liquids either vaporize or decompose. The boiling point of a liquid is the temperature where the vapor pressure of the liquid equals the external pressure. For normal boiling, the external pressure is one atmosphere [16.9].

16.2.1 Ideal Distillation

Models for ideal distillation assume that the vapor and liquid phases are in equilibrium. Such models incorporate Raoult's law and Dalton's law. In Raoult's law, it is assumed that the vapor pressure of a solution is determined by the vapor pressures and mole fractions of solution components. In Dalton's law, it is assumed the total pressure is the sum of the partial pressures of each component. Combining Raoult's law with Dalton's law gives the following expression

$$P = P_A x_A + P_B x_B + \dots,$$

where P is the total pressure; P_A and P_B are the partial pressures of A and B respectively; and x_A and x_B are the mole fractions of A and B respectively. Figure 16.7 illustrates Raoult's law for an ideal solution with two components.

When a mixture is heated, the vapor pressure of each component rises, causing the total vapor pressure to rise. A mixture with a given composition has only one boiling point. Hence, lighter components don't really *boil first*. In an ideal system, all volatile components boil at the boiling point of the mixture. As mentioned, in continuous fractional distillation, there

is a temperature gradient in the tower. At each level, the compositions of liquids and vapors are different. Mixtures at the top of the column contain components with the lowest boiling points and the highest vapor pressures. Mixtures at intermediate draw points contain components with intermediate vapor pressures and intermediate boiling points.

Ideal distillation models are highly accurate for mixtures in which the components are similar, such as benzene and toluene or n -hexane and n -decane. Deviations from ideal are caused by molecular interactions, such as the formation of azeotropes.

Fig. 16.7 Raoult's law for an ideal mixture of two components

In salt water, the vapor pressure of the salt is zero. In this case, boiling off the water is called evaporation.

16.2.2 Vapor–Liquid Equilibrium (VLE)

The difference between liquid and vapor compositions is the basis of distillation. Relative volatility is the difference between the boiling points of components. It indicates how easy or difficult a particular separation will be.

Boiling point diagrams show how equilibrium compositions of mixtures vary with temperature at a fixed pressure. Figure 16.8 shows a boiling point diagram for a mixture with two components, X and Y. The boiling point of X corresponds to temperature at which the mole fraction of X is 1.0 and Y is 0.0. Similarly, the boiling point of Y corresponds to temperature at which the mole fraction of X is 0.0 and Y is 1.0. In the figure, X is more volatile than Y.

The upper curve in the diagram is the dew-point curve, while the lower curve is the bubble-point curve. In the region above the dew-point curve, the vapor is superheated, while below the bubble-point curve, the liquid is subcooled. Consider a subcooled liquid in which the mole fraction of X = 0.4. When the mixture is heated from 80° (point A) to 90° (point B), the concentration of X remains constant until it reaches the bubble point (point B), where it starts to boil. At the bubble point, the mole fraction of X increases. The vapors evolved from the mixture have the equilibrium composition given by point C in Fig. 16.8, approxi-

Fig. 16.8 Boiling point curve at constant pressure for a binary mixture

mately 0.85 mol fraction X. The vapor is more than 100% richer in X than was the original liquid.

Vapor–liquid equilibrium (VLE) is an important concept. For each component of a binary mixture, one can prepare a VLE equilibrium diagram, such as the one shown in Fig. 16.9. The liquid mole fraction is shown on a horizontal (x -) axis and vapor mole fraction on a vertical (y -) axis. These diagrams are square with a diagonal line running from the ($x = 0, y = 0$) corner to the ($x = 1, y = 1$) corner for reference.

16.2.3 Theoretical Stages

The design of a distillation column requires the estimation of several fundamental parameters, including the number of required stages (plates) and the reflux ratio.

McCabe–Thiele Method

The McCabe–Thiele graphical method [16.10, 11] relies on VLE plots to determine the number of theoretical stages required for a given service. The method assumes that the liquid on a tray and the vapor above it are in equilibrium, and it assumes constant molar overflow, which implies that the heats of vaporization of the components are roughly the same. It also assumes that heats of solution, heat losses to and from column etc. are negligible. Finally, it assumes that for every mole of vapor that condenses, 1 mol of liquid is vaporized.

Figure 16.10 illustrates the method for a binary mixture. With the VLE diagram of the mixture, operating lines are drawn. The operating lines define

Fig. 16.9 Vapor–liquid equilibrium (VLE) curve

Fig. 16.10 Preparing a McCabe–Thiele diagram for the rectification section of a distillation column from a VLE diagram

the mass balance relationships between the liquid and vapor phases in the column. There is one operating line for the bottom (stripping) section and one for the top (rectification or enriching) section of the distillation tower (Fig. 16.4). For the rectification section, the desired top product composition (X_D) is located on the x -axis of the VLE diagram, and a vertical line is drawn to intersect a diagonal line that splits the VLE plot in half, shown in Fig. 16.10. An operation line with slope $R/(R+1)$ is then drawn from this intersection point where R is the reflux ratio – the ratio of reflux flow (L) to distillate flow (D). Hence, $R/(R+1)$ is equal to $L/(L+D)$, the portion of condensate from the condenser that returns to Tray n or the ratio of reflux liquid to vapor going into the condenser.

The operating line for the stripping section is constructed in a similar way. In this case, the starting point is the desired bottom product composition (X_B). A vertical line is drawn to the diagonal line as illustrated in Fig. 16.11. An operation line with slope L_S/V_S is drawn upward from the intersection point on the diagonal line, where L_S is the rate at which liquid flows down the stripping section of the column and V_S is the rate at which vapor flows up the stripping section of the column. The slope of the operating line is the ratio between the liquid and vapor flows.

As shown in Fig. 16.12, repeated application of the technique creates a number of corner sections, with

Fig. 16.11 Preparing a McCabe–Thiele diagram for the stripping section of a distillation column from a VLE diagram

each section being equivalent to a distillation stage. This is the basis of sizing distillation columns using the McCabe–Thiele graphical design method.

The required number of trays is one less than the number of stages, because the graphical construction includes the reboiler as a tray. Actual trays are not 100% efficient, so additional trays – more than the theoretical number – are used. Typical values for tray efficiency range from 0.5 to 0.7. Tray efficiency depends on the type of trays being used and internal liquid and vapor flow rates.

The Fenske Equation

The Fenske equation [16.13, 14] is used to calculate the minimum number of theoretical plates for continuous fractional distillation where the column is operated at total reflux.

For a binary mixture, the following equation is used

$$N = \frac{\log \left[\left(\frac{X_D}{1-X_D} \right) \left(\frac{1-X_B}{X_B} \right) \right]}{\log \alpha_{\text{avg}}}$$

where:

- N minimum number of theoretical plates
- X_D mole fraction of the more volatile component in the overhead distillate
- X_B mole fraction of the more volatile component in the bottom

Fig. 16.12 Composite McCabe–Thiele diagram (after [16.12])

α_{avg} average relative volatility of the more volatile component to the less volatile component.

For a multicomponent mixture, the following formula holds

$$N = \frac{\log \left[\left(\frac{LK_D}{HK_D} \right) \left(\frac{HK_B}{LK_B} \right) \right]}{\log \alpha_{\text{avg}}}$$

where:

- N minimum number of theoretical plates
- LK light key = mole fraction of more volatile components
- HK heavy key = mole fraction of less volatile components
- α_{avg} average relative volatility of the LK and HK components.

If the relative volatility of the LK to the HK is constant from the column top to the column bottom, then $\alpha_{\text{avg}} = \alpha$. If the relative volatility is not constant from top (α_t) to bottom (α_b) of the column, then the following approximation may be used

$$\alpha_{\text{avg}} = \sqrt{(\alpha_t)(\alpha_b)}$$

The most challenging aspects of the Fenske method are (a) deciding which components in a complex, continuous mixture are LK and HK, and (b) estimating relative volatilities.

Versions of the Fenske equation are relevant to liquid–liquid extraction problems and gas chromatography, both of which can be treated as a series of equilibrium stages with solubility differences between liquids in a mixture.

Theory versus Practice

The actual number of trays needed for a particular separation duty depends on the efficiency of the plates. Anything that decreases tray efficiency diminishes column performance. Efficiencies degrade over time due to fouling, corrosion, and pressure pulses. Naphthenic acids are the main cause of corrosion in a crude distillation unit. High-acid feeds have dissolved most of the trays in a distillation tower in a matter of months.

Other entrained acids, such as hydrogen chloride, are volatile. Hydrogen chloride vapors are relatively innocuous. But at the distillation tower overhead, where the vapor goes from the top tray to the reflux drum, the temperature falls below the dew point of water. If HCl is present, it dissolves in the condensed wa-

ter to form highly corrosive hydrochloric acid, which rapidly corrodes metals. The problem can be minimized by injection of ammonia, morpholine, or higher-boiling neutralizing amines into the overhead, or by adding judicious amounts of caustic to the desalter effluent.

A major issue, of course, is that actual distillation units don't always operate with design feeds at design flow rates. Operational flexibility can be increased during design and construction by adding extra trays and/or installing extra return lines (pump-arounds and pump-backs) to manage the temperature profile in the tower. Some columns are designed with multiple feed injection points.

Operation is also affected by foaming, entrainment, flooding, and weeping.

Insufficient vapor flow causes weeping. Low vapor flow allows liquid to flow down through bubble caps, further blocking vapor flow. Excessive weeping leads

to dumping, where the liquid on all trays drops to the bottom of the column. When this happens, the column must be cleared and restarted. As mentioned, valve trays prevent weeping.

Excessive vapor flow causes flooding. Liquid becomes entrained in the vapor traveling up the column. When it disengages from the vapor, the excess liquid blocks the downcomers, causing the liquid level (holdup) on the trays to increase. This blocks the upward flow of vapor, building pressure in the tower. Eventually, vapor blows through in a pulse. Until action is taken, the cycle repeats. Separation efficiency drops precipitously, and product quality deteriorates. Flooding causes a sharp increase in column differential pressure and a sharp drop in separation efficiency.

Ambient conditions also affect performance. In hot weather, air coolers may not be able to provide sufficient temperature reduction. For uninsulated columns, extreme weather of any kind can degrade performance.

16.3 Crude Oil Distillation

A crude oil distillation unit (CDU) includes an atmospheric distillation unit (ADU) and a vacuum distillation unit (VDU) as shown in Fig. 16.13. The light products from a CDU are gases and naphthas. Middle distillates include kerosene, light gas oil, and heavy gas oil. The residue, or bottom, of the ADU is also known as reduced crude. It goes to the VDU to be fractionated into vacuum gas oil and vacuum residue (vacuum resid). The figure includes a desalter, which in some refineries is considered part of the CDU complex.

16.3.1 Predistillation Processing

As mentioned, when a crude oil emerges from underground, it is mixed with a variety of contaminants. These must be removed before the crude oil can be transported and refined. Some cleanup takes place in oil fields. A field separator at a well site is often no more than a large covered vessel that provides enough residence time for gravity separation into four phases: gases, crude oil, water and solids. Generally, the crude

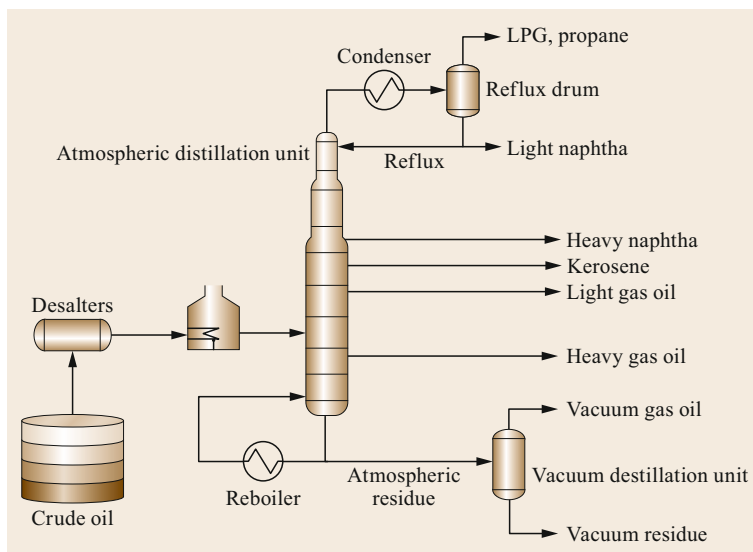

Fig. 16.13 A crude oil distillation complex includes three major operations: desalting, atmospheric distillation, and vacuum distillation

oil floats on the water. The water is withdrawn from the bottom; usually it is pumped into a wastewater injection well. Gases are withdrawn from the top and piped to a natural-gas processing plant or reinjected into the reservoir to maintain well pressure.

Crude oil is pumped to a refinery through a pipeline or to storage to await transportation by other means. Large quantities of crude oils are transported through pipelines or tankers. Others may be transported by barge, train or trucks. At the marine terminal, a cargo of crude oil may be routed through a pipeline directly to a storage tank in the refinery tank farm. Other tanks in a tank farm hold compressed gases, partially refined intermediate stocks, finished products, and chemicals for short- or long-term storage.

A refinery seldom refines single crude. Several crudes of similar characteristics are usually blended together. Incompatibilities between crude oils can occur, for example, between paraffinic crude oil and heavy asphaltic crude oil. Blending is used to maintain, as nearly as possible, constant feed quality suitable for the crude distillation unit. For example, high-acid crudes are mixed with low-acid crudes, and high-sulfur crudes are mixed with low-sulfur crudes to bring the acid or sulfur contents to a tolerable level for refinery operations.

16.3.2 Desalting

The impurities of most concern in crude oil include:

- The solid particulates (sand, clay, silt, rust etc.) or inorganic salts, which cause deposits and foul heat exchangers to pumps, pipelines etc. due to abrasion or erosion.
