Preface

First, we would like to introduce an addition to the editorial team that is responsible for organizing each of the new editions of the *Standard Handbook of Petroleum and Natural Gas Engineering*. Stemming from an original publication called *Practical Petroleum Engineer's Handbook* first published in the 1940s, the first edition of this handbook was published in 1996 after nearly 8 years of initial preparation by the handbook's first technical editor William (Bill) Lyons. For the second edition, Gary Plisga was added to the technical editorial staff. This second edition of the handbook was published in 2005 after 2 years of review of the original material organized by Bill Lyons and Gary Plisga. This new third edition required the addition of a third member to the technical editorial staff. This new member is Michael Lorenz. It is anticipated that Michael Lorenz will have to carry out the technical editing duties in a new fourth edition because of the present ages of Bill Lyons and Gary Plisga. Michael Lorenz in addition to learning the procedures this new third edition, has also written contributions for this present new handbook third edition.

As in the previous two editions of this handbook, this new third edition has been prepared in the spirit of the classic handbooks that have been prepared for the other important major engineering disciplines, namely, mechanical engineering, chemical engineering, and electrical engineering. In that regard, this new third edition of this handbook has been developed to allow the engineers and technicians that serve the upstream of the worldwide oil and gas industries to have a quick reference for technical definitions, data, calculation equations, and example solutions. The updated information from the old editions continues the effort to make the new edition more SI friendly. As in the second edition, this new third edition is available in a single hardback traditional handbook volume, or available as an e-book downloadable from the Elsevier website and other online retailers. An important quality of this new third edition is the editors' continued effort to make this

publication easily read and understood by any up-to-date engineer or technician, regardless of discipline.

The initial chapters of this edition set the tone by informing the reader of the common language and notation that all engineering disciplines utilize. This common language and notation is used throughout the handbook (in nearly all cases consistent with Society of Petroleum Engineers publication practices). The 120 contributing authors through the past three editions have tried to avoid the jargon that has crept into petroleum engineering literature over the past few decades. A classic example has been the use of the oil field slang term of "mud density" for the specific weight (lb/gal). In most places in the handbook, the use of either MW (lb/gal) or alternate term SG (for specific gravity) allows a reader to go easily to either SI, the British Imperial System, or the US Customary System.

The specific petroleum engineering discipline chapters cover drilling and well completions, reservoir engineering, production engineering, and economics (with valuation and risk analysis). These chapters contain information, data, and example calculations directed toward practical situations that petroleum engineers often encounter. Also, internal to each of these chapters is the growing role of natural gas in the world economies by integrating natural gas topics and related subjects throughout the new third edition.

As in both previous editions of this handbook, this new third edition has incorporated many important data bases from both the American Petroleum Institute and the Society of Petroleum Engineers publications. The authors and editors thank these two institutions for their cooperation. The authors and editors would also like to thank all the petroleum production and service company employees that have assisted in this project.

After nearly 30 years of college level teaching, Bill Lyons retired from the New Mexico Institute of Mining and Technology in 2006. In early 2007, he joined the BP Chevron Drilling Training Alliance (DTA) in Houston, Texas to continue his teaching career in the professional

development instruction arena. At the end of 2012, BP and Chevron dissolved the DTA and went their separate ways to carry out internal professional development of their staffs. The DTA was managed through most of its very successful 18 years of operation by Gary Massie with the competent managerial assistance of Saad Hashmi. At the end of 2012, the DTA was honored with ASME's Excellence in Professional Instruction. The readers will see in this new third edition the influence of operational engineering subjects that the technical editors experienced while with the BP Chevron DTA over the past decade.

In the detailed preparation of this new third edition, the co-authors and technical editors would like to specifically thank the many graphic artists that assisted in the

preparation of many of the included figures and drawings. These are Anton Hriczko, Ann Arens, and Jim Thacker. Further, the technical editors would like to thank the Elsevier's staff editors Katie Hammon, Kattie Washington, and Sruthi Satheesh. Thanks to each of you for all of your patience in dealing with all of the individual co-authors and the technical editors.

Chapter 1

Mathematics

1.1 GENERAL

See Reference 1 for additional information.

1.1.1 Sets and Functions

A *set* is a collection of distinct objects or *elements*. The intersection of two sets S and T is the set of elements which belong to S *and* which also belong to T. The *union* (or inclusive) of S and T is the set of all elements that belong to S or to T (or to both).

A *function* can be defined as a set of ordered pairs, denoted as (x, y) such that no two such pairs have the same first element. The element x is referred to as the independent variable, and the element y is referred to as the dependent variable. A function is established when a condition exists that determines y for each x, the condition usually being defined by an equation such as $y = f(x)$ [2].

REFERENCE

1. *Mark's Standard Handbook for Mechanical Engineers*, 8th Edition, Baumeister, T., Avallone, E. A., and Baumeister III, T. (Eds.), McGraw-Hill, New York, 1978.

1.2 GEOMETRY

See References 1 and 2 for additional information.

1.2.1 Angles

Angles can be measured using degrees or with radian measure. Using the degree system of measurement, a circle has 360° , a straight line has 180° , and a right angle has 90° . The radian system of measurement uses the arc length of a unit circle cut off by the angle as the measurement of the angle. In this system, a circle is measured as 2π radians, a straight line is π radians and a right angle is $\pi/2$ radians. An angle A is defined as *acute* if $0^\circ < A < 90^\circ$, *right* if $A = 90^\circ$, and *obtuse* if $90^\circ < A < 180^\circ$. Two angles

are *complementary* if their sum is 90° or are *supplementary* if their sum is 180° . Angles are *congruent* if they have the same measurement in degrees and line segments are congruent if they have the same length. A *dihedral angle* is formed by two half-planes having the same edge, but not lying in the same plane. A *plane angle* is the intersection of a perpendicular plane with a dihedral angle.

1.2.2 Polygons

A *polygon* is a closed figure with at least three line segments that lies within a plane. A *regular polygon* is a polygon in which all sides and angles are congruent. Two polygons are *similar* if their corresponding angles are congruent and corresponding sides are proportional. A segment whose end points are two nonconsecutive vertices of a polygon is a *diagonal*. The *perimeter* is the sum of the lengths of the sides.

1.2.3 Triangles

A *triangle* is a three-sided polygon. The sum of the angles of a triangle is equal to 180° . An *equilateral* triangle has three sides that are the same length, an *isosceles* triangle has two sides that are the same length, and a *scalene* triangle has three sides of different lengths.

A *median* of a triangle is a line segment whose end points are a vertex and the midpoint of the opposite side. An *angle bisector* of a triangle is a median that lies on the ray bisecting an angle of the triangle. The *altitude* of a triangle is a perpendicular segment from a vertex to the opposite side.

Two triangles are congruent if one of the following is given (where S = side length and A = angle measurement): SSS, SAS, AAS, or ASA.

1.2.4 Quadrilaterals

A *quadrilateral* is a four-sided polygon.

A *trapezoid* has one pair of opposite parallel sides. A *parallelogram* has both pairs of opposite sides congruent and parallel. The opposite angles are then congruent, and adjacent angles are supplementary. The diagonals bisect each other and are congruent. A *rhombus* is a parallelogram whose four sides are congruent and whose diagonals are perpendicular to each other.

A *rectangle* is a parallelogram having four right angles; therefore, both pairs of opposite sides are congruent. A rectangle whose sides are all congruent is a *square*.

1.2.5 Circles and Spheres

If P is a point on a given plane and r is a positive number, the *circle* with center P and radius r is the set of all points of the plane whose distance from P is equal to r. The *sphere* with center P and radius r is the set of all points in space whose distance from P is equal to r. Two or more circles (or spheres) with the same P but different values of r are *concentric*.

A *chord* of a circle (or sphere) is a line segment whose end points lie on the circle (or sphere). A line which intersects the circle (or sphere) in two points is a *secant* of the circle (or sphere). A *diameter* of a circle (or sphere) is a chord containing the center, and a *radius* is a line segment from the center to a point on the circle (or sphere).

The intersection of a sphere with a plane through its center is called a *great circle*.

A line that intersects a circle at only one point is a *tangent* to the circle at that point. Every tangent is perpendicular to the radius drawn to the point of intersection. Spheres may have tangent lines or tangent planes.

Pi (π) is the universal ratio of the circumference of any circle to its diameter and is approximately equal to 3.14159. Therefore, the circumference of a circle is πd or $2\pi r$.

1.2.6 Arcs of Circles

A *central angle* of a circle is an angle whose vertex is the center of the circle. If P is the center and A and B are points, not on the same diameter, which lie on C (the circle), the *minor arc* AB is the union of A, B, and all points on C in the interior of $\angle APB$. The *major arc* is the union of A, B, and all points on C on the exterior of $\angle APB$. A and B are the end points of the arc and P is the center. If A and B are the end points of a diameter, the arc is a semicircle. A *sector* of a circle is a region bounded by two radii and an arc of the circle.

1.2.7 Concurrency

Two or more lines are *concurrent* if there is a single point that lies on all of them. The three altitudes of a triangle (if taken as lines, not segments) are always concurrent, and their point of concurrency is called the *orthocenter*.

The angle bisectors of a triangle are concurrent at a point equidistant from their sides, and the medians are concurrent two thirds of the way along each median from the vertex to the opposite side. The point of concurrency of the medians is the *centroid*.

1.2.8 Similarity

Two figures with straight sides are *similar* if corresponding angles are congruent and the lengths of corresponding sides are in the same ratio. A line parallel to one side of a triangle divides the other two sides in proportion, producing a second triangle similar to the original one.

1.2.9 Prisms and Pyramids

A *prism* is a three-dimensional figure whose bases are any congruent and parallel polygons and whose sides are parallelograms. A *pyramid* is a solid with one base consisting of any polygon and with triangular sides meeting at a point in a plane parallel to the base.

Prisms and pyramids are described by their bases: a *triangular prism* has a triangular base, a *parallelepiped* is a prism whose base is a parallelogram and a *rectangular parallelepiped* is a right rectangular prism. A *cube* is a rectangular parallelepiped all of whose edges are congruent. A *triangular pyramid* has a triangular base, etc. A *circular cylinder* is a prism whose base is a circle and a *circular cone* is a pyramid whose base is a circle.

1.2.10 Coordinate Systems

Each point on a plane may be defined by a pair of numbers. The coordinate system is represented by a line X in the plane (the *x-axis*) and by a line Y (the *y-axis*) perpendicular to line X in the plane, constructed so that their intersection, the *origin*, is denoted by zero. Any point P on the plane can be described by its two coordinates, which form an ordered pair, so that $P(x_1, y_1)$ is a point whose location corresponds to the real numbers x and y on the x-axis and the y-axis.

If the coordinate system is extended into space, a third axis, the *z-axis*, perpendicular to the plane of the x_1 and y_1 axes, is needed to represent the third dimension coordinate defining a point $P(x_1, y_1, z_1)$. The z-axis intersects the x and y axes at their origin, zero. More than three dimensions are frequently dealt with mathematically but are difficult to visualize.

The *slope* m of a line segment in a plane with end points $P_1(x_1, y_1)$ and $P_2(x_2, y_2)$ is determined by the ratio of the change in the vertical (y) coordinates to the change in the horizontal (x) coordinates or

$$m = (y_2 - y_1)/(x_2 - x_1)$$

except that a vertical line segment (the change in x coordinates equal to zero) has no slope (i.e., m is undefined). A horizontal segment has a slope of zero. Two lines with the same slope are parallel and two lines whose slopes are negative reciprocals are perpendicular to each other.

Because the distance between two points $P_1(x_1, y_1)$ and $P_2(x_2, y_2)$ is the hypotenuse of a right triangle, the length (L) of the line segment P_1P_2 is equal to

$$L = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}$$

1.2.11 Graphs

A *graph* is a set of points lying in a coordinate system and a graph of a condition (such as $x = y + 2$) is the set of all points that satisfy the condition. The graph of the *slope-intercept equation*, $y = mx + b$, is a straight line which passes through the point $(0, b)$, where b is the y-intercept ($x = 0$) and m is the slope. The graph of the equation

$$(x - a)^2 + (y - b)^2 = r^2$$

is a circle with center (a, b) and radius r.

1.2.12 Vectors

A *vector* is described on a coordinate plane by a *directed segment* from its initial point to its terminal point. The directed segment represents the fact that every vector determines a magnitude and a direction. A vector \mathbf{v} is not changed when moved around the plane, if its magnitude and angular orientation with respect to the x-axis is kept constant. The initial point of \mathbf{v} may therefore be placed at the origin of the coordinate system and $\vec{\mathbf{v}}$ may be denoted by

$$\vec{\mathbf{v}} = \langle a, b \rangle$$

where a is the x-component and b is the y-component of the terminal point. The magnitude may then be determined by the Pythagorean theorem

$$|\mathbf{v}| = \sqrt{a^2 + b^2}$$

For every pair of vectors (x_1, y_1) and (x_2, y_2) , the *vector sum* is given by $(x_1 + x_2, y_1 + y_2)$. The *scalar product* of the vector $\mathbf{P} = (x, y)$ and a real number (a *scalar*) r is $r\mathbf{P} = (rx, ry)$. Also see the discussion of polar coordinates in the Section "Trigonometry" and Chapter 2, "Basic Mechanics."

1.2.13 Lengths and Areas of Plane Figures

For definitions of trigonometric functions, see "Trigonometry."

- *Right triangle* (Figure 1.2.1)

$$c^2 = a^2 + b^2 \text{ (Pythagorean theorem)}$$

$$\begin{aligned} \text{area} &= 1/2 \cdot ab = 1/2 \cdot a^2 \cot A \\ &= 1/2 \cdot b^2 \tan A = 1/4 \cdot c^2 \sin 2A \end{aligned}$$

- *Any triangle* (Figure 1.2.2)

$$\begin{aligned} \text{area} &= 1/2 \text{ base} \cdot \text{altitude} = 1/2 \cdot ah = 1/2 \cdot ab \sin C \\ &= \pm 1/2 \cdot \{(x_1y_2 - x_2y_1) \\ &\quad + (x_2y_3 - x_3y_2) \\ &\quad + (x_3y_1 - x_1y_3)\} \end{aligned}$$

where (x_1, y_1) , (x_2, y_2) , (x_3, y_3) are coordinates of vertices.

- *Rectangle* (Figure 1.2.3)

$$\begin{aligned} \text{area} &= ab = 1/2 \cdot D^2 \sin u \\ \text{where } u &= \text{angle between diagonals } D, D. \end{aligned}$$

- *Parallelogram* (Figure 1.2.4)

$$\begin{aligned} \text{area} &= bh = ab \sin c = 1/2 \cdot D_1 D_2 \sin u \\ \text{where } u &= \text{angle between diagonals } D_1 \text{ and } D_2. \end{aligned}$$

- Trapezoid (Figure 1.2.5)

area = $1/2 \cdot (a + b)h = 1/2 \cdot D_1 D_2 \sin u$
 where $u =$ angle between diagonals D_1 and D_2
 and where bases a and b are parallel.

- Any quadrilateral (Figure 1.2.6)

area = $1/2 \cdot D_1 D_2 \sin u$
 Note: $a^2 + b^2 + c^2 + d^2 = D_1^2 + D_2^2 + 4m^2$
 where $m =$ distance between midpoints of D_1 and D_2 .

- Circles

area = $\pi r^2 = 1/4 \cdot Cr = 1/4 \cdot Cd = 1/4 \cdot \pi d^2 = 0.785398 d^2$
 where $r =$ radius
 $d =$ diameter
 $C =$ circumference = $2\pi r = \pi d$.

- Annulus (Figure 1.2.7)

area = $\pi(R^2 - r^2) = \pi(D^2 - d^2)/4 = 2\pi R'b$
 where $R' =$ mean radius = $1/2 \cdot (R + r)$
 $b = R - r$

- Sector (Figure 1.2.8)

area = $1/2 \cdot rs = \pi r^2 A / 360^\circ = 1/2 \cdot r^2 \text{ rad } A$
 where rad $A =$ radian measure of angle A
 $s =$ length of arc = $r \text{ rad } A$

- Ellipse (Figure 1.2.9)

area of ellipse = πab
 area of shaded segment = $xy + ab \sin^{-1}(x/a)$
 length of perimeter of ellipse = $\pi(a + b)K$,
 where $K = (1 + 1/4 \cdot m^2 + 1/64 \cdot m^4 + 1/256 \cdot m^6 + \dots)$
 $m = (a - b)/(a + b)$

- Hyperbola (Figure 1.2.10)

For any hyperbola,
 shaded area $A = ab \cdot \ln[(x/a) + (y/b)]$
 For an equilateral hyperbola ($a = b$),
 area $A = a^2 \sinh^{-1}(y/a) = a^2 \cosh^{-1}(x/a)$
 where x and y are coordinates of point P .

- Parabola (Figure 1.2.11)

shaded area $A = \frac{2}{3} \cdot ch$

In Figure 1.2.12,
 length of arc $OP = s = \frac{1}{2} \cdot PT + \frac{1}{2} \cdot p \cdot \ln [\cot(\frac{1}{2} \cdot u)]$
 Here c = any chord
 p = semilatus rectum
 PT = tangent at P
 Note: $OT = OM = x$

1.2.14 Surfaces and Volumes of Solids

- *Regular prism* (Figure 1.2.13)

volume = $\frac{1}{2} \cdot nrah = Bh$
 lateral area = $nah = Ph$
 where n = number of sides
 B = area of base
 P = perimeter of base

- *Right circular cylinder* (Figure 1.2.14)

volume = $\pi r^2 h = Bh$
 lateral area = $2\pi r h = Ph$
 where B = area of base
 P = perimeter of base

- *Any prism or cylinder* (Figure 1.2.15)

volume = $Bh = Ni$
 lateral area = Ql
 where l = length of an element or lateral edge
 B = area of base
 N = area of normal section
 Q = perimeter of normal section

- *Hollow cylinder* (right and circular)
 volume = $\pi h(R^2 - r^2) = \pi h b(D - b) = \pi h b(d + b) = \pi h b D' = \pi h b(R + r)$
 where h = altitude
 $r, R (d, D)$ = inner and outer radii (diameters)
 b = thickness = $R - r$
 D' = mean diam = $\frac{1}{2} \cdot (d + D) = D - b = d + b$
- *Sphere*
 volume = $V = \frac{4}{3} \cdot \pi r^3 = 4.188790r^3 = \frac{1}{6} \cdot \pi d^3 = 0.523599d^3$
 area = $A = 4\pi r^2 = \pi d^2$
 where r = radius
 $d = 2r$ = diameter = $\sqrt[3]{\frac{6V}{\pi}} = 1.24070\sqrt[3]{V}$
 $= \sqrt[3]{\frac{A}{\pi}} = 0.56419\sqrt{A}$
- *Hollow sphere, or spherical shell*
 volume = $\frac{4}{3} \cdot \pi(R^3 - r^3) = \frac{1}{6} \cdot \pi(D^3 - d^3) = 4\pi R_1^2 t + \frac{1}{3} \cdot \pi t^3$
 where R, r = outer and inner radii
 D, d = outer and inner diameters
 t = thickness = $R - r$
 R_1 = mean radius = $\frac{1}{2} \cdot (R + r)$
- *Torus, or anchor ring* (Figure 1.2.16)

$$\text{volume} = 2\pi^2 cr^2$$

$$\text{area} = 4\pi r^2 cr \text{ (proof by theorems of Pappus)}$$

1.3 ALGEBRA

See Reference 1.3 for additional information.

1.3.1 Operator Precedence and Notation

Operations in an equation are performed in the following order of precedence:

1. Parenthesis and grouping symbols
2. Exponents
3. Multiplication or division (left to right)
4. Addition or subtraction (left to right)

For example:

$$a + b \bullet c - d^3/e$$

will be operated upon (calculated) as if it were written

$$a + (b \bullet c) - [(d^3)/e]$$

The symbol $|a|$ means “the absolute value of a,” or the numerical value of a regardless of sign, so that

$$|-2| = |2| = 2$$

The $n!$ means “n factorial” (where n is a whole number) and is the product of the whole numbers 1 to n inclusive, so that

$$4! = 1 \bullet 2 \bullet 3 \bullet 4 = 24$$

$$0! = 1 \text{ by definition}$$

The notation for the sum of any real numbers a_1, a_2, \dots, a_n is

$$\sum_{i=1}^n a_i$$

and for their product

$$\prod_{i=1}^n a_i$$

The notation “ $x \propto y$ ” is read “x varies directly with y” or “x is directly proportional to y,” meaning $x = ky$ where k

is some constant. If $x \propto 1/y$, then x is inversely proportional to y and $x = k/y$.

1.3.2 Rules of Addition

$$a + b = b + a \text{ (commutative property)}$$

$$(a + b) + c = a + (b + c) \text{ (associative property)}$$

$$a - (-b) = a + b \text{ and}$$

$$a - (x - y + z) = a - x + y - z$$

(i.e., a minus sign preceding a pair of parentheses operates to reverse the signs of each term within if the parentheses are removed)

1.3.3 Rules of Multiplication and Simple Factoring

$$a \bullet b = b \bullet a \text{ (commutative property)}$$

$$(ab)c = a(bc) \text{ (associative property)}$$

$$a(b + c) = ab + ac \text{ (distributive property)}$$

$$a(-b) = -ab \text{ and } -a(-b) = ab$$

$$(a + b)(a - b) = a^2 - b^2$$

$$(a + b)^2 = a^2 + 2ab + b^2$$

and

$$(a - b)^2 = a^2 - 2ab + b^2$$

$$(a + b)^3 = a^3 + 3a^2 + 3ab^2 + b^3$$

and

$$(a - b)^3 = a^3 - 3a^2 + 3ab^2 - b^3$$

(For higher-order polynomials, see the “Binomial Theorem.”) $a^n + b^n$ is factorable by $(a + b)$ if n is odd, and

$$a^3 + b^3 = (a + b)(a^2 - ab + b^2)$$

and $a^n - b^n$ is factorable by $(a - b)$, thus

$$a^n - b^n = (a - b)(a^{n-1} + a^{n-2}b + \dots + ab^{n-2} + b^{n-1})$$

1.3.4 Fractions

The numerator and denominator of a fraction may be multiplied or divided by any quantity (other than zero) without altering the value of the fraction, so that, if $m \neq 0$,

$$\frac{ma + mb + mc}{mx + my} = \frac{a + b + c}{x + y}$$

To add fractions, transform each to a common denominator and add the numerators ($b, y \neq 0$):

$$\frac{a}{b} + \frac{x}{y} = \frac{ay}{by} + \frac{bx}{by} = \frac{ay + bx}{by}$$

To multiply fractions (denominators $\neq 0$):

$$\frac{a}{b} \cdot \frac{x}{y} = \frac{ax}{by}$$

$$\frac{a}{b} \cdot x = \frac{ax}{b}$$

$$\frac{a}{b} \cdot \frac{x}{y} \cdot \frac{c}{z} = \frac{axc}{byz}$$

To divide one fraction by another, invert the divisor and multiply:

$$\frac{a}{b} \div \frac{x}{y} = \frac{a}{b} \cdot \frac{y}{x} = \frac{ay}{bx}$$

1.3.5 Exponents

$$a^m \cdot a^n = a^{m+n} \quad \text{and} \quad a^m \div a^n = a^{m-n}$$

$$a^0 = 1 \quad (a \neq 0) \quad \text{and} \quad a^1 = a$$

$$a^{-m} = 1/a^m$$

$$(a^m)^n = a^{mn}$$

$$a^{1/n} = \sqrt[n]{a} \quad \text{and} \quad a^{m/n} = \sqrt[n]{a^m}$$

$$(ab)^n = a^n b^n$$

$$(a/b)^n = a^n/b^n$$

Except in simple cases (square and cube roots), radical signs are replaced by fractional exponents. If n is odd,

$$\sqrt[n]{-a} = -\sqrt[n]{a}$$

but if n is even, the n th root of $-a$ is imaginary.

1.3.6 Logarithms

The logarithm of a positive number N is the power to which the base must be raised to produce N . So, $x = \log_b N$ means $b^x = N$. Logarithms to the base 10, frequently used in numerical computation, are called *common* or *denary logarithms*, and those to base e , used in theoretical work, are called *natural logarithms* and frequently notated as *ln*. In any case,

$$\log(ab) = \log a + \log b$$

$$\log(a/b) = \log a - \log b$$

$$\log(1/n) = -\log n$$

$$\log(a^n) = n \log a$$

$$\log_b(b) = 1, \text{ where } b \text{ is either } 10 \text{ or } e$$

$$\log 0 = -\infty$$

$$\log 1 = 0$$

$$\log_{10} e = M = 0.4342944819 \dots, \text{ so for conversion}$$

$$\log_{10} x = 0.4343 \log_e x$$

and since $1/M = 2.302585$, for conversion ($\ln = \log_e$)

$$\ln x = 2.3026 \log_{10} x$$

1.3.7 Binomial Theorem

Let

$$n_1 = n$$

$$n_2 = \frac{n(n-1)}{2!}$$

$$n_3 = \frac{n(n-1)(n-2)}{3!}$$

and so on. Then for any n , $|x| < 1$,

$$(1+x)^n = 1 + n_1x + n_2x^2 + n_3x^3 + \dots$$

If n is a positive integer, the system is valid without restriction on x and completes with the term $n_n x^n$.

Some of the more useful special cases follow [1]:

$$\sqrt{1+x} = (1+x)^{1/2} = 1 + \frac{1}{2}x - \frac{1}{8}x^2 + \frac{1}{16}x^3$$

$$- \frac{5}{128}x^4 + \dots \quad (|x| < 1)$$

$$\sqrt[3]{1+x} = (1+x)^{1/3} = 1 + \frac{1}{3}x - \frac{1}{9}x^2 - \frac{5}{81}x^3$$

$$- \frac{10}{243}x^4 + \dots \quad (|x| < 1)$$

$$\frac{1}{1+x} = (1+x)^{-1} = 1 - x + x^2 - x^3$$

$$+ x^4 - \dots \quad (|x| < 1)$$

$$\frac{1}{\sqrt{1+x}} = (1+x)^{-1/2} = 1 - \frac{1}{2}x + \frac{3}{8}x^2 - \frac{5}{16}x^3$$

$$+ \frac{35}{128}x^4 - \dots \quad (|x| < 1)$$

$$\frac{1}{\sqrt[3]{1+x}} = (1+x)^{-1/3} = 1 - \frac{1}{3}x + \frac{2}{9}x^2 - \frac{14}{81}x^3$$

$$+ \frac{35}{243}x^4 - \dots \quad (|x| < 1)$$

$$\sqrt{(1+x)^3} = (1+x)^{3/2} = 1 + \frac{3}{2}x + \frac{3}{8}x^2 + \frac{1}{16}x^3$$

$$+ \frac{3}{128}x^4 - \dots \quad (|x| < 1)$$

$$\frac{1}{\sqrt{(1+x)^3}} = (1+x)^{-3/2} = 1 - \frac{3}{2}x + \frac{15}{8}x^2 - \frac{35}{16}x^3$$

$$+ \frac{315}{128}x^4 - \dots \quad (|x| < 1)$$

with corresponding formulas for $(1-x)^{1/2}$, etc., obtained by reversing the signs of the odd powers of x . Provided $|b| < |a|$:

$$(a + b)^n = a^n \left(1 + \frac{b}{a}\right)^n$$

$$= a^n + n_1 a^{n-1} b + n_2 a^{n-2} b^2 + n_3 a^{n-3} b^3 + \dots$$

where n_1, n_2, \dots , have the values given earlier.

1.3.8 Progressions

In an *arithmetic progression*, ($a, a + d, a + 2d, a + 3d, \dots$), each term is obtained from the preceding term by adding a constant difference, d . If n is the number of terms, the last term is $p = a + (n - 1)d$, the “average” term is $1/2(a + p)$ and the sum of the terms is n times the average term or $s = n/2(a + p)$. The *arithmetic mean* between a and b is $(a + b)/2$.

In a *geometric progression*, (a, ar, ar^2, ar^3, \dots), each term is obtained from the preceding term by multiplying by a constant ratio, r . The n th term is ar^{n-1} , and the sum of the first n terms is $s = a(r^n - 1)/(r - 1) = a(1 - r^n)/(1 - r)$. If r is a fraction, r^n will approach zero as n increases and the sum of n terms will approach $a/(1 - r)$ as a limit.

The *geometric mean*, also called the “mean proportional,” between a and b is \sqrt{ab} . The *harmonic mean* between a and b is $2ab/(a + b)$.

1.3.9 Sums of the First n Natural Numbers

- To the first power:

$$1 + 2 + 3 + \dots + (n - 1) + n = n(n + 1)/2$$

- To the second power (squared):

$$1^2 + 2^2 + \dots + (n - 1)^2 + n^2 = n(n + 1)(2n + 1)/6$$

- To the third power (cubed):

$$1^3 + 2^3 + \dots + (n - 1)^3 + n^3 = [n(n + 1)/2]^2$$

1.3.10 Solution of Equations in One Unknown

Legitimate operations on equations include addition of any quantity to both sides, multiplication by any quantity of both sides (unless this would result in division by zero), raising both sides to any positive power (if \pm is used for even roots) and taking the logarithm or the trigonometric functions of both sides.

Any *algebraic equation* may be written as a polynomial of n th degree in x of the form

$$a_0 x^n + a_1 x^{n-1} + a_2 x^{n-2} + \dots + a_{n-1} x + a_n = 0$$

with, in general, n roots, some of which may be imaginary and some equal. If the polynomial can be factored in the form

$$(x - p)(x - q)(x - r) \dots = 0$$

then p, q, r, \dots are the roots of the equation. If $|x|$ is very large, the terms containing the lower powers of x are least important, while if $|x|$ is very small, the higher-order terms are least significant.

First-degree equations (*linear equations*) have the form

$$ax + b = c$$

with the solution $x = (c - b)/a$ and the root $b - a$.

Second-degree equations (*quadratic equations*) have the form

$$ax^2 + bx + c = 0$$

with the solution

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

and the roots

$$\frac{-b + \sqrt{b^2 - 4ac}}{2a}$$

and

$$\frac{-b - \sqrt{b^2 - 4ac}}{2a}$$

The sum of the roots is $-b/a$ and their product is c/a .

Third-degree equations (*cubic equations*) have the form, after division by the coefficient of the highest-order term,

$$x^3 + ax^2 + bx + c = 0$$

with the solution

$$x_1^3 = Ax_1 + B$$

where $x_1 = x - a/3$

$$A = 3(a/3)^2 - b$$

$$B = -2(a/3)^3 + b(a/3) - c$$

Exponential equations are of the form

$$a^x = b$$

with the solution $x = (\log b)/(\log a)$ and the root $(\log b)/(\log a)$. The complete logarithm must be taken, not just the mantissa.

1.3.11 Solution of Systems of Simultaneous Equations

A set of *simultaneous equations* is a system of n equations in n unknowns. The solutions (if any) are the sets of values for the unknowns that satisfy all the equations in the system.

First-degree equations in 2 unknowns are of the form

$$\begin{aligned} a_1x_1 + b_1x_2 &= c_1 \\ a_2x_1 + b_2x_2 &= c_2 \end{aligned}$$

The solution is found by multiplication of Equations 1.3.1 and 1.3.2 by some factors that will produce one term in each that will, upon addition of Equations 1.3.1 and 1.3.2, become zero. The resulting equation may then be rearranged to solve for the remaining unknown. For example, by multiplying Equation 1.3.1 by a_2 and Equation 1.3.2 by $-a_1$, adding Equation 1.3.1 and Equation 1.3.2 and rearranging their sum

$$x_2 = \frac{a_2c_1 - a_1c_2}{a_2b_1 - a_1b_2}$$

and by substitution in Equation 1.3.1:

$$x_1 = \frac{b_1c_2 - b_2c_1}{a_2b_1 - a_1b_2}$$

A set of n first-degree equations in n unknowns is solved in a similar fashion by multiplication and addition to eliminate $n - 1$ unknowns and then back substitution. Second-degree equations in 2 unknowns may be solved in the same way when two of the following are given: the product of the unknowns, their sum or difference, the sum of their squares. For further solutions, see “Numerical Methods.”

1.3.12 Determinants

Determinants of the second order are of the following form and are evaluated as

$$\begin{vmatrix} a_1b_1 \\ a_2b_2 \end{vmatrix} = a_1b_2 - a_2b_1$$

and of the third order as

$$\begin{vmatrix} a_1b_1c_1 \\ a_2b_2c_2 \\ a_3b_3c_3 \end{vmatrix} = a_1 \begin{vmatrix} b_2c_2 \\ b_3c_3 \end{vmatrix} - a_2 \begin{vmatrix} b_1c_1 \\ b_3c_3 \end{vmatrix} + a_3 \begin{vmatrix} b_1c_1 \\ b_2c_2 \end{vmatrix}$$

and of higher orders, by the general rules as follows. To evaluate a determinant of the n th order, take the elements of the first column with alternate plus and minus signs and form the sum of the products obtained by multiplying each of these elements by its corresponding *minor*. The minor corresponding to any element e_n is the determinant (of the next lowest order) obtained by striking out from the given determinant the row and column containing e_n .

Some of the general properties of determinants are

1. Columns may be changed to rows and rows to columns.
2. Interchanging two adjacent columns changes the sign of the result.

3. If two columns are equal or if one is a multiple of the other, the determinant is zero.
4. To multiply a determinant by any number m , multiply all elements of any one column by m .

Systems of simultaneous equations may be solved by the use of determinants using Cramer’s rule. Although the example is a third-order system, larger systems may be solved by this method. If

$$\begin{aligned} a_1x + b_1y + c_1z &= p_1 \\ a_2x + b_2y + c_2z &= p_2 \\ a_3x + b_3y + c_3z &= p_3 \end{aligned}$$

and if

$$D = \begin{vmatrix} a_1b_1c_1 \\ a_2b_2c_2 \\ a_3b_3c_3 \end{vmatrix} \neq 0$$

then

$$\begin{aligned} x &= D_1/D \\ y &= D_2/D \\ z &= D_3/D \end{aligned}$$

where

$$\begin{aligned} D_1 &= \begin{vmatrix} p_1b_1c_1 \\ p_2b_2c_2 \\ p_3b_3c_3 \end{vmatrix} \\ D_2 &= \begin{vmatrix} a_1p_1c_1 \\ a_2p_2c_2 \\ a_3p_3c_3 \end{vmatrix} \\ D_3 &= \begin{vmatrix} a_1b_1p_1 \\ a_2b_2p_2 \\ a_3b_3p_3 \end{vmatrix} \end{aligned}$$

1.4 TRIGONOMETRY

1.4.1 Directed Angles

If AB and AB' are any two rays with the same end point A , the directed angle $\angle BAB'$ is the ordered pair (\vec{AB}, \vec{AB}') . \vec{AB} is the initial side of $\angle BAB'$ and \vec{AB}' the terminal side. $\angle BAB' \neq \angle B'AB$ and any directed angle may be $\leq 0^\circ$ or $\geq 180^\circ$.

A directed angle may be thought of as an amount of rotation rather than a figure. If \vec{AB} is considered the initial

FIGURE 1.4.1 Trigonometric functions of angles.

position of the ray, which is then rotated about its end point A to form $\angle BAB'$, $\overrightarrow{AB'}$ is its terminal position.

1.4.2 Basic Trigonometric Functions

A trigonometric function can be defined for an angle θ between 0° and 90° by using Figure 1.4.1.

1.4.3 Trigonometric Properties

$$\begin{aligned} \sin \theta &= \text{opposite side/hypotenuse} = s_1/h \\ \cos \theta &= \text{adjacent side/hypotenuse} = s_2/h \\ \tan \theta &= \text{opposite side/adjacent side} = s_1/s_2 = \sin \theta / \cos \theta \end{aligned}$$

and the reciprocals of the basic functions (where the function $\neq 0$)

$$\begin{aligned} \text{cotangent } \theta &= \cot \theta = 1 / \tan \theta = s_2/s_1 \\ \text{secant } \theta &= \sec \theta = 1 / \cos \theta = h/s_2 \\ \text{cosecant } \theta &= \csc \theta = 1 / \sin \theta = h/s_1 \end{aligned}$$

To reduce an angle to the first quadrant of the unit circle, that is, to a degree measure between 0° and 90° , see Table 1.4.1. For function values at major angle values, see Tables 1.4.2 and 1.4.3. Relations between functions and the sum or difference of two functions are given in Table 1.4.4. Generally, there will be two angles between 0° and 360° that correspond to the value of a function.

The trigonometric functions sine and cosine can be defined for any real number by using the radian measure of the angle as described in the section on angles. The tangent function is defined on every real number except for places where cosine is zero.

1.4.4 Graphs of Trigonometric Functions

Graphs of the sine and cosine functions are identical in shape and periodic with a period of 360° . The sine function graph translated $\pm 90^\circ$ along the x-axis produces the graph

TABLE 1.4.1 Angle Reduction to First Quadrant

If	$90^\circ < x < 180^\circ$	$180^\circ < x < 270^\circ$	$270^\circ < x < 360^\circ$
$\sin x =$	$+\cos(x - 90^\circ)$	$-\sin(x - 180^\circ)$	$-\cos(x - 270^\circ)$
$\cos x =$	$-\sin(x - 90^\circ)$	$-\cos(x - 180^\circ)$	$+\sin(x - 270^\circ)$
$\tan x =$	$-\cot(x - 90^\circ)$	$+\tan(x - 180^\circ)$	$-\cot(x - 270^\circ)$
$\csc x =$	$+\sec(x - 90^\circ)$	$-\csc(x - 180^\circ)$	$-\sec(x - 270^\circ)$
$\sec x =$	$-\csc(x - 90^\circ)$	$-\sec(x - 180^\circ)$	$+\csc(x - 270^\circ)$
$\cot x =$	$-\tan(x - 90^\circ)$	$+\cot(x - 180^\circ)$	$-\tan(x - 270^\circ)$

TABLE 1.4.2 Trigonometric Function Values by Quadrant

If	$0^\circ < x < 90^\circ$	$90^\circ < x < 180^\circ$	$180^\circ < x < 270^\circ$	$270^\circ < x < 360^\circ$
$\sin x$	+0 to +1	+1 to +0	-0 to -1	-1 to -0

$\cot x$	$\sqrt{3}$	1	$1/3\sqrt{3}$

of the cosine function. The graph of the tangent function is discontinuous when the value of $\tan \theta$ is undefined, that is, at odd multiples of 90° ($\dots, 90^\circ, 270^\circ, \dots$). For abbreviated graphs of the sine, cosine, and tangent functions, see Figure 1.4.2.

TABLE 1.4.4 Relations Between Trigonometric Functions of Angles

Single Angle

$$\sin^2 x + \cos^2 x = 1$$

$$\tan x = (\sin x)/(\cos x)$$

$$\cot x = 1/(\tan x)$$

$$1 + \tan^2 x = \sec^2 x$$

$$1 + \cot^2 x = \csc^2 x$$

$$\sin(-x) = -\sin x, \cos(-x) = \cos x, \tan(-x) = -\tan x$$

Two Angles

$$\sin(x + y) = \sin x \cos y + \cos x \sin y$$

$$\sin(x - y) = \sin x \cos y - \cos x \sin y$$

$$\cos(x + y) = \cos x \cos y - \sin x \sin y$$

$$\cos(x - y) = \cos x \cos y + \sin x \sin y$$

$$\tan(x + y) = (\tan x + \tan y)/(1 - \tan x \tan y)$$

$$\tan(x - y) = (\tan x - \tan y)/(1 + \tan x \tan y)$$

$$\cot(x + y) = (\cot x \cot y - 1)/(\cot y + \cot x)$$

$$\cot(x - y) = (\cot x \cot y + 1)/(\cot y - \cot x)$$

$$\sin x + \sin y = 2 \sin[1/2(x + y)] \cos[1/2(x - y)]$$

$$\sin x - \sin y = 2 \cos[1/2(x + y)] \sin[1/2(x - y)]$$

$$\cos x + \cos y = 2 \cos[1/2(x + y)] \cos[1/2(x - y)]$$

$$\cos x - \cos y = -2 \sin[1/2(x + y)] \sin[1/2(x - y)]$$

$$\tan x + \tan y = [\sin(x + y)]/[\cos x \cos y]$$

$$\tan x - \tan y = [\sin(x - y)]/[\cos x \cos y]$$

$$\cot x + \cot y = [\sin(x + y)]/[\sin x \sin y]$$

$$\cot x - \cot y = [\sin(y - x)]/[\sin x \sin y]$$

$$\sin^2 x - \sin^2 y = \cos^2 y - \cos^2 x = \sin(x + y) \sin(x - y)$$

TABLE 1.4.4 Relations Between Trigonometric Functions of Angles—cont'd

$$\cos^2 x - \sin^2 y = \cos^2 y - \sin^2 x = \cos(x + y) \cos(x - y)$$

$$\sin(45^\circ + x) = \cos(45^\circ - x), \tan(45^\circ + x) = \cot(45^\circ - x)$$

$$\sin(45^\circ - x) = \cos(45^\circ + x), \tan(45^\circ - x) = \cot(45^\circ + x)$$

Multiple and Half Angles

$$\tan 2x = (2 \tan x)/(1 - \tan^2 x)$$

$$\cot 2x = (\cot^2 x - 1)/(2 \cot x)$$

$$\begin{aligned} \sin(nx) &= n \sin x \cos^{n-1} x - (n)_3 \sin^3 x \cos^{n-3} x \\ &\quad + (n)_5 \sin^5 x \cos^{n-5} x - \dots \end{aligned}$$

$$\cos(nx) = \cos^n x - (n)_2 \sin^2 x \cos^{n-2} x + (n)_4 \sin^4 x \cos^{n-4} x - \dots$$

(Note: $(n)_2, \dots$ are the binomial coefficients)

$$\sin(x/2) = \pm \sqrt{1/2(1 - \cos x)}$$

$$\cos(x/2) = \pm \sqrt{1/2(1 + \cos x)}$$

$$\tan(x/2) = (\sin x)/(1 + \cos x) = \pm \sqrt{(1 - \cos x)/(1 + \cos x)}$$

Three Angles Whose Sum = 180°

$$\sin A + \sin B + \sin C = 4 \cos(A/2) \cos(B/2) \cos(C/2)$$

$$\cos A + \cos B + \cos C = 4 \sin(A/2) \sin(B/2) \sin(C/2) + 1$$

$$\sin A + \sin B - \sin C = 4 \sin(A/2) \sin(B/2) \cos(C/2)$$

$$\cos A + \cos B - \cos C = 4 \cos(A/2) \cos(B/2) \sin(C/2) - 1$$

$$\sin^2 A + \sin^2 B + \sin^2 C = 2 \cos A \cos B \cos C + 2$$

$$\sin^2 A + \sin^2 B - \sin^2 C = 2 \sin A \sin B \cos C$$

$$\tan A + \tan B + \tan C = \tan A \tan B \tan C$$

$$\cot(A/2) + \cot(B/2) + \cot(C/2) = \cot(A/2) \cot(B/2) \cot(C/2)$$

$$\sin 2A + \sin 2B + \sin 2C = 4 \sin A \sin B \sin C$$

$$\sin 2A + \sin 2B - \sin 2C = 4 \cos A \cos B \sin C$$

FIGURE 1.4.2 Graphs of the trigonometric functions.

1.4.5 Inverse Trigonometric Functions

The inverse sine of x (also referred to as the arc sine of x), denoted by $\sin^{-1}x$, is the principal angle whose sine is x , that is,

$$y = \sin^{-1} x \text{ means } \sin y = x$$

Inverse functions $\cos^{-1}x$ and $\tan^{-1}x$ also exist for the cosine of y and the tangent of y . The principal angle for $\sin^{-1}x$ and $\tan^{-1}x$ is an angle a , where $-90^\circ < a < 90^\circ$, and for $\cos^{-1}x$, $0^\circ < a < 180^\circ$.

1.4.6 Solution of Plane Triangles

The solution of any part of a plane triangle is determined in general by any other three parts given by one of the following groups, where S is the length of a side and A is the degree measure of an angle:

- AAS
- SAS
- SSS

The fourth group, two sides and the angle opposite one of them, is ambiguous since it may give zero, one, or two solutions. Given an example triangle with sides a , b , and c and angles A , B , and C (A being opposite a , etc., and $A + B + C = 180^\circ$), the fundamental laws relating to the solution of triangles are

1. Law of sines: $a/(\sin A) = b/(\sin B) = c/(\sin C)$
2. Law of cosines: $c^2 = a^2 + b^2 - 2ab \cos C$

1.4.7 Hyperbolic Functions

The *hyperbolic sine*, *hyperbolic cosine*, etc., of any number x are functions related to the exponential function e^x . Their definitions and properties are very similar to the trigonometric functions and are given in Table 1.4.5.

The *inverse hyperbolic functions*, $\sinh^{-1}x$, etc., are related to the logarithmic functions and are particularly useful in integral calculus. These relationships may be defined for real numbers x and y as

$$\begin{aligned} \sinh^{-1}(x/y) &= \ln(x + \sqrt{x^2 + y^2}) - \ln y \\ \cosh^{-1}(x/y) &= \ln(x + \sqrt{x^2 - y^2}) - \ln y \\ \tanh^{-1}(x/y) &= 1/2 \bullet \ln[(y + x)/(y - x)] \\ \coth^{-1}(x/y) &= 1/2 \bullet \ln[(x + y)/(x - y)] \end{aligned}$$

1.4.8 Polar Coordinate System

The *polar coordinate system* describes the location of a point (denoted as $[r, \theta]$) in a plane by specifying a distance r and an angle θ from the origin of the system. There are several relationships between polar and rectangular coordi-

TABLE 1.4.5 Hyperbolic Functions

$\sinh x = 1/2(e^x - e^{-x})$
$\cosh x = 1/2(e^x + e^{-x})$
$\tanh x = \sinh x/\cosh x$
$\operatorname{csch} x = 1/\sinh x$
$\operatorname{sech} x = 1/\cosh x$
$\operatorname{coth} x = 1/\tanh x$
$\sinh(-x) = -\sinh x$
$\cosh(-x) = \cosh x$
$\tanh(-x) = -\tanh x$
$\cosh^2 x - \sinh^2 x = 1$
$1 - \tanh^2 x = \operatorname{sech}^2 x$
$1 - \operatorname{coth}^2 x = -\operatorname{csch}^2 x$
$\sinh(x \pm y) = \sinh x \cosh y \pm \cosh x \sinh y$
$\cosh(x \pm y) = \cosh x \cosh y \pm \sinh x \sinh y$
$\tanh(x \pm y) = (\tanh x \pm \tanh y)/(1 \pm \tanh x \tanh y)$
$\sinh 2x = 2 \sinh x \cosh x$
$\cosh 2x = \cosh^2 x + \sinh^2 x$
$\tanh 2x = (2 \tanh x)/(1 + \tanh^2 x)$
$\sinh(x/2) = \sqrt{1/2(\cosh x - 1)}$
$\cosh(x/2) = \sqrt{1/2(\cosh x + 1)}$
$\tanh(x/2) = (\cosh x - 1)/(\sinh x) = (\sinh x)/(\cosh x + 1)$

nates, diagrammed in Figure 1.4.3. From the Pythagorean theorem

$$r = \pm\sqrt{x^2 + y^2}$$

Also

$$\begin{aligned} \sin \theta &= y/r \quad \text{or} \quad y = r \sin \theta \\ \cos \theta &= x/r \quad \text{or} \quad x = r \cos \theta \\ \tan \theta &= y/x \quad \text{or} \quad \theta = \tan^{-1}(y/x) \end{aligned}$$

To convert rectangular coordinates to polar coordinates, given the point (x, y) , using the Pythagorean theorem and the preceding equations.

$$[r, \theta] = \left[\sqrt{x^2 + y^2}, \tan^{-1}(y/x) \right]$$

FIGURE 1.4.3 Polar coordinates.

FIGURE 1.4.4 The polar plane.

To convert polar to rectangular coordinates, given the point $[r, \theta]$:

$$(x, y) = [r \cos \theta, r \sin \theta]$$

For graphic purposes, the polar plane is usually drawn as a series of concentric circles with the center at the origin and radii 1, 2, 3, . . . Rays from the center are drawn at $0^\circ, 15^\circ, 30^\circ, \dots, 360^\circ$ or $0, \pi/12, \pi/6, \pi/4, \dots, 2\pi$ radians. The origin is called the *pole*, and points $[r, \theta]$ are plotted by moving a positive or negative distance r horizontally from the pole, and through an angle θ from the horizontal. See Figure 1.4.4 with θ given in radians as used in calculus. Also note that

$$[r, \theta] = [-r, \theta + \pi]$$

1.5 DIFFERENTIAL AND INTEGRAL CALCULUS

See References 1–4 for additional information.

1.5.1 Derivatives

Geometrically, the derivative of $y = f(x)$ at any value x_n is the slope of a tangent line T intersecting the curve at the point $P(x, y)$. Two conditions applying to differentiation (the process of determining the derivatives of a function) are

1. The primary (necessary and sufficient) condition is that

$$\lim_{\Delta x \rightarrow 0} \frac{\Delta y}{\Delta x}$$

exists and is independent of the way in which $\Delta x \rightarrow 0$

2. A secondary (necessary, not sufficient) condition is that

$$\lim_{\Delta x \rightarrow 0} f(x + \Delta x) = f(x)$$

A short table of derivatives will be found in Table 1.5.1.

1.5.2 Higher-Order Derivatives

The *second derivative* of a function $y = f(x)$, denoted $f''(x)$ or d^2y/dx^2 is the derivative of $f'(x)$ and the *third derivative*, $f'''(x)$ is the derivative of $f''(x)$. Geometrically, in terms of $f(x)$: if $f''(x) > 0$ then $f(x)$ is concave upwardly, if $f''(x) < 0$ then $f(x)$ is concave downwardly.

1.5.3 Partial Derivatives

If $u = f(x, y, \dots)$ is a function of two or more variables, the *partial derivative* of u with respect to x , $f_x(x, y, \dots)$ or $\partial u / \partial x$, may be formed by assuming x to be the independent variable and holding (y, \dots) as constants. In a similar manner, $f_y(x, y, \dots)$ or $\partial u / \partial y$ may be formed by holding (x, \dots) as constants. Second-order partial derivatives of $f(x, y)$ are denoted by the manner of their formation as f_{xx} , f_{xy} (equal to f_{yx}), f_{yy} or as $\partial^2 u / \partial x^2$, $\partial^2 u / \partial x \partial y$, $\partial^2 u / \partial y^2$, and the higher-order partial derivatives are likewise formed.

Implicit functions (i.e., $f(x, y) = 0$) may be solved by the formula

$$\frac{dy}{dx} = -\frac{f_x}{f_y}$$

at the point in question.

TABLE 1.5.1 Table of Derivatives^a

$\frac{d}{dx}(x) = 1$	$\frac{d}{dx} \sin^{-1} u = \frac{1}{\sqrt{1-u^2}} \frac{du}{dx}$
$\frac{d}{dx}(a) = 0$	$\frac{d}{dx} \cos^{-1} u = -\frac{1}{\sqrt{1-u^2}} \frac{du}{dx}$
$\frac{d}{dx}(u \pm v \pm \dots) = \frac{du}{dx} \pm \frac{dv}{dx} \pm \dots$	$\frac{d}{dx} \tan^{-1} u = \frac{1}{1+u^2} \frac{du}{dx}$
$\frac{d}{dx}(au) = a \frac{du}{dx}$	$\frac{d}{dx} \cot^{-1} u = -\frac{1}{1+u^2} \frac{du}{dx}$
$\frac{d}{dx}(uv) = u \frac{dv}{dx} + v \frac{du}{dx}$	$\frac{d}{dx} \sec^{-1} u = \frac{1}{u\sqrt{u^2-1}} \frac{du}{dx}$
$\frac{d}{dx} \frac{u}{v} = \frac{v \frac{du}{dx} - u \frac{dv}{dx}}{v^2}$	$\frac{d}{dx} \csc^{-1} u = -\frac{1}{u\sqrt{u^2-1}} \frac{du}{dx}$
$\frac{d}{dx}(u^a) = nu^{a-1} \frac{du}{dx}$	$\frac{d}{dx} \text{vers}^{-1} u = \frac{1}{\sqrt{2u-u^2}} \frac{du}{dx}$
$\frac{d}{dx} \log_a u = \frac{\log_a e}{u} \frac{du}{dx}$	$\frac{d}{dx} \sinh u = \cosh u \frac{du}{dx}$
$\frac{d}{dx} \log u = \frac{1}{u} \frac{du}{dx}$	$\frac{d}{dx} \cosh u = \sinh u \frac{du}{dx}$
$\frac{d}{dx} a^u = a^u \cdot \log_e a \cdot \frac{du}{dx}$	$\frac{d}{dx} \tanh u = \text{sech}^2 u \frac{du}{dx}$
$\frac{d}{dx} e^u = e^u \frac{du}{dx}$	$\frac{d}{dx} \coth u = -\text{csc}^2 u \frac{du}{dx}$
$\frac{d}{dx} u^v = uv^{v-1} \frac{du}{dx} + u^v \log_e u \frac{dv}{dx}$	$\frac{d}{dx} \text{sech} u = -\text{sech} u \tanh u \frac{du}{dx}$
$\frac{d}{dx} \sin u = \cos u \frac{du}{dx}$	$\frac{d}{dx} \text{csch} u = -\text{csch} u \coth u \frac{du}{dx}$
$\frac{d}{dx} \cos u = -\sin u \frac{du}{dx}$	$\frac{d}{dx} \sinh^{-1} u = \frac{1}{\sqrt{u^2+1}} \frac{du}{dx}$
$\frac{d}{dx} \tan u = \sec^2 u \frac{du}{dx}$	$\frac{d}{dx} \cosh^{-1} u = \frac{1}{\sqrt{u^2-1}} \frac{du}{dx}$
$\frac{d}{dx} \cot u = -\text{csc}^2 u \frac{du}{dx}$	$\frac{d}{dx} \tanh^{-1} u = \frac{1}{1-u^2} \frac{du}{dx}$
$\frac{d}{dx} \sec u = \sec u \tan u \frac{du}{dx}$	$\frac{d}{dx} \coth^{-1} u = -\frac{1}{u^2-1} \frac{du}{dx}$
$\frac{d}{dx} \csc u = -\text{csc} u \cot u \frac{du}{dx}$	$\frac{d}{dx} \text{sech}^{-1} u = -\frac{1}{u\sqrt{1-u^2}} \frac{du}{dx}$
$\frac{d}{dx} \text{vers} u = \sin u \frac{du}{dx}$	$\frac{d}{dx} \text{csc} h^{-1} u = -\frac{1}{u\sqrt{u^2-1}} \frac{du}{dx}$

^aThe u and v represent functions of x . All angles are in radians.

1.5.4 Maxima and Minima

A *critical point* on a curve $y = f(x)$ is a point where $y' = 0$, that is, where the tangent to the curve is horizontal. A critical value of x is therefore a value such that $f'(x) = 0$. All roots of the equation $f'(x) = 0$ are critical values of x , and the corresponding values of y are the critical values of the function.

A function $f(x)$ has a *relative maximum* at $x = a$ if $f(x) < f(a)$ for all values of x (except a) in some open interval containing a and a *relative minimum* at $x = b$ if $f(x) > f(b)$ for all x (except b) in the interval containing b . At the relative maximum a of $f(x)$, $f'(a) = 0$, i.e., slope = 0, and $f''(a) < 0$, i.e., the curve is downwardly concave at this point, and at the relative minimum b , $f'(b) = 0$ and $f''(b) > 0$ (upward concavity). In Figure 1.5.1 A, B, C, and D are critical points and $x_1, x_2, x_3,$ and x_4 are critical values of

FIGURE 1.5.1 Maxima and minima.

x . A and C are maxima, B is a minimum, and D is neither. D, F, G, and H are *points of inflection* where the slope is minimum or maximum. In special cases, such as E, maxima or minima may occur where $f'(x)$ is undefined or infinite.

The *absolute maximum* (or minimum) of $f(x)$ at $x = a$ exists if $f(x) \leq f(a)$ (or $f(x) \geq f(a)$) for all x in the domain of the function and need not be a relative maximum or minimum. If a function is defined and continuous on a closed interval, it will always have an absolute minimum and an absolute maximum, and they will be found either at a relative minimum and a relative maximum or at the endpoints of the interval.

1.5.5 Differentials

If $y = f(x)$ and Δx and Δy are the increments of x and y , respectively, because $y + \Delta y = f(x + \Delta x)$, then

$$\Delta y = f(x + \Delta x) - f(x)$$

As Δx approaches its limit 0 and (since x is the independent variable) $dx = \Delta x$

$$\frac{dy}{dx} \cong \frac{f(x + \Delta x) - f(x)}{\Delta x}$$

and

$$dy \cong \Delta y$$

By defining dy and dx separately, it is now possible to write

$$\frac{dy}{dx} = f'(x)$$

as

$$dy = f'(x)dx$$

In functions of two or more variables, where $f(x, y, \dots) = 0$, if dx, dy, \dots are assigned to the independent variables x, y, \dots , the differential du is given by differentiating term by term or by taking

$$du = f_x \bullet dx + f_y \bullet dy + \dots$$

If x, y, \dots are functions of t , then

$$\frac{du}{dt} = (f_x) \frac{dx}{dt} + (f_y) \frac{dy}{dt} + \dots$$

expresses the rate of change of u with respect to t , in terms of the separate rates of change of x, y, \dots with respect to t .

1.5.6 Radius of Curvature

The *radius of curvature* R of a plane curve at any point P is the distance along the normal (the perpendicular to the tangent to the curve at point P) on the concave side of the curve to the *center of curvature* (Figure 1.5.2). If the equation of the curve is $y = f(x)$

$$R = \frac{ds}{du} = \frac{[1 + f'(x)^2]^{3/2}}{f''(x)}$$

where the rate of change (ds/dx) and the differential of the arc (ds), s being the length of the arc, are defined as

$$\frac{ds}{dx} = \sqrt{1 + \left(\frac{dy}{dx}\right)^2}$$

and

$$ds = \sqrt{dx^2 + dy^2}$$

and $dx = ds \cos u$
 $dy = ds \sin u$
 $u = \tan^{-1}[f'(x)]$

with u being the angle of the tangent at P with respect to the x -axis. (Essentially, ds, dx , and dy correspond to the sides of a right triangle.) The curvature K is the rate at which u is changing with respect to s , and

$$K = \frac{1}{R} = \frac{du}{ds}$$

If $f'(x)$ is small, $K \cong f''(x)$.

FIGURE 1.5.2 Radius of curvature in rectangular coordinates.

FIGURE 1.5.3 Radius of curvature in polar coordinates.

In polar coordinates (Figure 1.5.3), $r = f(\theta)$, where r is the radius vector and θ is the polar angle, and

$$ds = \sqrt{d\rho^2 + \rho^2 d\theta^2}$$

so that by $x = \rho \cos \theta, y = \rho \sin \theta$ and $K = 1/R = d\theta/ds$, then

$$R = \frac{ds}{d\theta} = \frac{[r^2 + (r')^2]^{3/2}}{r^2 - rr'' + 2(r')^2}$$

If the equation of the circle is

$$R^2 = (x - \alpha)^2 + (y - \beta)^2$$

by differentiation and simplification

$$\alpha = x - \frac{y'[1 + (y')^2]}{y''}$$

and

$$\beta = y + \frac{1 + (y')^2}{y''}$$

The *evolute* is the locus of the centers of curvature, with variables α and β , and the parameter x (y, y' , and y'' all being functions of x). If $f(x)$ is the evolute of $g(x)$, $g(x)$ is the *involute* of $f(x)$.

1.5.7 Indefinite Integrals

Definition: The indefinite integral (antiderivative) may be defined as follows:

$$\int f(x)dx = F(x) + C \text{ if } F'(x) = f(x)$$

The constant C is called the constant of integration.

Integration by parts makes use of the differential of a product

$$d(uv) = u dv + v du$$

or

$$u \, dv = d(uv) - v \, du$$

and by integrating

$$\int u \, dv = uv - \int v \, du$$

where $\int v \, du$ may be recognizable as a standard form or may be more easily handled than $\int u \, dv$.

Integration by transformation may be useful when, in certain cases, particular transformations of a given integral to one of a recognizable form suggest themselves.

For example, a given integral involving such quantities as

$$\sqrt{u^2 - a^2}, \quad \sqrt{u^2 + a^2}, \quad \text{or} \quad \sqrt{a^2 - u^2}$$

may suggest appropriate trigonometric transformations such as, respectively,

$$u = a \csc \theta, \\ u = a \tan \theta,$$

or

$$u = a \sin \theta$$

Integration by partial fractions is of assistance in the integration of rational fractions. If

$$\frac{ax + b}{x^2 + px + q} = \frac{ax + b}{(x - \alpha)(x - \beta)} = \frac{A}{x - \alpha} + \frac{B}{x - \beta}$$

where $A + B = \alpha$

$$A\beta + B\alpha = -b$$

and A and B are found by use of determinants (see “Algebra”), then

$$\int \frac{(ax + b)dx}{(x - \alpha)(x - \beta)} = \int \frac{A dx}{x - \alpha} + \int \frac{B dx}{x - \beta} \\ = A \log(x - \alpha) + B \log(x - \beta) + C$$

Integration by tables is possible if an integral may be put into a form that can be found in a table of integrals, such as the one given in Table 1.5.2. More complete tables may be found in Bois, “Table of Indefinite Integrals,” Dover, and in others.

1.5.8 Definite Integrals

The *fundamental theorem of calculus* states that if $f(x)$ is the derivative of $F(x)$ and if $f(x)$ is continuous in the interval $[a, b]$, then

$$\int_a^b f(x)dx = F(b) - F(a)$$

TABLE 1.5.2 Table of Integrals^a

1. $\int df(x) = f(x) + C$
2. $d \int f(x)dx = f(x)dx$
3. $\int 0 \bullet dx = C$
4. $\int af(x)dx = a \int f(x)dx$
5. $\int (u \pm v)dx = \int udx \pm \int vdx$
6. $\int u \, dv = uv - \int v \, du$
7. $\int \frac{u \, dv}{dx} dx = uv - \int v \frac{du}{dx} dx$
8. $\int f(y)dx = \int \frac{f(y)dy}{\frac{dy}{dx}}$
9. $\int u^n du = \frac{u^{n+1}}{n+1} + C, n \neq -1$
10. $\int \frac{du}{u} = \log_e u + C$
11. $\int e^u du = e^u + C$
12. $\int b^u du = \frac{b^u}{\log_e b} + C$
13. $\int \sin u \, du = -\cos u + C$
14. $\int \cos u \, du = \sin u + C$
15. $\int \tan u \, du = \log_e \sec u + C = -\log_e \cos u + C$
16. $\int \cot u \, du = \log_e \sin u + C = -\log_e \csc u + C$
17. $\int \sec u \, du = \log_e(\sec u + \tan u) + C$ $= \log_e \tan \left(\frac{u}{2} + \frac{\pi}{4} \right) + C$
18. $\int \csc u \, du = \log_e(\csc u - \cot u) + C = \log_e \tan \frac{u}{2} + C$
19. $\int \sin^2 u \, du = \frac{1}{2}u - \frac{1}{2} \sin u \cos u + C$
20. $\int \cos^2 u \, du = \frac{1}{2}u + \frac{1}{2} \sin u \cos u + C$
21. $\int \sec^2 u \, du = \tan u + C$
22. $\int \csc^2 u \, du = -\cot u + C$
23. $\int \tan^2 u \, du = \tan u - u + C$
24. $\int \cot^2 u \, du = -\cot u - u + C$
25. $\int \frac{du}{u^2 + a^2} = \frac{1}{a} \tan^{-1} \frac{u}{a} + C$
26. $\int \frac{du}{u^2 - a^2} = \frac{1}{2a} \log_e \left(\frac{u-a}{u+a} \right) + C$ $= -\frac{1}{a} \coth^{-1} \left(\frac{u}{a} \right) + C, \text{ if } u^2 > a^2$ $= \frac{1}{2a} \log_e \left(\frac{a-u}{a+u} \right) + C$ $= -\frac{1}{a} \tanh^{-1} \left(\frac{u}{a} \right) + C, \text{ if } u^2 < a^2$
27. $\int \frac{du}{\sqrt{a^2 - u^2}} = \sin^{-1} \left(\frac{u}{a} \right) + C$
28. $\int \frac{du}{\sqrt{u^2 \pm a^2}} \log_e(u + \sqrt{u^2 \pm a^2})^t + C$
29. $\int \frac{du}{\sqrt{au - u^2}} = \cos^{-1} \left(\frac{a-u}{a} \right) + C$

TABLE 1.5.2 Table of Integrals—cont'd

30.	$\int \frac{du}{u\sqrt{u^2-a^2}} = \frac{1}{a} \sec^{-1} \left(\frac{u}{a} \right) + C = \frac{1}{a} \cos^{-1} \frac{a}{u} + C$
31.	$\int \frac{du}{u\sqrt{a^2 \pm u^2}} = -\frac{1}{a} \log_e \left(\frac{a+\sqrt{a^2-u^2}}{u} \right) + C$
32.	$\int \sqrt{a^2 - u^2} \bullet du = \frac{1}{2} \left(u\sqrt{a^2 - u^2} + a^2 \sin^{-1} \frac{u}{a} \right) + C$
33.	$\int \sqrt{u^2 \pm a^2} \bullet du$ $= \frac{1}{2} \left[u\sqrt{u^2 \pm a^2} \pm a^2 \log_e (u + \sqrt{u^2 \pm a^2}) \right] + C$
34.	$\int \sinh u \, du = \cosh u + C$
35.	$\int \cosh u \, du = \sinh u + C$
36.	$\int \tanh u \, du = \log_e (\cosh u) + C$
37.	$\int \coth u \, du = \log_e (\sinh u) + C$
38.	$\int \operatorname{sech} u \, du = \sin^{-1} (\tanh u) + C$
39.	$\int \operatorname{csch} u \, du = \log_e \left(\tanh \frac{u}{2} \right) + C$
40.	$\int \operatorname{sech} u \bullet \tanh u \bullet du = -\operatorname{sech} u + C$
41.	$\int \operatorname{csch} u \bullet \coth u \bullet du = -\operatorname{csch} u + C$

^aThe u and v represent functions of x .
[†] $\log_e \left(\frac{u+\sqrt{u^2+a^2}}{a} \right) = \sinh^{-1} \left(\frac{u}{a} \right)$; $\log_e \left(\frac{a+\sqrt{a^2-u^2}}{u} \right) = \operatorname{sech}^{-1} \left(\frac{u}{a} \right)$;
 $\log_e \left(\frac{u+\sqrt{u^2-a^2}}{a} \right) = \cosh^{-1} \left(\frac{u}{a} \right)$; $\log_e \left(\frac{a+\sqrt{a^2-u^2}}{u} \right) = \operatorname{csch}^{-1} \left(\frac{u}{a} \right)$

Geometrically, the integral of $f(x)dx$ over the interval $[a, b]$ is the area bounded by the curve $y = f(x)$ from $f(a)$ to $f(b)$ and the x -axis from $x = a$ to $x = b$, or the “area under the curve from a to b .”

1.5.9 Properties of Definite Integrals

$$\int_a^b = -\int_b^a$$

$$\int_a^c + \int_c^b = \int_a^b$$

The *mean value* of $f(x)$, \bar{f} , between a and b is

$$\bar{f} = \frac{1}{b-a} \int_a^b f(x)dx$$

If the upper limit b is a variable, then $\int_a^b f(x)dx$ is a function of b and its derivative is

$$f(b) = \frac{d}{db} \int_a^b f(x)dx$$

To differentiate with respect to a parameter

$$\frac{\partial}{\partial c} \int_a^b f(x, c)dx = \int_a^b \frac{\partial f(x, c)}{\partial c} dx$$

Some methods of integration of definite integrals are covered in “Numerical Methods.”

1.5.10 Improper Integrals

If one (or both) of the limits of integration is infinite, or if the integrand itself becomes infinite at or between the limits of integration, the integral is an *improper integral*. Depending on the function, the integral may be defined, may be equal to ∞ , or may be undefined for all x or for certain values of x .

1.5.11 Multiple Integrals

It is possible to integrate functions of several variables by using an *iterated integral*. An iterated integral is solved from the inner integral to the outer, and variables other than the variable of integration are held constant.

$$\iint f(x, y) \, dydx = \int \left(\int f(x, y) \, dy \right) dx$$

Definite multiple integrals may have variable inner limits of integration with respect to the outer variable of integration:

$$\int_c^d \int_{f(x)}^{g(x)} F(x, y) \, dydx$$

Uses for multiple integrals include finding areas, volumes, and the center of mass.

1.5.12 Differential Equations

An *ordinary differential equation* contains a single independent variable and a single unknown function of that variable, with its derivatives. A *partial differential equation* involves an unknown function of two or more independent variables, and its partial derivatives. The order of a differential equation is the order of the highest derivative in the equation. The general solution of a differential equation of order n is the set of all functions that possess at least n derivatives and satisfy the equation, as well as any auxiliary conditions.

1.5.13 Methods of Solving Ordinary Differential Equations

For *first-order equations*, if possible, separate the variables, integrate both sides, and add the constant of integration, C . If the equation is *homogeneous* in x and y , the value of dy/dx in terms of x and y is of the form $dy/dx = f(y/x)$ and the

variables may be separated by introducing new independent variable $v = y/x$ and then

$$x \frac{dv}{dx} + v = f(v)$$

The expression $f(x, y)dx + F(x, y)dy$ is an *exact differential* if

$$\frac{\partial f(x, y)}{\partial y} = \frac{\partial F(x, y)}{\partial x} \quad (= P, \text{ for example})$$

Then, the solution of $f(x, y)dx + F(x, y)dy = 0$ is

$$\int f(x, y)dx + \int \left[F(x, y) - \int P dx \right] dy = C$$

or

$$\int F(x, y)dy + \int \left[f(x, y) - \int P dy \right] dx = C$$

A *linear differential equation* of the first order such as

$$dy/dx + f(x) \bullet y = F(x)$$

has the solution

$$y = e^{-P} \left[\int e^P F(x) dx + C \right] \quad \text{where } P = \int f(x) dx$$

In the class of nonlinear equations known as *Bernoulli's equations*, where

$$dy/dx + f(x) \bullet y = F(x) \bullet y^n$$

substituting $y^{1-n} = v$ gives

$$dv/dx + (1 - n)f(x) \bullet v = (1 - n)F(x) \quad [n \neq 0 \text{ or } 1]$$

which is linear in v and x . In *Clairaut's equations*

$$y = xp + f(p) \quad \text{where } p = dy/dx,$$

the solution consists of the set of lines given by $y = Cx + f(C)$, where C is any constant, and the curve obtained by eliminating p between the original equation and $x + f'(p) = 0$ [1].

Some differential equation of the *second order* and their solutions follow:

For $d^2y/dx^2 = -n^2y$

$$y = C_1 \sin(nx + C_2) \\ = C_3 \sin nx + C_4 \cos nx$$

For $d^2y/dx^2 = +n^2y$

$$y = C_1 \sinh(nx + C_2) \\ = C_3 e^{nx} + C_4 e^{-nx}$$

For $d^2y/dx^2 = f(y)$

$$x = \int \frac{dy}{\sqrt{C_1 + 2P}} + C_2$$

where $P = \int f(y)dy$.

For $d^2y/dx^2 = f(x)$

$$y = \int P dx + C_1 x + C_2 \quad \text{where } P = \int f(x) dx \\ = xP - \int x f(x) dx + C_1 x + C_2$$

For $d^2y/dx^2 = f(dy/dx)$, setting $dy/dx = z$ and $d^2/dx^2 = dz/dx$

$$x = \int dz/f(z) + C_1 \text{ and}$$

$$y = \int z dz/f(z) + C_2, \text{ then eliminating } z$$

For $d^2y/dx^2 + 2b(dy/dx) + a^2y = 0$ (the equation for damped vibration)

- If $a^2 - b^2 > 0$,

$$\text{then } m = \sqrt{a^2 - b^2}$$

$$y = C_1 e^{-bx} \sin(mx + C_2) \\ = e^{-bx} [C_3 \sin(mx) + C_4 \cos(mx)]$$

- If $a^2 - b^2 = 0$,

$$y = e^{-bx} (C_1 + C_2 x)$$

- If $a^2 - b^2 < 0$,

$$\text{then } n = \sqrt{b^2 - a^2} \text{ and}$$

$$y = C_1 e^{-bx} \sinh(nx + C_2) \\ = C_3 e^{-(b+n)x} + C_4 e^{-(b-n)x}$$

For $d^2y/dx^2 + 2b(dy/dx) + a^2y = c$

$$y = c/a^2 + y_1$$

where y_1 is the solution of the previous equation with second term zero.

The preceding two equations are examples of linear differential equations with constant coefficients and their solutions are often found most simply by the use of Laplace transforms [1].

For the linear equation of the n^{th} order

$$A_n(x) d^n y/dx^n + A_{n-1}(x) d^{n-1} y/dx^{n-1} + \dots \\ + A_1(x) dy/dx + A_0(x) y = E(x)$$

the general solution is

$$y = u + c_1u_1 + c_2u_2 + \dots + c_nu_n,$$

where u is any solution of the given equation and u_1, u_2, \dots, u_n form a *fundamental system* of solutions to the homogeneous equation [$E(x) \leftarrow$ zero]. A set of functions has linear independence if its Wronskian determinant, $W(x), \neq 0$, where

$$W(x) = \begin{vmatrix} u_1 & u_2 & \dots & u_n \\ u_1' & u_2' & \dots & u_n' \\ \dots & \dots & \dots & \dots \\ u_1^{(m)} & u_2^{(m)} & \dots & u_n^{(m)} \end{vmatrix}$$

and $m = n - 1$ th derivative. (In certain cases, a set of functions may be linearly independent when $W(x) = 0$.)

1.5.14 The Laplace Transformation

The *Laplace transformation* is based on the Laplace integral which transforms a differential equation expressed in terms of time to an equation expressed in terms of a complex variable $\sigma + j\omega$. The new equation may be manipulated algebraically to solve for the desired quantity as an explicit function of the complex variable.

Essentially three reasons exist for the use of the Laplace transformation:

1. The ability to use algebraic manipulation to solve higher-order differential equations
2. Easy handling of boundary conditions
3. The method is suited to the complex-variable theory associated with the Nyquist stability criterion [1].

In Laplace-transformation mathematics, the following symbols and variables are used:

- $f(t)$ = a function of time
- s = a complex variable of the form $(\sigma + j\omega)$
- $F(s)$ = the Laplace transform of f , expressed in s , resulting from operating on $f(t)$ with the Laplace integral.
- \mathcal{L} = the Laplace operational symbol, i.e., $F(s) = \mathcal{L}[f(t)]$.

The Laplace integral is defined as

$$\mathcal{L} = \int_0^\infty e^{-st} dt \quad \text{and so}$$

$$\mathcal{L}[f(t)] = \int_0^\infty e^{-st} f(t) dt$$

Table 1.5.3 lists the transforms of some common time-variable expressions.

TABLE 1.5.3 Laplace Transforms

$f(t)$	$F(s) = \mathcal{L}[f(t)]$
A	A/s
$1 = u(t)$	$1/s$
$e^{-\alpha t}$	$\frac{1}{s+\alpha}$
$1/re^{-t/\tau}$	$\frac{1}{\tau s+1}$
$Ae^{-\alpha t}$	$\frac{A}{s+\alpha}$
$\sin \beta t$	$\frac{\beta}{s^2+\beta^2}$
$\cos \beta t$	$\frac{s}{s^2+\beta^2}$
$\frac{1}{\beta} e^{-\alpha t} \sin \beta t$	$\frac{1}{s^2+2\alpha s+\alpha^2+\beta^2}$
$\frac{e^{-\alpha t}}{\beta-\alpha} - \frac{e^{-\beta t}}{\beta-\alpha}$	$\frac{1}{(s+\alpha)(s+\beta)}$
$\frac{Ae^{-\alpha t} - Be^{-\beta t}}{C}$	$\frac{s+a}{(s+\alpha)(s+\beta)}$
where $A = a - \alpha$ $B = a - \beta$ $C = \beta - \alpha$	
$\frac{e^{-\alpha t}}{A} + \frac{e^{-\beta t}}{B} + \frac{e^{-\delta t}}{C}$	$\frac{1}{(s+\alpha)(s+\beta)(s+\delta)}$
where $A = (\beta - \alpha)(\delta - \alpha)$ $B = (\alpha - \beta)(\delta - \beta)$ $C = (\alpha - \delta)(\beta - \delta)$	
t^n	$\frac{n!}{s^{n+1}}$
$d/dt[f(t)]$	$sF(s) - f(0^+)$
$d^2/dt^2[f(t)]$	$s^2F(s) - sf(0^+) - \frac{df}{dt}(0^+)$
$d^3/dt^3[f(t)]$	$s^3F(s) - s^2f(0^+) - s\frac{df}{dt}(0^+) - \frac{d^2f}{dt^2}(0^+)$
$\int f(t) dt$	$\frac{1}{s} [F(s) + \int f(t) dt _{0^+}]$
$\frac{1}{\alpha} \sinh \alpha t$	$\frac{1}{s^2-\alpha^2}$
$\cosh \alpha t$	$\frac{s}{s^2-\alpha^2}$

The transform of a first derivative of $f(t)$ is

$$\mathcal{L} \left[\frac{d}{dt} f(t) \right] = sF(s) - f(0^+)$$

where $f(0^+) =$ initial value of $f(t)$ as $t \rightarrow 0$ from positive values.

The transform of a second derivative of $f(t)$ is

$$\mathcal{L}[f''(t)] = s^2F(s) - sf(0^+) - f'(0^+)$$

and of $\int f(t)dt$ is

$$\mathcal{L} \left[\int f(t)dt \right] = \frac{f^{-1}(0^+)}{s} + \frac{F(s)}{s}$$

Solutions derived by Laplace transformation are in terms of the complex variable s . In some cases, it is necessary to retransform the solution in terms of time, performing an *inverse transformation*

$$\mathcal{L}^{-1}F(s) = f(t)$$

Just as there is only one direct transform $F(s)$ for any $f(t)$, there is only one inverse transform $f(t)$ for any $F(s)$ and inverse transforms are generally determined through use of tables.

1.6 ANALYTIC GEOMETRY

1.6.1 Symmetry

Symmetry exists for the curve of a function about the y -axis if $F(x, y) = F(-x, y)$, about the x -axis if $F(x, y) = F(x, -y)$, about the origin if $F(x, y) = F(-x, -y)$, and about the 45° line if $F(x, y) = F(y, x)$.

1.6.2 Intercepts

Intercepts are points where the curve of a function crosses the axes. The x intercepts are found by setting $y = 0$ and the y intercepts by setting $x = 0$.

1.6.3 Asymptotes

As a point $P(x, y)$ on a curve moves away from the region of the origin (Figure 1.6.1a), the distance between P and some fixed line may tend to zero. If so, the line is called an asymptote of the curve. If $N(x)$ and $D(x)$ are polynomials with no common factor, and

$$y = N(x)/D(x)$$

where $x = c$ is a root of $D(x)$, then the line $x = c$ is an asymptote of the graph of y .

FIGURE 1.6.1A Asymptote of a curve.

FIGURE 1.6.1B Slope of a straight line.

1.6.4 Equations of Slope and Straight Lines

1. Equation for slope of line connecting two points (x_1, y_1) and (x_2, y_2)

$$m = \frac{y_2 - y_1}{x_2 - x_1}$$

2. Two-point equation (Figure 1.25)

$$\frac{y - y_1}{x - x_1} = \frac{y_2 - y_1}{x_2 - x_1}$$

3. Point-slope equation (Figure 1.25)

$$y - y_1 = m(x - x_1)$$

4. Slope-intercept equation (Figure 1.6.1b)

$$y = mx + b$$

1.6.5 Tangents

In the slope m of the curve of $f(x)$ at (x_1, y_1) is given by (Figure 1.6.2)

$$m = \frac{dy}{dx(x_1, y_1)} = f'(x)$$

then the equation of the line tangent to the curve at this point is

$$y - y_1 = f'(x_1)(x - x_1)$$

FIGURE 1.6.2 Tangent and normal to a curve.

and the normal to the curve is the line perpendicular to the tangent with slope m_2 where

$$m_2 = -1/m_1 = -1/f'(x)$$

or

$$y - y_1 = -(x - x_1)/f'(x_1)$$

1.6.6 Other Forms of the Equation of a Straight Line

- General equation

$$ax + by + c = 0$$

- Intercept equation

$$x/a + y/b = 1$$

- Normal form (Figure 1.6.3)

$$x \cos \theta + y \sin \theta - p = 0$$

- Distance d from a straight line ($ax + by + c = 0$) to a point $P(x_1, y_1)$

$$d = \frac{ax_1 + by_1 + c}{\pm\sqrt{a^2 + b^2}}$$

- If u is the angle between $ax + by + c = 0$ and $a'x + b'y + c' = 0$ then

FIGURE 1.6.3 Equation of a straight line (normal form).

$$\cos u = \frac{aa' + bb'}{\pm\sqrt{(a^2 + b^2)(a'^2 + b'^2)}}$$

1.6.7 Equations of a Circle (Center (h, k))

- $(x - h)^2 + (y - k)^2 = r^2$
- Origin at center

$$x^2 + y^2 = r^2$$

- General equation

$$x^2 + y^2 + Dx + Ey + F = 0$$

where center = $(-D/2, -E/2)$

$$\text{radius} = \sqrt{(D/2)^2 + (E/2)^2 - F}$$

- Tangent to circle at (x_1, y_1)

$$x_1x + y_1y + \frac{1}{2}D(x + x_1) + \frac{1}{2}E(y + y_1) + F = 0$$

- Parametric form, replacing x and y by

$$x = a \cos u$$

and

$$y = a \sin u$$

1.6.8 Equations of a Parabola

(Figure 1.6.4)

A parabola is the set of points that are equidistant from a given fixed point (the focus) and from a given fixed line (the directrix) in the plane. The key feature of a parabola is that it is second degree in one of its coordinates and first degree in the other.

- $(y - k)^2 = 4p(x - h)$
- Coordinates of the vertex $V(h, k)$ and of the focus $F(h + p, k)$

FIGURE 1.6.4 Equation of a parabola.

- Origin at vertex

$$y^2 = 4px$$

- Equation of the directrix

$$x = h - p$$

- Length of latus rectum

$$LL' = 4p$$

- Polar equation (focus as origin)

$$r = p/(1 - \cos \theta)$$

- Equation of the tangent to $y^2 = 2px$ at (x_1, y_1)

$$y_1y = p(x + x_1)$$

1.6.9 Equations of an Ellipse of Eccentricity e (Figure 1.6.5)

- $\frac{(x-h)^2}{a^2} + \frac{(y-k)^2}{b^2} = 1$
- Coordinates of center $C(h, k)$, of vertices $V(h + a, k)$ and $V'(h - a, k)$, and of foci $F(h + ae, k)$ and $F'(h - ae, k)$
- Center at origin

$$x^2/a^2 + y^2/b^2 = 1$$

- Equation of the directrices

$$x = h \pm a/e$$

- Equation of the eccentricity

$$e = \frac{\sqrt{a^2 - b^2}}{a} < 1$$

- Length of the latus rectum

$$LL' = 2b^2/a$$

- Parametric form, replacing x and y by

$$x = a \cos u \quad \text{and} \quad y = b \sin u$$

- Polar equation (focus as origin)

FIGURE 1.6.5 Ellipse of eccentricity e .

$$r = p/(1 - e \cos \theta)$$

- Equation of the tangent at (x_1, y_1)

$$b^2x_1x + a^2y_1y = a^2b^2$$

1.6.10 Equations of a Hyperbola (Figure 1.6.6)

- $\frac{(x-h)^2}{a^2} - \frac{(y-k)^2}{b^2} = 1$
- Coordinates of the center $C(h, k)$, of vertices $V(h + a, k)$ and $V'(h - a, k)$, and of the foci $F(h + ae, k)$ and $F'(h - ae, k)$
- Center at origin

$$x^2/a^2 - y^2/b^2 = 1$$

- Equation of the directrices

$$x = h \pm a/e$$

- Equation of the asymptotes

$$y - k = \pm b/a \bullet (x - k)$$

- Equation of the eccentricity

$$e = \frac{\sqrt{a^2 + b^2}}{a} > 1$$

- Length of the latus rectum

$$LL' = 2b^2/a$$

- Parametric form, replacing x and y

$$x = a \cosh u \quad \text{and} \quad y = b \sinh u$$

- Polar equation (focus as origin)

$$r = p/(1 - e \cos \theta)$$

- Equation of the tangent at (x, y)

$$b^2x_1x - a^2y_1y = a^2b^2$$

FIGURE 1.6.6 Equation of a hyperbola.

FIGURE 1.6.7 Three-dimensional coordinate systems.

1.6.11 Equations of Three-Dimensional Coordinate Systems (Figure 1.6.7)

- Distance d between two points

$$d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2 + (z_2 - z_1)^2}$$

1.7 NUMERICAL METHODS

See References 1–14 for additional information.

1.7.1 Expansion in Series

If the value of a function $f(x)$ can be expressed in the region close to $x = a$, and if all derivatives of $f(x)$ near a exist and are finite, then by the infinite power series

$$f(x) = f(a) + (x - a)f'(a) + \frac{(x - a)^2}{2!}f''(a) + \dots + \frac{(x - a)^n}{n!}f^n(a) + \dots$$

and $f(x)$ is *analytic* near $x = a$. The preceding power series is called the *Taylor series expansion* of $f(x)$ near $x = a$. If for some value of x as $[x - a]$ is increased, the series is no longer convergent, then that value of x is outside the radius of convergence of the series.

The error due to truncation of the series is partially due to $[x - a]$ and partially due to the number of terms (n) to which the series is taken. The quantities $[x - a]$ and n can be controlled, and the truncation error is said to be of the order of $(x - a)^{n+1}$ or $\mathcal{O}(x - a)^{n+1}$.

1.7.2 Finite Difference Calculus

In the finite difference calculus, the fundamental rules of ordinary calculus are employed, but Δx is treated as a small quantity, rather than infinitesimal.

Given a function $f(x)$ which is analytic (i.e., can be expanded in a Taylor series) in the region of a point x , where $h = \Delta x$, if $f(x + h)$ is expanded about x , $f'(x)$ can be defined at $x = x_i$ as

$$f'(x_i) = f'_i = (f_{i+1} - f_i)/h + \mathcal{O}(h)$$

The first *forward difference* of f at x_i may be written as

$$\Delta f_i = f_{i+1} - f_i$$

and then

$$f'(x) = (\Delta f_i)/h + \mathcal{O}(h)$$

The first *backward difference* of f at x_i is

$$\nabla f_i = f_i - f_{i-1}$$

and $f'(x)$ may also be written as

$$f'(x) = (\nabla f_i)/h + \mathcal{O}(h)$$

The second forward difference of $f(x)$ at x_i is

$$\Delta^2 f_i = f_{i+2} - 2f_{i+1} + f_i$$

and the second derivative of $f(x)$ is then given by

$$f''(x) = (\Delta^2 f_i)/h^2 + \mathcal{O}(h)$$

The second backward difference of f at x_i is

$$\nabla^2 f_i = f_i - 2f_{i-1} + f_{i-2}$$

and $f''(x)$ may also be defined as

$$f''(x) = (\nabla^2 f_i)/h^2 + \mathcal{O}(h)$$

Approximate expressions for derivatives of any order are given in terms of forward and backward difference expressions as

$$f_i^{(n)} = (\Delta^n f_i)/h^n + \mathcal{O}(h) = (\nabla^n f_i)/h^n + \mathcal{O}(h)$$

Coefficients of forward difference expressions for derivatives of up to the fourth order are given in [Figure 1.7.1](#) and of backward difference expressions in [Figure 1.7.2](#).

More accurate difference expressions may be found by expanding the Taylor series. For example, $f'(x)$ to $\nabla(h)$ is given by forward difference by

$$f'(x) = (-f_{i+2} + 4f_{i+1} - 3f_i)/(2h) + \mathcal{O}(h^2)$$

	f_i	f_{i+1}	f_{i+2}	f_{i+3}	f_{i+4}	
$hf'(x_i) =$	-1	1				
$h^2 f''(x_i) =$	1	-2	1			$+ \mathcal{O}(h)$
$h^3 f'''(x_i) =$	-1	3	-3	1		
$h^4 f''''(x_i) =$	1	-4	6	-4	1	

FIGURE 1.7.1 Forward difference coefficients of $\sigma(h)$.

	f_{i-4}	f_{i-3}	f_{i-2}	f_{i-1}	f_i	
$hf'(x_i) =$				-1	1	
$h^2 f''(x_i) =$			1	-2	1	$+ \mathcal{O}(h)$
$h^3 f'''(x_i) =$		-1	3	-3	1	
$h^4 f''''(x_i) =$	1	-4	6	-4	1	

FIGURE 1.7.2 Backward difference coefficients of $\sigma(h)$.

and a similar backward difference representation can also be easily obtained. These expressions are exact for a parabola. Forward and backward difference expressions of $\mathcal{O}(h^2)$ are contained in Figures 1.7.3 and 1.7.4.

A central difference expression may be derived by combining the equations for forward and backward differences.

$$\delta f_i = 1/2 \bullet (\Delta f_i + \nabla f_i) = 1/2 \bullet (f_{i+1} - f_{i-1})$$

The first derivative of f at x_i may then be given in terms of the central difference expression as

$$f'_i = (\delta f_i)/h + \mathcal{O}(h^2)$$

and is accurate to a greater degree than the forward or backward expressions of f' . Central difference expressions for derivatives of any order in terms of forward and backward differences are given by

$$f_i^{(n)} = [\nabla^n f_{i+n/2} + \Delta^n f_{i-n/2}]/(2h^n) + \mathcal{O}(h^2), n \text{ even}$$

and

$$f_i^{(n)} = [\nabla^n f_{i+(n-1)/2} + \Delta^n f_{i-(n-1)/2}]/(2h^n) + \mathcal{O}(h^2), n \text{ odd}$$

Coefficients of central difference expressions for derivatives up to order four of $\mathcal{O}(h^2)$ are given in Figure 1.7.5 and of $\mathcal{O}(h^4)$ in Figure 1.7.6.

	f_i	f_{i+1}	f_{i+2}	f_{i+3}	f_{i+4}	f_{i+5}	
$2hf'(x_i)$	=	-3	4	-1			
$h^2f''(x_i)$	=	2	-5	4	-1

1.7.3 Interpolation

A forward difference table may be generated (see also “Algebra”) using notation consistent with numerical methods as given in Table 1.7.1. In a similar manner, a backward difference table can be calculated as in Table 1.7.2. A central difference table is constructed in the same general manner, leaving a space between each line of original data, then taking the differences and entering them on alternate full lines and half lines (Table 1.7.3). The definition of the central difference δ is

$$\delta f_{i+1/2} = f_{i+1} - f_i$$

The quarter lines in the table are filled with the arithmetic mean of the values above and below (Table 1.7.4).

Given a data table with evenly spaced values of x, and rescaling x so that h = one unit, forward differences are usually used to find f(x) at x near the top of the table and backward differences at x near the bottom. Interpolation near the center of the set is best accomplished with central differences.

The Gregory-Newton forward formula is given as

$$f(x) = f(0) + x(\Delta f_0) + \frac{x(x-1)}{2!} \Delta^2 f_0 + \frac{x(x-1)(x-2)}{3!} \Delta^3 f_0 + \dots$$

and the Gregory-Newton backward formula as

$$f(x) = f(0) + x(\nabla f_0) + \frac{x(x+1)}{2!} \nabla^2 f_0 + \frac{x(x+1)(x+2)}{3!} \nabla^3 f_0 + \dots$$

To use central differences, the origin of x must be shifted to a base line (shaded area in Table 1.7.5) and x rescaled so one full (two half) line spacing = 1 unit. Sterling's formula (full lines as base) is defined as

$$f(x) = f(0) + x(\delta y_0) + \frac{x^2}{2!}(\delta^2 y_0) + \frac{x(x^2 - 1)}{3!}(\delta^3 y_0) + \frac{x^2(x^2 - 1)}{4!}(\delta^4 y_0) + \frac{x(x^2 - 1)(x^4 - 4)}{5!}(\delta^5 y_0) + \dots$$

and *Bessel's formula* (half line as base) as

$$f(x) = f(0) + x(\delta y_0) = \frac{(x^2 - \frac{1}{4})}{2!}(\delta^2 y_0) + \frac{x(x^2 - \frac{1}{4})}{3!}(\delta^3 y_0) + \frac{(x^2 - \frac{1}{4})(x^2 - \frac{9}{4})}{4!}(\delta^4 y_0) + \frac{x(x^2 - \frac{1}{4})(x^2 - \frac{9}{4})}{5!}(\delta^5 y_0) + \dots$$

Interpolation with nonequally spaced data may be accomplished by the use of *Lagrange Polynomials*, defined as a set of n^{th} degree polynomials such that each one, $P_j(x)$ ($j = 0, 1, \dots, n$), passes through zero at each of the data points except one, x_k , where $k = j$. For each polynomial in the set

$$P_j(x) = A_j \prod_{\substack{i=0 \\ i \neq j}}^n (x - x_i)$$

where if

$$A_j = \frac{1}{\prod_{\substack{i=0 \\ i \neq j}}^n (x_j - x_i)}$$

then

$$P_j(x) = \begin{cases} 0, & k \neq j \\ 1, & k = j \end{cases}$$

and the linear combination of $P_j(x)$ may be formed

$$p_n(x) = \sum_{j=0}^n f(x_j)P_j(x)$$

It can be seen that for any x_i , $p_n(x_i) = f(x_i)$.

Interpolation of this type may be extremely unreliable toward the center of the region where the independent variable is widely spaced. If it is possible to select the values of x for which values of $f(x)$ will be obtained, the maximum error can be minimized by the proper choices. In this particular case Chebyshev polynomials can be computed and interpolated [3].

Neville's algorithm constructs the same unique interpolating polynomial and improves the straightforward Lagrange implementation by the addition of an error estimate.

If $P_i(i = 1, \dots, n)$ is defined as the value at x of the unique polynomial of degree zero passing through the point (x_i, y_i) and $P_{ij}(i = 1, \dots, n-1, j = 2, \dots, n)$ the polynomial of degree one passing through both (x_i, y_i) and (x_j, y_j) , then the higher-order polynomials may likewise be defined up to $P_{123\dots n}$, which is the value of the unique interpolating polynomial passing through all n points. A table may be constructed (e.g., if $n = 3$):

$$\begin{array}{l} x_1 : y_1 = P_1 \\ x_2 : y_2 = P_2 \\ x_3 : y_3 = P_3 \end{array} \quad \begin{array}{l} P_{12} \\ P_{23} \end{array} \quad P_{123}$$

Neville's algorithm recursively calculates the preceding columns from left to right as

$$P_{i(i+1)\dots(i+m)} = \frac{(x - x_{i+m})P_{i(i+1)\dots(i+m-1)} + (x_i - x)P_{(i+1)\dots(i+m)}}{x_i - x_{i+m}}$$

In addition, the differences between the columns may be calculated as

$$D_{m+1,i} = \frac{(x_{i+m+1} - x)(C_{m,i+1} + D_{m,i})}{x_i - x_{i+m+1}}$$

$$C_{m+1,i} = \frac{(x_i - x)(C_{m,i+1} - D_{m,i})}{x_i - x_{i+m+1}}$$

and $P_{12\dots n}$ is equal to the sum of any y_i plus a set of C s and/or D s that lead to the rightmost member of the table [14].

Functions with localized strong inflections or poles may be approximated by *rational functions* of the general form

$$R(x) = \frac{\sum_{i=0}^n a_i x^i}{\sum_{i=0}^m b_i x^i}$$

as long as there are sufficient powers of x in the denominator to cancel any nearby poles. Stoer and Bulirsch [8] give a Neville-type algorithm that performs rational function extrapolation on tabulated data

$$R_{i(i+1)\dots(i+m)} = R_{(i+1)\dots(i+m)} + \left\{ (R_{(i+1)\dots(i+m)} - R_{i\dots(i+m-1)}) / [(x - x_i)/(x - x_{i+m})] \times [1 - (R_{(i+1)\dots(i+m)} - R_{i\dots(i+m-1)}) / (R_{(i+1)\dots(i+m)} - R_{(i+1)\dots(i+m-1)})] - 1 \right\}$$

starting with $R_i = y_i$ and returning an estimate of error, calculated by C and D in a manner analogous with Neville's algorithm for polynomial approximation.

In a high-order polynomial, the highly inflected character of the function can more accurately be reported by the *cubic spline function*. Given a series of $x_i(i = 0, 1, \dots, n)$ and corresponding $f(x_i)$, consider that for two arbitrary and adjacent points x_i and x_{i+j} , the cubic fitting these points is

$$F_i(x) = a_0 + a_1x + a_2x^2 + a_3x^3$$

$$(x_i \leq x \leq x_{i+1})$$

The approximating cubic spline function $g(x)$ for the region $(x_0 \leq x \leq x_n)$ is constructed by matching the first and second derivatives (slope and curvature) of $F_i(x)$ to those of $F_{i-1}(x)$, with special treatment (outlined below) at the end points, so that $g(x)$ is the set of cubics $F_i(x)$, $i = 0, 1, 2, \dots, n - 1$, and the second derivative $g''(x)$ is continuous over the region. The second derivative varies linearly over $[x_0, x_n]$ and at any $x(x_i \leq x \leq x_{i+1})$

$$g''(x) = g''(x_i) + \frac{x - x_i}{x_{i+1} - x_i} [g''(x_{i+1}) - g''(x_i)]$$

Integrating twice and setting $g(x_i) = f(x_i)$ and $g(x_{i+1}) = f(x_{i+1})$, then using the derivative matching conditions

$$F'_i(x_i) = F'_{i+1}(x_i) \quad \text{and} \quad F''_i(x_i) = F''_{i-1}(x_i)$$

and applying the condition for $i = [1, n - 1]$ finally yields a set of linear simultaneous equations of the form

$$[\Delta x_{i-1}]g''(x_{i-1}) + [2(x_{i+1} - x_{i-1})]g''(x_i) + [\Delta x_i]g''(x_{i+1})$$

$$= 6 \left[\frac{f(x_{i+1}) - f(x_i)}{\Delta x_i} - \frac{f(x_i) - f(x_{i-1})}{\Delta x_{i-1}} \right]$$

where $i = 1, 2, \dots, n - 1$

$$\Delta x_i = x_{i+1} - x_i$$

If the x_i are equally spaced by Δx , then the preceding equation becomes

$$[1]g''(x_{i-1}) + [4]g''(x_i) + [1]g''(x_{i+1})$$

$$= 6 \left[\frac{f(x_{i+1}) - 2f(x_i) + f(x_{i-1}))}{(\Delta x_i)^2} \right]$$

There are $n - 1$ equations in $n + 1$ unknowns and the two necessary additional equations are usually obtained by setting

$$g''(x_0) = 0 \quad \text{and} \quad g''(x_n) = 0$$

and $g(x)$ is now referred to as a *natural cubic spline*. $g''(x_0)$ or $g''(x_n)$ may alternatively be set to values calculated so as to make g' have a specified value on either or both boundaries. The cubic appropriate for the interval in which the x value lies may now be calculated (see “Solutions of Sets of Simultaneous Linear Equations”).

Extrapolation is required if $f(x)$ is known on the interval $[a, b]$, but values of $f(x)$ are needed for x values not in the interval. In addition to the uncertainties of interpolation, extrapolation is further complicated since the function is fixed only on one side. Gregory-Newton and Lagrange formulas may be used for extrapolation (depending on the

spacing of the data points), but all results should be viewed with extreme skepticism.

1.7.4 Roots of Equations

Finding the root of an equation in x is the problem of determining the values of x for which $f(x) = 0$. *Bisection*, although rarely used now, is the basis of several more efficient methods. If a function $f(x)$ has one and only one root in $[a, b]$, then the interval may be bisected at $x_m = (a + b)/2$. If $f(x_m) \bullet f(b) < 0$, the root is in $[x_m, b]$, while if $f(x_m) \bullet f(b) > 0$, the root is in $[a, x_m]$. Bisection of the appropriate intervals, where $x'_m = (a' + b')/2$, is repeated until the root is located $\pm \epsilon$, ϵ being the maximum acceptable error and $\epsilon \leq 1/2 \bullet$ size of interval.

The *Regula Falsa* method, or the method of false position, is a refinement of the bisection method, in which the new end point of a new interval is calculated from the old end points by

$$x_m = a - (b - a) \frac{f(a)}{f(b) - f(a)}$$

Whether x_m replaces a or replaces b depends on the sign of a product, and

if $f(a) \bullet f(x_m) < 0$, then the new interval is $[a, x_m]$

or

if $f(x_m) \bullet f(b) < 0$, then the new interval is $[x_m, b]$.

Because of round off errors, the *Regula Falsa* method should include a check for excessive iterations. A *modified Regula Falsa method* is based on the use of a *relaxation factor*, i.e., a number used to alter the results of one iteration before inserting into the next. (See the section on relaxation methods and “Solution of Sets of Simultaneous Linear Equations.”)

By iteration, the general expression for the *Newton-Raphson method* may be written (if f' can be evaluated and is continuous near the root):

$$x^{(n+1)} - x^{(n)} = \delta^{(n+1)} = -\frac{f(x^{(n)})}{f'(x^{(n)})}$$

where (n) denotes values obtained on the n^{th} iteration and $(n+1)$ those obtained on the $(n+1)^{\text{th}}$ iteration. The iterations are terminated when the magnitude of $|\delta^{(n+1)} - \delta^{(n)}| < \epsilon$, being the predetermined error factor and $\epsilon \cong 0.1$ of the permissible error in the root.

The *modified Newton method* [4] offers one way of dealing with multiple roots. If a new function is defined

$$u(x) = \frac{f(x)}{f'(x)}$$

because $u(x) = 0$ when $f(x) = 0$ and if $f(x)$ has a multiple root at $x = c$ of multiplicity r , then Newton's method can be applied and

$$x^{(n+1)} - x^{(n)} = \delta^{(n+1)} = -\frac{u(x^{(n)})}{u'(x^{(n)})}$$

where

$$u'(x) = 1 - \frac{f(x)f''(x)}{[f'(x)]^2}$$

If multiple or closely spaced roots exist, both f and f' may vanish near a root and methods that depend on tangents will not work. Deflation of the polynomial $P(x)$ produces, by factoring,

$$P(x) = (x - r)Q(x)$$

where $Q(x)$ is a polynomial of one degree lower than $P(x)$ and the roots of Q are the remaining roots of P after factorization by synthetic division. Deflation avoids convergence to the same root more than one time. Although the calculated roots become progressively more inaccurate, errors may be minimized by using the results as initial guesses to iterate for the actual roots in P .

Methods such as Graeffe's root-squaring method, Muller's method, Laguerre's method, and others exist for finding all roots of polynomials with real coefficients [4, 7, 8].

1.7.5 Solution of Sets of Simultaneous Linear Equations

A matrix is a rectangular array of numbers, its size being determined by the number of rows and columns in the array. In this context, the primary concern is with square matrices, and matrices of column dimension 1 (column vectors) and row dimension 1 (row vectors).

Certain configurations of square matrices are of particular interest. If

$$C = \begin{vmatrix} c_{11} & \cdot & \cdot & c_{14} \\ \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \\ c_{41} & \cdot & \cdot & c_{44} \end{vmatrix}$$

the diagonal consisting of c_{11} , c_{22} , c_{33} and c_{44} is the *main diagonal*. The matrix is *symmetric* if $c_{ij} = c_{ji}$. If all elements below the main diagonal are zero (blank), it is an *upper triangular matrix*, while if all elements above the main diagonal are zero, it is a *lower triangular matrix*. If all elements are zero except those on the main diagonal, the matrix is a *diagonal matrix* and if a diagonal matrix has all ones on the diagonal, it is the *unit, or identity, matrix*.

Matrix addition (or subtraction) is denoted as $S = A + B$ and defined as

$$s_{ij} = a_{ij} + b_{ij}$$

where A , B , and S have identical row and column dimensions. Also,

$$\begin{aligned} A + B &= B + A \\ A - B &= -B + A \end{aligned}$$

Matrix multiplication, represented as $P = AB$, is defined as

$$P_{ij} = \sum_{k=1}^n a_{ik}b_{kj}$$

where n is the column dimension of A and the row dimension of B . P will have row dimension of A and column dimension of B . Also

$$AI = A$$

and

$$IA = A$$

while, in general,

$$AB \neq BA$$

Matrix division is not defined, although if C is a square matrix, C^{-1} (the *inverse* of C) can usually be defined so that

$$CC^{-1} = I$$

and

$$(C^{-1})^{-1} = C$$

The *transpose* of A if

$$A = \begin{vmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \\ a_{31} & a_{32} \end{vmatrix}$$

is

$$A^T = \begin{vmatrix} a_{11} & a_{21} & a_{31} \\ a_{12} & a_{22} & a_{32} \end{vmatrix}$$

A square matrix C is *orthogonal* if

$$C^T = C^{-1}$$

The *determinant* of a square matrix C ($\det C$) is defined as the sum of all possible products found by taking one element from each row in order from the top and one element from each column, the sign of each product multiplied by $(-1)^r$, where r is the number of times the column index decreases in the product.

For a 2×2 matrix

$$C = \begin{vmatrix} c_{11} & c_{12} \\ c_{21} & c_{22} \end{vmatrix}$$

$$\det C = c_{11}c_{22} - c_{12}c_{21}$$

(Also see discussion of determinants in “Algebra.”)

Given a set of simultaneous equations, for example, four equations in four unknowns:

$$\begin{aligned} c_{11}x_1 + c_{12}x_2 + c_{13}x_3 + c_{14}x_4 &= r_1 \\ c_{21}x_1 + c_{22}x_2 + c_{23}x_3 + c_{24}x_4 &= r_2 \\ c_{31}x_1 + c_{32}x_2 + c_{33}x_3 + c_{34}x_4 &= r_3 \\ c_{41}x_1 + c_{42}x_2 + c_{43}x_3 + c_{44}x_4 &= r_4 \end{aligned}$$

and in matrix form

$$\begin{vmatrix} c_{11} & c_{12} & c_{13} & c_{14} \\ c_{21} & c_{22} & c_{23} & c_{24} \\ c_{31} & c_{32} & c_{33} & c_{34} \\ c_{41} & c_{42} & c_{43} & c_{44} \end{vmatrix} \begin{vmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{vmatrix} = \begin{vmatrix} r_1 \\ r_2 \\ r_3 \\ r_4 \end{vmatrix}$$

or

$$CX = R$$

The solution for x_k in a system of equations such as given in the matrix above is

$$x_k = (\det C_k) / (\det C)$$

where C_k is the matrix C , with its k^{th} column replaced by R (Cramer’s Rule). If $\det C = 0$, C and its equations are singular and there is no solution.

Sets of simultaneous linear equations are frequently defined as [12]

- *Sparse* (many zero elements) and large
- *Dense* (few zero elements) and small. A *banded matrix* has all zero elements except for a band centered on the main diagonal, e.g.,

$$C = \begin{vmatrix} c_{11} & c_{12} & & & \\ c_{21} & c_{22} & c_{23} & & \\ & c_{32} & c_{33} & c_{34} & \\ & & c_{43} & c_{44} & \end{vmatrix}$$

then C is a banded matrix of bandwidth 3, also called a *tridiagonal matrix*.

Equation-solving techniques may be defined as *direct*, expected to yield results in a predictable number of operations, or *iterative*, yielding results of increasing accuracy with increasing numbers of iterations. Iterative techniques are in general preferable for very large sets and for large, sparse (not banded) sets. Direct methods are usually more suitable for small, dense sets and also for sets having banded coefficient matrices.

Gaussian elimination is the sequential application of the two operations:

1. Multiplication, or division, of any equation by a constant.
2. Replacement of an equation by the sum, or difference, of that equation and any other equation in the set, so that a set of equations

$$\begin{vmatrix} c_{11} & c_{12} & c_{13} & c_{14} \\ c_{21} & c_{22} & c_{23} & c_{24} \\ c_{31} & c_{32} & c_{33} & c_{34} \\ c_{41} & c_{42} & c_{43} & c_{44} \end{vmatrix} \begin{vmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{vmatrix} = \begin{vmatrix} r_1 \\ r_2 \\ r_3 \\ r_4 \end{vmatrix}$$

becomes, by division of the first equation by c_{11} ,

$$\begin{vmatrix} 1 & c'_{12} & c'_{13} & c'_{14} \\ c_{21} & c_{22} & c_{23} & c_{24} \\ c_{31} & c_{32} & c_{33} & c_{34} \\ c_{41} & c_{42} & c_{43} & c_{44} \end{vmatrix} \begin{vmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{vmatrix} = \begin{vmatrix} r'_1 \\ r_2 \\ r_3 \\ r_4 \end{vmatrix}$$

then, by replacement of the next three equations,

$$\begin{vmatrix} 1 & c'_{12} & c'_{13} & c'_{14} \\ 0 & c'_{22} & c'_{23} & c'_{24} \\ 0 & c'_{32} & c'_{33} & c'_{34} \\ 0 & c'_{42} & c'_{43} & c'_{44} \end{vmatrix} \begin{vmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{vmatrix} = \begin{vmatrix} r'_1 \\ r'_2 \\ r'_3 \\ r'_4 \end{vmatrix}$$

and finally

$$\begin{vmatrix} 1 & c'_{12} & c'_{13} & c'_{14} \\ & 1 & c'_{23} & c'_{24} \\ & & 1 & c'_{34} \\ & & & 1 \end{vmatrix} \begin{vmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{vmatrix} = \begin{vmatrix} r'_1 \\ r'_2 \\ r'_3 \\ r'_4 \end{vmatrix}$$

Gauss-Jordan elimination is a variation of the preceding method, which by continuation of the same procedures yields

$$\begin{vmatrix} 1 & & & \\ & 1 & & \\ & & 1 & \\ & & & 1 \end{vmatrix} \begin{vmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{vmatrix} = \begin{vmatrix} r''_1 \\ r''_2 \\ r''_3 \\ r''_4 \end{vmatrix}$$

Therefore, $x_1 = r''_1$, etc., i.e., the r vector is the solution vector. If the element in the current pivot position is zero or very small, switch the position of the entire pivot row with any row below it, including the x vector element, but not the r vector element.

If $\det C \neq 0$, C^{-1} exists and can be found by *matrix inversion* (a modification of the Gauss-Jordan method), by writing C and I (the identity matrix) and then performing the same operations on each to transform C into I and, therefore, I into C^{-1} .

For any square matrix, a condition number can be defined as the product of the norm of the matrix and the

norm of its inverse. If this number is large, the matrix is *ill conditioned*. For an ill-conditioned matrix, it can be difficult to compute the inverse. Two quick ways to recognize possible ill conditioning are

1. If there are elements of the inverse of the matrix that are larger than elements of the original matrix.
2. If the magnitude of the determinant is small, such as

$$\frac{\det C}{\sqrt{\sum_{i=1}^n \sum_{j=1}^n c_{ij}^2}} \leq 1$$

Gauss-Siedel method is an iterative technique for the solution of sets of equations. Given, for example, a set of three linear equations

$$\begin{aligned} c_{11}x_1 + c_{12}x_2 + c_{13}x_3 &= r_1 \\ c_{21}x_1 + c_{22}x_2 + c_{23}x_3 &= r_2 \\ c_{31}x_1 + c_{32}x_2 + c_{33}x_3 &= r_3 \end{aligned}$$

solving for the unknowns yields

$$\begin{aligned} x_1 &= \frac{r_1 - c_{12}x_2 - c_{13}x_3}{c_{11}} \\ x_2 &= \frac{r_2 - c_{21}x_1 - c_{23}x_3}{c_{22}} \\ x_3 &= \frac{r_3 - c_{31}x_1 - c_{32}x_2}{c_{33}} \end{aligned}$$

By making an initial guess for $x_1, x_2,$ and $x_3,$ denoted as $x_1^0, x_2^0,$ and $x_3^0,$ the value of x_1 on the first iteration is

$$x_1^{(1)} = \frac{r_1 - c_{12}x_2^{(0)} - c_{13}x_3^{(0)}}{c_{11}}$$

Using the most recently obtained values for each unknown (as opposed to the fixed point or Jacobi method), then

$$\begin{aligned} x_2^{(1)} &= \frac{r_2 - c_{21}x_1^{(1)} - c_{23}x_3^{(0)}}{c_{22}} \\ x_3^{(1)} &= \frac{r_3 - c_{31}x_1^{(1)} - c_{32}x_2^{(1)}}{c_{33}} \end{aligned}$$

If the equations have the proper characteristics, the iterative process will eventually converge. Commonly used convergence criteria are of two types:

1. *Absolute convergence* criteria of the form

$$|x_i^{(n+1)} - x_i^{(n)}| \leq \epsilon$$

are most useful when approximate magnitudes of x_i are known beforehand so that ϵ may be chosen to be proportional to $x_i.$

2. *Relative convergence* criteria of the form

$$\left| \frac{x_i^{(n+1)} - x_i^{(n)}}{x_i^{(n+1)}} \right| \leq \epsilon$$

is the choice if the magnitudes of x_i are uncertain.

Relaxation methods may also be used to modify the value of an unknown before it is used in the next calculation. The effect of the relaxation factor λ may be seen in the following equation, where $x_i^{(n+1)\bullet}$ is the value obtained at the present iteration.

$$x_i^{(n+1)} = \lambda x_i^{(n+1)\bullet} + (1 - \lambda)x_i^{(n)}$$

and $0 < \lambda < 2.$ If $0 < \lambda < 1,$ the effect is termed under relaxation, which is frequently employed to produce convergence in a nonconvergent process. If $1 < \lambda < 2,$ the effect, overrelaxation, will be to accelerate an already convergent process.

1.7.6 Least Squares Curve Fitting

For a function $f(x)$ given only as discrete points, the measure of accuracy of the fit is a function $d(x) = |f(x) - g(x)|$ where $g(x)$ is the approximating function to $f(x).$ If this is interpreted as minimizing $d(x)$ over all x in the interval, one point in error can cause a major shift in the approximating function towards that point. The better method is the least squares curve fit, where $d(x)$ is minimized if

$$E = \sum_{i=1}^n [g(x_i) - f(x_i)]^2$$

is minimized, and if $g(x_i)$ is a polynomial of order m

$$E = \sum_{i=1}^n [a_0 + a_1x_i + a_2x_i^2 + \dots + a_mx_i^m - f(x_i)]^2$$

Setting the partial derivatives of E with respect to each of the coefficients of $g(x)$ equal to zero, differentiating and summing over $1, \dots, n$ forms a set of $m + 1$ equations [9] so that

$$\begin{vmatrix} n & \sum x_i & \sum x_i^2 & \dots \\ \sum x_i & \sum x_i^2 & \sum x_i^3 & \dots \\ \dots & \dots & \dots & \dots \end{vmatrix} \begin{vmatrix} a_0 \\ a_1 \\ \dots \end{vmatrix} = \begin{vmatrix} \sum f(x_i) \\ \sum x_i f(x_i) \\ \dots \end{vmatrix}$$

If the preceding solution is reduced to a linear approximation ($n = 1$), the matrix will be ($n = 1$)

$$\begin{vmatrix} n & \sum x_i \\ \sum x_i & \sum x_i^2 \end{vmatrix} \begin{vmatrix} a_0 \\ a_1 \end{vmatrix} = \begin{vmatrix} \sum f(x)_i \\ \sum x_i f(x_i) \end{vmatrix}$$

and for a parabola ($n = 2$), the first three rows and columns.

Another possible form is the exponential function

$$F(t) = \alpha e^{\beta t}$$

and although partial differentiation will produce two equations in two unknowns, they will be nonlinear and cannot be written in matrix form. However, a change in variable

form may produce a model that is linear, for example, for the preceding equation

$$\ln(F) = \ln(\alpha) + \beta t$$

and if X is defined to be t , Y to be $\ln(F)$, $a_0 = \ln(\alpha)$, and $a_1 = \beta$, the equation becomes

$$Y(x) = a_0 + a_1 X$$

and linear least squares analysis may be applied.

In order to determine the quality (or the validity) of fit of a particular function to the data points given, a comparison of the deviation of the curve from the data to the size of the experimental error can be made. The deviations (i.e., the scatter off the curve) should be of the same order of magnitude as the experimental error, so that the quantity “chi-squared” is defined as

$$X^2 = \sum_{i=1}^n \frac{[y'_i - y_i]^2}{(\Delta y_i)^2}$$

where y'_i is the fitted function and y_i is the measured value of y at x_i , so that Δy_i is the magnitude of the error of y'_i . The sum is over n points and if the number of parameters in the model function is g_2 , then if $\mathcal{O}(X^2) > \mathcal{O}(n - g)$, the approximating function is a poor fit, while if $\mathcal{O}(X^2) < \mathcal{O}(n - g)$, the function may be overfit, representing noise [10].

The simplest form of approximation to a *continuous* function is some polynomial. Continuous functions may be approximated in order to provide a “simpler form” than the original function. Truncated power series representations (such as the Taylor series) are one class of polynomial approximations.

The Chebyshev polynomials $T_n(x)$ or T_n , which exist on the interval $-1 \leq x \leq 1$, form the series

$$\begin{aligned} T_0 &= 1 \\ T_1 &= x \\ &\vdots \\ T_{n+1} &= 2xT_n - T_{n-1} \end{aligned}$$

(see Table 1.7.6 for a more complete list). If these polynomials are inverted, powers of x are given in terms of $T_n(x)$ (Table 1.7.7). Any finite interval $a \leq y \leq b$ can be mapped onto the interval $-1 \leq x \leq 1$ by the formula

$$x = (2y - b - a)/(b - a)$$

and the inverted Chebyshev polynomials can be substituted for powers of x in a power series representing any function $f(x)$. Because the maximum magnitude for $T_n = 1$ because of the interval, the sum of the magnitudes of lower-order terms is relatively small. Therefore, even with truncation of

TABLE 1.7.6 Chebyshev Polynomials

$T_0(x) = 1$
$T_1(x) = x$
$T_2(x) = 2x^2 - 1$
$T_3(x) = 4x^3 - 3x$
$T_4(x) = 8x^4 - 8x^2 + 1$
$T_5(x) = 16x^5 - 20x^3 + 5x$
$T_6(x) = 32x^6 - 38x^4 + 18x^2 - 1$
$T_7(x) = 64x^7 - 112x^5 + 56x^3 - 7x$
$T_8(x) = 128x^8 - 256x^6 + 160x^4 - 32x^2 + 1$

TABLE 1.7.7 Inverted Chebyshev Polynomials

$1 = T_0$
$x = T_1$
$x^2 = \frac{1}{2}(T_0 + T_2)$
$x^3 = \frac{1}{4}(3T_1 + T_3)$
$x^4 = \frac{1}{8}(3T_0 + 4T_2 + T_4)$
$x^5 = \frac{1}{16}(10T_1 + 5T_3 + T_5)$
$x^6 = \frac{1}{32}(10T_0 + 15T_2 + 6T_4 + T_6)$
$x^7 = \frac{1}{64}(35T_1 + 21T_3 + 7T_5 + T_7)$
$x^8 = \frac{1}{128}(35T_0 + 56T_2 + 28T_4 + 8T_6 + T_8)$

the series after comparatively few terms, the altered series can provide sufficient accuracy.

See also the discussion on cubic splines in “Interpolation.”

1.7.7 Numerical Integration

By assuming that a function can be replaced over a limited range by a simpler function and by first considering the simplest function, a straight line, the areas under a complicated curve may be approximated by the *trapezoidal rule*. The area is subdivided into n panels and

$$I = T_n = \frac{1}{2} \Delta x_n \left(f_a + 2 \sum_{i=1}^{n-1} f_i + f_b \right)$$

where $\Delta x_n = (b - a)/n$ and f_i is the value of the function at each x_i . If the number of panels $n = 2^k$, an alternate form of the trapezoidal can be given, where

$$I = T_k = \frac{1}{2}T_{k-1} + \Delta x_k \sum_{\substack{i=1 \\ i \text{ odd}}}^{n-1} f(a + i\Delta x_k)$$

where $\Delta x_k = (b - a)/2^k$, $T_0 = \frac{1}{2}(f_a + f_b)(b - a)$, and the equation for T_k is repeatedly applied for $k=1, 2, \dots$ until sufficient accuracy has been obtained.

If the function $f(x)$ is approximated by parabolas, *Simpson's rule* is obtained, by which (the number of panels n being even)

$$I = S_n = \frac{1}{3}\Delta x \left[f_0 + 4 \sum_{\substack{i=1 \\ i \text{ odd}}}^{n-1} f_i + 2 \sum_{\substack{i=2 \\ i \text{ even}}}^{n-2} f_i + f_n \right] + E$$

where E is the dominant error term involving the fourth derivative of f , so that it is impractical to attempt to provide error correction by approximating this term. Instead, *Simpson's rule with end correction* (sixth order rather than fourth order) may be applied where

$$I = S_n = \frac{1}{15}\Delta x \left[14 \left\{ \frac{1}{2}(f_0 + f_n) + \sum_{\substack{i=2 \\ i \text{ even}}}^{n-2} f_i \right\} + 16 \sum_{\substack{i=1 \\ i \text{ odd}}}^{n-1} f_i + \Delta x[f'(a) - f'(b)] \right]$$

The original Simpson's formula without end correction may be generalized in a similar way as the trapezoidal formula for $n=2^k$ panels, using $\Delta x_k = (b - a)/2^k$ and increasing k until sufficient accuracy is achieved, where

$$S_k = \frac{1}{3}\Delta x_k \left[f_a + 4 \sum_{\substack{i=1 \\ i \text{ odd}}}^{n-1} f(a + i\Delta x_k) + 2 \sum_{\substack{i=2 \\ i \text{ even}}}^{n-2} f(a + i\Delta x_k) + f_b \right]$$

For the next higher level of integration algorithm, $f(x)$ over segments of $[a, b]$ can be approximated by a cubic, and if this k^{th} order result is C_k , then *Cote's rule* can be given as

$$C_k = S_k + (S_k - S_{k-1})/15$$

and the next higher degree approximation as

$$D_k = C_k + (C_k - C_{k-1})/63$$

The limit suggested by the sequence

$$T_k \rightarrow S_k \rightarrow C_k \rightarrow D_k \rightarrow \dots$$

is known as *Romberg integration*.

If a new notation $T_k^{(m)}$ is defined, where k is the order of the approximation ($n=2^k$) and m is the level of the integration algorithm, then $m=0$ (trapezoidal rule)

$$T_k^{(0)} = T_k$$

$m=1$ (Simpson's rule)

$$T_k^{(1)} = S_k$$

$m=2$ (Cote's rule)

$$T_k^{(2)} = C_k$$

$m=3$

$$T_k^{(3)} = D_k$$

and so forth.

The generalization of the preceding definitions leads to the Romberg equation

$$T_k^{(m+1)} = T_k^{(m)} + \frac{T_k^{(m)} - T_{k-1}^{(m)}}{4^{(m+1)} - 1}$$

The procedure is to start with the one-panel trapezoidal rule

$$T_0 \rightarrow T_0^{(0)} = \frac{1}{2}(b - a)(f_a + f_b)$$

and then increase the order (k) of the calculation by

$$T_k = \frac{1}{2}T_{k-1} + \Delta x_k \bullet \sum_{\substack{i=1 \\ i \text{ odd}}}^{n-1} f(a + i\Delta k_k)$$

and next increase the level of the algorithm m by the equation for $T_k^{(m+1)}$ just shown. In terms of $T_k^{(m)}$ for the first few k and m [10].

m	0	1	2	3	4
k					
0	$T_0^{(0)}$				
1	$T_1^{(0)}$	$T_1^{(1)}$			
2	$T_2^{(0)}$	$T_2^{(1)}$	$T_2^{(2)}$		
3	$T_3^{(0)}$	$T_3^{(1)}$	$T_3^{(2)}$	$T_3^{(3)}$	
4	$T_4^{(0)}$	$T_4^{(1)}$	$T_4^{(2)}$	$T_4^{(3)}$	$T_4^{(4)}$

Increasing accuracy may be obtained by stepping down or across the table, while the most accurate approximation will be found on the lower vertex of the diagonal. The

Romberg procedure is terminated when the values along the diagonal no longer change significantly, i.e., when the relative convergence criterion is less than some predetermined ϵ . In higher-level approximations, subtraction of like numbers occurs and the potential for round-off error increases. In order to provide a means of detecting this problem, a value is defined

$$R_k^{(m)} = \frac{1}{4^{(m+1)}} \frac{T_{k-1}^{(m)} - T_{k-2}^{(m)}}{T_k^{(m)} - T_{k-1}^{(m)}}$$

and since $R_k^{(m)}$ should approach 1 as a limit, a satisfactory criterion of error is if $R_k^{(m)}$ begins to differ significantly from 1.

An improper integral has one or more of the following qualities [38]:

1. Its integrand goes to finite limiting values at finite upper and lower limits, but cannot be integrated right on one or both of these limits.
2. Its upper limit equals ∞ , or its lower limit equals $-\infty$.
3. It has an integrable singularity at (a) either limit, (b) a known place between its limits, or (c) an unknown place between its limits.

In the case of 3b, Gaussian quadrature can be used, choosing the weighting function to remove the singularities from the desired integral. A variable step size differential equation integration routine [Computer Applications, ref. 8] produces the only practicable solution to 3c.

Improper integrals of the other types whose problems involve both limits are handled by open formulas that do not require the integrand to be evaluated at its endpoints. One such formula, the extended midpoint rule, is accurate to the same order as the extended trapezoidal rule and is used when the limits of integration are located halfway between tabulated abscissas:

$$I = M_n = \Delta x(f_{3/2} + f_{5/2} + \dots + f_{n-3/2} + f_{n-1/2})$$

Semi-open formulas are used when the problem exists at only one limit. At the closed end of the integration, the weights from the standard closed-type formulas are used and at the open end, the weights from open formulas are used. (Weights for closed and open formulas of various orders of error may be found in standard numerical methods texts.) Given a closed extended trapezoidal rule of one order higher than the preceding formula,

$$I = T_{2c} = \Delta x \left[\frac{5}{12}(f_1 + f_n) + \frac{13}{12}(f_2 + f_{n-1}) + \sum_{i=2}^{n-2} f_i \right]$$

and the open extended formula of the same order of accuracy

$$I = T_{2o} = \Delta x \left[\frac{23}{12}(f_1 + f_{n-1}) + \frac{7}{12}(f_3 + f_{n-2}) + \sum_{i=4}^{n-3} f_i \right]$$

a semi-open formula can be constructed that, in this example, is closed on the right and open on the left:

$$I = T_{2s} = \Delta x \left[\frac{23}{12}f_2 + \frac{7}{12}f_3 + \left(\sum_{i=4}^{n-2} f_i \right) + \frac{13}{12}f_{n-1} + \frac{5}{12}f_n \right]$$

To eliminate the restriction of evenly spaced points, *Gauss quadrature* algorithms may be constructed. In these algorithms not only the function values are weighted, but the position of the function evaluations as well as the set of weight factors are left as parameters to be determined by optimizing the overall accuracy. If the function is evaluated at points x_0, x_1, \dots, x_n , the procedure has $2n + 2$ parameters to be determined (the x_i , and the w_i for each x_i) and is required to be accurate for any polynomial of degree $N = 2n + 1$ or less.

These algorithms are frequently stated in terms of integrals over $[-1, 1]$, termed Gauss-Legendre quadrature, and the general formula then is

$$\int_{-1}^1 f(x)dx \cong w_0f_0 + w_1f_1 + \dots + w_nf_n$$

For example, for $n = 1$,

$$\int_{-1}^1 f(x)dx \cong f\left(x = \frac{-1}{\sqrt{3}}\right) + f\left(x = \frac{1}{\sqrt{3}}\right)$$

For each choice of n (the number of points), the w_k and the n zeros (ξ_k) of the n th degree Legendre polynomial must be determined by requiring that the approximation be exact for polynomials of degree less than $2n + 1$. These have been determined for $n = 2$ through 95 and an abbreviated table for some n is given in Table 1.7.8. The interval $-1 \leq \xi \leq 1$ is transformed onto the interval $a \leq x \leq b$ by calculating for each x_k ($k = 1, \dots, n$)

$$x_k = \frac{b + a}{2} + \frac{b - a}{2} \xi_k$$

and an approximation to the integral is then

$$I \cong \frac{b - a}{2} \sum_{k=1}^m w_k f(x_k)$$

Some other typical Gaussian quadrature formulas are

(a, b)	W(x)	Gauss-
(-1, 1)	$\frac{1}{\sqrt{1-x^2}}$	Chebyshev
(0, ∞)	$x^c e^{-x}$	Laguerre (c = 0, 1, ...)
(-∞, ∞)	e^{-x^2}	Hermite

^aPoints and weight factors are symmetric with respect to zero.

Weights and zeros for these formulas (and for other Gaussian formulas) may be found in references such as Stroud (*Gaussian quadrature formulas*, Prentice-Hall, 1966).

Because the dominant error term in Gauss Quadrature involves very high-order derivatives, the best method for determining the accuracy of an integration is to compare the results for several different n. However, in certain cases, a comparison may result in a set of significantly different answers, due to the presence of one or more singularities in f(x) or to a highly oscillatory function. If very large values of n are employed, round-off error can cause a major deterioration in accuracy (see previous discussion of Romberg integration).

1.7.8 Numerical Solution of Differential Equations

The two major categories of *ordinary differential equations* are

1. *Initial value problems* where conditions are specified at some starting value of the independent variable.
2. *Boundary value problems* where conditions are specified at two (or, rarely, more) values of the independent variable.

(The solution of boundary value problems depends to a great degree on the ability to solve initial value problems.) Any nth-order initial value problem can be represented as a system of n coupled first-order ordinary differential equations, each with an initial condition. In general

$$\begin{aligned} \frac{dy_1}{dt} &= f_1(y_1, y_2, \dots, y_n, t) \\ \frac{dy_2}{dt} &= f_2(y_1, y_2, \dots, y_n, t) \\ \frac{dy_n}{dt} &= f_n(y_1, y_2, \dots, y_n, t) \end{aligned}$$

and

$$y_1(0) = y_{10}, y_2(0) = y_{20}, \dots, y_n(0) = y_{n0}$$

The *Euler method*, while extremely inaccurate, is also extremely simple. This method is based on the definition of the derivative

$$\frac{dy}{dx} \cong \frac{y(x_i + \Delta x) - y(x_i)}{\Delta x}$$

or

$$y_{i+1} = y_i + f_i \Delta x$$

where $f_i = f(x_i, y_i)$ and $y(x = a) = y_0$ (initial condition).

Discretization error depends on the step size, i.e., if $\Delta x_i \rightarrow 0$, the algorithm would theoretically be exact. The error for Euler method at step N is $\mathcal{O}(\Delta x)^2$ and total

accumulated error is $\mathcal{O}(\Delta x)$, that is, it is a first-order method.

The *modified Euler method* needs two initial values y_0 and y_1 and is given by

$$y_n = y_{n-2} + f_{n-1}(2\Delta x) + \mathcal{O}(\Delta x)^2$$

If y_0 is given as the initial value, y_1 can be computed by Euler's method, or more accurately as

$$\Delta y_a = f(x_0, y_0)\Delta x$$

$$y_1 = y_0 + \Delta y_a$$

$$f_1 = f(x_1, y_1)$$

and

$$\Delta y_b = f_1 \Delta x$$

therefore

$$\Delta y = \frac{1}{2}(\Delta y_a + \Delta y_b)$$

and

$$y_1 = y_0 + \Delta y$$

Another improvement on the basic Euler method is to approximate the slope in the middle of the interval by the average of the slopes at the end points, or

$$y_{i+1} = y_i + \frac{1}{2}(f_i + f_{i+1})\Delta x$$

This form is a *closed-type* formula because it does not allow direct steps from x_i to x_{i+1} but uses the basic Euler's method to estimate y_{i+1} :

$$y_{i+1} = y_i + f_i \Delta x$$

$$f_{i+1} = f(x_{i+1}, y_{i+1})$$

$$y_{i+1} = y_i + \frac{1}{2}(f_i + f_{i+1})\Delta x$$

The *Runge-Kutta method* takes the weighted average of the slope at the left end point of the interval and at some intermediate point. This method can be extended to a fourth-order procedure with error $\mathcal{O}(\Delta x)^4$ and is given by

$$y_{i+1} = y_i + \frac{1}{6}[\Delta y_0 + 2\Delta y_1 + 2\Delta y_2 + \Delta y_3]$$

where $\Delta y_0 = f(x_i, y_i)\Delta x$

$$\Delta y_1 = f\left(x_i + \frac{1}{2}\Delta x, y_i + \frac{1}{2}\Delta y_0\right) \Delta x$$

$$\Delta y_2 = f\left(x_i + \frac{1}{2}\Delta x, y_i + \frac{1}{2}\Delta y_1\right) \Delta x$$

$$\Delta y_3 = f(x_{i+1}, y_i + \Delta y_2)\Delta x$$

Runge-Kutta formulas of the sixth and eighth orders are also available but are less commonly used.

If two values of y_{i+1} are calculated, y_{i+1} by using one step between x_i and x_{i+1} with Δx , and \hat{y}_{i+1} by taking two steps with $\Delta x/2$, the estimate of the truncation error is

$$E_{i+1} \sim \frac{\hat{y}_{i+1} - y_{i+1}}{2^{-k} - 1}$$

where k is the order of the expression (e.g., $k=4$ for the foregoing Runge-Kutta formula). The step size can be adjusted to keep the error E below some predetermined value.

The *Adams open formulas* are a class of multistep formulas such that the first-order formula reproduces the Euler formula. The second-order Adams open formula is given by

$$y_{i+1} = y_i + \Delta x \left[\frac{3}{2}f_i - \frac{1}{2}f_{i-1} \right] + \mathcal{O}(\Delta x)^2$$

This formula and the higher-order formulas are not self starting since they require f_{i-1} , f_{i-2} , etc. The common practice is to employ a Runge-Kutta formula of the same order to compute the first term(s) of y_i . The general Adams open formula may be written as

$$y_{i+1} = y_i + \Delta x \sum_{k=0}^n \beta_{nk} f_{i-k} + \mathcal{O}(\Delta x)^{n+2}$$

and the coefficients β are given in [Table 1.7.9](#) for $n = 0, 1, \dots, 5$.

Adams closed formulas require an iterative method to solve for y_{i+1} , because the right side of the expression requires a value of f_{i+1} . The iteration of estimating y , evaluating f , and obtaining a new estimate of y is repeated until it converges to the desired accuracy. The general formula is

$$y_{i+1} = y_i + \Delta x \sum_{k=0}^n \beta_{nk}^* f_{i+1-k} + \mathcal{O}(\Delta x)^{n+2}$$

and the coefficients β^* are given in [Table 1.7.10](#).

A combination of open- and closed-type formulas is referred to as the *predictor-corrector method*. First the open equation (the predictor) is used to estimate a value of y_{i+1} , this value is then inserted into the right side of the corrector equation (the closed formula) and iterated to improve the accuracy of y . The predictor-corrector sets may be the low-order modified (open) and improved (closed) Euler equations, the Adams open and closed formulas, or the *Milne method*, which gives the following system

1. Predictor

$$y_{i+1} = y_{i-3} + \frac{4}{3}\Delta x(2f_i - f_{i-1} + 2f_{i-2})$$

TABLE 1.7.9 Coefficients β_{nk} of the Open Adams Formulas

n^k	0	1	2	3	4	5	\mathcal{O}^a
0	1						1
1	3/2	-1/2					2
2	23/12	-16/12	5/12				3
3	55/24	-59/24	37/24	-9/24			4
4	1901/720	-2774/720	2616/720	-1274/720	251/720		5
5	4277/1440	-7923/1440	9982/1440	-7298/1440	2877/1440	-475/1440	6

^a \mathcal{O} is the order of the method.

TABLE 1.7.10 Coefficients β_{nk}^* of the Closed Adams Formulas

n^k	0	1	2	3	4	5	\mathcal{O}^a
0	1						1
1	1/2	1/2					2

3	9/24	19/24	-5/24	1/24			4
4	251/720	646/720	-264/720	106/720	-19/720		5
5	475/1440	1427/1440	-798/1440	482/1440	-173/1440	27/1440	6

^a \mathcal{O} is the order of the method.

2. Corrector

$$y_{i+1} = \frac{1}{3}\Delta x(f_{i+1} + 4f_i + f_{i-1})$$

although the Milne method, like the Adams formulas, is not self starting.

The *Hamming method* [4] applies a predictor y^0 and then a modifier \hat{y}^0 , which provides a correction for the estimate of error in the predictor and corrector, and then iterates the corrector y^n as desired. The procedure is

1. Predictor

$$y_{i+1}^{(0)} = y_{i-3} + \frac{4}{3}\Delta x(2f_i - f_{i-1} + 2f_{i-2})$$

2. Modifier

$$\hat{y}_{i+1}^{(0)} = y_{i+1}^{(0)} + \frac{112}{121} (y_i - y_i^{(0)})$$

3. Corrector

$$y_{i+1}^{(n+1)} = \frac{1}{8}(9y_i - y_{i-2}) + \frac{3}{8}\Delta x(f_{i+1}^{(n)} + 2f_i - f_{i-1})$$

Truncation error estimates can be made to determine if the step size should be reduced or increased. For example, for the Hamming method,

$$E_{i+1} \sim \frac{9}{121} (y_{i+1} - y_{i+1}^{(0)})$$

The *Gear algorithm* [15], based on the Adams formulas, adjusts both the order and mesh size to produce the desired local truncation error. *Bulirsch and Stoer method* [16, 22] is capable of producing accurate solutions using step sizes that are much smaller than conventional methods. Packaged Fortran subroutines for both methods are available.

One approach to second-order *boundary value problems* is a matrix formulation. Given

$$\frac{d^2y}{dx^2} + Ay = B, \quad y(0) = 0, \quad y(L) = 0$$

the function can be represented at i by

$$\frac{y_{i+1} - 2y_i + y_{i-1}}{(\Delta x)^2} + Ay_i = B$$

1.8 APPLIED STATISTICS

See References 1–6 for additional information.

A *discrete random variable* is one that may take on only distinct, usually integer, values. A *continuous random variable* is one that may take on any value within a continuum of values.

1.8.1 Moments

The moments describe the characteristics of a sample or distribution function. The *mean*, which locates the average value on the measurement axis, is the first moment of values measured about the origin. The mean is denoted by μ for the population and \bar{X} for the sample and is given for a continuous random variable by

$$\bar{X} \text{ or } \mu = \int_{-\infty}^{\infty} Xf(X)dX$$

For a discrete random variable, the mean is given by

$$\bar{X} \text{ or } \mu = \sum_{i=1}^n X_i f(X_i)$$

and if each observation is given equal weight, $f(X) = 1/n$ and

$$\bar{X} \text{ or } \mu = \frac{1}{n} \sum_{i=1}^n X_i$$

The *variance* is the second moment about the mean and indicates the closeness of values to the mean. It is denoted by σ^2 (population) or S^2 (sample) and is given for a continuous random variable by

$$\sigma^2 \text{ or } S^2 = \int_{-\infty}^{\infty} (X - \mu)^2 f(X)dX$$

For a discrete random variable, the variance is

$$\sigma^2 \text{ or } S^2 = \sum_{i=1}^n (X_i - \mu)^2 f(X_i)$$

and if $f(X) = 1/n$

$$\sigma^2 \text{ or } S^2 = \frac{1}{n} \sum_{i=1}^n (X_i - \mu)^2 \text{ (biased)}$$

or

$$\sigma^2 \text{ or } S^2 = \frac{1}{n-1} \sum_{i=1}^n (X_i - \mu)^2 \text{ (unbiased)}$$

The *standard deviation* is the square root of the variance and is denoted by σ (population) or S (sample).

The *skew*, the third moment about the mean, is a measure of symmetry of distribution and can be denoted by γ (population) or g (sample). It is given for a continuous random variable by

$$\gamma \text{ or } g = \int_{-\infty}^{\infty} (X - \mu)^3 f(X)dX$$

and for a discrete random variable by

$$\gamma \text{ or } g = \sum_{i=1}^n (X_i - \mu)^3 f(X_i)$$

A completely symmetrical distribution will have a skew = 0, and in a non-symmetric distribution the sign of the skew will depend upon the location of the tail of the distribution.

The *kurtosis*, the fourth moment, is a measure of peakedness or flatness of a distribution. It has no common notation (k is used here) and is given for a continuous random variable by

$$k = \int_{-\infty}^{\infty} (X - \mu)^4 f(X)dX$$

and for a discrete random variable by

$$k = \sum_{i=1}^n (X_i - \mu)^4 f(X_i)$$

1.8.2 Moment Ratios

The *moment ratios* are dimensionless coefficients used to compare characteristics of distributions measured on different scales.

The *coefficient of variation* is a measure of relative dispersion of a set of values and is given for the population by

$$C_v = \sigma/\mu$$

and for the sample by

$$C_v = S/\bar{X}$$

The *coefficient of skewness* is a measure of relative symmetry of a distribution and is given for the population by

$$\beta_1 = \gamma^2/\sigma^6$$

and for the sample by

$$\beta_1 = g^2/S^6$$

The *coefficient of kurtosis* is a measure of relative peakedness and is given by

$$\beta_2 = k/S^4$$

1.8.3 Common Probability Distributions for Continuous Random Variables

The *parameters* of a distribution control its geometric characteristics [1]:

1. A *location parameter* is the abscissa of a location point and may be a measure of central tendency, such as a mean.
2. A *scale parameter* determines the location of fractiles of the distribution relative to some specified point, often the value of the location parameter.
3. *Shape parameters* control the geometric configuration of a distribution. There may be zero, one, or multiple shape parameters.

A bounded continuous random variable with *uniform distribution* has the probability function

$$f(X) = \begin{cases} 1/(\beta - \alpha) & \alpha \leq X \leq \beta \\ 0 & \text{otherwise} \end{cases}$$

where α = location parameter, representing lower limit of the distribution

β = scale parameter, representing upper bound of the distribution

Probabilities are determined by integration over the necessary range:

$$P(X_1 < X < X_2) = \int_{x_1}^{x_2} 1/(\beta - \alpha)dX$$

The *normal (Gaussian) distribution* is the most frequently used probability function and is given by

$$f(X) = \frac{1}{\sqrt{2\pi}\sigma} \exp \left[-\frac{1}{2} \left(\frac{X - \mu}{\sigma} \right)^2 \right] \text{ for } -\infty < X < \infty$$

where μ = location parameter and σ = scale parameter.

The cumulative function for this distribution is $\int f(X)$.

The *standard normal distribution* is determined by calculating a random variable z where

$$z = (X - \mu) / \sigma \text{ for the population}$$

$$z = (X - \bar{X}) / S \text{ for the sample}$$

The probability function for the standard normal distribution is then

$$f(z) = \frac{1}{\sqrt{2\pi}} e^{-.05z^2}$$

where z has mean of zero and a standard deviation of one. Probability estimates are evaluated by integrating $f(z)$.

$$P(z_1 \leq z \leq z_2) = \int_{z_1}^{z_2} \frac{1}{\sqrt{2\pi}} e^{-.05z^2} dz$$

The *t (Student's t) distribution* is an unbounded distribution where the mean is zero and the variance is $v/(v - 2)$, v being the scale parameter (also called degrees of freedom). As $v \rightarrow \infty$, the variance $\rightarrow 1$ (standard normal distribution). A t table such as [Table 1.8.1](#) is used to find values of the t statistic where v is located along the vertical margin and the probability is given on the horizontal margin. (For a one-tailed test, given the probability for the left tail, the t value must be preceded by a negative sign.)

The *chi-square distribution* gives the probability for a continuous random variable bounded on the left tail. The probability function has a shape parameter v (degrees of freedom), a mean of v , and a variance of $2v$. Values of the χ^2 characteristic are obtained from a table such as [Table 1.8.2](#), which is of similar construction as the t table (see [Table 1.8.1](#)).

The *F distribution* has two shape parameters, v_1 and v_2 . [Table 1.8.3](#) shows F values for 1% and 5% probabilities.

$$F(v_1, v_2) \neq F(v_2, v_1)$$

1.8.4 Probability Distributions for Discrete Random Variables

The *binomial distribution* applies to random variables where there are only two possible outcomes (A or B) for each trial and where the outcome probability is constant over all n trials. If the probability of A occurring on any one trial is denoted as p and the number of occurrences of A is denoted as x , then the *binomial coefficient* is given by

$$\binom{n}{x} = \frac{n!}{x!(n-x)!}$$

and the probability of getting x occurrences of A in n trials is

$$b(x; n, p) = \binom{n}{x} p^x (1-p)^{n-x} \text{ for } x = 0, 1, 2, \dots, n$$

The cumulative probability of the binomial distribution is given by

$$B(x; n, p) = \sum_{i=0}^x b(i; n, p)$$

For the binomial distribution

$$\mu = np$$

$$\sigma = \sqrt{np(1-p)}$$

For $np \geq 5$ and $n(1 - p) \geq 5$, an approximation of binomial probabilities is given by the standard normal distribution where z is a standard normal deviate and

$$z = \frac{x - np}{\sqrt{np(1 - p)}}$$

The *negative binomial distribution* defines the probability of the k^{th} occurrence of an outcome occurring on the x^{th} trial as

$$b^-(x; k, p) = \binom{x - 1}{k - 1} p^k (1 - p)^{x - k}$$

for $x = k, k + 1, k + 2, \dots$

and

$$\mu = k(1 - p) / p$$

$$\sigma^2 = k(1 - p) / p^2$$

If the probabilities do not remain constant over the trials and if there are k (rather than two) possible outcomes of each trial, the *hypergeometric distribution* applies. For a sample of size N of a population of size T , where

$$t_1 + t_2 + \dots + t_k = T, \text{ and}$$

$$n_1 + n_2 + \dots + n_k = N$$

the probability is

$$h(n_i; N, t_i, T) = \frac{\binom{t_1}{n_1} \binom{t_2}{n_2} \dots \binom{t_k}{n_k}}{\binom{T}{N}}$$

The *Poisson distribution* can be used to determine probabilities for discrete random variables where the random variable is the number of times that an event occurs in a single trial (unit of time, space, etc.). The probability function for a Poisson random variable is

$$P(x; \mu) = \frac{e^{-\mu} \mu^x}{x!} \text{ for } x = 0, 1, 2, \dots$$

where μ =mean of the probability function (and also the variance)

The cumulative probability function is

$$F(X; \mu) = \sum_{i=0}^x P(i; \mu)$$

1.8.5 Univariate Analysis

For multivariate analysis, see McCuen, Reference 23, or other statistical texts.

FIGURE 1.8.1 Probability paper for frequency analysis.

The first step in data analysis is the selection of the best fitting probability function, often beginning with a graphical analysis of the frequency histogram. Moment ratios and *moment-ratio diagrams* (with β_1 as abscissa and β_2 as ordinate) are useful since probability functions of known distributions have characteristic values of β_1 and β_2 .

Frequency analysis is an alternative to moment-ratio analysis in selecting a representative function. Probability paper (Figure 1.8.1) is available for each distribution, and the function is presented as a cumulative probability function. If the data sample has the same distribution function as the function used to scale the paper, the data will plot as a straight line.

The procedure is to fit the population frequency curve as a straight line using the sample moments and parameters of the proposed probability function. The data are then plotted by ordering the data from the largest event to the smallest and using the rank (i) of the event to obtain a probability plotting position. Two of the more common formulas are Weibull

$$pp_w = i/(n + 1)$$

and Hazen

$$pp_h = (2i - 1)/(2n)$$

where n is the sample size. If the data do not show a reasonable fit to the population curve, a different function should be investigated.

Estimation of model parameters is frequently accomplished by the *method of moments*. For example, for the uniform distribution, the mean is

$$\mu = \int_{\alpha}^{\beta} X \left(\frac{1}{\beta - \alpha} \right) dX = \frac{\beta + \alpha}{2} = \bar{X}$$

and the variance is

$$\sigma^2 = (\beta - \alpha)^2 / 12 = S^2$$

Solving for α and β gives

$$\alpha = \bar{X} - S\sqrt{3}$$

$$\beta = \bar{X} + S\sqrt{3}$$

1.8.6 Confidence Intervals

Confidence intervals provide a method of calculating the range of values that contains the true value of an estimate. A general equation for a two-sided confidence interval is

$$K_{est} = \pm FD$$

where K_{est} = estimated value of the K statistic

F = distribution factor

D = measure of dispersion

(For one-sided confidence intervals, the \pm is replaced by + or by -.)

If σ is known, the *confidence interval on the mean* is

- Two sided

$$\bar{X} - z_{\alpha/2} \frac{\sigma}{\sqrt{n}} \leq \mu \leq \bar{X} + z_{\alpha/2} \frac{\sigma}{\sqrt{n}}$$

- One sided, lower limit

$$\bar{X} - z_{\alpha} \frac{\sigma}{\sqrt{n}} \leq \mu \leq \infty$$

- One sided, upper limit

$$-\infty \leq \mu \leq \bar{X} + z_{\alpha} \frac{\sigma}{\sqrt{n}}$$

where \bar{X} = sample mean = K_{est}
 n = sample size

$z_{\alpha}, z_{\alpha/2}$ = values of random variables, with standard normal distribution, cutting off $(1 - \gamma)$ and $(1 - \gamma/2)$ respectively in the tail of the distribution, and $\alpha = 1 - \gamma$ (the level of significance) = F

σ/\sqrt{n} = measure of dispersion

If σ is unknown, the equations are

- Two sided

$$\bar{X} - t_{\alpha/2} \frac{s}{\sqrt{n}} \leq \mu \leq \bar{X} + t_{\alpha/2} \frac{s}{\sqrt{n}}$$

- One sided, lower limit

$$\bar{X} - t_{\alpha} \frac{s}{\sqrt{n}} \leq \mu \leq \infty$$

- One sided, upper limit

$$-\infty \leq \mu \leq \bar{X} + t_{\alpha} \frac{s}{\sqrt{n}}$$

where s = standard deviation of sample

$t_{\alpha}, t_{\alpha/2}$ = values of variables having a t distribution with $v = n - 1$, and $\alpha\%$ of distribution cut off in one tail and $\alpha/2\%$ in both tails = F

s/\sqrt{n} = measure of dispersion

The *confidence interval on the variance* is computed by

- $\frac{(n-1)S^2}{X_{\alpha/2}^2} \leq \sigma^2 \leq \frac{(n-1)S^2}{X_{(1-\alpha/2)}^2}$
- $\frac{(n-1)S^2}{X_{\alpha}^2} \leq \sigma^2 \leq \infty$
- $-\infty \leq \sigma^2 \leq \frac{(n-1)S^2}{X_{(1-\alpha)}^2}$

where $X_{\alpha/2}^2, X_{\alpha}^2$ = values of a random variable with a chi-square distribution cutting off $\alpha/2\%$ and $\alpha\%$, respectively, of the right tail

$X_{(1-\alpha/2)}^2, X_{(1-\alpha)}^2$ = values of a random variable with a chi-square distribution cutting off $(1 - \alpha/2)\%$ and $(1 - \alpha)\%$, respectively, of the left tail

$$S^2 = K_{est}$$

X^2 values = distribution factors

1.8.7 Correlation

Correlation analysis quantifies the degree to which the value of one variable can be used to predict the value of another. The most frequently used method is the *Pearson product-moment correlation coefficient*.

The *coefficient of determination* is the fraction of the variation that is explained by a linear relationship between two variables and is given by

$$R^2 = \frac{\sum_{i=1}^n (\hat{Y}_i - \bar{Y})^2}{\sum_{i=1}^n (Y_i - \bar{Y})^2}$$

where Y = observation on the random variable

\hat{Y} = value of Y estimated from the best linear relationship with the second variable X

\bar{Y} = mean of the observations on Y

and R is the *correlation coefficient*. A perfect association is indicated by $R = 1$ for a direct relationship and $R = -1$ for an inverse relationship. $R = 0$ indicates no linear association between X and Y .

A second definition of R is

$$R = \frac{1}{nS_x S_y} \sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y})$$

where n = number of observations on Y

S_x, S_y = biased (n degrees of freedom) estimates of the standard deviations of X and Y

Note: For small n , even high correlation may not indicate a significant relationship between the variables.

1.8.8 Regression

The relationship between a criterion variable and two or more predictor variables is given by a *linear multivariate model*:

$$\hat{Y} = b_0 + b_1 x_1 + b_2 x_2 + \dots + b_p x_p$$

where p = number of predictor variables

x_i = i^{th} predictor variable

b_i = i^{th} slope coefficient

b_0 = intercept coefficient

$i = 1, 2, \dots, p$

The coefficients b_i are the *partial regression coefficients*.

The *principle of least squares* is used to correlate Y with the X_i values. The error e (or residual) is defined as

$$e_i = \hat{Y}_i - Y_i$$

where \hat{Y}_i = i^{th} predicted value of the criterion variable

Y_i = i^{th} measured value of the criterion variable

e_i = i^{th} error

The purpose of the principle of least squares is to minimize the sum of the squares of the errors so that

$$E = \min \sum_{i=1}^n (\hat{Y}_i - Y_i)^2$$

where n = number of observations of the criterion variable (i.e., sample size)

$$E = \sum_{i=1}^n (b_0 + b_1 X_i - Y_i)^2$$

By differentiating with respect to b_0 and b_1 and setting the equations equal to zero, two equations in two unknowns are obtained (the summations are for $I = 1, \dots, n$)

$$b_1 = \frac{\sum X_i Y_i - (\sum X_i \sum Y_i) / n}{\sum X_i^2 - (\sum X_i)^2 / n}$$

and

$$b_0 = \frac{\sum Y_i}{n} - \frac{b_1 \sum X_i}{n}$$

and by solutions of the set, b_0 and b_1 can be obtained.

The standard deviation S_y gives the accuracy of prediction. If Y is related to one or more predictor variables, the error of prediction is reduced to the *standard error of estimate* S_e (the standard deviation of the errors), where

$$S_e = \left[\frac{1}{v} \sum_{i=1}^n (\hat{Y}_i - Y_i)^2 \right]^{0.5}$$

where v = degrees of freedom, or sample size – number of unknowns. For the general linear model with an intercept, there are $(p + 1)$ unknowns and $v = n - (p + 1)$.

If $S_e = 0$, then $R = 1$, and if $S_e = S_y$, then $R = 0$.

The *standardized partial regression coefficient* t is a measure of the relative importance of the corresponding predictor and is given by

$$t = (b_1 S_x) / S_y$$

where $-1 < t < 1$ for rational models

The two-sided confidence intervals for the coefficients b_0 and b_1 , when β_0 and β_1 are random variables having t distributions with $(n - 2)$ degrees of freedom and error variances of

$$S_e^2(b_0) = \frac{S_e^2 \sum X_i^2}{n \sum (X_i - \bar{X})^2}$$

and

$$S_e^2(b_1) = \frac{S_e^2}{\sum (X_i - \bar{X})^2}$$

are (if α is the level of significance)

$$b_0 \pm t_{(\alpha/2, n-2)} S_e(b_0)$$

$$b_1 \pm t_{(\alpha/2, n-2)} S_e(b_1)$$

The confidence interval for a line of m points may be plotted by computing the confidence limits \hat{Y}_{ci} at each point, $(X_{xi}, \hat{Y}_{ai}, i = 1, 2, \dots, m)$ of the regression line when

$$\hat{Y}_{ci} = \hat{Y}_{ai} \pm S_e \sqrt{2F} \left[\frac{1}{n} + \frac{(X_{ai} - \bar{X})^2}{\sum (X - \bar{X})^2} \right]^{0.5}$$

where $\hat{Y}_{ai} = \bar{Y} + b_1 (X_{ai} - \bar{X})$

F = F statistic obtained for $(2, n - 2)$ degrees of freedom and a level of significance $\alpha = 1 - \gamma$, γ being the level of confidence.

The confidence interval for a single point, say X_o , can be computed using the interval

$$\hat{Y} \pm t_{\alpha/2} S_e \left[\frac{1}{n} + \frac{(X_o - \bar{X})^2}{\sum (X - \bar{X})^2} \right]^{0.5}$$

where $t_{\alpha/2}$ = value of random variable having at t distribution with $(n - 2)$ degrees of freedom and a level of confidence $\alpha = 1 - \gamma$.

$$\hat{Y} = \bar{Y} + b_1 (X_o - \bar{X})$$

The confidence interval for a future value X_f is given by

$$\hat{Y} \pm t_{\alpha/2} S_e \left[1 + \frac{1}{n} + \frac{(X_f - \bar{X})^2}{\sum (X - \bar{X})^2} \right]^{0.5}$$

where $\hat{Y} = \bar{Y} + b_1 (X_f - \bar{X})$.

1.9 COMPUTER APPLICATIONS

See References 1–12 for additional information.

Some areas of digital computer use that are highly applicable to the engineering field include

- Numerical computations for design and modeling
- Information storage and retrieval
- Data sorting and reduction
- Computer-aided graphics for illustration and for design
- Word processing
- Communication networks and database access
- Artificial intelligence applications such as expert systems and neural networks (see Reference 40 for more information).

1.9.1 Problem Solving

The initial outline of a solution to a problem is the *algorithm* (i.e., a list of English-language instructions with the following properties):

1. The execution of the proposed algorithm must be completed after a finite number of operations, the number depending on the complexity of the problem and the degree of detail of the algorithm.
2. The representation of the solution must have a *unique interpretation*, so when executing the steps with the same input data, the same outputs are obtained.
3. The algorithm must present the computer with sufficient information and instructions to carry out the solution.
4. The scope of the algorithm may be predefined by the range of the inputs.

1.9.2 Programming Languages

A wide variety of programming languages are available ranging from *machine code*, composed of sequences of 0's and 1's representing either data or instructions,

which is completely processor dependent and not transferable, through *assembly languages* consisting of mnemonics for instructions and usually hexadecimal representation of storage location addresses and of data to *high-level programming languages* such as FORTRAN, C, and JAVA. High-level languages may be divided into procedure-oriented languages and problem-oriented languages.

The term problem-oriented languages should be read as “special-purpose languages” or “applications-oriented languages,” because in a more general context all high-level languages may be used to solve problems. Some of these languages have been designed for special applications such as electronic circuit analysis, while others are more general purpose, such as those written for simulation or statistical packages. An example is the programming language available in many computer algebra systems (CAS) such as Maple or Matlab.

Procedure-oriented languages, so called because they allow the programmer to concentrate on the process rather than on the machine architecture, include familiar languages, such as FORTRAN, as well as many more recently developed ones. Three of the high-level languages of common interest to engineers are:

1. Formula Translating Language (FORTRAN) the original, still most commonly used language for engineering computations. It is a compiled language (the entire program is translated to object code and saved before execution) that links to many libraries of subroutines and has a number of special purpose extensions. FORTRAN has been much improved by the addition of control structures which eliminate the necessity for many unstructured leaps of logic through the program. The basic structure of many programming languages is similar (see the FORTRAN language section for details on the structure and syntax of this language).
2. C is a programming language developed in the 1970s and originally associated with the Unix operating system. C++ is an update to C that adds *object-oriented* features to C. Object-oriented programming is a relatively new approach to programming that differs from traditional structured or procedural programming in that it is based on the use of *objects*, which are members of *classes* or categories of objects that have similar features [11].
3. Java is a fully object-oriented language that is based on the creation of *applets*, which are small programs that can be attached to Web pages and move across the Internet [11]. One important feature of Java is that, unlike other programs that require a specific operating system, a Java program runs on all operating systems and hardware platforms.

Packaged programs are available in many areas of general interest to engineers, including mathematics, statistics,

and structural design. The popular Microsoft Office software contains a spreadsheet program, Excel, and a database management program, Access, that are used in many petroleum engineering applications. Excel has many built-in functions, including common statistical and mathematical functions, and it has the ability to easily perform operations on large amounts of data. A number of vendors also offer specialized petroleum engineering packages relating to such areas as EOR, drilling fluids, corrosion control, cementing, and well production histories. Some private vendors also maintain databases on specific subjects such as well production histories.

1.9.3 Common Data Types

Although the number of data types available varies with the programming language and a particular vendor’s restrictions and extensions of the standard, the following types are particularly useful in scientific programming. (Some languages permit user definition of nonstandard data types, usually for the purpose of limiting the range of values accepted by a variable of that type.)

1. *Integer* — A signed number with no fractional part.
2. *Real* — A signed number with an integer part and a fractional part.
3. *Double precision* — Value stored as two words, rather than one, representing a real number, but allowing for approximately double the number of significant digits.
4. *Complex* — Value stored as two words, one representing the real part of the number and the other representing the imaginary part.
5. *Character* — Alphanumerical item (2, m, !, etc.) represented in memory as a binary code (see Table 1.9.1 for ASCII and Table 1.9.2 for EBCDIC).
6. *Logical* — Data type with only two possible values: True (represented as 1) and False (represented as 0), also referred to as Boolean.
7. *Pointer* — Identifies addresses of other data items; used to create linked data structures.

1.9.4 Common Data Structures

The following data structures are available or can be constructed in most high-level languages.

1. *Variable* — Named data item of a specific type; may be assigned one or more values during the course of a program run (in some languages, a constant may be defined with a specified initial value that may not be changed).

TABLE 1.9.1 ASCII (American Standard Code for Information Exchange)^a

Left Digits	Right Digits									
	0	1	2	3	4	5	6	7	8	9
3				!	"	#	\$	%	&	'
4	()	*	+	,	-	.	/	0	1

12	x	y	z	{		}	~			

^aDecimal codes 00 to 31 and 127 and higher represent nonprintable characters and special character codes.

2. *Array* — A collection of data items of the same type, referred to collectively by a single name. The individual items, the *array elements*, are ordered by their subscripts, the number of subscripts being determined by the dimensionality of the array. An element is referred to by the array name followed by its parenthesized subscripts (e.g., TEMP(I, J) might refer to the temperature at the Ith time increment and at the Jth pipe node).
3. *Record* — A collection of data items (fields) of various types, which may also be records themselves. If EMP1 is a record in the master file of employees, EMP1.NAME may be a character field, EMP1.ZIP an integer field, and EMP1.SAL a real field.
4. *File* — Collection of records that normally consist of matching types of fields. Records in a file may be accessed sequentially (the entire file must be read until the needed record is reached) or randomly (the record contains a key field, which determines its physical location in storage).
5. *Linked lists* — Data items linked by pointers. In the general form, each item, except the first, has one predecessor, and each item, except the last, has one successor, with pointers linking items to their successors. *Doubly linked lists* have pointers to both the predecessor and the successor of an item and a *circular list* has a pointer from the final item to the initial item (producing a predecessor to the initial item and a successor to the final item). Restricted lists also exist, such as *stacks*, where items may only be added (pushed) or deleted (popped) at one

TABLE 1.9.2 EBCDIC (Extended Binary Coded Decimal Interchange Code)^a

^aDecimal codes 00 to 63 and 250 to 255 represent nonprintable control characters.

end (the top), and *queues*, where items must be inserted at one end and deleted from the other. *Trees* are linked lists in which each item (node) except the root node has one predecessor, but all nodes may have any finite number, or zero, successors; *graphs* contain both nodes and edges, which connect the nodes and define their relationships.

- 6. Class** — A description of data and the procedures used to work with the data. Examples of classes common in *graphical user interfaces* (GUI) are Scrollbar and Button.
- 7. Object** — An object is a specific member of a class.

1.9.5 Program Statements

The statements of which the program consists may be either executable or nonexecutable. *Nonexecutable statements* consist of comments, which explain the data and logic of the program, and declarations, which are orders to the translator or to other system programs and which usually serve to allocate memory space for data.

Executable statements, which are translated into machine code, are instructions by which operations are performed on data or by which the sequence of execution is changed. Statements producing operations on data are

- 1. Assignment** — Assign a value, either a constant or a computed value, to a variable, an array element, a node, or a field.
- 2. Input** — Transfer data from external devices, such as a keyboard or disk file, to the program.
- 3. Output** — Transfer data from the program to an external device, such as a printed, screen, or a disk file.

Executable statements affecting the order in which the program instructions are executed include conditional (branching) statements, iterative (looping) statements, and statements which call subprogram units.

- 1. Conditional statements** — Change the sequence in which instructions are executed depending upon the logical relationship(s) between variables and/or between variable(s) and set value(s).
- 2. Iterative statements** — Force the repetition of instructions depending on preset conditions.
- 3. Calling statements** — Transfer control to a subprogram unit.

1.9.6 Subprograms

The division of a program into a main program unit and one or more subprogram units allows logical organization of the program into sections of related operations and facilitates the coding, debugging, and replacement of units of the program. Data are passed from one unit (or module) to another through parameters (arguments) and/or through shared memory locations. There are two types of subprograms usually available:

- 1. Function subprograms** — Return a single value as the value of the function name; these may be either extrinsic (user-defined) or intrinsic (provided as part of the system library).
- 2. Subroutine or procedure subprograms** — Return values through parameters or global variables (see scope).

The *scope* of a data item in a program determines which program units may access (and change) the value of that data item. *Global* data may be accessed by all program

units, whereas *local* data are visible only to the unit(s) in which they are defined. The method by which scope is determined depends on the type of language being used. In FORTRAN, a COMMON block defined by a COMMON statement in the main program allows data in that block to be accessed by any module in which the block is defined. Parameters allow two units to share data values; some types of parameters allow the passing of only the value and not the location of the item, so that the subunit can read, but not change, the value. In block structured languages, such as Pascal, the structure determines the scope of the variables; the scope of a variable is the block in which it was defined and all blocks contained therein. A variable in this case is global to a sub-unit if it was declared not in that sub-unit but in a higher-level unit which contains the sub-unit, e.g., all variables declared in the main program are global to all program units.

Recursion is available in languages having dynamic memory allocation. Direct recursion occurs when a program unit calls itself; indirect recursion occurs when a chain of subprogram calls results in the original calling unit being called again without returning to a higher-level unit, such as MAIN→SUBA→SUBB→SUBC→SUBA, where

1.9.7 General Programming Principles

Two characteristics of well-designed programs are

1. *Generality* — To as great an extent as possible for a particular problem, a program should be able to operate on a wide variety of data sets with a minimum of program revision, and the necessary changes should be as simple to make as possible.
2. *Portability* — A program should adhere as closely as possible to a standard version of a language and avoid highly machine-dependent constants and constructions. Unidentified machine-dependent information should be localized and identified for simplification of transport.

With little extra effort, code can be written so as to minimize the difficulty a reader will encounter in comprehending the program logic. Several considerations in improving readability of a program are

1. Names should be as descriptive as possible (e.g., DEPTH rather than 12).
2. Comments should be liberally used to describe the data and logic of the program; they should be brief when placed in the body of a program unit, but may be longer and more descriptive at the beginning of a program unit.

3. Indentation, when possible, clarifies conditional and iterative constructions, and spacing improves the general readability of a program.
4. The use of subprogram units allows separation of the various operations of a program into modules, thereby clearly delineating the program logic. Specific types of calculations, input, and output may be done in distinct modules; in many cases, the main unit will consist primarily of calling statements to a few modules.

The proper handling of certain common errors can improve the run-time behavior of programs. In most cases, awareness of inherent problems in machine handling of data and attention to program details can avoid program crashes due to error. The following should be considered when the program code is being designed:

1. Input validation statements should be used to automatically check input data, to produce a clear message when an error is found, and to allow reentry of erroneous data. Data input should be echoed for user verification and an opportunity allowed for alteration of specific data items.
2. A method of exiting the program in case of a run-time error, which produces a message to the user as to the type and location of the error, should be provided. The possibility of certain errors occurring can be anticipated, and the use of flags and conditional constructions may provide a path to exit the program gracefully.
3. It is necessary to avoid predicting the exact value of a real variable, because after several operations, it may have been rounded off one or more times.
4. Side effects in subprogram units are unintentional changes in data values defined in other units. These frequently occur when the scope of a variable is mistakenly considered because of insufficient cross-checking to be local, when it is, in fact, global.

1.9.8 FORTRAN Language

FORTRAN names (e.g., unit, variable, array) consist of an initial letter (see defaults for real and integer types in the following) followed by letters or digits, the maximum length of which is 6 characters.

1.9.8.1 Data Types

See the section “Statements” for forms of declaration of type.

Integer — Variable names starting with I-N, unless otherwise declared.

Real — Variable names starting with A-H and O-Z, unless otherwise declared.

Double precision — Must be declared.

Complex — Must be declared.

Logical — Must be declared.

Character — Must be declared with length of string; default length is 1.

1.9.8.2 Data Structures

Variable — May be assigned value by a numerical or character constant, by input, or by an expression.

Array — May have up to seven dimensions; number and size (upper and lower boundaries) of dimensions are declared in DIMENSION or TYPE statements.

File — External (physical) only; may be sequential or random access.

1.9.8.3 Statements

Most statements, except where noted otherwise, begin in the seventh column of a page considered to be 80 columns wide; *continuation lines* are indicated by a “+” (symbol may vary with version of language) in the sixth column. The first five columns are reserved for *labels* (line numbers), which are only required if the line is referenced by another statement, and for *comment lines*, which are determined by a character in the first column. Columns 7 to 72 are reserved for statements; 73–80 are not read. (See Table 1.9.3 for required order of statements in FORTRAN.)

1.9.8.3.1 Nonexecutable Statements

Program unit heading — Program name, function name, or subroutine name.

Type declaration — Specifies data type to be represented by a variable name (overrides defaults):

```
REAL MSR
INTEGER COUNT, PNUM, AP
LOGICAL TEST1
CHARACTER*10 LNAME
```

Implicit declaration — Allows type specification for all names beginning with the given first letter(s)

IMPLICIT DOUBLE PRECISION (A-Z)

IMPLICIT COMPLEX (C)

Dimension statement — Specifies number and size of dimensions for each array (may be included in Type statement); lower bound default is 1

```
DIMENSION A1(5:10), A2(15)
```

```
DIMENSION A3(0:5, 0:10, 10:100), A4(10, 10, 10, 10)
```

or

```
INTEGER A1(5:10), A2(15)
```

Common statement — Defines a common block of global variables (one common block may have no specified name)

```
COMMON/blockname/varnames/blockname/varnames
```

```
COMMON X, Y, Z/C2BLK/A, B, C
```

Data may be entered into variables declared in a labeled COMMON block by an assignment or an input statement or through a BLOCK DATA subprogram as defined in subprogram statements.

Equivalence statement — Assigns two or more variable names to the same memory location

```
EQUIVALENCE(A, B, C)
```

Parameter statement — Declares the name of a constant whose value cannot be changed in the program

```
PARAMETER name
```

End statement — Compiler signal for end of unit

```
END
```

1.9.8.3.2 Executable Statements

Assignment statements may be DATA statements and are used mainly to assign initial values to variables

```
DATA A, B, C, D, E/1., 2., 3., 4., 5./X, Y, Z/3*10.
```

TABLE 1.9.3 Order of Statements in FORTRAN

PROGRAM, FUNCTION, SUBROUTINE or BLOCK DATA Statements

TABLE 1.9.4 Precedence of FORTRAN Operators

Class	Level	Symbol of Mnemonic
Exponential	First	**
	Second	–(negation) and +(identity)
Arithmetic	Third	*, /
	Fourth	+, –
Relational	Fifth	.GT., .GE., .LT., .LE., .EQ., .NE.
	Sixth	.NOT.
Logical	Seventh	.AND.
	Eighth	.OR.
	Ninth	.EQV., .NEQV.

or values assigned by numerical or character constants or by expressions (see [Table 1.9.4](#) for arithmetic operators and precedence)

```
PI = 3.1415927
```

```
C1 = 'This is a test'
```

```
X(I, J) = X(I-1, J) + Y(J)*Z**3
```

Input/output statements may be either list-directed (stream) or formatted. List-directed I/O statements may be

```
READ(device#, *)var1, var2, ...
```

```
WRITE(device#, *)var1, var2, ...
```

```
PRINT *var1, var2, ... i
```

where device# refers to either a device such as a screen or printer or to a disk file. Usually, the default input device (referenced by an asterisk rather than a device#) is the keyboard and the default output device (also referenced by an asterisk) is the screen. PRINT connects only to the printer. Other devices and files may be assigned device numbers through file handling statements (see later). A statement requesting list-directed input from the default device (the keyboard) might be, for example,

```
READ(*, *)TEMP, PRSSR, LENGTH
```

Formatted I/O statements require edit specifiers ([Table 1.9.5](#)) for each variable to be handled and may also include strings of characters enclosed in single quote marks. The format may be given in a separate format statement (referenced by a line number and labeled) or, in many systems, may be enclosed in quotes and parentheses in the I/O statement itself. The general form for formatted I/O statements is

```
READ(device#, label)var1, var2, ...
```

```
WRITE(device#, label)var1, var2, ...
```

```
PRINT label var1, var2, ...
```

```
label FORMAT(list of specifications)
```

TABLE 1.9.5 FORTRAN Edit Specifiers

A	Character data fields
D	Double precision data fields
E	Real data fields-exponential (E) notation
F	Real data fields-decimal notation
G	General form
H	Character constants
I	Integer data fields
L	Logical data fields
P	Scale factors, used with D, E, F, and G specifiers to shift the decimal point or exponent size for output
S	Restores the optional + convention to the compiler
SP	Prints + with all subsequent positive data
SS	Suppresses + for all subsequent positive data
TL	Next character will be input/output the specified number of spaces left of the current position
TR	Next character will be input/output the specified number of spaces right of the current position
X	Skip the specified number of spaces before next character is input/output
:	Ends format control if no more data items in list
/	Skips a record
Specifiers for Input Operations Only	
BN	Specifies that blank characters are to be ignored
BZ	Specifies blank characters are to be read as zeros
Specifications for Time: Four Most Common Data Types	
Integer	Iw
Real	Fw.d
Character	Aw
Exponential	Ew.d

For example,

```
READ(*, 100)X(1), Y, I
```

```
100 FORMAT (1X, 2F12.4, 15)
```

```
WRITE(6, 110)(TEMP(I), I = 1, 5)
```

```
110 FORMAT(1X, 5(F7.3, 2X))
```

```
WRITE(*, '(“TEMP AT SURFACE IS”,  
F8.2)')TSURF
```

File handling statements allow the manipulation of sequential and random access files. (Because there is considerable variation from one system to the next, the following information is given in general terms only.) Devices are treated as sequential files, while disk files may be sequential or random access. The following statements are generally accepted forms.

OPEN(list of specifiers) — Connects an existing file to an I/O device or generates a new file, and specifies a device (unit) number. The specifiers (required and optional) are

UNIT =	file unit (device) number
IOSTAT	integer variable for I/O status
FILE	name of file
ERR	label for error transfer
STATUS	file status descriptor, may be OLD, NEW, SCRATCH, or UNKNOWN
ACCESS	may be SEQUENTIAL or DIRECT
FORM	may be FORMATTED or UNFORMATTED
RECL	record length, if file access is DIRECT
BLANK	specifies blank handling, either NULL or ZERO

CLOSE(list of specifiers) — Disconnects a file. The specifiers may be

UNIT =	file unit (device) number
IOSTAT	as in OPEN
ERR	as in OPEN
STATUS	may be KEEP or DELETE

INQUIRE(list of specifiers) — Returns information about the attributes of a file. Besides the UNIT=, IOSTAT, and ERR specifiers, the following specifiers may be included:

EXIST	returns .TRUE. if file exists, else .FALSE.
OPENED	returns .TRUE. if open, else .FALSE.
NUMBER	returns number of connected device
NAMED	returns .TRUE. or .FALSE.
NAME	returns name of file
FORM	returns FORMATTED or UNFORMATTED
RECL	returns record length in direct access file
NEXT REC	returns number of next record in direct access file
BLANK	returns whether blanks or zeros specified

The following statements must include the UNIT = and may include the IOSTAT and/or the ERR specifiers:

REWIND	— Causes a sequential file to be
(list of specifiers)	rewound to first record
BACKSPACE	— Causes a sequential file to rewind
(list of specifiers)	one record
ENDFILE	— Places an end-of-file mark on a
(list of specifiers)	sequential file

A few examples of file-handling statements are

```
OPEN(UNIT = 6, IOSTAT = FSTAT, FILE =
'PRINTER', STATUS = 'NEW')
```

```
OPEN(4, FILE = 'DATA1', STATUS = 'OLD')
```

```
CLOSE(6)
BACKSPACE(4, ERR = 500)
```

Control statements affect the flow of instructions within a program unit. (For control between units, see subprogram statements later.) These may be general, conditional, or iterative statements. *General control statements* follow.

PAUSE n — Interrupts program run, resumption on pressing "Enter"; n is an optional character constant or integer of less than 5 digits:

```
PAUSE 'VALUE INVALID'
```

STOP n — Halts program run (n as above)

```
STOP 10050
```

GOTO i — Transfers control to statement labeled i, where i is an integer constant or variable with value of label:

```
GOTO 700
```

Conditional statements are as follows.

IF(e)s1, s2, s3 — Arithmetic if, where e is an arithmetic expression and s1, s2, s3 are statement labels; transfers control to a labeled statement depending on whether e evaluates to a negative, zero, or positive value, respectively. For example,

```
IF(I - 5) 30, 40, 50
```

will transfer control to the statement labeled 40 if I = 5.

IF(e)st—Logical if, where e is a logical expression (see Table 1.9.5 for relational and logical operators) and st is any executable statement except DO, IF, ELSEIF, ENDIF, or END. For example,

```
IF(I.EQ.1) WRITE(*, *)'YES'
```

IF(e) THEN—Block if, where e is a logical expression, followed by a sequence of statements and completed by an ENDIF statement. The block may include sub-blocks introduced by one or more ELSEIF statements and/or one ELSE statement and all sub-blocks may contain nested IF-THEN-ELSE blocks within them. For example,

```
IF(I.EQ.J) THEN
  X = 4
  Y = 5
ENDIF
IF(I.EQ.J) THEN
  X = 4
ELSE
  X = 5
ENDIF
```

```

IF(I.EQ.J) THEN
  X = 4
ELSEIF(I.EQ.K) THEN
  X = 5
ELSE
  X = Y
ENDIF

```

The **iterative statement** in FORTRAN is the DO statement (although others may be constructed using conditional statements and GOTOs), where

```
DO st i = init, term, incr
```

introduces the repetitive section, and st is the label of the executable statement marking the end of the loop (usually, but not necessarily, a CONTINUE statement), i is the index or control integer variable and init, term, and incr (optional) are the initial value for i, the terminal value for i, and the increment of i to be used, respectively. These values must be integer constants, variables, or expressions in standard FORTRAN 77, but many extensions to the language allow real values to be used. DO loops may be nested to a level determined by a specific compiler. For example,

```

DO 100 I = 1, 10, 2
  PR(I) = PPE(I - 1)
100 CONTINUE
DO 100 I = 10, 1, - 1
  DO 100 J = 1, 10
100 ATR(I, J) = P(J, I)*FRIC
DO 100 I = -5, 25, 5
  PF(I) = TFP(I) - FFG
  IF(PF(I).GE.LMT) GOTO 110
100 CONTINUE
110 MAXC = I

```

Statement functions are defined before any other executable statements in the program and are called in the same way that subprogram or intrinsic functions are called (see later subprogram statements). They are one-line expressions that receive one or more parameters from the calling statement and return a single calculated value to the function name in the calling statement. For example, a statement function defined as

```
FDPT(X(I), Y(I), Z, I) = X(I)*Y(I) + Z**I
```

will calculate a value depending on the values of X(I), Y(I), Z, and I at the time of calling and return the calculated value to the calling statement through FDPT.

Subprogram statements are those used to transfer control between program units — the main program, functions, and subroutines. A *function call* is performed by invoking the name of the function module in an assignment statement, such as

```
X = FDPR(Z, Y(I))*PRF
```

which will transfer control to the function FDPR and pass the values Z, and Y(I) to that unit. An intrinsic function or a statement function may be called in the same way. (See Table 1.9.6 for a list of FORTRAN 77 intrinsic functions.) A *subroutine call* is performed by a statement such as

```
CALL CALCSUB(MATFOR, I, J, PVAL)
```

which will transfer control to the subroutine CALCSUB and pass (and/or return) the values MATFOR, I, J, and PVAL. A subroutine may have an ENTRY name (parameter list) statement embedded within it, which when called in the same manner as the main subroutine call, will receive control transfer at that point. Control passes from the called unit back to the calling unit when a RETURN statement is encountered. Given a subroutine

```

Subroutine CALCSUB(MAT, M, N, P1)
  REAL MAT(100)
  P1 = MAT(M) + MAT(N)
  RETURN
  ENTRY NEWCALC(MAT, M, N, P2)
  P2 = MAT(M) + MAT(N)
  RETURN
END

```

a call to CALCSUB as before will return a value through P1 to PVAL and a call

```
CALL NEWCALC(MAT, K, L, PVAL)
```

will transfer control in at the ENTRY statement and return a value through P2 to PVAL. A BLOCK DATA subprogram enters data into the variables declared in a labeled COMMON block and has the form

```

BLOCK DATA
(DATA, DIMENSION, IMPLICIT, TYPE, EQUIVALENCE, COMMON and PARAMETER statements)
END

```

1.9.9 System Software

System software is the connection between the user and the machine. It provides management of the system resources and utilities which simplify development of applications programs. Essential system software includes the following:

1. **Translators** — Assemblers, interpreters, and/or compilers that translate symbolic language into machine code.
2. **Linkers and loaders** — Linkers resolve references between program units and allow access to system libraries; loaders place code into the main memory locations from which it will be executed.

TABLE 1.9.6 FORTRAN Intrinsic Functions

	Integer
IABS	Returns the absolute value of an argument
IDIM	Returns the positive difference between two arguments
IDINT	Converts a double-precision argument to integer by truncation
IFIX	Converts a real argument to integer by truncation
INT	Truncates the decimal part of an argument
ISIGN	Transfers the sign from one integer argument to the other
MAX0	Selects the largest value of several arguments
MAX1	Selects the largest value of several arguments, but converts any real result to integer
MIN0	Selects the smallest value of several arguments
MIN1	Selects the smallest value of several arguments, but converts any real result to integer
MOD	Returns the remainder from division of two arguments
	Real
ABS	Returns the absolute value of an argument
ACOS	Returns the arc cosine of an argument
AIMAG	Returns the imaginary part of a complex number
AINT	Truncates the decimal part of an argument
ALOG	Returns the natural logarithm of an argument
ALOG10	Returns the common logarithm of an argument
AMAX1	Selects the largest value of several arguments
AMIN1	Selects the smallest value of several arguments
AMOD	Returns the remainder from division of two arguments
ANINT	Returns the whole number nearest in value to the argument
ASIN	Returns the arc sine of an argument
ATAN	Returns the arc tangent of an argument
ATAN2	Returns the arc tangent of two arguments [$\arctan(a_1/a_2)$]
COS	Returns the cosine of an argument
COSH	Returns the hyperbolic cosine of an argument
DIM	Returns the positive difference between two arguments
EXP	Returns the exponential e raised to the power of the argument
FLOAT	Converts an argument to a real number
NINT	Returns the nearest integer value
REAL	Converts a complex argument to a real value
SIGN	Transfers the sign from one argument to the other
SIN	Returns the sine of an argument
SINH	Returns the hyperbolic sine of an argument
SQRT	Returns the square root of an argument

TABLE 1.9.6 FORTRAN Intrinsic Functions—cont'd

SNGL	Converts a double precision argument to single precision
TAN	Returns the tangent of an argument
TANH	Returns the hyperbolic tangent of an argument
Double Precision	
DABS	Returns the absolute value of an argument
DACOS	Returns the arc cosine of an argument
DASIN	Returns the arc sine of an argument
DATAN	Returns the arc tangent of one argument
DATAN2	Returns the arc tangent of two arguments [$\arctan(a_1/a_2)$]
DBLE	Converts an argument to double precision
DCOS	Returns the cosine of an argument
DCOSH	Returns the hyperbolic cosine of an argument
DDIM	Returns the positive difference between two arguments
DEXP	Returns the exponential e raised to the power of the argument
DINT	Truncates the decimal part of an argument
DLOG	Returns the natural logarithm of an argument
DLOG10	Returns the common logarithm of an argument
DMAX1	Selects the largest value of several arguments
DMIN1	Selects the smallest value of several arguments
DMOD	Returns the remainder from division of two arguments
DNINT	Returns the whole number closest in value to the argument
DPROD	Converts the product of two real arguments to double precision
DSIGN	Transfers the sign from one argument to the other
DSIN	Returns the sine of an argument
DSINH	Returns the hyperbolic sine of an argument
DSQRT	Returns the square root of an argument
DTAN	Returns the tangent of an argument
DTANH	Returns the hyperbolic tangent of an argument
IDINT	Converts the argument to the nearest integer value
Complex	
CABS	Returns the absolute value of an argument
CCOS	Returns the cosine of an angle
CEXP	Returns the exponential e raised to the power of the argument
CLOG	Returns the natural logarithm of the argument
CMPLX	Converts the argument to a complex number
CONJ	Returns the conjugate of a complex function
CSQRT	Returns the square root of an argument
CSIN	Returns the sine of an argument

3. **Operating systems** — Manage hardware resources of the computer system. Utilization may be of the *batch* method, in which program units, libraries, and data are submitted to the system along with the job control language statements needed to run the program. The operating system allocates the central processing unit to one batch job at a time, according to a hierarchical system. *Time-sharing* systems provide interactive sharing of resources by many users. The system must interweave allocation of resources to users and manage memory locations.
4. **Utility programs** — Simplify use by performing particular tasks for the programmer, such as editing, debugging, etc.
5. **File manager systems** — Maintain files and handle data input to and output from the files. *Database management systems* (DBMS) contain integrated sets of files related by their use and provide uniform software interfaces for accessing data. The essential relationships between records in the files may be of several types, including sequential, associative, or hierarchical.
6. **Telecommunications monitors** — Supervise communications between remote terminals and the central computer.

1.9.10 System Hardware

System hardware consists of the central processor, the input devices (usually a keyboard), the output devices (probably both a video display terminal and a hardcopy printer), long-term storage devices, and perhaps communications components. In smaller systems, more than one of these components may be “built in” to one unit, while in larger systems there may be many units each of several components associated with the system.

The *central processing unit* (CPU) consists of the arithmetic-logic unit (ALU), the control unit, and the central storage (short-term memory) unit. The CPU is normally classified by size of the word (number of bits in one piece of information or address), size of memory (which is usually expressed in MB or megabytes, with a byte being a group of 8 bits and a bit being a single value, either 0 or 1) and by speed of operations (usually given in gigahertz or GHz). Input may also be from files stored on a disk or CD. There are many combinations of these factors, depending on the processor chip used and upon the architecture of the machine. Speed of operation and of data transfer is of major importance in large number-crunching programs. Memory size affects the size of the program and the amount of data that may be held at one time, while word size primarily

affects the size of memory available. A useful addition to the system, if a need for large-scale number crunching is anticipated, is the arithmetic coprocessor chip, which performs high-speed numerical operations.

Keyboards are the most widely used *input devices*, but optical scanners and digital pads (for computer-aided design) are some additional input devices. Input may also be from files stored on a disk or tape.

Video display terminals for output are available in several sizes (measured diagonally in inches) and various resolutions. Laser printers are common forms of *hardcopy output devices*. Color and even photo-quality laser printers are readily available. For engineering and design use, plotters, either black-white or multicolored are frequently added to the system. Output may also be sent to a disk or CD for long-term storage.

Long-term memory storage devices include floppy disks, zip disks, and CDs. The choice between storage devices is based on the amount of available storage needed. Floppy disks can store up to 1.44 MB of data, and CDs can store up to 700 MB of data.

Systems may also include *modems*, which connect computers to other computers or servers. Computers may be connected to other computers over telephone lines, through cables, or using satellite transmission or other wireless methods. Modem speed is usually measured in bps or bits per second. Telephone modems usually have a rate of 56 Kbps.

General Engineering and Science

2.1 BASIC MECHANICS (STATICS AND DYNAMICS)

Section reviewed by Bill Lyons, Ivan W. Clay, and Anton Hriczko

Mechanics is the physical science that deals with the effects of forces on the state of motion or rest of solid, liquid, or gaseous bodies. The field may be divided into the mechanics of rigid bodies, the mechanics of deformable bodies, and the mechanics of fluids.

A rigid body is one that does not deform. True rigid bodies do not exist in nature; however, the assumption of rigid body behavior is usually an acceptable accurate simplification for examining the state of motion or rest of structures and elements of structures. The rigid body assumption is not useful in the study of structural failure. Rigid body mechanics is further subdivided into the study of bodies at rest, *statics*, and the study of bodies in motion, *dynamics*.

2.1.1 Definitions, Laws, and Units

2.1.1.1 Fundamental Quantities

All of Newtonian mechanics is developed from the independent and absolute concepts of *space*, *time*, and *mass*. These quantities cannot be exactly defined, but they may be functionally defined as follows:

Space. Some fixed reference system in which the position of a body can be uniquely defined. The concept of space is generally handled by imposition of a coordinate system, such as the Cartesian system, in which the position of a body can be stated mathematically.

Time. Physical events generally occur in some causal sequence. Time is a measure of this sequence and is required in addition to position in space in order to fully specify an event.

Mass. A measure of the resistance of a body to changes in its state of motion.

2.1.1.2 Derived Quantities

The concept of space, time, and mass may be combined to produce additional useful measures and concepts.

Particle. An entity which has mass, but can be considered to occupy a point in space. Rigid bodies that are not subject to the action of an unbalanced couple often may be treated as particles.

Body. A collection of particles. A rigid body is a rigidly connected collection of particles.

Force. The action of one body on another. This action will cause a change in the motion of the first body unless counteracted by an additional force or forces. A force may be produced either by actual contact or remotely (gravitation, electrostatics, magnetism, etc.). Force is a vector quantity.

Couple. If two forces of equal magnitude, opposite direction, and different lines of action act on a body, they produce a tendency for rotation, but no tendency for translation. Such a pair of forces is called a couple. The magnitude of the moment produced by a couple is calculated by multiplying the magnitude of one of the two forces times the perpendicular distance between them. Moment is a vector quantity, and its sense of direction is considered to be outwardly perpendicular to the plane of counterclockwise rotation of the couple. The moment of a single force about some point A is the magnitude of the force times the perpendicular distance between A and the line of action of the force.

Velocity. A measure of the instantaneous rate of change of position in space with respect to time. Velocity is a vector quantity.

Acceleration. A measure of the instantaneous rate of change in velocity with respect to time. Acceleration is a vector quantity.

Gravitational acceleration. Every body falling in a vacuum at a given position above and near the surface of the earth will have the same acceleration, *g*. Although this acceleration varies slightly over the earth's surface due to

local variations in its shape and density, it is sufficiently accurate for most engineering calculations to assume that $g = 32.2 \text{ ft/s}^2$ or 9.81 m/s^2 at the surface of the earth.

Weight. A measure of the force exerted on a body of mass M by the gravitational attraction of the earth. The magnitude of this force is

$$\mathbf{W} = M\mathbf{g} \quad (2.1.1)$$

where \mathbf{W} is the weight of the body. Strictly speaking, weight is a vector quantity since it is a force acting in the direction of the gravitational acceleration.

2.1.1.3 General Laws

The foregoing defined quantities interact according to the following fundamental laws, which are based upon empirical evidence.

Conservation of mass. The mass of a system of particles remains unchanged during the course of ordinary physical events.

Parallelogram law for the addition of forces. Two forces, \mathbf{F}_1 and \mathbf{F}_2 , acting on a particle may be replaced by a single force, \mathbf{R} , called their resultant. If the two forces are represented as the adjacent sides of a parallelogram, the diagonal of the parallelogram will represent the resultant (Figure 2.1.1).

Principle of transmissibility. A force acting at a point on a body can be replaced by a second force acting at a different point on the body without changing the state of equilibrium or motion of the body as long as the second force has the same magnitude and line of action as the first.

2.1.1.3.1 Newton's Laws of Motion

1. A particle at rest will remain at rest, and a particle in motion will remain in motion along a straight line with no acceleration unless acted upon by an unbalanced system of forces.
2. If an unbalanced system of forces acts upon a particle, it will accelerate in the direction of the resultant force at a rate proportional to the magnitude of the resultant force. This law expresses the relationship between force, mass, and acceleration and may be written as

$$\mathbf{F} = M\mathbf{a} \quad (2.1.2)$$

where \mathbf{F} is the resultant force, M is the mass of the particle, and \mathbf{a} is the acceleration of the particle.

FIGURE 2.1.1 Parallelogram law for addition of forces.

3. Contact forces between two bodies have the same magnitude, the same line of action, and opposite direction.

Gravitation. Two particles in space are attracted toward each other by a force that is proportional to the product of their masses and inversely proportional to the square of the distance between them. Mathematically this may be stated as

$$|\mathbf{F}| = \frac{Gm_1m_2}{r^2} \quad (2.1.3)$$

where $|\mathbf{F}|$ is the magnitude of the force of gravitational attraction, G is the universal gravitational constant ($6.673 \times 10^{-11} \text{ m}^3/\text{kg} - \text{s}^2$ or $3.44 \times 10^{-8} \text{ ft}^4/\text{lb} - \text{s}^4$), m_1 and m_2 are the masses of particles 1 and 2, and r is the distance between the two particles.

2.1.1.4 Systems of Units

Two systems of units are in common usage in mechanics. The first, the SI system, is an absolute system based on the fundamental quantities of space, time, and mass. All other quantities, including force, are derived. In the SI system the basic unit of mass is the kilogram (kg), the basic unit of length (space) is the meter (m), and the basic unit of time is the second (s). The derived unit of force is the Newton (N), which is defined as the force required to accelerate a mass of 1 kg at a rate of 1 m/s^2 .

The U.S. customary or English system of units is a gravitational system based upon the quantities of space, time, and force (weight). All other quantities including mass are derived. The basic unit of length (space) is the foot (ft), the basic unit of time is the second (s), and the basic unit of force is the pound (lb). The derived unit of mass is the slug, which is the unit of mass that will be accelerated by a force of one pound at a rate of 1 ft/s^2 . To apply the slug in practice, as in Equation 2.1.2, the weight in pounds mass must first be divided by $g = 32.2 \text{ ft/s}^2$, thus generating a working mass in units of $\text{lb} - \text{s}^2/\text{ft}$, or slugs.

2.1.2 Statics

If there are no unbalanced forces acting on a *particle*, the particle is said to be in static equilibrium, and Newton's second law reduces to

$$\sum \mathbf{F} = 0 \quad (2.1.4)$$

Solving a problem in particle statics reduces to finding the unknown force or forces such that the resultant force will be zero. To facilitate this process it is useful to draw a diagram showing the particle of interest and all the forces acting on it. This is called a *free-body diagram*. Next a coordinate system (usually Cartesian) is superimposed on the free-body diagram, and the forces are decomposed into

their components along the coordinate axes. For the particle to be in equilibrium, the sum of the force components along each of the axes must be zero. This yields a set of algebraic equations to be solved for the forces in each coordinate direction.

Example 2.1.1

Block W, weighing 100 lb (see Figure 2.1.2) is attached at point A to a cable, which is, in turn, attached to vertical walls at points B and C. What are the tensions in segments AB and AC.

Breaking down the diagram into the various forces (Figure 2.1.2b):

- Force balance in the y direction:

$$\begin{aligned} \sum F_y &= -100 + T_{AC} \sin 45^\circ + T_{AB} \sin 15^\circ = 0 \\ 0.707T_{AC} + 0.259T_{AB} &= 100 \end{aligned} \tag{a}$$

- Force balance in the x direction:

$$\begin{aligned} \sum F_x &= T_{AC} \cos 45^\circ - T_{AB} \cos 15^\circ = 0 \\ 0.707T_{AC} - 0.966T_{AB} &= 0 \end{aligned} \tag{b}$$

and solving Example 2.1.1 Equations a and b simultaneously yields

$$\begin{aligned} T_{AB} &= 81.6 \text{ lb} \\ T_{AC} &= 111.5 \text{ lb} \end{aligned}$$

If there are no unbalanced forces and no unbalanced moments acting on a rigid body, the rigid body is said to be in static equilibrium. That is, Equation 2.1.4 must be satisfied just as for particles, and furthermore

$$\sum \mathbf{M}_A = 0 \tag{2.1.5}$$

where $\sum \mathbf{M}_A$ is the sum of the vector moments of all the forces acting on the body about any arbitrarily selected point A. In two dimensions this constitutes an algebraic equation because all moments must act about an axis perpendicular to the plane of the forces. In three dimensions the moments must be decomposed into components parallel to the principal axes, and the components along each axis must sum algebraically to zero.

Example 2.1.2

A weightless beam 10 ft in length (see Figure 2.1.3a) supports a 10-lb weight, W, suspended by a cable at point C. The beam is inclined at an angle of 30° and rests against a step at point A and a frictionless fulcrum at point B, a distance of $L_1 = 6$ ft from point A. What are the reactions at points A and B?

Breaking the diagram down into the various forces (Figure 2.1.3b):

- Force balance in the x direction:

$$\begin{aligned} \sum F_x &= R_{Ax} - 10 \cos 60^\circ = 0 \\ R_{Ax} &= 5 \text{ lb} \end{aligned}$$

FIGURE 2.1.2 Diagram for Example 2.1.1.

FIGURE 2.1.3 Diagram for Example 2.1.2.

- Moment balance about point A:

$$+\sum M_A = (10)(10) \sin 60^\circ - 6R_{By} = 0$$

$$R_{By} = 14.43 \text{ lb}$$

$$\bar{y} = \frac{\sum_i \bar{y}_i W_i}{\sum_i W_i} \tag{2.1.10}$$

$$\bar{z} = \frac{\sum_i \bar{z}_i W_i}{\sum_i W_i} \tag{2.1.11}$$

- Force balance in the y direction:

$$\sum F_y = R_{Ay} + R_{By} - 10 \sin 60^\circ = 0$$

$$R_{Ay} = 10 \sin 60^\circ - R_{By}$$

$$R_{Ay} = -4.43 \text{ lb}$$

Note that although the direction assumed for R_{Ay} was incorrect, the sign of the result indicates the correct direction.

Whenever the weight of a body is significant in comparison to the external forces, the weight, or body force, must be considered in both the force and moment balances.

The weight W of the body acts at the *center of gravity*, the Cartesian coordinates of which are found by

$$\bar{x} = \frac{1}{W} \int_v x dw \tag{2.1.6}$$

$$\bar{y} = \frac{1}{W} \int_v y dw \tag{2.1.7}$$

$$\bar{z} = \frac{1}{W} \int_v z dw \tag{2.1.8}$$

The foregoing are volume integrals evaluated over the entire volume of the rigid body and dw is an infinitesimal element of weight. If the body is of uniform density, then the center of gravity is also called the *centroid*. Centroids of common lines, areas, and volumes are shown in Tables 2.1.1, 2.1.2, and 2.1.3. For a composite body made up of elementary shapes with known centroids and known weights the center of gravity can be found from

$$\bar{x} = \frac{\sum_i \bar{x}_i W_i}{\sum_i W_i} \tag{2.1.9}$$

Example 2.1.3

A mallet is composed of a section of a right circular cylinder welded to a cylindrical shaft, as shown in Figure 2.1.4a and b. Both components are steel, and the density is uniform throughout. Find the centroid of the mallet.

$$r = 2 \text{ in.} \quad d = 1 \text{ in.}$$

$$L_1 = 6 \text{ in.} \quad L_2 = 5 \text{ in.}$$

$$L_3 = 1.5 \text{ in.} \quad \gamma = 0.283 \text{ lb/in.}^3$$

Letting the center of the bottom of the handle be the origin, the centroid of section 1, the handle, can be found by inspection as

$$\bar{x}_1 = 0$$

$$\bar{y}_1 = \frac{L_1}{2} = 3 \text{ in.}$$

$$w_1 = \frac{\pi}{4} d^2 L_1 \gamma = 1.33 \text{ lb}$$

In section 2, the integral formula, 2.1.7, is applied

$$\bar{x}_2 = 0$$

$$\bar{y}_2 = a + \frac{1}{W_2} \int_{L_1}^b y dW_2$$

where

$$a = L_1 - (r - L_3)$$

$$b = L_1 + L_3$$

Transforming the integral to polar coordinates as shown in Figure 2.1.4c:

Shape	Diagram	\bar{x}	\bar{y}	Length

FIGURE 2.1.4 Diagram for Example 2.1.3.

FIGURE 2.1.5 Dry friction force.

friction force is developed that opposes the motion. For dry surfaces this is called *dry friction* or *coulomb friction*. For lubricated surfaces the friction force is called viscous friction or lubricated, and it is treated in the study of fluid mechanics. Consider a block of weight W resting on a flat surface as shown in Figure 2.1.5. The weight of the block is balanced by a normal force N that is equal and opposite to the body weight. If some sufficiently small sidewise force P is applied (Figure 2.1.5b), it will be opposed by a friction force F that is equal and opposite to P , and the block will remain fixed. If P is increased, F will simultaneously increase at the same rate until the maximum value of the static friction force is reached, at which point the block will begin to slide.

The maximum value of the static friction force is proportional to the normal force as

$$F_f = \mu_s N \tag{2.1.12}$$

where μ_s is called the *coefficient of static friction*. Once the block begins to slide, the friction force decreases slightly and remains at a constant value defined by

$$F_f = \mu_k N \tag{2.1.13}$$

where μ_k is the *coefficient of kinetic friction*. The magnitude of the friction force as a function of the applied force P is illustrated in Figure 2.1.5c, and typical values for μ_s and μ_k are give for both dry and lubricated surfaces in Table 2.1.4.

From Reference 1.

It is often necessary to compute the forces in *structures* made up of connected rigid bodies. A free-body diagram of the entire structure is used to develop an equation or equations of equilibrium based on the body weight of the structure and the external forces. Then the structure is decomposed into its elements and equilibrium equations are written for each element, taking advantage of the fact that by Newton's third law the forces between two members at a common frictionless joint are equal and opposite.

One of the simplest structures is the *truss*. A truss consists of straight members connected at their end points only (two force members). All loads, including the weight of the members themselves, are considered to be supported at the joints. Due to its construction and the assumption of loading at joints only, the members of a truss support only loads of axial tension or axial compression. A *rigid truss* or a rigid structure will not collapse and can only deform if its members deform. A *simple truss* is one that can be constructed, starting with three members arranged in a triangle, by adding new members in pairs, first connecting one end of each together to form a new joint, and then connecting the other ends at separate existing joints of the truss.

A *frame* is a structure with at least one member that supports more than two forces. Members of a frame may support lateral as well as axial forces. Connections in a frame need not be located at the ends of the members. Frames, like trusses, are designed to support loads, and are usually motionless. A *machine* also has multforce members. It is designed to modify and transmit forces and, though it may sometimes be stationary, it always includes parts that move during some phase of operation.

Not all structures can be fully analyzed by the methods of statics. If the number of discrete equilibrium equations is

equal to the number of unknown loads, then the structure is said to be *statically determinate* and rigid. If there are more unknowns than equations, then the structure is *statically indeterminate*. If there are more equations than unknowns, then the structure is said to be *statically indeterminate and nonrigid*.

For further information on this subject, refer to References 1–5.

2.1.3 Dynamics

Dynamics is the study of the mechanics of rigid bodies in motion. It is usually subdivided into *kinematics*, the study of the motion of bodies without reference to the forces causing that motion or to the mass of bodies, and *kinetics*, the study of the relationship between the forces acting on a body, the mass and geometry of the body, and the resulting motion of the body.

2.1.3.1 Kinematics

Kinematics is based on one-dimensional differential equations of motion. Suppose a particle is moving along a straight line, and its distance from some reference point is S (see [Figure 2.1.6a](#)). Then its linear velocity and linear acceleration are defined by the differential equations given in the top half of Column 1, [Table 2.1.5](#). The solutions to these equations are in Columns 2–5, for the cases of constant acceleration, acceleration as a function of time, acceleration as a function of velocity, and acceleration as a function of position.

For rotational motion, as illustrated in [Figure 2.1.6b](#), a completely analogous set of equations and solutions are

FIGURE 2.1.6 Diagrams of motion: (a) one-dimensional linear; (b) rotational.

TABLE 2.1.5 One-dimensional Differential Equations of Motion and Their Solutions					
	Differential Equations	$a/\alpha = \text{constant}$	$a = a(t); \alpha = \alpha(t)$	$a = a(v); \alpha = \alpha(\omega)$	$a = a(s); \alpha = \alpha(\theta)$
Linear	$v = \frac{ds}{dt}$	$v_f = v_i = at$	$s_f = s_i + \int_0^t v(t) dt$		$t = \int_{s_i}^{s_f} \frac{ds}{v(s)}$
	$a = \frac{dv}{dt}$	$s_f = s_i + v_i t + \frac{1}{2} at^2$	$v_f = v_i + \int_0^t a(t) dt$	$t = \int_{v_i}^{v_f} \frac{dv}{a(v)}$	
	$v dv = a ds$	$v_f^2 = v_i^2 + 2a\Delta s$		$s_f = s_i + \int_{v_i}^{v_f} \frac{v dv}{a(v)}$	$v_f^2 = v_i^2 + 2 \int_{s_i}^{s_f} a(s) ds$

	$\alpha = \frac{d\omega}{dt}$	$\theta_f = \theta_i + \omega_i t + \frac{1}{2} \alpha t^2$	$\omega_f = \omega_i + \int_0^t \alpha(t) dt$	$t = \int_{\omega_i}^{\omega_f} \frac{d\omega}{\alpha(\omega)}$	
	$\omega d\omega = \alpha d\theta$	$\omega_f^2 = \omega_i^2 + 2\alpha\Delta\theta$		$\theta_f = \theta_i + \int_{\omega_i}^{\omega_f} \frac{\omega d\omega}{\alpha(\omega)}$	$\omega_f^2 = \omega_i^2 + 2 \int_{\theta_i}^{\theta_f} \alpha(\theta) d\theta$

given in the bottom half of Table 2.1.5. There ω is called the angular velocity and has units of radians/s, and α is called angular acceleration and has units of radians/s².

The equations of Table 2.1.5 are all scalar equations representing discrete components of motions along orthogonal axes. The axes along which the component ω or α acts is defined in the same fashion as for a couple. That is, the direction of ω is outwardly perpendicular to the plane of counterclockwise rotation (Figure 2.1.7).

The equations of Table 2.1.5 can be used to define orthogonal components of motion in space, and these components are then combined vectorally to give the complete motion of the particle or point in question.

The calculation and combination of the components of particle motion requires imposition of a coordinate system. Perhaps the most common is the Cartesian system illus-

trated in Figure 2.1.8. Defining unit vectors \hat{i} , \hat{j} , and \hat{k} along the coordinate axes x , y , and z , the position of some point in space, P , can be defined by a position vector, \mathbf{r}_P :

$$\mathbf{r}_P = x_P \hat{i} + y_P \hat{j} + z_P \hat{k} \quad (2.1.14)$$

In Equation 2.1.14, x , y , and z represent the coordinates of point P . The velocity of P is the vector sum of the component velocities:

$$v_x = \frac{dx_P}{dt}, \quad v_y = \frac{dy_P}{dt}, \quad v_z = \frac{dz_P}{dt}$$

$$\mathbf{v}_P = v_x \hat{i} + v_y \hat{j} + v_z \hat{k} \quad (2.1.15)$$

Likewise, the acceleration of P is the vector sum of the components of the accelerations where

FIGURE 2.1.7 W_x is a vector of magnitude W_x acting along the x axis.

FIGURE 2.1.8 Equations of motion in a Cartesian coordinate system.

$$a_x = \frac{dv_x}{dt}, \quad a_y = \frac{dv_y}{dt}, \quad a_z = \frac{dv_z}{dt}$$

$$\mathbf{a}_p = a_x \hat{i} + a_y \hat{j} + a_z \hat{k} \quad (2.1.16)$$

For any vector, the magnitude is the square root of the sum of the squares of the components. Thus the magnitude of the velocity of point P would be

$$|v_p| = (v_x^2 + v_y^2 + v_z^2)^{0.5} \quad (2.1.17)$$

The angle between the total velocity (or any other vector) and any particular coordinate axis can be calculated from the scalar product of said vector and the unit vector along that axis. The scalar product is defined as

$$\mathbf{a} \cdot \mathbf{b} = a_x b_x + a_y b_y + a_z b_z = |a| |b| \cos \theta$$

where θ is the angle between vectors \mathbf{a} and \mathbf{b} . Thus the angle between the velocity and the x axis is

$$\theta_x = \cos^{-1} \left(\frac{v_x \hat{i}}{|v|} \right)$$

$$= \cos^{-1} \left[\frac{v_x}{(v_x^2 + v_y^2 + v_z^2)^{0.5}} \right] \quad (2.1.18)$$

If the magnitude and direction of a vector are known, its components are the products of the magnitude and the respective direction cosines. In the case of the velocity vector, for example, the components are

$$v_x = |v_p| \cos \theta_x$$

$$v_y = |v_p| \cos \theta_y \quad (2.1.19)$$

$$v_z = |v_p| \cos \theta_z$$

Example 2.1.4

A projectile is fired at an angle of 30° to the surface of the earth with an initial velocity of 1000 ft/s (Figure 2.1.9). What will be its velocity and the angle of its trajectory as a function of time?

x Component: The initial velocity in the x direction is

$$v_{x0} = |v| \cos \theta_x = 1000 \text{ ft/s} \cos 30^\circ$$

$$v_{x0} = 866 \text{ ft/s}$$

Assuming no air friction, this velocity is constant; that is $v_x^{(t)} = v_{x0} = 866 \text{ ft/s}$.

y Component: The initial velocity in the y direction is

$$v_{y0} = |v| \cos \theta_y = |v| \sin \theta_x = 1000 \text{ ft/s} \sin 30^\circ$$

$$v_{y0} = 500 \text{ ft/s}$$

In the y direction, the projectile has a constant acceleration of $-g = -32.2 \text{ ft/sec}^2$. By the first Equation, Column 2, Table 2.1.5, its velocity as a function of time is

$$v_y(t) = v_{y0} + at = v_{y0} - gt$$

$$= 500 \text{ ft/s} - \frac{32.2 \text{ ft}}{\text{s}^2} t$$

and the total velocity vector is

$$v = 866 \hat{i} + (500 - 32.2t) \hat{j}$$

The angle of the trajectory is found from Equation 2.1.18 as

$$\theta_x = \cos^{-1} \left\{ \frac{866}{[866^2 + (500 - 32.2t)^2]^{0.5}} \right\}$$

It is often convenient to use some other coordinate system besides the Cartesian system. In the normal/tangential system (Figure 2.1.10), the point of reference is not fixed

FIGURE 2.1.9 Diagram for Example 2.1.4.

FIGURE 2.1.10 Normal and tangential unit vectors at different points on a path.

in space but is located on the particle and moves as the particle moves. There is no position vector and the velocity and acceleration vectors are written in terms of unit vectors $\hat{\tau}$, tangent to the path of motion, and \hat{n} , inwardly perpendicular to the path of motion.

The velocity is always tangent to the path of motion, and thus the velocity vector has only one component (Equation 2.1.20).

$$\mathbf{v} = v\hat{\tau} \quad (2.1.20)$$

The acceleration vector has a component tangent to the path $a_t = d|v|/dt$, which is the rate at which the magnitude of the velocity vector is changing, and a component perpendicular to the path $a_n = |v|^2/\rho$, which represents the rate at which the direction of motion is changing (Equation 2.1.21)

$$\mathbf{a} = a_t\hat{\tau} + a_n\hat{n} = \frac{d|v|}{dt}\hat{\tau} + \frac{|v|^2}{\rho}\hat{n} \quad (2.1.21)$$

In Equation 2.1.21 ρ is the local radius of curvature of the path. The normal component of acceleration can also be expressed as $a_n = \rho|\omega|^2$ or $a_n = |v||\omega|$ where ω is the angular velocity of the particle.

Example 2.1.5

A car is increasing in speed at a rate of 10 ft/s^2 when it enters a curve with a radius of 50 ft at a speed of 30 ft/s . What is the magnitude of its total acceleration?

$$\begin{aligned} a_t &= \frac{d|v|}{dt} = 10 \text{ ft/s}^2 \\ a_n &= \frac{v^2}{\rho} = \frac{(30 \text{ ft/s})^2}{50 \text{ ft}} = 18 \text{ ft/s}^2 \\ \mathbf{a} &= 10\hat{\tau} + 18\hat{n} \\ |\mathbf{a}| &= (10^2 + 18^2)^{0.5} = 20.6 \text{ ft/s}^2 \end{aligned}$$

In addition to the Cartesian and normal/tangential coordinate systems, the cylindrical (Figure 2.1.11) and spherical (Figure 2.1.12) coordinate systems are often used.

When dealing with the motions of rigid bodies or systems of rigid bodies, it is sometimes quite difficult to directly write out the equations of motion of the point in question as was done in Examples 2.1.4 and 2.1.5. It is sometimes more practical to analyze such a problem by *relative motion*. That is, first find the motion with respect to a nonaccelerating reference frame of some point on the body, typically the center of mass or axis of rotation, and vectorially add to this the motion of the point in question with respect to the reference point.

Example 2.1.6

Consider an arm 2 ft long rotating in the counter clockwise direction about a fixed axis at point A at a rate of 2 rpm (Figure 2.1.13a). Attached to the arm at point B is a disk with a radius of 1 ft , which is rotating in the clockwise direction about point B at a rate of 5 rpm . What is the velocity and acceleration of some arbitrary point C on the

FIGURE 2.1.11 Equations of motion in a cylindrical coordinate system.

FIGURE 2.1.12 Equations of motion in a spherical coordinate system.

rim of the disk? (Consider that at $t_0 = 0$, the configuration is that of Figure 2.1.13d.)

$$\mathbf{v}_C = \mathbf{v}_B + \mathbf{v}_{C/B} \tag{2.1.23}$$

By relative motion the position vector of C is the sum of the position vector of B and the position vector of C with respect to B

$$\mathbf{a}_C = \mathbf{a}_B + \mathbf{a}_{C/B} \tag{2.1.24}$$

$$\mathbf{r}_C = \mathbf{r}_B + \mathbf{r}_{C/B} \tag{2.1.22}$$

Analyzing the motion of point B (Figure 2.1.13b),

$$\mathbf{r}_B = L \cos \theta_B \hat{i} + L \sin \theta_B \hat{j}$$

and likewise with the velocity and acceleration, which is

Assuming rotation starts at $\theta_B = 0$,

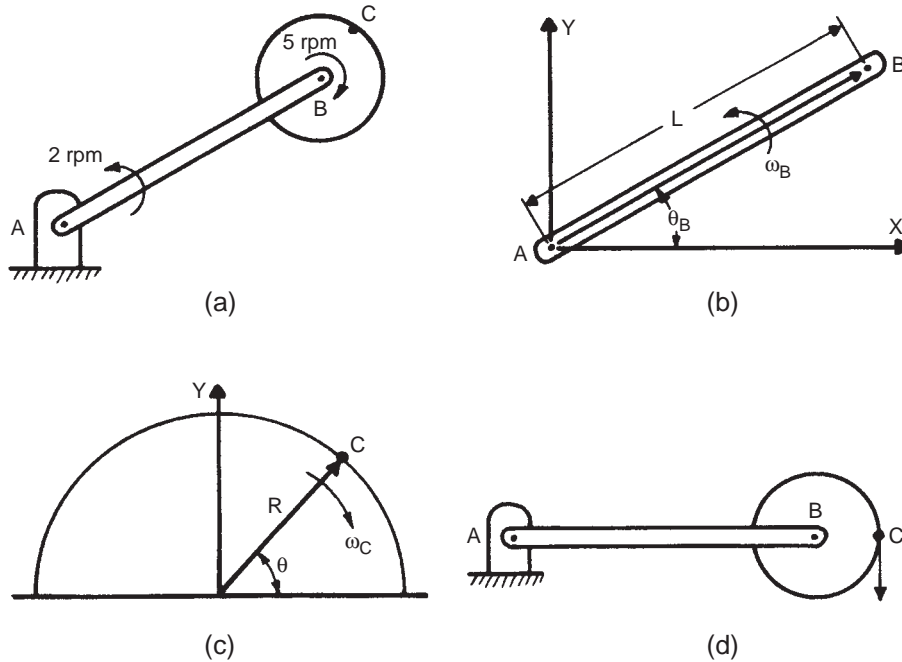

FIGURE 2.1.13 Diagram for Example 2.1.6.

$$\theta_B = \omega_B t$$

$$\mathbf{v}_B = \frac{d}{dt}(\mathbf{R}_B) = -L\omega_B \sin \omega_B t \hat{i} + L\omega_B \cos \omega_B t \hat{j}$$

$$\mathbf{a}_B = \frac{d}{dt}(\mathbf{v}_B) = -L\omega_B^2 \cos \omega_B t \hat{i} - L\omega_B^2 \sin \omega_B t \hat{j}$$

Assuming point B is fixed and analyzing the motion of Point C with respect to B (see Figure 2.1.13c),

$$\mathbf{r}_{C/B} = R \cos \theta_C \hat{i} + R \sin \theta_C \hat{j}$$

$$\theta_C = \omega_C t$$

$$\mathbf{v}_{C/B} = -R\omega_C \sin \omega_C t \hat{i} + R\omega_C \cos \omega_C t \hat{j}$$

$$\mathbf{a}_{C/B} = -R\omega_C^2 \cos \omega_C t \hat{i} - R\omega_C^2 \sin \omega_C t \hat{j}$$

The velocity of point C is

$$\mathbf{v}_C = \mathbf{v}_B + \mathbf{v}_{C/B} = -(L\omega_B \sin \omega_B t + R\omega_C \sin \omega_C t) \hat{i} + (L\omega_B \cos \omega_B t + R\omega_C \cos \omega_C t) \hat{j}$$

$$\omega_B = \frac{2 \text{ rev} | 1 \text{ min} | 2\pi \text{ rad}}{\text{min} | 60 \text{ s} | \text{ revolution}} = 0.209 \text{ rad/s}$$

$$L\omega_B = \frac{2 \text{ ft} | 0.209 \text{ rad/s}}{\text{s}} = 0.418 \text{ ft/s}$$

$$\omega_C = -0.524 \text{ rad/s}$$

$$R\omega_C = -0.524 \text{ ft/s}$$

$$\mathbf{v}_C = -[0.418 \sin(0.209 t) - 0.524 \sin(-0.524 t)] \hat{i} + [0.418 \cos(0.209 t) - 0.524 \cos(-0.524 t)] \hat{j}$$

(b)

(c)

(d)

At $t = 0$, for instance, the velocity is (Figure 2.1.13d)

$$\mathbf{v}_C = -0.106 \hat{j} \text{ ft/s}$$

Likewise, the general expression for the acceleration of point C is

$$\mathbf{a}_C = \mathbf{a}_B + \mathbf{a}_{C/B} = -(L\omega_B^2 \cos \omega_B t + R\omega_C^2 \cos \omega_C t) \hat{i} - (L\omega_B^2 \sin \omega_B t + R\omega_C^2 \sin \omega_C t) \hat{j}$$

At $t = 0$ this reduces to

$$\mathbf{a}_C = -(L\omega_B^2 + R\omega_C^2) \hat{i} = -[2 \times 0.209^2 + 1 \times (-0.524)^2] \hat{i}$$

$$\mathbf{a}_C = -0.362 \hat{i} \text{ ft/s}^2$$

When looking for the velocities of points on a rigid body, the method of *instantaneous centers* can often be used. If the velocity of two points on the body are known, those points and all other points on the body can be considered to be rotating with the same angular velocity about some motionless central point. This central point is called the instantaneous center of zero velocity. The instantaneous center generally moves through space as a function of time and has acceleration. It does *not* represent a point about which acceleration may be determined.

Example 2.1.7

Link AB of length 2 ft (see Figure 2.1.14a) is sliding down a wall with point A moving downward at 4 ft/s when θ is 30° .

FIGURE 2.1.14 Diagram for Example 2.1.7.

What is the angular velocity of the link and linear velocity of point B?

Because v_A (Figure 2.1.14b) is parallel to the vertical wall, it is rotating about a point on a line through A perpendicular to the wall. Likewise B is rotating about a point on a line through B perpendicular to v_B . These two lines intersect at C, the instantaneous center.

$$AC = L \cos \theta = 2 \times 0.866 = 1.73 \text{ ft}$$

$$|v_A| = AC|\omega_{AB}|$$

$$\omega_{AB} = \frac{|v_A|}{AC} = \frac{4 \text{ ft/s}}{1.73 \text{ ft}}$$

where $\omega_{AB} = 2.31 \text{ rad/s}$ = the angular velocity of the link and of any line on the link

$$|v_B| = BC|\omega_{AB}| = L \sin \theta |\omega_{AB}| = \frac{2 \text{ ft} |0.5| 2.31 \text{ rad}}{s}$$

$$|v_B| = 2.31 \text{ ft/s}$$

As an exercise, show that the locus of the instantaneous center of rotation represents a quarter circle. What is the radius of the circle?

2.1.3.2 Kinetics

In *kinetics*, Newton's second law, the principles of kinematics, conservation of momentum, and the laws of conservation of energy and mass are used to develop relationships

between the forces acting on a body or system of bodies and the resulting motion.

2.1.3.3 Applications of Newton's Second Law

Problems involving no unbalanced couples can often be solved with the second law and the principles of kinematics. As in statics, it is appropriate to start with a free-body diagram showing all forces, decompose the forces into their components along a convenient set of orthogonal coordinate axes, and then solve a set of algebraic equations in each coordinate direction. If the accelerations are known, the solution will be for an unknown force or forces, and if the forces are known the solution will be for an unknown acceleration or accelerations.

Example 2.1.8

In Figure 2.1.15a, a 10-lb block slides down a ramp inclined at an angle of 30° . If the coefficient of kinetic friction between the block and the ramp is 0.1, what will be the acceleration of the block?

As shown in the free-body diagram of Figure 2.1.15b, all the motion of the block is parallel to the surface of the ramp, and there is a static force balance in the y direction.

$$\sum F_y = N - W \cos 30^\circ = 0$$

$$N = W \cos 30^\circ$$

$$\rightarrow F_f = \mu N = \mu W \cos 30^\circ$$

By Newton's second law, the force in the x direction produces an acceleration a_x :

$$\sum F_x = W \sin 30^\circ - F_f = ma_x = \frac{W}{g} a_x$$

$$a_x = g(\sin 30^\circ - \mu \cos 30^\circ)$$

$$a_x = 13.31 \text{ ft/s}^2$$

When unbalanced couples are involved, a rotational analog to Newton's second law can be applied:

$$\sum \vec{M} = \bar{I} \alpha \tag{2.1.25}$$

where $\sum \vec{M}$ is the sum of all moments acting about the center of mass in the plane of rotation, \bar{I} is the mass moment of inertia about the center of mass, and α is the angular acceleration of the body. The mass moment of inertia is defined by

$$I = \int r^2 dm = mk^2 \tag{2.1.26}$$

where r is the perpendicular distance from the axis of rotation to the differential element of mass, dm. I is sometimes expressed in terms of k, the radius of gyration, and m, the mass of the body. If the axis of rotation passes through

FIGURE 2.1.15 Diagram for Example 2.1.8.

the center of mass, then the mass moment of inertia is designated as \bar{I} . Mass moments of inertia of common shapes are compiled in Tables 2.1.6 and 2.1.7.

It is often convenient to sum the moments about some arbitrary point 0, other than the mass center. In this case, Equation 2.1.25 becomes

$$\sum \mathbf{M}_0 = \bar{I}\alpha + m\bar{\mathbf{a}}d \quad (2.1.27)$$

where m is the mass of the body, $\bar{\mathbf{a}}$ is the linear acceleration of the mass center, and d is the perpendicular distance between the vector $\bar{\mathbf{a}}$ and point 0.

If 0 is a fixed axis or the instantaneous center of zero velocity, then Equation 2.1.27 reduces to

$$\sum \mathbf{M}_0 = I_0\alpha \quad (2.1.28)$$

where I_0 is the mass moment of inertia about point 0, I_0 may be found from Equation 2.1.26, or it may be calculated from the parallel axis theorem

$$I_0 = \bar{I} + m\bar{r}^2 \quad (2.1.29)$$

where \bar{r} is the distance from 0 to the center of mass. The parallel axis theorem may be used to find I_0 regardless of whether I_0 is a fixed axis of instantaneous center of zero velocity.

Example 2.1.9

In Figure 2.1.16a a 10 lb cylinder with a 3-in. radius rolls down a 30° incline. What is its angular acceleration and the linear acceleration of its center of mass?

In the free-body diagram of Figure 2.1.16, the point of contact between the wheel and the ramp is the instantaneous center of zero velocity. Thus,

$$\begin{aligned} \sum \mathbf{M}_0 &= rw \sin 30^\circ = I_0\alpha \\ \alpha &= \frac{rw \sin 30^\circ}{I_0} \end{aligned}$$

From Tables 2.1.6 and 2.1.7 and the parallel axis theorem,

$$\begin{aligned} I_0 &= \frac{W}{2g}r^2 + \frac{W}{g}r^2 = \frac{3}{2} \frac{W}{g}r^2 \\ \alpha &= \frac{2g \sin 30^\circ}{3r} = 3.57 \text{ rad/s} \\ a_x &= r\alpha = 10.73 \text{ ft/s}^2 \end{aligned}$$

2.1.3.4 Conservation of Momentum

If the mass of a body or system of bodies remains constant, then Newton’s second law can be interpreted as a balance between force and the time rate of change of momentum, *momentum* being a vector quantity defined as the product of the velocity of a body and its mass.

$$\mathbf{F} = m\mathbf{a} = \frac{d}{dt}m\mathbf{v} = \frac{d}{dt}\mathbf{G} \quad (2.1.30)$$

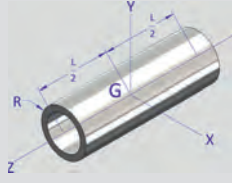

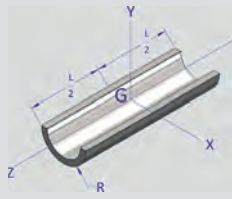

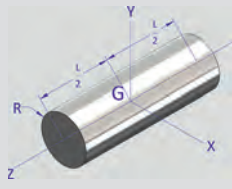

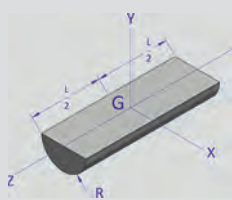

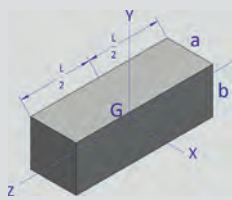

Integrating Equation 2.1.30 with respect to time yields the impulse/momentum equation

$$\int \mathbf{F}dt = \Delta\mathbf{G} \quad (2.1.31)$$

where $\mathbf{F}dt$ is called the impulse, and $\Delta\mathbf{G}$ is the change in momentum. Equation 2.1.31 can be applied explicitly and is particularly useful when the force is known as a function of time.

In collisions between two bodies the contact force and the duration of contact are usually unknown. However, the duration of contact is the same for both bodies, and the force on the first body is the negative of the force on the second

TABLE 2.1.6 Mass Centers and Moments of Inertia

Body	Mass Center	Moments of Inertia
 <p>Circular Cylindrical Shell</p>	—	$I_{xx} = \frac{1}{2}mr^2 + \frac{1}{12}ml^2$ $I_{x_1x_1} = \frac{1}{2}mr^2 + \frac{1}{2}ml^2$ $I_{zz} = mr^2$
 <p>Half Cylindrical Shell</p>	$\bar{x} = \frac{2r}{\pi}$	$I_{xx} = I_{yy}$ $= \frac{1}{2}mr^2 + \frac{1}{2}ml^2$ $I_{x_1x_1} = I_{y_1y_1}$ $= \frac{1}{2}mr^2 + \frac{1}{3}ml^2$ $I_{zz} = mr^2$
 <p>Circular Cylinder</p>	—	$\bar{I}_{zz} = \left(1 - \frac{4}{\pi^2}\right)mr^2$ $I_{xx} = \frac{1}{4}mr^2 + \frac{1}{12}ml^2$ $I_{x_1x_1} = \frac{1}{4}mr^2 + \frac{1}{3}ml^2$ $I_{zz} = \frac{1}{2}mr^2$
 <p>Semicylinder</p>	$\bar{x} = \frac{4r}{3\pi}$	$I_{xx} = I_{yy}$ $= \frac{1}{4}mr^2 + \frac{1}{12}ml^2$ $I_{x_1x_1} = I_{v_1v_1}$ $= \frac{1}{4}mr^2 + \frac{1}{3}ml^2$ $I_{zz} = \frac{1}{2}mr^2$ $I_{zz} = \left(\frac{1}{2} - \frac{16}{9\pi^2}\right)mr^2$
 <p>Rectangular Parallelepiped</p>	—	$I_{xx} = \frac{1}{12}m(a^2 + l^2)$ $I_{yy} = \frac{1}{12}m(b^2 + l^2)$ $I_{zz} = \frac{1}{12}m(a^2 + b^2)$ $I_{y_1y_1} = \frac{1}{12}mb^2 + \frac{1}{3}ml^2$

From Reference 3.

body. The net change in momentum is zero. This is called the principle of *conservation of momentum*.

If a collision is purely plastic, then the two colliding bodies will adhere to each other and move on as a single body. Knowing the initial velocities and masses allows calculation of the final velocity:

$$m_1v_1 + m_2v_2 = (m_1 + m_2)v \tag{2.1.32}$$

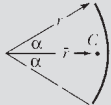

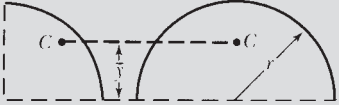

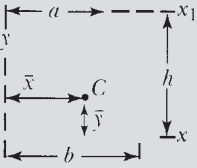

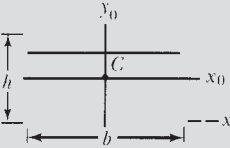

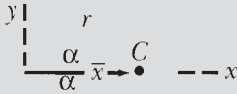

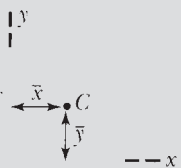

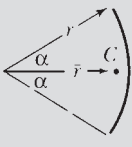

If the collision is purely elastic or elasto-plastic, then the two bodies will depart the collision with different velocities.

$$m_1v_{11} + m_2v_{21} = m_1v_{12} + m_2v_{22} \tag{2.1.33}$$

In this case, an additional equation is required before the final velocities may be found. Thus, the coefficient of restitution e is defined as the ratio of the velocity of separation to the velocity of approach:

$$e = \frac{v_{22x} - v_{12x}}{v_{11x} - v_{21x}} = \frac{v_{22y} - v_{12y}}{v_{11y} - v_{21y}} \tag{2.1.34}$$

From Reference 3, pp. 498–499.

FIGURE 2.1.16 Diagram for Example 2.1.9.

Note that e is defined in terms of the components of the velocities, not the vector velocities, whereas the momentum balance is defined in terms of the vector velocities. To solve Equations 2.1.32 and 2.1.33 when all the velocities are not colinear, one writes the momentum balances along the principal axes and solves the resulting equations simultaneously.

For purely elastic impacts, $e = 1$, and for purely plastic impacts, $e = 0$. For elastoplastic impacts, e lies between zero and one and is a function of both the material properties and the velocity of impact.

Example 2.1.10

Sphere 1 weighs 1 lb and is traveling at 2 ft/s in the positive x direction when it strikes sphere 2, weighing 5 lb and traveling in the negative x direction at 1 ft/s. What will be the final velocity of the system if the collision is (a) plastic, or (b) Elastoplastic with $e = 0.5$?

(a) By Equation 2.1.32

$$v = \frac{m_1 v_{11} - m_2 v_{21}}{m_1 + m_2} = \frac{2 - 5}{6} = -0.5 \text{ ft/s}$$

(b) By Equation 2.1.34

$$e = \frac{v_{22} - v_{12}}{v_{11} - v_{21}}$$

$$v_{22} = v_{12} + 0.5[2 - (-1)] = v_{12} + 1.5$$

By Equation 2.1.33

$$m_1 v_{11} + m_2 v_{21} = m_1 v_{12} + m_2 v_{22}$$

$$= m_1 v_{12} + m_2 (v_{12} + 1.5)$$

$$= (m_1 + m_2) v_{12} + 1.5 m_2$$

$$v_{12} = \frac{m_1 v_1 + m_2 (v_2 - 1.5)}{m_1 + m_2}$$

$$= \frac{1 \times 2 + 5(-1 - 1.5)}{1 + 5}$$

$$= -1.75 \text{ ft/s}$$

$$v_{22} = -0.25 \text{ ft/s}$$

The foregoing discussion of impulse and momentum applies only when no change in rotational motion is involved. There is an analogous set of equations for angular impulse and impulse momentum. The angular momentum about an axis through the center of mass is defined as

$$\vec{H} = \vec{I}\omega \tag{2.1.35}$$

and the angular momentum about any arbitrary point O is defined as

$$\mathbf{H}_o = \vec{I}\omega + m\vec{v}d \tag{2.1.36}$$

where \vec{v} is the velocity of the center of mass and d is the perpendicular distance between the vector \vec{v} and the point O . And if O is a fixed axis or instantaneous center of zero velocity, then

$$\mathbf{H}_0 = I_0\omega \tag{2.1.37}$$

Likewise, the angular impulse is defined as

$$\int \mathbf{M}_0 dt = \Delta \mathbf{H}_0 \tag{2.1.38}$$

In collisions, angular momentum, like linear momentum, is conserved.

2.1.3.5 Conservation of Energy

In a rigid-body system, energy is conserved in the sense that the net change in mechanical energy must be equal to the net work done on the system.

$$U = \Delta T + \Delta V_g + \Delta V_e \quad (2.1.39)$$

U is the net work done on the system and is defined as the sum of the work done by external forces and external moments.

$$U = \int \mathbf{F} \cdot d\mathbf{s} + \int \mathbf{M} \cdot d\theta \quad (2.1.40)$$

The work of the force \mathbf{F} is positive if it acts in the direction of the displacement $d\mathbf{s}$, and the work of the moment \mathbf{M} is positive if it acts in the direction of rotation $d\theta$.

ΔT is the change the kinetic energy, made up of a change in linear kinetic energy and rotational kinetic energy.

$$\Delta T = \frac{1}{2}m(\bar{v}_f^2 - \bar{v}_i^2) + \frac{1}{2}\bar{I}(\omega_f^2 - \omega_i^2) \quad (2.1.41)$$

If the body in question has a fixed axis or an instantaneous center of zero velocity, then Equation 2.1.41 can be simplified to

$$\Delta T = \frac{1}{2}I_0(\omega_f^2 - \omega_i^2) \quad (2.1.42)$$

ΔV_g is the net change in gravitational potential energy. This term is path independent and depends only on the initial and final heights, h_i and h_f , above some arbitrary reference height with respect to the surface of the earth.

$$\Delta V_g = mg(h_f - h_i) = W(h_f - h_i) \quad (2.1.43)$$

ΔV_e is the net change in elastic energy stored in a massless spring, due to extension or compression (no spring is massless, but this assumption is reasonably accurate for most engineering calculations).

$$\Delta V_e = \frac{1}{2}k(X_f^2 - X_i^2) \quad (2.1.44)$$

The constant k , called the spring constant, represents the ratio of the force exerted by the spring to X , its net compression or extension from the rest length.

Example 2.1.11

A 1-lb sphere is dropped from a height of 20 ft to strike a 2-ft-long relaxed vertical spring with a constant of 100 lb/ft (Figure 2.1.17). What will be the velocity of the sphere at a height of 2 ft when it strikes the spring? What will be the maximum compression of the spring?

The sphere and the spring may be considered as a system in which no outside forces or moments are acting. The work

FIGURE 2.1.17 Diagram for Example 2.1.11.

term in Equation 2.1.39 is zero. Before the collision with the spring, $\Delta V_e = 0$ also, and Equation 2.1.39 reduces to

$$\Delta T + \Delta V_g = 0$$

$$\Delta T = \frac{1}{2} \frac{W}{g} (v_f^2 - v_i^2) = -\frac{1}{2} \frac{W}{g} v_f^2$$

$$\Delta V_g = W(h_f - h_i)$$

which can be solved for the impact velocity.

$$v_f = [2g(h_i - h_f)]^{0.5} = [2 \times 32.2(20 - 2)]^{0.5}$$

$$v_f = 34 \text{ ft/s}$$

At full compression the velocity of the sphere is zero. Equation 2.1.39 reduces to

$$\Delta V_e + \Delta V_g = 0$$

$$\Delta V_e = \frac{1}{2}k(X_f^2 - X_i^2) = \frac{1}{2}kX_f^2$$

$$\Delta V_g = W(h_f - h_i)$$

$$h_f = L - X_f$$

where L is the relaxed height of the spring which can be solved for X_f , the maximum compression of the spring.

$$\frac{1}{2}kX_f^2 + W(L - X_f - h_i) = 0$$

$$X_f^2 \frac{2W}{k} X_f + \frac{2W}{k}(L - h_i) = 0$$

$$X_f = \frac{2W/k \pm [(2W/k)^2 - 4((2W/k)(L - h_i))]^{0.5}}{2}$$

$$= \frac{0.02 \pm [0.02^2 - 4[0.02(2 - 20)]]^{0.5}}{2}$$

$$X_f = 0.61 \text{ ft}$$

The negative root is ignored because it represents an extension of the spring rather than a compression.

2.2 FLUID MECHANICS

In fluid mechanics, the principles of conservation of mass, conservation of momentum, the first and second laws of thermodynamics, and empirically developed correlations are used to predict the behavior of gases and liquids at rest or in motion. The field is generally divided into hydrostatics and hydrodynamics and further subdivided on the basis of compressibility. Liquids can usually be considered as incompressible, while gases are usually assumed to be compressible.

2.2.1 Fluid Statics

Pressure is the force per unit area exerted by or on a fluid. In a static fluid, the pressure increases with depth, but according to *Pascal's principle*, it is the same in all directions at any given depth. Pressure may be specified as either *absolute* or *gauge*, the relationship between the two being

$$P_g = P_a - P_{atm} \quad (2.2.1)$$

where P_g is gauge pressure, P_a is absolute pressure, and P_{atm} is the *atmospheric pressure*. Fluid mechanics calculations are generally done in absolute pressure, and hereafter, P will represent absolute pressure.

The governing equation for the pressure within a fluid at any depth h is

$$dP = \rho g dh \quad (2.2.2)$$

where ρ is the fluid density in mass per unit volume, and g is the acceleration due to gravity. In engineering calculations, it is often convenient to replace the quantity ρg with γ , the *specific weight*, which is a measure of the weight of the fluid per unit volume.

If γ can be considered to be constant, the fluid is said to be incompressible and Equation 2.2.2 can be solved to yield

$$P = P_0 + \gamma(h - h_0) \quad (2.2.3)$$

where h_0 is some reference depth, h is depth increasing downward, and P_0 is the pressure at h_0 . In a gas, the specific weight of the fluid is a function of pressure and temperature. The concept of an *ideal* or *perfect gas* as one in which the molecules occupy no volume and the only intermolecular forces are due to intermolecular collisions leads to the *ideal gas law*:

$$\gamma = \frac{PS}{RT} \quad (2.2.4)$$

where P is the absolute pressure in pounds per square foot, T is the temperature in degrees Rankine, S is the specific gravity (the ratio of the density of the gas in question to the density of air at standard conditions), and R is Boltzman's constant (53.3 ft-lb/lb-°R). Under the assumption of an ideal gas at constant temperature, Equation 2.2.2 can be solved to yield

$$P = P_0 \exp \left[\frac{(h - h_0)S}{RT} \right] \quad (2.2.5)$$

If the gas behavior deviates markedly from ideal, the real gas law can be written as

$$\gamma = \frac{P_s}{ZRT} \quad (2.2.6)$$

where Z is an empirical compressibility factor that accounts for nonideal behavior (see Volume 2, Chapter 5).

Substituting the real gas law into Equation 2.2.3 yields

$$\frac{ZT}{P} dP = \frac{S}{R} dh \quad (2.2.7)$$

Equation 2.2.7 can be integrated under the assumption that Z and T are constant to yield Equation 2.2.8, or, if extreme accuracy is required, it is necessary to account for variations in Z and T and a numerical integration may be required.

$$P = P_0 \exp \left[\frac{(h - h_0)S}{ZRT} \right] \quad (2.2.8)$$

Example 2.2.1

Consider a 1,000-ft-deep hole. What will be the absolute pressure at the bottom if (a) it is filled with pure water or (b) it is filled with air at a constant temperature of 85°F?

(a) $P = P_0 + \gamma(h - h_0)$

$$h_0 = 0$$

$$h = 1,000 \text{ ft}$$

$$P_0 = \frac{14.7 \text{ lb}}{\text{in.}^2} \left| \frac{144 \text{ in.}^2}{\text{ft}^2} \right. = 2,116.8 \text{ lb/ft}^2$$

$$\gamma = 62.4 \text{ lb/ft}^3$$

$$P = 2,116.8 + 62.4(1,000 - 0) = 64,516.8 \text{ lb/ft}^2$$

$$P = 448 \text{ psi}$$

(b)
$$P = P_0 \exp \left[\frac{(h - h_0)s}{ZRT} \right]$$

$$s = 1$$

Assume

$$Z = 1$$

$$T = 85 + 460 = 545^\circ\text{R}$$

$$P = 2,116.8 \exp \left[\frac{(1,000 - 0)1}{1(53.3)(545)} \right] = 2,190.94 \text{ lb/ft}^2$$

$$P = 15.21 \text{ psi}$$

In a case where $Z \neq 1$, it is practical to assume $Z = 1$, perform Calculation (b), and then, based on the resultant, estimate for $P_{\text{avg}} = (P+P_0)/2$, find the value of Z , and repeat the calculation. Three iterations are generally sufficient. If T varies, it is usually sufficiently accurate to use an estimate of T_{avg} such as $T_{\text{avg}} = (T + T_0)/2$.

2.2.1.1 Fluid Dynamics

When fluids are in motion, the *pressure losses* may be determined through the principle of conservation of energy. For slightly compressible fluids, this leads to *Bernoulli's equation* (Equation 2.2.9), which accounts for static and *dynamic pressure losses* (due to changes in velocity), but does not account for frictional pressure losses, energy losses due to heat transfer, or work done in an engine.

$$\frac{P_1}{\gamma_1} + \frac{v_1^2}{2g} + h_1 = \frac{P_2}{\gamma_2} + \frac{v_2^2}{2g} + h_2 \quad (2.2.9)$$

where $v_1, v_2 \equiv$ velocity at points 1 and 2
 $g \equiv$ the acceleration due to gravity
 (See Figure 2.2.1.)

For flow in pipes and ducts, where frictional pressure losses are important, Equation 2.2.9 can be modified into

$$\frac{P_1}{\gamma_1} + \frac{v_1^2}{2g} + h_1 = \frac{P_2}{\gamma_2} + \frac{v_2^2}{2g} + h_2 + \frac{fLv^2}{2gD} \quad (2.2.10)$$

where $f \equiv$ an empirical friction factor (Moody friction factor)
 $v \equiv$ the average velocity along the flow path
 $L \equiv$ the length of the flow path

FIGURE 2.2.1 Flow in an inclined pipe.

TABLE 2.2.1 Critical Expansion Rates

Gas	C_p Btu/(lb mole) ($^\circ\text{F}$)	$k = C_p/C_v$ at 1 atm, 60°F	P_e/P_1	Acoustical velocity at 60°F , ft/sec
Air	7.00	1.410	0.528	1,031
Helium	4.968	1.66	0.486	2,840
Methane	8.44	1.308	0.545	1,350
Ethane	12.30	1.193	0.565	967
Propane	17.10	1.133	0.577	793
Isobutane	22.4	1.097	0.585	681
n-Butane	23.0	1.094	0.585	680
0.6 gravity	8.84	1.299	0.546	1,309
0.7 gravity	9.77	1.279	0.550	1,035

From Reference 2.

$D \equiv$ the hydraulic diameter, $2(\text{flow area})/(\text{wetted perimeter})$ (See Figure 2.2.1.)

If the fluid is highly compressible, Equation 2.2.9 must be further modified:

$$\frac{P_1}{\gamma_1} \left(\frac{k}{k-1} \right) + \frac{v_1^2}{2g} + h_1 = \frac{P_2}{\gamma_2} \left(\frac{k}{k-1} \right) + \frac{v_2^2}{2g} + h_2 \quad (2.2.11)$$

where $k \equiv$ ratio of specific heats, c_p/c_v ; see Table 2.2.1. (See Figure 2.2.1.)

The *Moody friction factor* in Equations 2.2.10 and 2.2.11 is a function of the *surface roughness* of the pipe and the *Reynolds number*. Typical surface roughnesses of new commercial pipes are shown in Table 2.2.2. Old or corroded pipes may have a significantly higher roughness.

The Reynolds number is the ratio of the inertia forces acting on the fluid to the viscous forces acting on the fluid. It is dimensionless and may be calculated as

$$R = \frac{\gamma Dv}{g\mu} = \frac{\rho Dv}{\mu} \quad (2.2.12)$$

The term μ in Equation 2.2.12 is the *dynamic viscosity* of the fluid. The dynamic viscosity is the ratio of the shear stress to the shear rate. It has units of (force \times time)/(area). The most common unit of viscosity is the centipoise (1 centipoise = 0.01 g/cm-s). Dynamic viscosity may be a function of temperature, pressure, and shear rate.

For *Newtonian fluids* the dynamic viscosity is constant (Equation 2.2.13), for *power-law fluids* the dynamic viscosity varies with shear rate (Equation 2.2.14), and for *Bingham plastic fluids* flow occurs only after some minimum shear stress, called the *yield stress*, is imposed (Equation 2.2.15).

TABLE 2.2.2 Values of Absolute Roughness, New, Clean, Commercial Pipes

Type of pipe or tubing	ϵ ft (0.3048 m) $\times 10^6$		Probable max variation of f from design, %
	Range	Design	
Asphalted cast iron	400	400	-5 to +5
Brass and copper	5	5	-5 to +5
Concrete	1,000 10,000	4,000	-35 to 50
Cast iron	850	850	-10 to +15
Galvanized iron	500	500	0 to +10
Wrought iron	150	150	-5 to 10
Steel	150	150	-5 to 10
Riverted steel	3,000 30,000	6,000	-25 to 75
Wood stave	600 3,000	2,000	-35 to 20

Compiled from data given in "Pipe Friction Manual," Hydraulic Institute, 3d ed., 1967.

$$\tau = \mu \left(\frac{dv}{dy} \right) \quad (\text{Newtonian}) \quad (2.2.13)$$

$$= \mu \left(\frac{dv}{dy} \right)^n \quad (\text{Power law}) \quad (2.2.14)$$

$$= \tau_0 + \mu \left(\frac{dv}{dy} \right) \quad (\text{Bingham}) \quad (2.2.15)$$

where τ is the shear stress in force per unit area, dv/dy is the shear rate (rate of change in velocity with respect to distance from measured perpendicular to the flow). The behavior of all three types of fluids is illustrated in Figure 2.2.2. Viscosities of common fluids that are normally Newtonian are given in Tables 2.2.3 and 2.2.4. Viscosities for hydrocarbon gases can be estimated from Figure 2.2.3.

If the calculated value of the Reynolds number is below 2,000, the flow will generally be laminar, that is, the fluid particles will follow parallel flow paths. For laminar flow the friction factor is

$$f = 64/R \quad (2.2.16)$$

If the Reynolds number is greater than 4,000, the flow will generally be turbulent and the friction factor can be calculated from the Colebrook equation:

$$\frac{1}{\sqrt{f}} = -2 \log_{10} \left[\frac{\epsilon/D}{3.7} + \frac{2.51}{R\sqrt{f}} \right] \quad (2.2.17)$$

FIGURE 2.2.2 Viscous behavior of fluids.

where ϵ is the surface roughness. Equation 2.2.17 can be solved iteratively. If the Reynolds number falls between 2,000 and 4,000, the flow is said to be in the critical zone, and it may be either laminar or turbulent.

Equations 2.2.16 and 2.2.17 are illustrated graphically in Figure 2.2.4. This chart is called a Moody diagram, and it may be used to find the friction factor, given the Reynolds number and the surface roughness.

A better approach to determine the friction factor used in Equation 2.2.10 is to calculate f using Equation 2.2.16 (laminar flow) and Equation 2.2.17 (turbulent) and take the largest value.

The friction factor presented in this text is the called *Moody friction factor*. Other texts may use the term *Fanning friction factor*. Both use the Colebrook empirical implicit formula for calculation but differ in the definition of the friction factor. The Moody friction factor is defined by

$$f = \frac{(dp/dL)D}{e_k}$$

where dp/dL is the pressure drop gradient, D the diameter of the pipe, and e_k is the specific kinetic energy of the flowing fluid. The Fanning friction factor is defined as

$$f = \frac{\tau}{e_k}$$

where τ is the shear stress acting on the walls of the pipe. Working these two expressions shows that the Moody friction factor is four times the Fanning Friction factor. To use Equation 2.2.10, a friction factor obtained with the Fanning formula or read from the Stanton chart must be multiplied by four.

Example 2.2.2

Suppose 1,000 gal/min of light machine oil (see Table 2.2.3) flow through a 100-ft-long straight steel pipe with a square

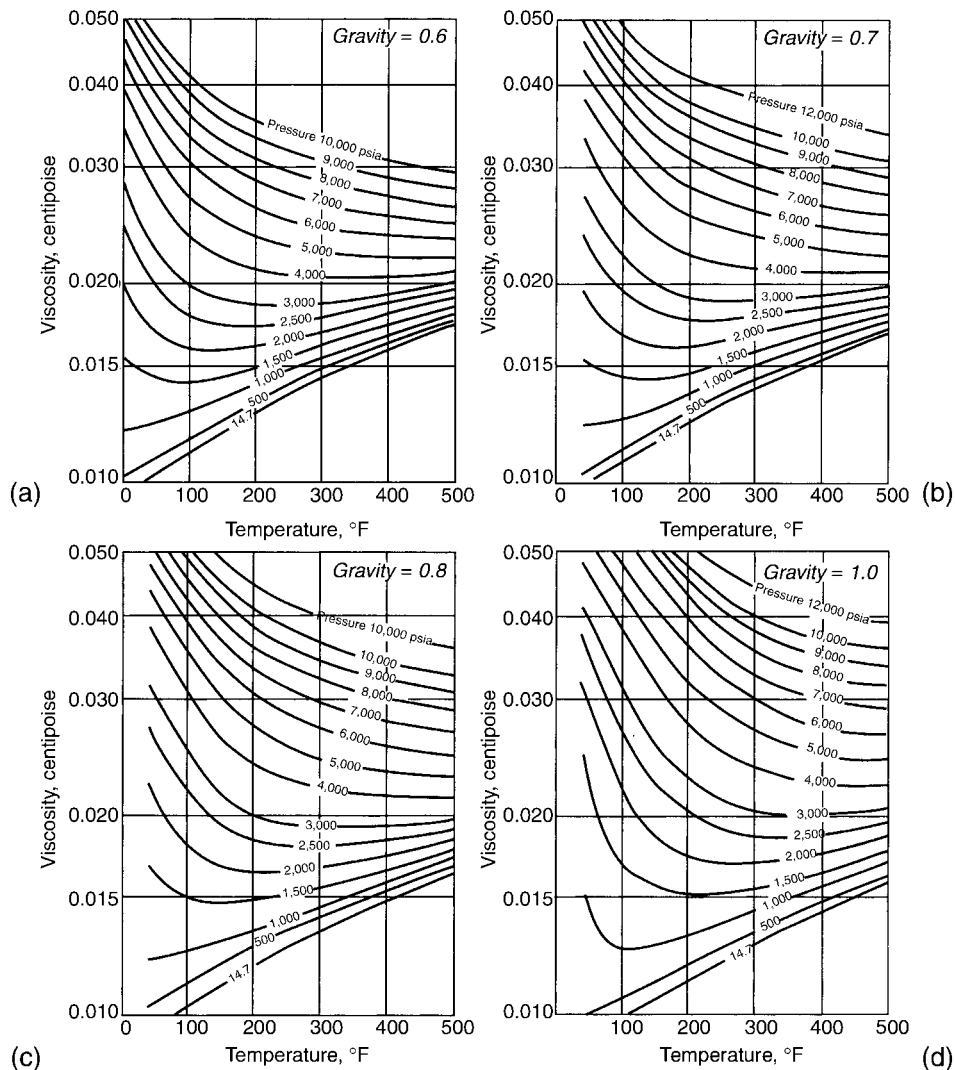

FIGURE 2.2.3 Viscosity of natural gases: (a) 0.6 gravity; (b) 0.7 gravity; (c) 0.8 gravity; (d) 1.0 gravity.

cross-section, 2 in. on a side. At the inlet of the pipe the pressure is 2,000 psi and the elevation is 150 ft. At the outlet the elevation is 100 ft. What will be the pressure at the outlet when the temperature is 32°F? When the temperature is 104°F?

$$\begin{aligned} \gamma &= (0.907)(62.4 \text{ lb/ft}^3) = 56.60 \text{ lb/ft}^3 \\ A &= [(2 \text{ in.})/(12 \text{ in./ft})]^2 = 0.0278 \text{ ft}^2 \\ C &= 4(2 \text{ in.})/(12 \text{ in./ft}) = 0.667 \text{ ft} \\ D &= 2A/C = 0.0833 \text{ ft} \\ v &= Q/A = [(1,000 \text{ gal/min})(0.1337 \text{ ft}^3/\text{gal})/(60 \text{ s/min})] \\ &= .0278 \text{ ft}^2 = 80.21 \text{ ft/s} \\ \mu &= 7,380 \times 10^{-6} \text{ lb} - \text{s/ft}^2 @ 32^\circ\text{F} \\ &= 647 \times 10^{-6} \text{ lb} - \text{s/ft}^2 @ 104^\circ\text{F} \\ g &= 32.2 \text{ ft/s}^2 \end{aligned}$$

At 32°F

$$R = \frac{(56.60)(0.0833)(80.21)}{(32.2)(7,380 \times 10^{-6})} = 1,591$$

Because $R < 2000$ the flow is laminar and $f = 64/R = 0.04022$. Assuming that the fluid is incompressible implies that $\gamma_1 = \gamma_2$ and $v_1 = v_2$, and Equation 2.2.10 can be rewritten as

$$\begin{aligned} P_2 &= P_1 + \gamma \left[(h_1 - h_2) - \frac{fLv^2}{2gD} \right] \\ &= 2,000 \\ &+ 56.60 \left[(150 - 100) - \frac{(0.04022)(100)(80.21)^2}{2(32.2)(0.0833)} \right] / \\ &(144 \text{ in.}^2/\text{ft}^2) \\ &= 124 \text{ psi} \end{aligned}$$

FIGURE 2.2.4 Friction factor for flow in pipes [5].

At 104°F

$$R = \frac{(56.6)(0.0833)(80.21)}{(32.2)(647 \times 10^{-6})} = 18,150$$

Because $R > 4000$ the flow is turbulent. From Table 2.2.2, $\epsilon = 150 \times 10^{-6}$, and $\epsilon/D = 0.0018$. Interpolating from Figure 2.2.4 yields $f = 0.03$. Now apply the Colebrook equation:

$$\frac{1}{\sqrt{f}} = -2 \log_{10} \left[\frac{0.0018}{3.7} + \frac{2.51}{(18,150)(0.03)^{0.5}} \right]$$

$$f = 0.02991$$

$$P_2 = 2,000 + \left(\frac{56.60}{144} \right) \times \left[(150 - 100) - \frac{(0.02991)(100)(80.21)^2}{2(32.2)(0.0833)} \right]$$

$$= 610 \text{ psi}$$

In piping systems fittings, valves, bends, etc., all cause additional pressure drops. For such components the pressure drop can be estimated by modifying the frictional component of Equation 2.2.10 with a resistance coefficient, $K = fL/D$, or an equivalent length, L/D . Typical resistance coefficients are given in Table 2.2.5 and typical equivalent lengths are given in Table 2.2.6. To correctly apply either the resistance coefficient or the equivalent length, the flow must be turbulent.

FIGURE 2.2.5 Diagram for Example 2.2.3.

$$v_1 = \frac{Q}{A_1} = \frac{[(1,000 \text{ gal/min})(0.1337 \text{ ft}^3/\text{gal})(60 \text{ s/min})]}{[\pi/4 (4/12)^2 \text{ ft}^2]}$$

$$= 25.53 \text{ ft/s}$$

$$v_2 = \frac{[(1,000)(0.1337)/(60)]}{[\pi/4 (1/12)^2]} = 408.6 \text{ ft/s}$$

$$\gamma_1 = \gamma_2 = 62.4 \text{ lb/ft}^3$$

From Table 2.2.1, $D_{in}/d_{out} = 4$; $k = 0.45$.
From Equation 2.2.10,

$$P_1 - P_2 = \Delta P = \frac{\gamma}{2g} [v_2^2 - v_1^2 + kv_2^2]$$

$$= \frac{\gamma}{2g} [v_2^2(1 + k) - v_1^2]$$

$$= \frac{62.4}{2(32.2)} [408.6^2(1 + 0.45) - 25.53^2] \frac{1}{144}$$

$$= 1,625 \text{ psi}$$

The 1,120 psi of this pressure drop is a dynamic loss due to the change in velocity, and 505 psi is a frictional loss due to the fitting.

Components of a piping system that are connected in *series* produce additive pressure drops, while components that are connected in *parallel* must produce the same pressure drop.

While the modified energy equation provides for calculation of the flow rates and pressure drops in piping systems, the *impulse-momentum* equation is required in order to calculate the reaction forces on curved pipe sections. The impulse-momentum equation relates the force acting on the solid boundary to the change in fluid momentum. Because force and momentum are both vector quantities, it is most convenient to write the equations in terms of the scalar components in the three orthogonal directions.

$$\sum F_x = \dot{M}(V_{x1} - V_{x2})$$

$$\sum F_y = \dot{M}(V_{y1} - V_{y2}) \quad (2.2.18)$$

$$\sum F_z = \dot{M}(V_{z1} - V_{z2})$$

where \dot{M} is the fluid mass flow rate, $\sum F_x$ is the sum of forces in the x direction, V_{x1} is the initial fluid velocity in the x direction, etc.

Example 2.2.4

Water flows through a 120°F reducing bend at a rate of 100 gpm. The inlet diameter of the bend is 2 in. and the outlet diameter is 1 in. (Figure 2.2.6). What is the reaction force on the bend?

FIGURE 2.2.6 Diagram for Example 2.2.4.

Assuming that the flow is incompressible,

$$\dot{M} = \frac{(100 \text{ gal/min})(0.1337 \text{ ft}^3/\text{gal})(62.4 \text{ lb/ft}^3)}{[(32.2 \text{ ft/s}^2)(60 \text{ s/min])}$$

$$\dot{M} = 0.4318 \frac{\text{lb} \cdot \text{s}^4}{\text{ft}} = 0.4318 \text{ slugs/s}$$

$$A_1 = \frac{\pi}{4} \left(\frac{2}{12} \right)^2 = 0.02182 \text{ ft}^2$$

$$A_2 = \frac{\pi}{4} \left(\frac{1}{12} \right)^2 = 0.005454 \text{ ft}^2$$

$$v_1 = v_{y1} = -\frac{Q}{A_1} = \frac{(100)(0.1337)(1/60)}{0.02182} = 10.21 \text{ ft/s}$$

$$v_2 = \frac{Q}{A_2} = \frac{(100)(0.1337)(1/60)}{0.005454} = 40.86 \text{ ft/s}$$

$$v_{y2} = -v_2 \sin 30^\circ = -20.43 \text{ ft/s}$$

$$v_{x2} = v_2 \cos 30^\circ = 35.38 \text{ ft/s}$$

$$F_x = \dot{M}(v_{x1} - v_{x2}) = 0.4318 \frac{\text{lb} \cdot \text{s}}{\text{ft}} (0 - 35.38 \text{ ft/s}) \\ = -15.28 \text{ lb}$$

$$F_y = \dot{M}(v_{y1} - v_{y2}) = 0.4318(-10.21 + 20.43) = 4.413 \text{ lb}$$

Flow through *chokes and nozzles* is a special case of fluid dynamics. For *incompressible fluids* the problem can be handled by mass conservation and Bernoulli's equation. Bernoulli's equation is solved for the pressure drop across the choke, assuming that the velocity of approach and the vertical displacement are negligible. The velocity term is replaced by the volumetric flow rate times the area at the choke throat to yield

$$\Delta P = \frac{Q^2 \gamma}{2gC^2 A^2} \quad (2.2.19)$$

C is a constant introduced to account for frictional effects. In general, $0.94 \leq C \leq 0.98$.

Example 2.2.5

Assume 100 ft³/min of water is to be pumped through a nozzle with a throat diameter of 3/4 in. What pressure drop should be expected?

$$Q = \frac{100}{60} = 1.67 \text{ ft}^3/\text{s}$$

$$A = \frac{\pi(0.75^2)}{4(144)} = 3.068 \times 10^{-3} \text{ ft}^2$$

$$\gamma = 62/4 \text{ lb/ft}^3$$

Assume $C = 0.95$; then

$$\Delta P = \frac{(1.67^2)(62.4)}{2(32.2)(0.95^2)(3.068 \times 10^{-3})^2(144)} = 2,210 \text{ psia}$$

To analyze *compressible flow through chokes* it is assumed that the entropy of the fluid remains constant. The equation of *isentropic* flow is

$$P_1 V_1^k = P_2 V_2^k \quad (2.2.20)$$

where P_1 and V_1 are the pressure and specific volume of the fluid at point 1, immediately upstream of the choke, and P_2 and V_2 are the pressure and specific volume immediately downstream of the choke. Equation 2.2.20 can be combined with the ideal gas law to provide an estimate for the temperature drop across the choke

$$T_2 = T_1 \left(\frac{P_2}{P_1} \right)^{(k-1)/k} \quad (2.2.21)$$

where T_2 and T_1 are temperatures in °R. Furthermore, the first law of thermodynamics can also be imposed, yielding the following equation for the volumetric flow rate:

$$Q = 864 CA \frac{P_1}{(ST_1)^{0.5}} \left\{ \frac{k}{k-1} \left[\left(\frac{P_2}{P_1} \right)^{2/k} - \left(\frac{P_2}{P_1} \right)^{(k+1)/k} \right] \right\}^{0.5} \quad (2.2.22)$$

where Q is the volumetric flow rate in scfm, C is a *discharge coefficient* that accounts for friction and velocity of approach (Figure 2.2.7). A is the choke area in square inches, P_1 is the inlet pressure in pounds per square inch absolute (psia), P_2 is the outlet pressure in psia, T_1 is the inlet temperature in °R, and S is the specific gravity of the gas.

Equations 2.2.21 and 2.2.22 apply only as long as the fluid velocity at the throat of the choke is subsonic. Sonic velocity is the speed of a pressure wave in a fluid. Once *sonic velocity* is achieved, the effects of the downstream pressure can no longer be transmitted to the upstream side of the choke.

There is a critical pressure ratio beyond which the flow at the throat is always sonic. This is termed *critical flow*.

$$\frac{P_2}{P_1} = \left(\frac{2}{k+1} \right)^{k/(k-1)} \quad (2.2.23)$$

If the pressure ratio is less than or equal to that specified by Equation 2.2.23; the flow will be sonic at the choke throat and the temperature at the throat can be found from

$$T_2 = T_1 \left(\frac{2}{k+1} \right) \quad (2.2.24)$$

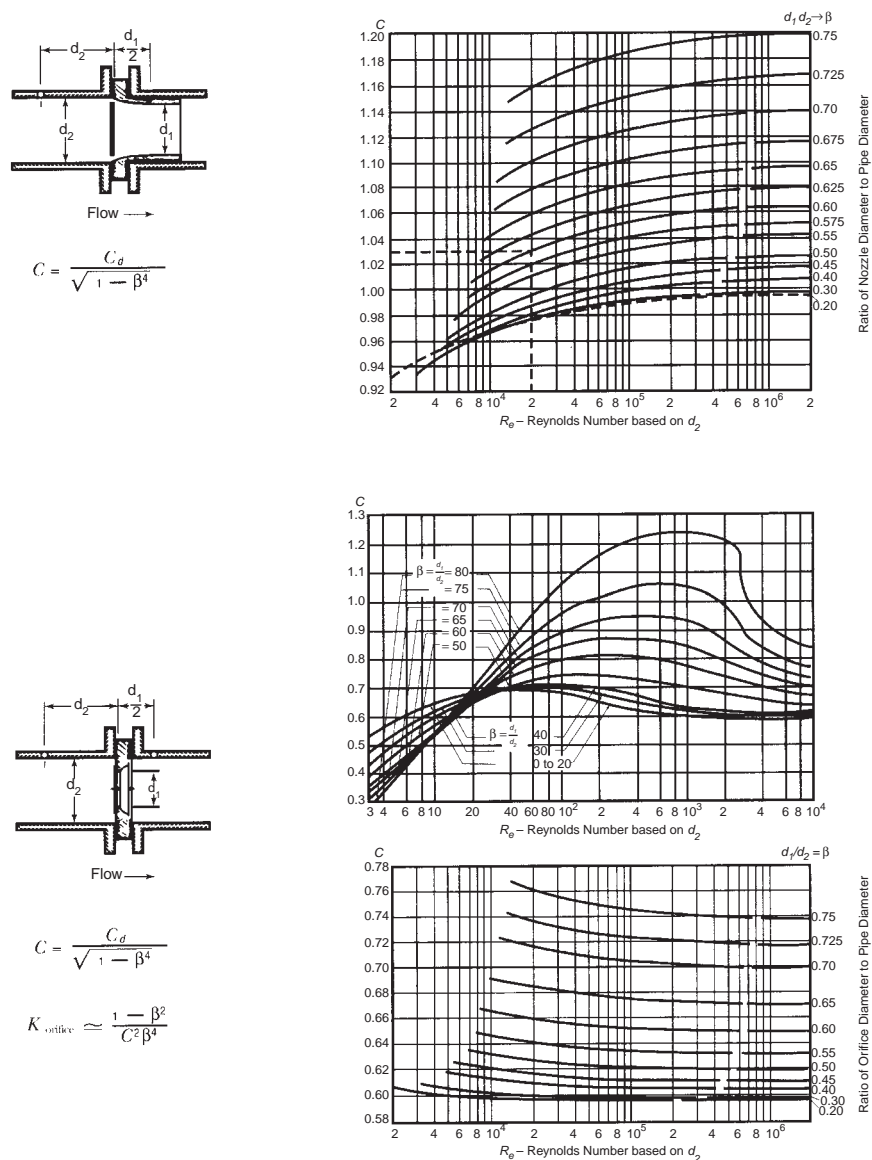

FIGURE 2.2.7 Flow coefficient for nozzles and orifices (From Reference 1, p. 226).

The flow rate can be found from

$$Q = 610CA \frac{P_1}{(ST_1)^{0.5}} \left[k \left(\frac{2}{k+1} \right)^{(k+1)/(k-1)} \right]^{0.5} \tag{2.2.25}$$

For critical flow the discharge coefficient is dependent upon the geometry of the choke and its diameter or the ratio β of its diameter to that of the upstream pipe (see Figure 2.2.7).

Example 2.2.6

A 0.6 gravity hydrocarbon gas flows from a 2-in. ID pipe through a 1-in. ID orifice plate. The upstream temperature and pressure are 75°F and 800 psia, respectively. The

downstream pressure is 200 psia. Does heating need to be applied to assure that frost does not clog the orifice? What will be the flow rate?

Check for critical flow. From Table 2.2.1 it is determined that $k = 1.299$. Checking the pressure ratio, Equation 2.2.23, gives

$$\frac{P_2}{P_1} = 0.25 < \left(\frac{2}{k+1} \right)^{k/(k-1)} = 0.546$$

Therefore, critical flow conditions exist and the fluid velocity in the choke is sonic.

Temperature in the choke. From Equation 2.2.24, the temperature in the throat is calculated as

$$T_2 = T_1 \left(\frac{2}{k+1} \right) = 535 \left(\frac{2}{1+1.299} \right) = 465.4^\circ\text{R} = 5.4^\circ\text{F}$$

Therefore, if the gas contains water, icing or hydrate formation may occur, causing the throat to clog. A heating system may be needed.

Flow rate. Assume that the discharge coefficient is $C = 1.0$. The choke area is $A = \pi(1/2)^2 = 0.785 \text{ in.}^2$. Thus, from Equation 2.2.25,

$$\begin{aligned} Q &= 610(1.0)(0.785) \frac{800}{[(0.6)(535)]^{0.5}} \\ &\times \left[1.299 \left(\frac{2}{1.299+1} \right)^{(1.299+1)/(1.299-1)} \right]^{0.5} \\ &= 14,021 \text{ scfm} \end{aligned}$$

Now check on the discharge coefficient.

The Reynolds number for gases can be calculated directly in terms of flow rate and gas gravity as

$$Re = \frac{28.8 Qs}{\mu d} \quad (2.2.26)$$

where Q is in scfm, s is the specific gravity of the gas, d is the pipe hydraulic diameter in inches, and μ is in centipoise. From Figure 2.2.3 the viscosity of the gas is

$$\mu = 0.0123 \text{ cp}$$

and

$$Re = \frac{(28.8)(14021)(0.6)}{(0.0123)(2)} = 9,850,000$$

From Figure 2.2.7, using $\beta = 0.5$, the value of the discharge coefficient is read as $C = 0.62$, and a new estimate of Q is

$$Q = 0.62(14,021) = 8,693 \text{ scfm}$$

A further iteration produces no change in the estimated flow rate for this case.

In subcritical flow the discharge coefficient is affected by the velocity of approach as well as the type of choke and the ratio of choke diameter to pipe diameter. Discharge coefficients for subcritical flow are given in Figure 2.2.7 as a function of the diameter ratio and the upstream Reynolds number. Because the flow rate is not initially known, it is expedient to assume $C = 1$, calculate Q , use this Q to calculate the Reynolds number, and then use the charts to find a better value of C . This cycle should be repeated until the value of C no longer changes.

Example 2.2.7

A 0.65 gravity, natural gas ($K = 1.25$) flows from a 2-in. line through a 1.5-in. nozzle. The upstream temperature is

90°F . The upstream pressure is 100 psia, and the downstream pressure is 80 psia. Is icing a potential problem? What will be the flow rate?

Check for critical flow using Equation 2.2.23.

$$\frac{P_2}{P_1} = 0.8 > \left[\frac{2}{k+1} \right]^{k/(k-1)} = 0.549$$

The flow is clearly subcritical.

Check the outlet temperature using Equation 2.2.21.

$$T_2 = 550(0.8^{0.25/1.25}) = 506.86^\circ\text{R} = 66^\circ\text{F}$$

There will be no icing.

Calculate the flow rate.

$$A = \pi \left(\frac{1.5}{2} \right)^2 = 1.767 \text{ in.}^2$$

Assuming $C = 1$ and applying Equation 2.2.22 gives

$$\begin{aligned} Q &= (864)(1)(1.767) \frac{100}{[(0.65)(530)]^{1/2}} \\ &\times \left\{ \frac{1.25}{1.25-1} \left[\left(\frac{80}{100} \right)^{2/1.25} - \left(\frac{80}{100} \right)^{(1.25+1)/1.25} \right] \right\}^{1/2} \\ &= 3,214 \text{ scfm} \end{aligned}$$

From Figure 2.2.3, the viscosity of the gas is

$$\mu = 0.0106 \text{ cp}$$

and from Equation 2.2.26

$$Re = \frac{(28.8)(3,214)(0.65)}{(0.0106)(2)} = 2.84 \times 10^6$$

From Figure 2.2.7, using $\beta = 0.75$, the value of the discharge coefficient is read as $c = 1.2$. Now a new estimate of Q can be found as

$$Q = \left(\frac{1.2}{1} \right) 3214 = 3,857 \text{ scfm}$$

Because further increases in the flow rate (see Figure 2.2.7) produce no increase in the discharge coefficient, it is unnecessary to do any further iterations.

2.3 STRENGTH OF MATERIALS

The principles of strength of materials are applied to the design of structures to assure that the elements of the structures will operate reliably under a known set of loads. The field encompasses both the calculation of the strength and deformation of members and the measurement of the mechanical properties of engineering materials.

2.3.1 Stress and Strain

Consider a bar of length L and uniform cross-sectional area A to which an axial, uniformly distributed load with a magnitude, P , is applied at each end (Figure 2.3.1). Then within the bar there is said to be *uniaxial stress* σ , defined as the load, or force per unit area

$$\sigma = \frac{P}{A} \tag{2.3.1}$$

If the load acts to elongate the bar, the stress is said to be *tensile* (+), and if the load acts to compress the bar, the stress is said to be *compressive* (-). For all real materials, an externally applied load will produce some *deformation*. The ratio of the deformation to the undeformed length of the body is called the *strain* ϵ . In the simple case illustrated in Figure 2.3.1, the strain is

$$\epsilon = \delta/L \tag{2.3.2}$$

where δ is the longitudinal deformation. The strain is tensile or compressive depending upon the sign of δ . The relationship between stress and strain in an axially loaded bar can be illustrated in a stress-strain curve (Figure 2.3.2). Such curves are experimentally generated through *tensile tests*.

In the region where the relationship between stress and strain is linear, the material is said to be *elastic*, and the constant of proportionality is E , *Young's modulus*, or the *elastic modulus*.

$$\sigma = E\epsilon \tag{2.3.3}$$

Equation 2.3.3 is called *Hooke's law*.

FIGURE 2.3.1 Uniaxial loading of a bar.

FIGURE 2.3.2 Idealized stress-strain curve.

In the region where the relationship between stress and strain is nonlinear, the material is said to be *plastic*. Elastic deformation is recoverable upon removal of the load, whereas plastic deformation is permanent. The stress at which the transition occurs, σ_y , is called the *yield strength* or *yield point* of the material, and the maximum stress is called the *ultimate tensile strength*, UTS, of the material. Standard engineering practice is to define the yield point as 0.2% permanent strain.

When a bar is elongated axially, as in Figure 2.3.1, it will contract laterally. The negative ratio of the lateral strain to the axial strain is called *Poisson's ratio* ν . For *isotropic* materials, materials that have the same elastic properties in all directions, Poisson's ratio has a value of about 0.3.

Now consider a block to which a uniformly distributed load of magnitude P is applied parallel to opposed faces with area A (Figure 2.3.3). These loads produce a *shear stress* within the material τ .

$$\tau = P/A \tag{2.3.4}$$

Note that in order for the block of Figure 2.3.3 to be in static equilibrium, there must also be a stress τ applied parallel to each of the faces B . Any given shear stress always implies a second shear stress of equal magnitude acting perpendicularly to the first so as to produce a state of static equilibrium. The shear stress will produce a deformation of the block, manifested as a change in the angle between

FIGURE 2.3.3 Shear loading of a block.

the face perpendicular to the load and the face over which the load is applied. This change in angle is called the *shear strain* γ .

$$\gamma = \Delta\alpha \quad (2.3.5)$$

For an elastic material the shear stress is related to the shear strain through a constant of proportionality G , called the *shear modulus*. The shear strain is dimensionless, and the shear modulus has units of force per unit area.

$$\tau = G\gamma \quad (2.3.6)$$

The shear modulus is related to Young's modulus and Poisson's ratio by

$$G = \frac{E}{2(1 + \nu)} \quad (2.3.7)$$

In practice, loads are not necessarily uniformly distributed nor uniaxial, and cross-sectional areas are often variable. It becomes necessary to define the stress at a point as the limiting value of the load per unit area as the area approaches zero. Furthermore, there may be tensile or compressive stresses (σ_x , σ_y , σ_z) in each of three orthogonal directions and as many as six shear stresses (τ_{xy} , τ_{yx} , τ_{xz} , τ_{zx} , τ_{yz} , τ_{zy}). The direction of the shear stress is indicated by two subscripts, the first of which indicates the direction normal to the plane in which the load is applied, and the second of which indicates the direction of the load. Note that for static equilibrium to exist, $\tau_{xy} = \tau_{yx}$, $\tau_{xz} = \tau_{zx}$, and $\tau_{yz} = \tau_{zy}$.

If a multidimensional state of stress exists, the effect of Poisson's ratio causes the tensile and compressive strains to be dependent on each of the components of stress.

$$\varepsilon_x = \frac{1}{E}[\sigma_x - \nu(\sigma_y + \sigma_z)] \quad (2.3.8)$$

$$\varepsilon_y = \frac{1}{E}[\sigma_y - \nu(\sigma_x + \sigma_z)] \quad (2.3.9)$$

$$\varepsilon_z = \frac{1}{E}[\sigma_z - \nu(\sigma_y + \sigma_x)] \quad (2.3.10)$$

Likewise the stresses may be written in terms of the components of strain.

$$\sigma_x = \frac{E}{(1 + \nu)(1 - 2\nu)}[(1 - \nu)\varepsilon_x + \nu(\varepsilon_y + \varepsilon_z)] \quad (2.3.11)$$

$$\sigma_y = \frac{E}{(1 + \nu)(1 - 2\nu)}[(1 - \nu)\varepsilon_y + \nu(\varepsilon_x + \varepsilon_z)] \quad (2.3.12)$$

$$\sigma_z = \frac{E}{(1 + \nu)(1 - 2\nu)}[(1 - \nu)\varepsilon_z + \nu(\varepsilon_x + \varepsilon_y)] \quad (2.3.13)$$

The components of the shear stress all obey Equation 2.3.6.

While the foregoing discussion of stress and strain is based on a Cartesian coordinate system, any orthogonal coordinate system may be used.

2.3.2 Elementary Loading Configurations

2.3.2.1 Torsion of a Cylinder

Consider a uniform cylindrical bar or tube to which some balanced torque T is applied (Figure 2.3.4). The bar will be subject to a *torsional stress*, or shear stress $\tau_{z\theta}$, which increases with the radial position within the bar.

$$\tau_{z\theta} = Tr/J \quad (2.3.14)$$

where r is the radial distance from the z axis, and J is the polar moment of inertia. The polar moment of inertia for a hollow cylinder with an internal radius r_i and an external radius, r_o , is

$$J = \frac{\pi}{2}(r_o^4 - r_i^4) \quad (2.3.15)$$

The strain due to the torque T is given by

$$\gamma_{z\theta} = \frac{2(1 + \nu) Tr}{E J} \quad (2.3.16)$$

FIGURE 2.3.4 Torsional loading of a right circular cylinder.

FIGURE 2.3.5 Supported Beam.

and the total angular deflection between any two surfaces perpendicular to the z axis is

$$\Theta = 2(1 + \nu) \frac{TL}{EJ} \quad (2.3.17)$$

where L is the distance between the two surfaces.

Example 2.3.1

A uniform steel bar 3 ft long and 2.5 in. in diameter is subjected to a torque of 800 ft-lb. What will be the maximum torsional stress and the angular deflection between the two ends?

Assume $E = 30 \times 10^6$ psi and $\nu = 0.3$. Then

$$J = \frac{\pi}{2}(1.25^4 - 0^4) = 3.83 \text{ in.}^4$$

$$\tau_{z\theta} = \frac{800 \text{ ft-lb} \left| \frac{12 \text{ in.}}{\text{ft}} \right| \left| \frac{1.25 \text{ in.}}{3.83 \text{ in.}^4} \right|}{3.83 \text{ in.}^4} = 3133 \text{ psi}$$

$$\theta = 2(1 + 0.3)$$

$$\frac{800 \text{ ft-lb} \left| \frac{12 \text{ in.}}{\text{ft}} \right| \left| \frac{3 \text{ ft}}{\text{ft}} \right| \left| \frac{12 \text{ in.}}{\text{ft}} \right| \left| \frac{\text{in.}^2}{30 \times 10^6 \text{ lb}} \right| \left| \frac{1}{3.83 \text{ in.}^4} \right|}{30 \times 10^6 \text{ lb}}$$

$$= 7.8 \times 10^{-3} \text{ rad} \frac{360^\circ}{2\pi \text{ rad}} = 0.45^\circ$$

2.3.2.2 Pure Bending

A beam is subjected to a pure bending moment when no other loading (shear, torsion, or axial) exists. A typical situation is shown in Figure 2.3.5a. Because the moment $M = Fd$ is the same along the portion BC, this portion will bend in an arc of a circle. An imaginary longitudinal fiber in the upper side of the beam will be in compression (negative strain), and an imaginary fiber in the lower side of the beam will be in tension (positive strain). It is reasonable to conclude that somewhere in between a longitudinal fiber will have no strain, and therefore no axial stress. If the beam has a vertical axis of symmetry, all zero strain lines will form a cylindrical surface perpendicular to the plane of bending, called *neutral plane of bending*. If ρ is the radius of the circle determined by the neutral plane, the length L' of a fiber passing in a point of the cross-section with coordinate y with respect to the neutral plane is (Figure 2.3.5b).

$$L' = (\rho - y)\theta$$

Because the undeformed length of the fiber is $L = \rho\theta$, we have for the strain of the deformed fiber

$$\epsilon = \frac{L' - L}{L} = -\frac{y}{\rho}$$

Consequently, the stress in a point of coordinate y in any cross-section of the beam is

$$\sigma = E\epsilon = -\frac{E}{\rho}y \quad (2.3.18)$$

The equilibrium of forces acting on a cross-section is zero, resulting in the following expression:

$$0 = \int_A \sigma dA = -\frac{E}{\rho} \int_A y dA$$

where A is the area of the cross-section of the beam. This leads us to conclude that the neutral plane of bending passes at the centroid of the cross section.

The equilibrium of moments acts on the cross-section results in

$$M = - \int_A y \sigma A = \frac{E}{\rho} \int_A y^2 dA = \frac{EI_z}{\rho} \quad (2.3.19)$$

where I_z is the moment of inertia (or second moment) of the cross-section. Combining equation 2.3.21 with 2.3.22 results in

$$\sigma = -\frac{My}{I_z} \quad (2.3.20)$$

FIGURE 2.3.6 Transverse loading of a beam.

2.3.2.3 Transverse Loading of Beams

A beam subjected to a simple transverse load (Figure 2.3.6a) will bend. Furthermore, if the beam is cut (Figure 2.3.6b) and free-body diagrams of the remaining sections are constructed, then a shear force V and a moment M must be applied to the cut ends to maintain static equilibrium.

The magnitude of the shearing force and the moment can be determined from the conditions of static equilibrium of the beam section. For the cut shown in Figure 2.3.6b, the shear force and the moment on the left-hand section are

$$V = -R_A = (-b/L)P \quad (2.3.21)$$

$$M = R_A x = (b/L)Px \quad (2.3.22)$$

If the cut had been to the right of the point of application of load P , then the shear force and the moment on the left-hand section would be

$$V = -R_A + P = (-b/L)P + P = (a/L)P \quad (2.3.23)$$

$$M = R_A x - P(x - a) = P \left(\frac{bx}{L} - x + a \right) = \frac{a}{L}P(L - x) \quad (2.3.24)$$

In the loading configuration of Figure 2.3.6, the beam will bend in the concave upward direction, thus putting the lowermost fiber in tension and the uppermost fiber in compression. The magnitude of this axial stress is

$$\sigma_x = -\frac{My}{I_z} \quad (2.3.25)$$

The position of the centroidal axis of common areas is given in Table 2.3.1. The areal moments of inertia about any axis, w for instance, is defined by

$$I_w = \int_A r^2 dA \quad (2.3.26)$$

where A is the cross-sectional area of the body and r is the perpendicular distance from axis w to the differential element of area dA . Values for the areal moments of inertia of common cross-sections are given in Table 2.3.1.

The beam is also subject to a shear stress that varies over the beam cross-section.

$$\tau_{xy} = \frac{VQ}{I_z b} \quad (2.3.27)$$

where b is the width of the beam. The moment area about the z axis Q is defined as

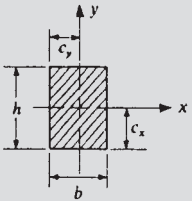

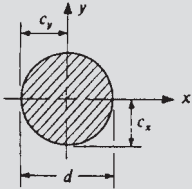

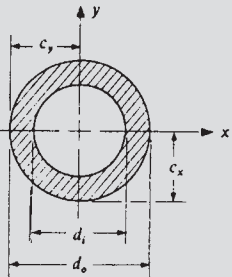

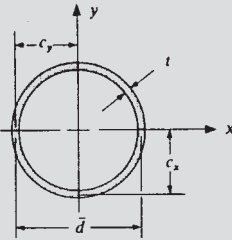

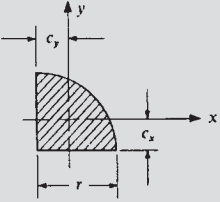

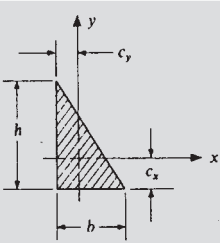

$$Q = \int_{y_0}^{y_{\max}} y dA \quad (2.3.28)$$

where y_0 is the location of the shear stress.

Example 2.3.2

Assuming that the beam in Figure 2.3.6 has a rectangular cross-section with a height of 1 ft and a width of 3 in. and given that $L = 10$ ft, $a = 4$ ft, and $P = 1,000$ lb, what are the maximum values of the shear and tensile stresses within the beam?

TABLE 2.3.1 Properties of Cross-Sections

Section		Area	Centroid	Area Moments of Inertia
Rectangle		bh	$c_x = \frac{h}{2}$ $c_y = \frac{b}{2}$	$I_x = \frac{bh^3}{12}$ $I_y = \frac{hb^3}{12}$
Circle		$\frac{\pi d^2}{4}$	$c_x = \frac{d}{2}$ $c_y = \frac{d}{2}$	$I_x = \frac{\pi d^4}{64}$ $I_y = \frac{\pi d^4}{64}$ $I_z = J = \frac{\pi d^4}{32}$
Thick-walled tube		$\frac{\pi}{4} (d_o^2 - d_i^2)$	$c_x = \frac{d_o}{2}$ $c_y = \frac{d_o}{2}$	$I_x = \frac{\pi}{64} (d_o^4 - d_i^4)$ $I_y = \frac{\pi}{64} (d_o^4 - d_i^4)$ $I_z = J = \frac{\pi}{32} (d_o^4 - d_i^4)$
Thin-walled tube ($\bar{d} \gg t$)		$\pi \bar{d} t$	$c_x = \frac{\bar{d}}{2}$ $c_y = \frac{\bar{d}}{2}$	$I_x = \frac{\pi}{8} \bar{d}^3 t$ $I_y = \frac{\pi}{8} \bar{d}^3 t$ $I_x = J = \frac{\pi}{4} \bar{d}^3 t$
Circular quadrant		$\frac{\pi}{4} r^2$	$c_x = \frac{4r}{3\pi}$ $c_y = \frac{4r}{3\pi}$	$I_x = \left(\frac{\pi}{16} - \frac{4}{9\pi} \right) r^4$ $I_y = \left(\frac{\pi}{16} - \frac{4}{9\pi} \right) r^4$ $P_{xy} = \left(\frac{1}{8} - \frac{4}{9\pi} \right) r^4$
Triangle		$\frac{1}{2} bh$	$c_x = \frac{h}{3}$ $c_y = \frac{b}{3}$	$I_x = \frac{bh^3}{36}$ $I_y = \frac{hb^3}{36}$ $P_{xy} = -\frac{b^2 h^2}{72}$

Tensile stress. The maximum moment occurs at the point of application of the load P and has the value

$$M = \frac{ba}{L} = \frac{(4)(6)}{10} 1,000 = 2,400 \text{ ft}\cdot\text{lb} = 28,800 \text{ in}\cdot\text{lb}$$

The areal moment of inertia of the beam can be found from Table 2.3.1 as

$$I_z = \frac{1}{12} bh^3 = \frac{1}{12} (3)(12^3) = 432 \text{ in}^4$$

The maximum tensile stress occurs at the outer fiber of the beam (at $y = -6$ in.) and has the value

$$\sigma_{x_{\max}} = -\frac{My}{I_z} = -\frac{(28,800)(-6)}{432} = 400 \text{ lb/in}^2$$

Shear stress. For a rectangular cross-section, the maximum value of Q occurs at the neutral axis, and, because the width b of the beam is a constant 3 in., the maximum value of the shear stress occurs at the neutral axis.

$$Q = \int_0^6 yb \, dy = \frac{1}{2} by^2 \Big|_0^6 = \frac{1}{2} (3)(6)^2 = 54 \text{ in}^3$$

$$V = -\frac{4}{10} \times 1,000 = -400 \text{ lb}$$

$$\tau_{xy} = \frac{(-400)(54)}{(3)(432)} = -16.67 \text{ lb/in}^2$$

Thin-walled pressure vessels. A thin-walled pressure vessel is one in which the wall thickness t is small compared to the local radius of curvature r . At a point in the wall of the vessel where the radius of curvature varies with the direction, the wall stresses are

$$\frac{\sigma_\theta}{r_\theta} + \frac{\sigma_\alpha}{r_\alpha} = \frac{p}{t} \quad (2.3.29)$$

where p is the net internal pressure and θ and α indicate any two orthogonal directions tangent to the vessel surface at the point in question. For a spherical vessel, $r_\theta = r_\alpha = r$, and Equation 2.3.29 reduces to

$$\sigma_\theta = \sigma_\alpha = \frac{Pr}{2t} \quad (2.3.30)$$

For a cylindrical vessel, the radius of curvature in the axial direction is infinite, and the stress in the direction of the circumference, called the *hoop stress*, is

$$\sigma_\theta = \frac{Pr}{t} \quad (2.3.31)$$

The stress in the axial direction in a cylindrical vessel is found by taking a cross-section perpendicular to the

longitudinal axis and imposing the conditions of static equilibrium. This yields

$$\sigma_z = \frac{Pr}{2t} \quad (2.3.32)$$

2.3.3 Prediction of Failure

For most practical purposes, the onset of plastic deformation constitutes failure. In an axially loaded part, the yield point is known from testing (see Tables 2.3.2 through 2.3.5), and failure prediction is no problem. However, it is often necessary to use uniaxial tensile data to predict yielding due to a multidimensional state of stress. Many failure theories have been developed for this purpose. For elastoplastic materials (steel, aluminum, brass, etc.), the *maximum distortion energy theory* or *von Mises theory* is in general application. With this theory the components of stress are combined into a single effective stress, denoted as σ_e , which can be compared to known data for uniaxial yielding. The ratio of the measure yield stress to the effective stress is known as the factor of safety.

$$\sigma_e = \left\{ \frac{1}{2} [(\sigma_x - \sigma_y)^2 + (\sigma_x - \sigma_z)^2 + (\sigma_y - \sigma_z)^2 + 6(\tau_{xy}^2 + \tau_{yz}^2 + \tau_{xz}^2)] \right\}^{1/2} \quad (2.3.33)$$

For brittle materials such as glass or cast iron, the maximum shear-stress theory is usually applied.

Example 2.3.3

A cylindrical steel pressure vessel (AISI SAE 1035, cold rolled) with a wall thickness of 0.1 in. and an inside diameter of 1 ft is subject to an internal pressure of 1,000 psia and a torque of 10,000 ft·lb (see Figure 2.3.7). What is the effective stress at point A in the wall? What is the factor of safety in this design?

Hoop stress:

$$\sigma_\theta = \frac{(1,000 \text{ psi})(6 \text{ in.})}{(0.1 \text{ in.})} = 60,000 \text{ psi}$$

Axial stress:

$$\sigma_z = \frac{(1,000 \text{ psi})(6 \text{ in.})}{2(0.1 \text{ in.})} = 30,000 \text{ psi}$$

Torsion:

$$J = \pi/2(6.05^4 - 6.00^4) = 68.71 \text{ in}^4$$

$$\tau_{z\theta} = \frac{10,000 \text{ ft}\cdot\text{lb} \cdot 12 \text{ in.} \cdot 6.05 \text{ in.}}{|ft|68.71 \text{ in}^4} = 10,566 \text{ psi}$$

TABLE 2.3.2 Mechanical Properties of Metals and Alloys

No.	Material	Nominal composition				Form and condition	Typical mechanical properties				Comments
							Yield strength (0.2% offset), 1000 lb/sq in.	Tensile strength, 1000 lb/sq in.	Elongation, in 2 in., %	Hardness, Brinell	
FERROUS ALLOYS											
Ferrous alloys comprise the largest volume of metal alloys used in engineering. The actual range of mechanical properties in any particular grade of alloy steel depends on the particular history and heat treatment. The steels listed in this table are intended to give some idea of the range of properties readily obtainable. Many hundreds of steels are available. Cost is frequently an important criterion in the choice of material; in general the greater the percentage of alloying elements present in the alloy, the greater will be the cost.											
IRON

CAST IRONS AND CAST STEELS											
These alloys are used where large and or intricate-shaped articles are required or where over-all dimensional tolerances are not critical. Thus the article can be produced with the fabrication and machining costs held to a minimum. Except for a few heat-treatable cast steels, this class of alloys does not demonstrate high-strength qualities.

SUPER ALLOYS											
<p>The advent of engineering applications requiring high temperature and high strength, as in jet engines and rocket motors, has led to the development of a range of alloys collectively called super alloys. These alloys require excellent resistance to oxidation together with strength at high temperatures, typically 1800°F in existing engines. These alloys are continually being modified to develop better specific properties, and therefore entries in this group of alloys should be considered "fluid." Both wrought and casting-type alloys are represented. As the high temperature properties of cast materials improve, these alloys become more attractive, since great dimensional precision is now attainable in investment castings.</p>

ALUMINUM ALLOYS											
Although the strength of aluminum alloys is in general less than that attainable in ferrous alloys or copper-base alloys, their major advantage lies in their high strength-to-weight ratio due to the low density of aluminum. Aluminum alloys have good corrosion resistance for most applications except in alkaline solutions.											
43	3003 ASTM B221	Cu	0.12	Al bal.		Annealed-O	6	16	40	28	Good formability, weldable, medium strength; chemical equipment

Because of their corrosion resistance and the fact that copper alloys have been used for many thousands of years, the number of copper alloys available is second only to the ferrous alloys. In general copper alloys do not have the high-strength qualities of the ferrous alloys, while their density is comparable. The cost per strength-weight ratio is high; however, they have the advantage of ease of joining by soldering, which is not shared by other metals that have reasonable corrosion resistance.

MAGNESIUM ALLOYS

Because of their low density, these alloys are attractive for use where weight is at a premium. The major drawback to the use of these alloys is their ability to ignite in air (this can be a problem in machining); they are also costly. Magnesium alloys are used in both the wrought and die-cast forms, the latter being the most frequently used form.

TITANIUM ALLOYS																	
The main application for these alloys is in the aerospace industry. Because of the low density and high strength of titanium alloys, they present excellent strength-to-weight ratios.																	
95	Commercial titanium ASTM B265-58T	Ti	99.4			Annealed at 1100 to 1350°F (593 to 732°C)	70	80	20	—	Moderate strength, excellent fabricability; chemical industry pipes						
96	Titanium alloy ASTM B265 58T 5 Ti 6 Al 4V					Water-quenched from 1750°F (954°C); aged at 1000 F (538 C) for 2 hr	160	170	13	—	High-temperature strength needed in gas-turbine compressor blades						
97	Titanium alloy Ti 4 Al 4Mn					Water-quenched from 1450°F (788°C); aged at 900°F (482°C) for 8 hr	170	185	13	—	Aircraft forgings and compressor parts						
98	Ti Mn alloy ASTM B265 58T 7	Fe	0.5	<i>Ti bal.</i>		Sheet	140	150	18	—	Good formability, moderate high-temperature strength; aircraft skin						
		Mn	7.0	8.0													

ZINC ALLOYS

A major use for these alloys is for low-cost die-cast products such as household fixtures, automotive parts, and trim.

99	Zinc ASTM B69	Cd Pd	0.35 0.08	Zn bal.		Hot-rolled	—	19.5	65	38	Battery cans, grommets lithographer's sheet
100	Zilloy-15	Cu Mg	1.00 0.010	Zn bal.		Hot-rolled Cold-rolled	— —	29 36	20 25	61 80	Corrugated roofs, articles with maximum stiffness
101	Zilloy 40	Cu	1.00	Zn bal.		Hot-rolled Cold-rolled	— —	24 31	50 40	52 60	Weatherstrip, spun articles
102	Zamac-5 ASTM 25	Zn (99.99% pure remainder) Mg 0.03–0.08		Al Cu	3.5–4.3 0.75 1.25	Die-cast	—	47.6	7	91	Die-casting for automobile parts, padlocks; used also for die material

ZIRCONIUM ALLOYS

These alloys have good corrosion resistance but are easily oxidized at elevated temperatures in air. The major application is for use in nuclear reactors.

103	Zirconium, commercial	O ₂ Hf	0.07 1.90	C Zn bal.	0.15	Annealed	40	65	27	B80 (Rockwell)	
104	Zircaloy 2	Hf Fe Su	0.02 0.15 1.46	Ni Other Zn bal.	0.05 0.25	Annealed	50	75	22	B90 (Rockwell)	Nuclear power-reactor cores at elevated temperatures

TABLE 2.3.4 Allowable Unit Stresses for Lumber
SPECIES, SIZES, ALLOWABLE STRESSES, AND MODULUS OF ELASTICITY
Normal Loading Conditions: Moisture Content Not Over 19 Percent

Species and grades (visual grading)*	Sizes, nominal	Typical grading agency 1968*	Allowable unit stresses, psi*				Modulus of elasticity, psi
			Extreme fiber in bending	Tension parallel to grain	Compression perpendicular	Compression parallel	
Idaho white pine	2×4	W	850	500	240	1,050	1,120,000
	2×6 and wider		1,200	800	240	1,100	1,400,000
Ponderosa pine	2×4	W	850	500	280	1,000	950,000
	2×6 and wider		1,150	800	280	1,000	1,190,000
Lodgepole pine	2×4	W	1,400	850	250	1,100	1,030,000
	4×4		1,350	800	240	1,050	1,000,000
Southern pine	2×4	S	1,810	1,190	405	1,190	1,800,000
	4×4	S	1,810	1,190	405	1,300	1,700,000
Douglas fir	2×4	W	1,700	1,000	385	1,510	1,800,000
	2×6 and wider	W	1,900	1,250	385	1,800	1,810,000
Western hemlock	2×4	W	1,450	850	245	1,350	1,210,000
	2×6 and wider		1,650	1,100	245	1,450	1,520,000
Western spruce	2×4	W	1,150	650	220	950	920,000
	2×6 and wider		1,050	700	220	1,000	1,150,000
Wester cedar	2×4	W	850	500	295	1,150	860,000
	2×6 and wider		1,200	800	295	1,150	1,070,000
Redwood (unseasoned)	2" and 4" "Construction"	R	1,640	—	305	1,190	1,240,000

Note: Allowable unit stresses in horizontal sheat are in the range of 75 to 150 psi.

*There is no single grade designation that applies to all lumber. Values in the table apply approximately to "No. 1," although this designation is often modified by terms such as dense or dry. For grades better than No. 1, such terms as structural, heavy, select, dense, etc. are used. Lower grades are No. 2, No. 3 factory, light industrial etc., but there are seldom more than four grades of a single size in a given species. The allowable stresses are for "repetitive member" users.

*Most lumber is graded by the following agencies, although there are other grading organizations.

W = Western Wood Products Association

S = Southern Pine Inspection Bureau

R = Redwood Inspection Service

*Load applied to joists or planks. For beam or stringer grades, stresses are for load applied to the narrow face.

*For engineered uses the allowable stresses are slightly lower; for kiln-dried lumber slightly higher. For short-term loads, such as wind, earthquake, or impact, higher unit stresses are allowed.

2.4 THERMODYNAMICS

2.4.1 Introduction

Historically, the word thermodynamics stems from the Greek words *therme* (heat) and *dynamis* (force), and the discipline grew out of considerations involving the motive power of heat (i.e., the capacity of hot bodies to produce work). Thermodynamics involves terms and concepts that often are used in a nontechnical setting. In thermodynamics, these terms are abstractions of the ordinary concepts and have precise meanings that may differ drastically from everyday usage. It is therefore necessary to begin the discussion of thermodynamics by defining some of these words and concepts.

System. A system is the particular part of the observable universe in which an investigator is interested. Typical thermodynamic systems are a quantity of a gas, a liquid

and its vapor, a mixture of two liquids, a solution, and a crystalline solid.

Surroundings. Everything in the observable universe except the system is called the surroundings.

Boundary. A boundary separates the system from the surroundings. Ideally, boundaries are mathematical surfaces that are endowed with various ideal properties, such as rigidity and impermeability. Real boundaries only approximate the properties or ideal thermodynamic boundaries. A system enclosed by a boundary impermeable to matter is called a *closed system*, and one enclosed by a permeable boundary is called an *open system*.

Thermodynamic Variables. Thermodynamic variables are quantities found from experimentation to be necessary or convenient to specify to give a macroscopic description of a system. Most such quantities are drawn from other branches of science or engineering; accordingly, no detailed, all-inclusive definitions of thermodynamic variables can be given.

State of a System. When all of the variables necessary to describe a system are specified, the *state of the system* is said to be specified. The specification of the state of a system gives no information on the process by which the system was brought to this state.

Processes and Cycles. When one or more properties of a system change, the system is said to have undergone a *change in state*. The path of the succession of states through which the system passes is called the *process*. When a system in a given initial state goes through a number of different changes of state or processes and finally returns to its initial state, the system has undergone a *cycle*.

Equilibrium. A fundamental concept in thermodynamics is that of equilibrium. The key idea is that the variables describing a system in equilibrium do not change with time. This idea does not form a sufficient basis for a definition of equilibrium, because it fails to exclude a number of steady-state processes (principally various types of flow processes) that cannot be handled by classic thermodynamic methods. To exclude these, a more restrictive definition is used: *A system is in equilibrium if and only if it is in a state from which no change is possible without net changes in the surroundings*. In steady-state processes, there must be continual changes in the surroundings to maintain the variables of the system at constant values. Classic thermodynamics deals only with systems in equilibrium.

Equilibrium is an abstraction, and real systems are never strictly in equilibrium, but so long as the variables do not change measurably during the time spent making a measurement on the system, the system can be considered to be in equilibrium, and thermodynamic reasoning can be applied to it. A system may be in equilibrium with respect to some variables but not with respect to others.

2.4.2 Fundamentals

Thermodynamics is the science that deals with “energy in transit” and is quantified in terms of heat and work and the properties of substances that bear a relation to heat and work. The science of thermodynamics deals very broadly with concepts of how systems and processes work, why some systems and processes cannot work, and why some systems and processes do not work as intended. Like all sciences, the basis of thermodynamics is experimental observation. In thermodynamics, these findings have been formalized into certain basic laws, which are known as the first, second, and third law of thermodynamics. The zeroth law of thermodynamics, which is the definition of the thermodynamic temperature scale, precedes the first law. These laws of thermodynamics can be summarized as follows:

<i>Zeroth Law of Thermodynamics</i>	When two objects or bodies have equality of temperature with a third body, they have equality of temperature with each other.
<i>First Law of Thermodynamics</i>	The law of conservation of energy applies to all thermodynamic systems.
<i>Second Law of Thermodynamics</i>	This law deals with a quantity (entropy) that serves as a means of determining whether a process is possible. One way of stating this law is as follows: <i>It is impossible to make any transformation whose only final result is the exchange of a non-zero amount of heat with less than two heat reservoirs and the appearance of a positive amount of work in the surroundings.</i>
<i>Third Law of Thermodynamics</i>	This law deals with the entropy of substances at the temperature of absolute zero. In essence, it states that the entropy of a perfect crystal is zero at absolute zero.

From a purely thermodynamic point of view, the third law is in a different class from the first and second laws. Its purely thermodynamic content is rather limited, and it is difficult to state the law so that there do not seem to be several experimentally observable exceptions. The second law is not believed to have any macroscopic exceptions; for example, it is not believed possible to construct a perpetual motion machine. However, there are experimental exceptions to many of the common statements of the third law. Some care is required to frame the statement so that it is free of exceptions and does not claim anything that is not in principle susceptible of measurement on a macroscopic level. The following is the most satisfactory statement from a purely thermodynamic point of view:

The first and second laws of thermodynamics are applicable down to the limit of absolute zero, provided that at this limit entropy changes vanish for any reversible process.

This statement of the third law defines only entropy *differences* at absolute zero, not absolute values. Just as the absolute value of energy is undefined and only energy differences can be measured, so can only entropy differences be measured. However, if entropy values for all reversibly connected states are equal at absolute zero, this entropy value may as well be taken to be zero for convenience.

2.4.3 Units of Energy

A concept in the study of thermodynamics is the concept of energy. In classic thermodynamics, energy is a fundamental quantity, such as mass or force, and as is often the case with such concepts, it is difficult to define. A general definition that results in analytical predictions that can be verified by experimentation is energy is the property of a system to produce an effect. However, the absolute value of energy cannot be defined or calculated; only the changes in energy as a system transitions from one state to another state has any significance. Energy can be stored within a system in various macroscopic forms and can also be *transformed* from one form to another, such as potential energy and kinetic energy exchanges. It can be *transferred* between systems by various modes of heat transfer across the boundary or by the work associated with the motion of the boundary.

Work has units of force times distance, with the units of kinetic energy being the same as work. In the SI (Système International d’Unités) system, work and kinetic energy have units of newton (N)–meters (m), which is the definition of joules (J). In the English engineering system, work and kinetic energy have units of pound force (lbf)–foot (ft).

Heat transfer is a transit phenomenon and can be thought of as energy transfer across the boundary per unit time. In the SI system of units, heat transfer is measured in watts (W), which is the number of joules per unit time crossing the boundary. In the English engineering system of units, heat transfer is usually measured in British thermal units per hour or Btu/hr.

When working in the SI system and equating the heat transfer rate with the rate of doing work, the units are entirely consistent, because both are measured in joules/s, which are defined as watts. In the English engineering system, however, a conversion factor is required to maintain consistency of units because the heat transfer rate is specified in Btu/s but the rate of doing work is specified in ft-lbf/s. In addition, 550 ft-lbf/s is called 1 horsepower (hp). This conversion factor between Btu and ft-lbf is determined from the definition of Btu:

$$1 \text{ Btu} = 778.17 \text{ ft-lbf} \quad (2.4.1)$$

This conversion factor is often referred to as the mechanical equivalent of heat. The following table expresses relationships between several other useful energy units:

$$\begin{aligned}
 1 \text{ J} &= 0.3756 \text{ ft-lbf} \\
 1 \text{ kJ} &= 0.9478 \text{ Btu} \\
 1 \text{ kJ/kg} &= 0.42992 \text{ Btu/lbm} \\
 1 \text{ ft-lbf} &= 1.35562 \text{ J} \\
 1 \text{ kcal} &= 4.1868 \text{ kJ} \\
 1 \text{ W} &= 1 \text{ J/s} = 3.413 \text{ Btu/hr} \\
 1 \text{ hp} &= 550 \text{ ft-lbf/s} \\
 1 \text{ hp} &= 2545 \text{ Btu/h} \\
 1 \text{ hp} &= 0.7457 \text{ kW}
 \end{aligned}$$

A = work function (Helmholtz free energy),
 Btu/lb_m or Btu
 C = heat capacity, Btu/lb_m°R
 C_p = heat capacity at constant pressure
 C_v = heat capacity at constant volume
 F = (Gibbs) free energy, Btu/lb_m or Btu
 g = acceleration due to gravity = 32.174 ft/s²
 g_c = conversion factor between force and
 mass = 32.174 (lb_m)(ft/s²)/lb_f
 h, H = enthalpy or heat content, Btu/lb_m or Btu
 κ = ratio C_p/C_v
 Mw = molecular weight, lb_m/lb_m-mole
 m, M = mass of fluid, lb_m
 m, M = mass flow rate, lb_m/s
 P = absolute pressure, lb_f/ft²
 P_s = entropy production rate, Btu/°R.s
 Q = heat transferred to system across
 a system boundary, Btu/lb_m or Btu
 Q = rate of heat transfer, Btu/s
 R = universal gas constant, lb_f - ft³/mole . °R
 s, S = entropy, Btu/lb_m°R or Btu/°R
 T = absolute temperature, °R
 u, U = internal energy, Btu/lb_m or Btu
 V = volume, ft³/lb_m or ft³
 v = flow velocity, ft/s
 W = work done by a system against its
 surroundings, Btu/lb_m or Btu
 Z = height from center of gravity of a fluid
 mass to a fixed base level, ft

2.4.4 The First Law of Thermodynamics

The differential form of the first law as applied to a *closed* system, for which there is no exchange of matter between the system and its surroundings, is given by

$$dU = \delta Q - \delta W \quad (2.4.2)$$

where dU represents an infinitesimal increase in the internal energy of the system, δQ is the heat absorbed by the system from its surroundings, and δW is the work done by the system on its surroundings. The state of a system is defined by its temperature, pressure, specific volume, and chemical composition. The change in internal energy expressed by Equation 2.4.2 depends only on the difference between the final and initial states and not upon the process or processes that occurred during the change. The heat and work terms depend on the process path. For a change from a state A to a state B, the first law becomes

$$\Delta U = U_B - U_A = Q - W \quad (2.4.3)$$

Work interchange between a system and its surroundings can take on any of a variety of forms including mechanical shaft work, electrical work, magnetic work, surface tension, etc. For many applications, the only work involved is that of compression or expansion against the surroundings, in which case the work term in Equation 2.4.2 becomes

$$\delta W = PdV$$

or

$$W = \int_{V_A}^{V_B} PdV \quad (2.4.4)$$

where V_B is the final volume and V_A the initial volume of the system, and P is the system pressure. Thus, for a *constant pressure* process,

$$W = P\Delta V = P(V_B - V_A) \quad (\text{constant pressure process}) \quad (2.4.5)$$

or, combining Equations 2.4.3 and 2.4.4.

$$\Delta U = U_B - U_A = Q - PV_B + PV_A \quad (2.4.6)$$

or

$$Q = (U_B + PV_B) - (U_A + PV_A) \quad (2.4.7)$$

The combination of properties ($U + PV$) occurs so frequently in thermodynamics that it is given a special symbol, H , and termed the *enthalpy* or *heat content* of the system. Thus Equation 2.4.7 can be written as

$$\begin{aligned}
 Q &= \Delta(U + PV) = H_B - H_A \\
 &= \Delta H \quad [\text{constant pressure process}] \quad (2.4.8)
 \end{aligned}$$

Enthalpy is a *property* of the system independent of the path selected. Processes can be conveniently represented graphically. For example, a P - V diagram can be used to illustrate the work done when a system undergoes a change in state (see Figure 2.4.1) In each of the cases depicted in Figure 2.4.1, the work is equal to the shaded area under the P - V curve as shown.

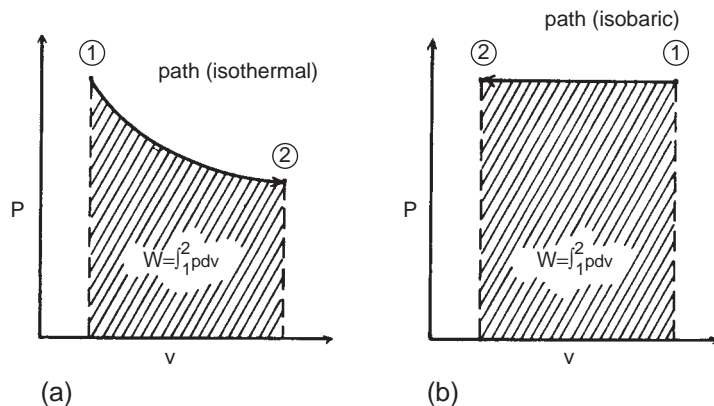

FIGURE 2.4.1 P-V process diagrams: (a) isothermal expansion; (b) isobaric compression.

Because the mass is fixed for a closed system, the equations in this discussion will be valid for the entire mass (M) or on a unit mass basis.

2.4.5 The First Law of Thermodynamics Applied to Open Systems

An open system is one which exchanges mass with its surroundings in addition to exchanging energy. For open systems, the first law is formulated from a consideration of the conservation of energy principle which can be stated as follows:

$$\begin{aligned} & \left(\begin{array}{c} \text{Net increase} \\ \text{of stored energy} \\ \text{of system} \end{array} \right) \\ &= \left(\begin{array}{c} \text{Stored} \\ \text{energy} \\ \text{of mass} \\ \text{entering} \end{array} \right) - \left(\begin{array}{c} \text{Stored} \\ \text{energy} \\ \text{of mass} \\ \text{leaving} \end{array} \right) + \left(\begin{array}{c} \text{Net energy} \\ \text{entering as} \\ \text{heat and all} \\ \text{forms of work} \end{array} \right) \end{aligned}$$

Consider the arbitrary open thermodynamic system illustrated in Figure 2.4.2. The foregoing statement of the first law for this open system can be written as

$$\begin{aligned} & m_f U_f - m_i U_i + \frac{m_f v_f^2 - m_i v_i^2}{2g_c} + \frac{g}{g_c} (m_f Z_f - m_i Z_i) \\ &= \int \left(H_1 + \frac{v_1^2}{2g_c} + \frac{g}{g_c} Z_1 \right) \delta m_1 \\ & \quad - \int \left(H_2 + \frac{v_2^2}{2g_c} + \frac{g}{g_c} Z_2 \right) \delta m_2 + Q - W \end{aligned} \quad (2.4.9)$$

where δm refers to a differential mass of fluid, and the subscripts f and i refer to the entire system in its final state and initial state, respectively. Clearly, for a closed

system defined as one which exchanges no mass with its surroundings, Equation 2.4.9 reduces to Equation 2.4.3.

For an open system at *steady state*, as in the case of turbines, compressors, pumps, etc., Equation 2.4.9 can be written (for unit mass flow rate) as

$$\begin{array}{ccccccc} \Delta H & + & \frac{\Delta v^2}{2g_c} & + & \frac{g}{g_c} \Delta Z & = & Q & - & W_{\text{net}} \\ \uparrow & & \uparrow & & \uparrow & & \uparrow & & \uparrow \\ \text{Increase} & & \text{Increase} & & \text{Increase} & & \text{Net heat} & & \text{Net work} \\ \text{in enthalpy} & & \text{in kinetic} & & \text{in potential} & & \text{exchanged} & & \text{exchanged} \\ & & \text{energy} & & \text{energy} & & \text{with} & & \text{with} \\ & & & & & & \text{surroundings} & & \text{surroundings} \end{array} \quad (2.4.10)$$

where W_{net} is the net useful work (or shaft work) done by the fluid.

Example 2.4.1. Isobaric Compression of an Ideal Gas

One pound-mole of an ideal gas is compressed at a constant pressure of 1 atm in a piston-like device from an initial volume of 1.5 ft³ to a final volume of 0.5 ft³. The internal energy is known to decrease by 20 Btu. How much heat was transferred to or from the gas?

FIGURE 2.4.2 An open thermodynamic system.

2.4.5.0.1 Solution

This is an isobaric (constant pressure) process in a closed system. Equation 2.4.3 applies.

$$\begin{aligned} Q &= \Delta U + W = \Delta U + \int_{V_1}^{V_2} P dV \\ &= -20 \text{ Btu} + P(V_2 - V_1) \\ &= -20 \text{ Btu} + (1 \text{ atm}) \left(\frac{14.7 \text{ lb}_f}{\text{in.}^2 \text{ atm}} \right) \left(\frac{144 \text{ in.}^2}{\text{ft}^2} \right) \\ &\quad \times (0.5 \text{ ft}^3 - 1.5 \text{ ft}^3) \left(\frac{1 \text{ Btu}}{778 \text{ ft. lb}_f} \right) \\ &= -20 \text{ Btu} - 2.72 \text{ Btu} \\ &= -22.72 \text{ Btu} \end{aligned}$$

Because Q is negative, 22.72 Btu of heat were transferred from the gas to its surroundings.

Example 2.4.2. Hydroelectric Power System

A hydroelectric power plant proposes to use 1500 ft³/s of river water to generate electricity. The water enters the system at 1 atm and 50°F and is discharged at 1 atm and 50.4°F after passing through a turbine generator. The discharge point is 600 ft below the inlet. The increase in enthalpy of the water is known to be 0.36 Btu/lb_m. Assuming 70% efficiency for the conversion, what power output can be expected from the power plant?

2.4.5.0.2 Solution

The following assumptions pertain to this *open* system:

1. Steady-state flow.
2. No heat transferred between system and surroundings.
3. Change in kinetic energy of the flow streams is negligible.

With these assumptions, we take as a reference point the discharge level of the water, and apply Equation 2.4.10. Thus, $Z_2 = 0$, $Z_1 = 600$ ft and the energy balance becomes

$$\Delta H + \frac{g}{g_c} \Delta Z = -W_{\text{net}}$$

where

$$\begin{aligned} \Delta H &= \left(0.36 \frac{\text{Btu}}{\text{lb}_m} \right) \left(\frac{1,500 \text{ ft}^3}{\text{s}} \right) \left(\frac{62.4 \text{ lb}_m}{\text{ft}^3} \right) \left(\frac{3,600 \text{ s}}{\text{hr}} \right) \\ &= 1.213 \times 10^8 \text{ Btu/hr} \\ &= 35,553 \text{ kW} \end{aligned}$$

and

$$\frac{g}{g_c} \Delta Z = \left(\frac{32.2 \text{ ft/s}^2}{32.2 \text{ ft} \cdot \text{lb}_m / \text{lb}_f \cdot \text{s}^2} \right) (0 - 600 \text{ ft}) \left(\frac{1,500 \text{ ft}^3}{\text{s}} \right)$$

$$\begin{aligned} &\times \left(\frac{62.4 \text{ lb}_m}{\text{ft}^3} \right) \left(\frac{3,600 \text{ s}}{\text{hr}} \right) \\ &= -2.599 \times 10^8 \text{ Btu/hr} \\ &= -76,163 \text{ kW} \end{aligned}$$

Therefore,

$$W_{\text{net}} = -35,553 \text{ kW} + 76,163 \text{ kW} = 40,610 \text{ kW}$$

At 70% efficiency, this would yield

$$W_{\text{actual}} = (0.70)(40,610) = 28,427 \text{ kW} = 28.427 \text{ MW}$$

2.4.6 Entropy and the Second Law

The second law of thermodynamics provides a basis for determining whether or not a process is possible. It is concerned with availability of the energy of a given system for doing work. All natural systems proceed towards a state of equilibrium and, during any change process, useful work can be extracted from the system. The property called *entropy*, and given the symbol S or s , serves as a quantitative measure of the extent to which the energy of a system is “degraded” or rendered unavailable for doing useful work.

For any *reversible process*, the sum of the changes in entropy for the system and its surroundings is zero. All natural or *real* processes are *irreversible* and are accompanied by a net *increase* in entropy.

Several useful statements have been formulated concerning the second law that are helpful in analyzing thermodynamic systems, such as:

- No thermodynamic cycle can be more efficient than a reversible cycle operating between the same temperature limits.
- The efficiency of all reversible cycles absorbing heat from a single-constant higher temperature and rejecting heat at a single-constant lower temperature must be the same.
- Every real system tends naturally towards a state of maximum probability.
- For any actual process, it is impossible to devise a means of restoring to its original state every system participating in the process.
- For any reversible process, the increase in entropy of any participating system is equal to the heat absorbed by that system divided by the absolute temperature at which the transfer occurred. That is, for a system, i ,

$$dS_i = \frac{\delta Q_i}{T_i} \quad (\text{reversible processes}) \quad (2.4.11)$$

Alternatively, for an ideal reversible process, the sum of all the changes in entropy must be zero or

$$\sum dS_i = \sum \frac{\delta Q_i}{T_i} = 0 \quad (\text{reversible processes}) \quad (2.4.12)$$

Because all *real* processes are *irreversible* as a result of friction, electrical resistance, etc., any processes involving real systems experience an *increase in entropy*. For such systems

$$\sum dS_i > 0 \quad (\text{irreversible processes}) \quad (2.4.13)$$

The entropy change of a system during any process depends only upon its initial and final states and not upon the path of the process by which it proceeds from its initial to its final state. One can devise a reversible idealized process to restore a system to its initial state following a change and thereby determine $\Delta S = S_{\text{final}} - S_{\text{initial}}$. This is one of the most useful aspects of the concepts of a reversible process.

2.4.7 Entropy Production: Flow Systems

In general, for all real processes, there is a net production of entropy and Equation 2.4.13 applies. Because many practical engineering processes involve open systems, it is useful to develop a generalized expression of the second law applied to such systems.

For the generalized control volume shown in Figure 2.4.3, and entropy balance can be stated as follows:

$$\begin{aligned} & \left(\begin{array}{c} \text{Rate of entropy} \\ \text{in} \end{array} \right) - \left(\begin{array}{c} \text{Rate of entropy} \\ \text{out} \end{array} \right) \\ & + \left(\begin{array}{c} \text{Rate of entropy} \\ \text{production} \end{array} \right) = \left(\begin{array}{c} \text{Rate of entropy} \\ \text{accumulation} \end{array} \right) \\ & \left[\sum_{\text{in}} (\dot{M}S) + \sum_{\text{in}} \frac{\delta \dot{Q}_i}{T_i} \right] - \left[\sum_{\text{out}} \dot{M}S + \sum_{\text{out}} \frac{\delta \dot{Q}_i}{T_i} \right] \\ & + \dot{P}_s = \frac{d(SM)}{dt} \end{aligned} \quad (2.4.14)$$

In Equation 2.4.14, \dot{P}_s is the rate of entropy production within the control volume; symbols with dots refer to the time rate of change of the quantity in question. The second law requires that the rate of entropy production be positive.

$$\dot{P}_s \geq 0 \quad (2.4.15)$$

2.4.8 Heat Capacity

The heat capacity of a substance is extremely important in thermodynamic analysis involving both the first and second laws.

Heat capacity per unit mass is defined by the relationship

$$C \equiv \frac{\delta Q}{dT} \quad (2.4.16)$$

where δQ is the heat absorbed by unit mass of the system over the infinitesimal temperature change, dT .

FIGURE 2.4.3 Generalized control volume for a flow system.

For *constant pressure* when only P–V work is involved, the first law yields

$$C_P = \left(\frac{\partial H}{\partial T} \right)_P \quad (2.4.17)$$

For constant volume

$$C_V = \left(\frac{\partial U}{\partial T} \right)_V \quad (2.4.18)$$

C_P is related to C_V by the following expression:

$$C_P - C_V = \left[P + \left(\frac{\partial U}{\partial V} \right)_T \right] \left(\frac{\partial V}{\partial T} \right)_P \quad (2.4.19)$$

For an ideal gas for which $PV = RT/M_w$, with M_w representing the molecular weight, the enthalpy and internal energy are functions only of temperature and Equation 2.4.19 becomes

$$C_P - C_V = P \left(\frac{\partial V}{\partial T} \right)_P = \frac{R}{M_w} \quad (2.4.20)$$

The ratio of the heat capacity at constant pressure to that at constant volume is

$$\frac{C_P}{C_V} = \kappa \quad (2.4.21)$$

For an ideal gas, this ratio becomes

$$\kappa = 1 + \frac{R}{C_V M_w} \quad (2.4.22)$$

2.4.9 Application of the Second Law

2.4.9.1 Heat Engines

The purpose of a heat engine is to remove heat Q_1 from a thermal reservoir at a higher absolute temperature T_1 ; extract useful work W ; and reject heat Q_2 to a second thermal reservoir at a lower absolute temperature T_2 . The device used to obtain the useful work is the heat engine.

Considering an ideal heat engine as the system, the first law as applied to the engine undergoing a series of reversible changes in a cyclical fashion becomes

$$\sum \Delta U_i = 0, \quad \text{or} \quad W = Q_1 - Q_2 \quad (2.4.23)$$

The second law yields

$$\sum \Delta S_i = 0 \quad \text{or} \quad \frac{Q_1}{T_1} - \frac{Q_2}{T_2} = 0 \quad \text{or} \quad \frac{Q_1}{Q_2} = \frac{T_1}{T_2} \quad (2.4.24)$$

To obtain the fraction of the heat input Q_1 that is converted to useful work, Equations 2.4.23 and 2.4.24 are combined to give

$$\frac{W}{Q_1} = \frac{T_1 - T_2}{T_1} \quad (2.4.25)$$

This important result is called the *Carnot engine efficiency* and yields the *maximum thermal efficiency* that can be achieved by *any* heat engine cycle operating between any two given temperature limits. Heat engines have been proposed to operate within the temperature gradients of the ocean as a means of harnessing the vast amounts of renewable energy available from that source.

2.4.9.2 Heat Pumps

A heat pump, which is the opposite of a heat engine, uses work energy to transfer heat from a cold reservoir to a “hot” reservoir. In households, the cold reservoir is often the surrounding air or the ground while the hot reservoir is the home. For an ideal heat pump system with Q_1 and T_1 referring to the hot reservoir and Q_2 and T_2 referring to the cold reservoir, the work required is, from the first and second laws,

$$\frac{W}{Q_1} = \frac{T_1 - T_2}{T_1} \quad (2.4.26)$$

Application of this result shows that if 100 units of heat Q_1 are needed to maintain a household at 24°C (297°K) by “pumping” heat from the outside surroundings at 0°C (273°K), it would require a minimum of $(24 \times 100/297) = 8.08$ units of work energy.

2.4.9.3 Refrigeration Machines

Refrigerating machines absorb heat Q_2 from a cold reservoir at temperature T_2 , and discharge heat Q_1 , into a “hot” reservoir at T_1 . To accomplish this, work energy must also be absorbed. The minimum required work is obtained as shown before, using the first and second laws:

$$\frac{W}{Q_2} = \frac{T_1 - T_2}{T_1} \quad (2.4.27)$$

2.4.9.4 Reversible Work of Expansion or Compression

Many systems involve only work of expansion or compression of the system boundaries. For such systems the first law is written for unit mass of fluid as the basis:

$$dU = \delta Q - PdV \quad (2.4.28)$$

where $\int_{V_1}^{V_2} PdV$ represents the reversible work of compression or expansion.

From the second law, for a reversible process,

$$dS = \frac{\delta Q}{T} \quad \text{or} \quad \delta Q = TdS \quad (2.4.29)$$

Combining Equations 2.4.28 and 2.4.29 gives

$$dU = TdS - PdV \text{ (reversible, P-V work only)} \quad (2.4.30)$$

2.4.9.5 Reversible Isobaric Processes

The second law is written as

$$\delta Q = TdS$$

but, since the heat capacity $C = \delta Q/dT$, the second law becomes

$$CdT = TdS \quad (2.4.31)$$

For constant pressure processes, the entropy increase is written as

$$dS = C_p \frac{dT}{T} = C_p d(\ln T) \text{ (reversible isobaric process)} \quad (2.4.32)$$

2.4.9.6 Reversible Constant Volume Processes

A constant-volume process is called *isochoric*, and for such processes, the entropy increase is written as

$$dS = C_v \frac{dT}{T} = C_v d(\ln T) \text{ (reversible isochoric process)} \quad (2.4.33)$$

2.4.9.7 Reversible Isothermal Changes: Maximum Work

The variation of entropy with volume and pressure under conditions of constant temperature is determined by using Equation 2.4.30:

$$\left(\frac{\partial U}{\partial V}\right)_T = T \left(\frac{\partial S}{\partial V}\right)_T - P \quad (2.4.34)$$

or rearranging:

$$\left(\frac{\partial S}{\partial V}\right)_T = \frac{1}{T} \left[\left(\frac{\partial U}{\partial V}\right)_T + P \right] \text{ (constant T)} \quad (2.4.35)$$

The variation of entropy with pressure is likewise written as

$$\left(\frac{\partial S}{\partial P}\right)_T = \frac{1}{T} \left[P \left(\frac{\partial V}{\partial P}\right)_T + \left(\frac{\partial U}{\partial P}\right)_T \right] \text{ (constant T)} \quad (2.4.36)$$

or

$$\left(\frac{\partial S}{\partial P}\right)_T = \frac{1}{T} \left[-V + \left(\frac{\partial H}{\partial P}\right)_T \right] \text{ (constant T)} \quad (2.4.37)$$

Combining the first law Equation 2.4.2 with the second law Equation 2.4.11 yields the expression

$$dU = TdS - \delta W = d(TS) - \delta W$$

or

$$\delta W = -d(U - TS)$$

which, upon integration between states 1 and 2, yields

$$W = -\Delta(U - TS) \text{ (reversible isothermal processes)} \quad (2.4.38)$$

The combination of properties $U - TS$ occurs so frequently in thermodynamic analysis that it is given a special name and symbol, namely A , the *work function* or *maximum work* (because it represents the maximum work per unit mass, obtainable during any isothermal reversible change in any given system). Therefore, it is seen that

$$W_{\max} = -\Delta A \text{ (reversible isothermal process)} \quad (2.4.39)$$

Note that the maximum work depends only upon the initial and final states of a system and not upon the path.

2.4.9.8 Maximum Useful Work: Free Energy

The first and second law expressions can be combined and written for constant temperature, constant pressure processes:

$$dU = TdS - \delta W = TdS - PdV - \delta W' \quad (2.4.40)$$

where $\delta W'$ represents all work energy exchanged with the surroundings except P-V work that is written as PdV . Therefore, solving for $\delta W'$ gives

$$-\delta W' = dU + PdV - TdS \quad (2.4.41)$$

or, because both T and P constant,

$$-\delta W' = dU + d(PV) - d(TS)$$

or

$$-\delta W' = -d(U + PV - TS) \quad (2.4.42)$$

By integration this becomes

$$\begin{aligned} W' &= -\Delta(U + PV - TS) \\ &= -\Delta(H - TS) \text{ (constant temperature and pressure)} \end{aligned} \quad (2.4.43)$$

This expression shows that the maximum possible *useful work* (i.e., reversible work) that can be obtained from any process occurring at constant temperature and pressure is a function of the initial and final states only and is independent of the path. The combination of properties $U + PV - TS$

or $H - TS$ occurs so frequently in thermodynamic analysis that it is given a special name and symbol, F , the *free energy* (sometimes called the Gibbs free energy). Using this definition, Equation 2.4.44 is written

$$W'_{\max} = -\Delta F \quad (2.4.44)$$

Because F is a function of temperature and pressure, its differential can be written as

$$dF = \left(\frac{\partial F}{\partial P}\right)_T dP + \left(\frac{\partial F}{\partial T}\right)_P dT \quad (2.4.45)$$

Because $F = U + PV - TS$, we can also write

$$dF = dU + PdV + VdP - TdS - SdT \quad (2.4.46)$$

Using Equation 2.4.30, this becomes

$$dF = VdP - SdT \quad (2.4.47)$$

Comparison with Equation 2.4.45 shows that

$$\left(\frac{\partial F}{\partial P}\right)_T = V \quad (2.4.48)$$

$$\left(\frac{\partial F}{\partial T}\right)_P = -S \quad (2.4.49)$$

Example 2.4.3

An inventor claims to have devised a CO_2 compressor that requires no shaft work. The device operates at steady state by transferring heat from a feed stream of $2 \text{ lb}_m/\text{s}$ of CO_2 at 150 psia and 100°F . The CO_2 is compressed to a final pressure of 500 psia and a temperature of 40°F . Kinetic and potential energy effects are negligible. A cold source

at -140°F “drives” the device at a heat transfer rate of 60 Btu/s . Check the validity of the inventor’s claim.

2.4.9.8.1 Solution

The device will be impossible if it violates either the first or second law of thermodynamics. From Figure 2.4.4 the inlet and outlet properties are

State 1	State 2
$T_1 = 100^\circ\text{F}$	$T_2 = 40^\circ\text{F}$
$P_1 = 150 \text{ psia}$	$P_2 = 500 \text{ psia}$
$h_1 = 315 \text{ Btu/lb}_m$	$h_2 = 285 \text{ Btu/lb}_m$
$S_1 = 1.318 \text{ Btu/lb}_m^\circ\text{R}$	$S_2 = 1.215 \text{ Btu/lb}_m^\circ\text{R}$

Referring to Figure 2.4.5 (process diagram), the first law for this steady-state flow system becomes

$$\dot{M}(h_2 - h_1) + \dot{Q} = (2)(285 - 315) + 60 = 0 \text{ Btu/s}$$

Because energy is not created, the device does not violate the first law. Application of the second law (Equation 2.4.14) yields

$$\begin{aligned} \dot{P}_s &= \dot{M}(S_2 - S_1) + \frac{\dot{Q}_c}{T_c} \\ &= (2)(1.215 - 1.318) + \frac{60}{(-140 + 460)} \\ &= -0.206 + 0.1875 = -0.0185 \text{ Btu/s}\cdot^\circ\text{R} \end{aligned}$$

Because the rate of entropy production is negative, the device violates the second law and is therefore impossible. Note that the device would be theoretically possible if the final pressure were specified as 400 psia or less by the inventor. That is, at $P_2 = 400 \text{ psia}$, $T_2 = 40^\circ\text{F}$, $h_2 = 290$

Thermodynamic properties of carbon dioxide (CO_2). Diagram copy supplied by General Dynamics Corporation, Liquid Carbonic Division. T in $^\circ\text{F}$, h in Btu/lb_m , v in ft^3/lb_m , s in $\text{Btu/lb}_m^\circ\text{F}$; at critical point $P = 1066.3 \text{ psia}$, $T = 87.8^\circ\text{F}$

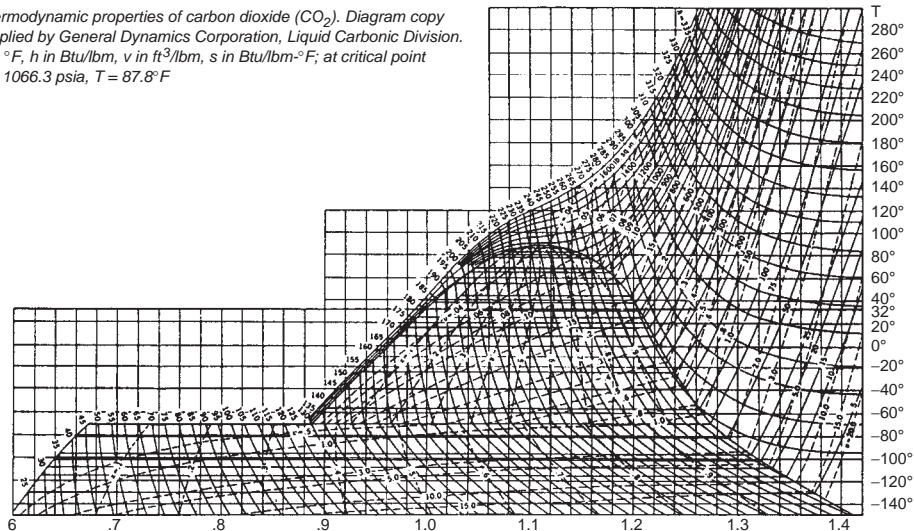

FIGURE 2.4.4 Thermodynamic properties of carbon dioxide.

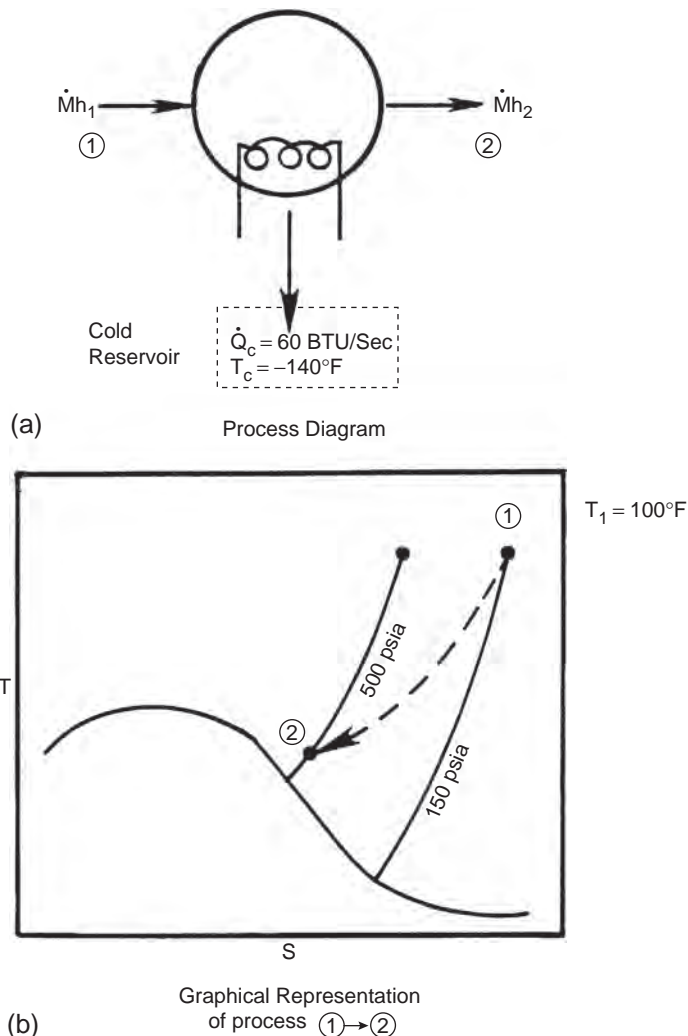

FIGURE 2.4.5 (a) Process diagram. (b) Graphical representation of Processes 1 and 2.

Btu/lb_m, and $S_2 = 1.25 \text{ Btu/lb}_m^\circ\text{R}$, the entropy production rate would be

$$\dot{P}_s = 2(1.25 - 1.318) + 0.1875 = +0.0515 \text{ Btu/s}^\circ\text{R}$$

Because entropy is produced in this case, the device is theoretically possible.

2.4.10 Summary of Thermodynamic Equations

The thermodynamic relations formulated earlier for a pure substance are summarized in Table 2.4.1 with unit mass of fluid as the basis. Several additional important relationships can be derived from them and these are shown in the third column of Table 2.4.1.

By mathematical manipulation, numerous additional relationships can be derived from those given in Table 2.4.1. Of particular significance are expressions that relate enthalpy H and internal energy U to the measurable variables, P , V , and T . Thus, choosing the basis as one pound mass,

$$\left(\frac{\partial H}{\partial P}\right)_T = V - T\left(\frac{\partial V}{\partial T}\right)_P \quad (2.4.50)$$

and

$$\left(\frac{\partial U}{\partial V}\right)_T = -P + T\left(\frac{\partial P}{\partial T}\right)_V \quad (2.4.51)$$

Equations 2.4.50 and 2.4.51 apply to any substance or system and are called *equations of state* because they

TABLE 2.4.1 Summary of Thermodynamic Relations (Basis: Unit mass of Fluid)

Function of Definition	Common Name for Terminology	Differential Equation	Derived Relationships Among Variables
$C_P = \left(\frac{\delta Q}{\partial T}\right)_P = \left(\frac{\partial H}{\partial T}\right)_P = T \left(\frac{\partial S}{\partial T}\right)_P$	Heat Capacity at Constant Pressure	$\delta Q_P = C_P dT$	$C_P = \left(\frac{\partial U}{\partial T}\right)_P + P \left(\frac{\partial V}{\partial T}\right)_P$

completely determine the state of a system in terms of its thermodynamic properties.

2.4.11 Thermal Properties for Selected Systems

For practical applications of the numerous thermodynamic relationships, it is necessary to have available the properties of the system. In general, a given property of a pure substance can be expressed in terms of any other two properties to completely define the state of the substance. Thus, one can represent an equation of state by the functional relationship:

$$P = f(T, V) \tag{2.4.52}$$

which indicates that the pressure is a function of the temperature and specific volume.

Plots of the properties of various substances as well as tables and charts are extremely useful in solving engineering thermodynamic problems. Two-dimensional representations of processes on P-V, T-S, or H-S diagrams are especially useful in analyzing cyclical processes. The use of the P-V diagram was illustrated earlier. A typical T-S diagram for a Rankine vapor power cycle is depicted in Figure 2.4.6.

For the Rankine cycle, the area enclosed by the line segments connecting points 1, 2, 3, 4, 1 on Figure 2.4.6

represents the net heat transferred into the system per unit mass, because

$$Q_{net} = \int_{s_4}^{s_1} TdS - \int_{s_2}^{s_3} TdS \tag{2.4.53}$$

The efficiency of power cycles such as the Rankine cycle is given by the ratio of the net work out to the heat added. From Figure 2.4.6, the efficiency is

$$\eta = \frac{W_{net}}{Q_{in}} = \frac{Q_{in} - Q_{out}}{Q_{in}} \tag{2.4.54}$$

The H-S plot is called a Mollier diagram and is particularly useful in analyzing throttling devices, steam turbines, and other fluid flow devices. A Mollier diagram for steam is presented in Figure 2.4.7 (standard engineering units) and in Figure 2.4.8 in SI units.

Thermodynamic properties may be presented in various ways, including:

- Equations of state (e.g., perfect gas laws, Van der Waals equation, etc.).
- Charts or graphs.
- tables.

Tables 2.4.2–2.4.7 present thermodynamic properties for several pure substances commonly encountered in petroleum engineering practice.

For further information on this subject, refer to References 1–8.

2.5 GEOLOGICAL ENGINEERING

Section reviewed by Bill Lyons

Geology is the study of the Earth, its internal and surface composition, structure, and the processes that cause changes in its composition and structure. The Earth is constantly changing. The processes within the Earth and the history of these processes are important factors in determining how minerals deposits were formed, where they accumulated, and how they have been preserved. The composition and structure of the Earth and the history of the processes that resulted in the present geological settings of rocks are very important in the prediction of where accumulations of economically valuable hydrocarbons (oil and gas) may be found.

Studies of surface geological features and interpretations of past processes, coupled with surface geophysical investigation techniques such as seismic, gravity, magnetic, radioactive, electrical, and geochemical methods, are used to locate probable subsurface target regions that may contain economically valuable accumulations of hydrocarbons. However, only by drilling from the surface to these subsurface regions is it possible to definitely assess whether hydrocarbons exist and to determine quantitatively their distribution and composition. Drilling from the surface—whether on land or from floating platforms—allows drill holes to test subsurface rocks and provides a direct sampling of rocks and fluids from subsurface regions. These subsurface fluids, if present, can be assessed for their economic value.

Geology is important in exploring for hydrocarbons, and engineers must study the present composition and structure of the Earth to successfully drill boreholes. After hydrocarbons have been found and have proved to be economically recoverable, studies of the physical and chemical aspects of the Earth in such regions are important to production and

reservoir engineering. These studies help to ensure that the accumulated hydrocarbons are recovered in an economic and a sustainable manner.

2.5.1 General Rock Types

The Earth is composed of three general rock types: igneous, sedimentary, and metamorphic. Reference 1 provides a general background of these three rock types and their relationships in the *rock cycle*, sometimes called the *rock recycle*.

Igneous rocks represent the solidified products of magmatism and volcanism—processes that bring molten materials close to the Earth's surface, allowing these materials to erupt on the surface (volcanic rocks) or freeze at shallow levels within (intrusive or plutonic rocks) the Earth. Such rocks comprise variable yet definable mineral assemblages, usually constituting relatively dense, compact, and weakly porous materials. Fracturing in igneous rocks may provide substantial permeability; however, because igneous rocks generally are not found in sedimentary basins that otherwise would preserve hydrocarbon accumulations, this rock type seldom hosts significant hydrocarbon concentrations.

Sedimentary rocks comprise materials derived from the weathering and erosion of preexisting rocks and soils. These materials have been variably consolidated and cemented (clastic sedimentary rocks) or precipitated directly from water (chemical sedimentary rocks). Particulate materials and dissolved rock components are transported by water, wind, and ice (as glaciers) to new locations, where they eventually assemble by means of the general process of lithification into a new rock mass. The eroded material from which sedimentary rocks are derived, called *protolith*, may be igneous, sedimentary, or metamorphic or some combination of these forms. During the process of weathering and erosion, especially by water, geochemical components of the original rock mass may be dissolved and may therefore be transported separately from the original rock fragments. This is an important characteristic of the genesis of sedimentary rocks because such dissolved components may reprecipitate—re-form from solution—and constitute the cementing agent in sedimentary rocks. These pore-filling cements are very important in determining the hydrocarbon storage capacity of sedimentary rock units and require assessment for any rock considered a potential hydrocarbon source.

In continental coastal regions, as the rivers and streams bring sediment into the seas surrounding the continentals, the larger clastic particles will settle in the delta regions first, next further downstream smaller clastic particles will begin to settle with some clay, and finally in the slowest moving river water very small fines and abundant clay materials settle. Also, flowing off the continents in these rivers and streams would be the debris of past aquatic and

land life (flora and fauna). Particularly, in the delta regions where the water flow is, the slowest abundant marine life would be living to get a meal from this river debris in the erosion runoff. As rapid burial took place in the delta over time, the local marine life would be entombed in the resulting beds of pre-shale material. Eventually, over time the heat and pressure would make these fast layering beds into shale rock. It is in these shale beds that ultimately, it is believed, the reducing environment together with the heat and pressure of the rapid burial yields the hydrocarbons of crude oil and natural gas that is produced today through man-made wellbores. As new deltas form over the old ones over time, the location where pre-shale materials were laid down may have a bed of small clastic particles being deposited on top of the older pre-shale beds. In this manner, continuous layers of alternating layers of shale, sandstone, carbonate (i.e., limestone and dolomite) formation layers are created over millions of years. Empirical evidence collected over hundreds of years by geologists and other researchers suggests that the formation of shale beds was where hydrocarbons were initially created.

Metamorphic rocks represent igneous, sedimentary, or other metamorphic rocks that have changed texturally and, in some cases, compositionally. Because the processes that engender these changes — called *metamorphism* — involve application of substantial heat and pressure to the original rock, changes may take place in the rock that preclude or inhibit completely the ability of the rock to produce or store hydrocarbons. These temperature-pressure effects may force rocks to endure conditions outside of the “petroleum window” defining suitable conditions for hydrocarbon generation and storage. These changes usually result in a reduction in pore volume by means of compaction and consolidation, including mineral deformation; therefore, metamorphic rocks, unless they are near the surface and well fractured, seldom make suitable storage media for hydrocarbons.

2.5.2 Historical Geology

Based on studies of radioactive isotopes derived from meteorites, the age of the Earth is estimated to be approximately 4,650 million years; the oldest known rocks, found in metamorphic rock assemblages in northern Canada and in Australia, are approximately 3,800 million years old [2]. Radiometric age dating, first devised in the early part of the 20th century, provides geologists with a means of establishing the absolute ages of rock units containing radioactive minerals that were formed at the same time as the enclosing rock. However, in the search for petroleum and gas resources and because most hydrocarbons occur in sedimentary rocks, petroleum geologists rely on the relative geological ages of rock units to unravel the sedimentary and structural history of potential hydrocarbon-bearing rocks.

Geologists generally use two characteristics of geological processes to determine the relative ages of rock units, especially of sedimentary rock sequences.

1. The *principle of uniformity* states that the internal and external processes affecting the Earth today have been operating unchanged and at the same rates throughout the developmental history of Earth. This means that an historical geological event preserved in the rock record can be identified and compared to similar events occurring at the present time in terms of the elapsed time and the geological processes necessary for that event to have occurred. Therefore, rates of deposition, erosion, igneous emplacement, and structural development are preserved in the geological column and can be compared with current similar processes [2,3].
2. *Relative time* is based on the occurrence of geological events relative to each other. Dating in this manner requires the development of a sequence of events that can be established on the basis of obvious consecutive criteria, as indicated later. This requires the geologist to identify a geological continuum such that the events within the sequence are sufficiently identifiable (events such as uplift, erosion, and deposition) and widespread (acting over geographically large areas on the scale of hundreds of square kilometers) to have practical significance. Such dating in relative time allows events to be identified throughout the world [2,3].

Examples of the types of observations used to establish relative time are given in the following list:

- *Superposition* is fundamental to the study of layered rocks. This means that in a normal layered sedimentary rock sequence, the oldest rocks were deposited first and are at the sedimentary base of the sequence. Younger rocks were deposited last and are at the top of the sequence.
- *Succession of flora and fauna* refers to the deposition of sedimentary material that includes the remains of contemporaneous plant and animal life. Fossils of these plants and animals may be preserved in the rock formations that result from the processes of deposition and lithification. The presence, absence, or change of the plant and animal life within a sequence of the geological column, as indicated by the presence, abundance, and diversity of fossil evidence, provides important information that allows geologists to correlate rock formations and thereby relative time from area to area. The fossil records within sedimentary sequences also provide important information regarding the evolution of life through geological time.
- *Inclusion* of one rock type within another indicates that the included rock is necessarily older than the rock

in which it is enclosed. This is significant in interpretation of sedimentary sequences, especially those that have been structurally deformed by faulting or folding, because it allows a geologist to ascertain lateral and vertical continuity of rock units or structures that may comprise source regions or host rocks for hydrocarbons.

- *Cross-cutting relationships* are essential for the determination of the relative ages of rocks that show rock-to-rock contact. The idea is that any rock (especially igneous rocks) or structure (such as a fault or sedimentary bedding feature) that transects or “cuts” another must be younger than that feature. The feature that has been transected must have been present (older) before the cross-cutting feature (younger) existed.
- Physiographic development of the surface of the earth refers to the landforms and shapes of the landscape. These surface features are subject to continuous change from constructive (e.g., uplift, volcanic activity, deposition of sediments) and destructive (e.g., erosion) processes. Landform modifications are continuous and sequential. These modifications establish a predictable

continuity that can be helpful in determining certain aspects of relative geologic ages.

The relationship between time units, time-rock units, and rock units is as follows:

Time Units	Time-Rock Units	Rock Units
Eon		
Era	Erathem	Group
Period	System	Formation
Epoch	Series	Member
Age	Stage	

This system for keeping track of these important units is used as the basis for the standard geologic time and the evolution of the animal life on earth (see also [Tables 2.5.1](#) and [2.5.2](#)). [Table 2.5.3](#) gives the relationship between geologic time and important physical and evolutionary events that are used to aid in the identification of rock units in relative geologic time [3].

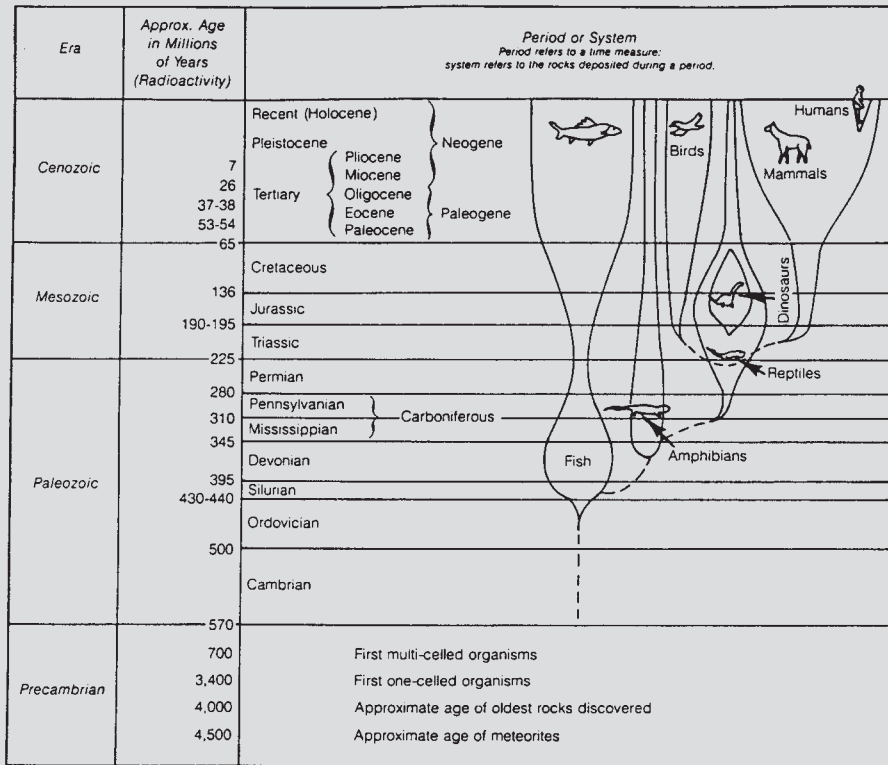

There are two historical geologic events which altered the deposition of sediments and, in turn, altered the life forms that would survive or become extinct as earth evolved. These events can be seen in [Table 2.5.2](#). The

TABLE 2.5.2 Geological Time and Evolution of Ancient Life [3]

“Great Dying” occurred at the end of the Permian period at about 225 million years ago. This event in the geologic record forced the extinction of numerous large marine and land animals, and many other smaller species. It is not clear what exactly caused the Great Dying, but it is known that the climate changed radically and eliminated the food sources for the animals that existed at that time. The latest evidence for what caused this climate change points toward massive volcanic eruptions over a large surface of the earth in what is now Siberia. These eruptions placed magma materials and gases into earth’s atmosphere for over a thousand years. Some species of animals survived which allowed the evolution of the mammals and the dinosaurs among others. The second important historical geologic event that affected the evolution of life on earth was the climate change created by the impact of a large asteroid that struck the earth in the area near what is now the Yucatan about 65 million years ago. This more recent event resulted in the extinction of the dinosaurs and other smaller species. But more importantly this latest geologic event altered the flow of the many rivers and streams within the various continents that existed at that time.

2.5.3 Petroleum Geology

Petroleum geologists have considered that shale rock formations are the source beds for the original deposition of the organic materials that ultimately have become crude oil and natural gas deposits in the earth’s crust. In a way today these deposits of hydrocarbons are the ultimate solar energy collection or solar energy “batteries.”

Organic material deposited with these marine sediments becomes entrained with the clastic debris and eventually forms sedimentary source rocks. Whether a sedimentary sequence becomes a substantial source of hydrocarbons is a function of a number of physical and geochemical parameters, including the origin and amount of original organic materials deposited, the burial and thermal history (see discussion of Equation 2.5.1) of the evolving sediment-to-rock mass, and the nature and continuity of permeability within the source rock. Conversion of organic matter to various liquid and gaseous hydrocarbons takes place as heat, pressure, and biological activity geochemically change the entrained organic materials in a reducing environment through a series of processes collectively called *maturation*.

TABLE 2.5.3 Geological Time and Important Events [3]

If geochemically significant oxygen is present during any stages of the hydrocarbon maturation process, at least some of the hydrocarbons will be destroyed by oxidation and will be converted to water plus carbon dioxide with or without sulfur.

Because trapping of organic materials with resultant prevention of organic material oxidation is essential to the generation of economically important hydrocarbon accumulations, rapid burial of organic-bearing sediments is geologically favorable; as such, sedimentary basins in which sediment input is high and basins in which reducing conditions are maintained over extended periods, along with input of elevated amounts of marine organic materials, are considered most prospective for hydrocarbon-source rocks. For this reason, geologists and geophysicists are employed to interpret the sedimentation and tectonic history and the lithologic settings of rock volumes that are considered favorable for petroleum and gas occurrence [3–6].

2.5.3.1 Source Rocks

Source regions for hydrocarbons (shale) are required to have a substantial input of organic material and, to preserve that material so that it may mature in to liquid and gaseous hydrocarbons, a geochemically reducing environment. Restricted sedimentary basins accumulating detrital continental debris and marine organic matter represent the most favorable environments for the storage and generation of hydrocarbons.

Generation of chemically precipitated sediments, notably limestones and related calcareous components of clastic rocks, usually results in at least initial trapping of organic matter. This matter may be released for migration after fracturing of the host carbonate or if the carbonate is subjected to thermal stress such that volatile organic materials are driven from the otherwise stable carbonate source rock. Other chemical precipitates such as gypsum (a sulfate), halite, and related halide minerals such as potash salts and anhydrite derived from gypsum may host organic matter as

a burial component and therefore may serve as source rocks under some sedimentary-geochemical conditions.

2.5.3.2 Migration

Organic matter buried in reducing environments (usually of marine nature) may accumulate in sufficient quantities to be considered geochemically and economically important source rocks. Because of thermal and load stresses applied to such sediments and the organic materials they host, this organic matter may change chemically and may be driven from the source rock along more permeable and porous pathways. These chemically and thermally changed hydrocarbons may, if structural and thermal conditions permit (see sections on “Structural Geology” and “Traps”), cease migration, accumulating in rock masses called *reservoir rock*.

This migration from source to reservoir is generated by hydrodynamic forces, thermal stress, or a combination of these factors. Water generally moves in conjunction with hydrocarbons and is usually segregated from gas and oil by buoyancy (density) contrast (Figure 2.5.1). Migration of hydrocarbons is attenuated or ceases entirely when applied stresses, the existing stress regime of enclosing rock, and hydrocarbon with or without water pore pressures reach transient equilibrium. Because such equilibrium is dynamic

and therefore transient, fluids may continue to migrate if any of the factors controlling fluid movement are changed.

2.5.3.3 Accumulation

Over the past many decades, the commercial production of hydrocarbons through boreholes drilled from surface to reservoir rock formations has been mainly from hydrocarbon accumulations within sandstone and carbonate reservoirs. Accumulation and storage of hydrocarbons occurs when structural settings appropriate to the preservation of oil and gas (see section on “Traps”) receive hydrocarbons and, usually, water. The migration of hydrocarbons is strongly influenced by geological structures and the nature and lateral continuity of sedimentary rock bedding features (see Figure 2.5.10). Gases generally travel as dissolved components of liquid hydrocarbons or as a component of water. The amount of gas dissolved and therefore transported is a function of the temperature and pressure of the source region and adjacent rock masses through which the hydrocarbon-water fluids pass. After accumulation, hydrocarbons tend to stratify according to the relative densities of gas, oil, and water, with gases accumulating in the structurally highest portions of the reservoir, liquid hydrocarbons lower, and water lowest. Most reservoirs “leak” somewhat, with lighter components, such as gases and

FIGURE 2.5.1 Anticlinal hydrocarbon accumulation.

lighter liquid hydrocarbon fractions, capable of continuing migration, effectively leaving behind heavier and more viscous hydrocarbons.

After hydrocarbons accumulate in a rock mass serving as a reservoir, the hydrocarbons must be preserved from oxidation, from escape along other structural avenues, and from bacterial activity that might convert the hydrocarbons to sulfur, as in sulfur deposits of west Texas, the Gulf Coast region of the southern United States, the Misraq area of eastern Iraq, and southern Poland. Because the Earth is dynamic, the stability of any reservoir rock is transitory, and rocks that otherwise appear to be excellent storage media may no longer host hydrocarbons because of changes in local or regional structural, tectonic, or sedimentary regimes. Recently however, the mystery of accumulation of hydrocarbons has expanded since petroleum geologists and engineers have learned how to commercially produce hydrocarbons from shale reservoirs which hitherto have been considered too tight a pore space to provide commercial accumulations.

2.5.4 Structural Geology

The *law of original horizontality* states that all sediments are deposited essentially horizontally in response to gravity and the approximate Stoke's law of settling of particles. Sedimentary rocks, originally deposited as horizontal or near-horizontal sediment beds, undergo diagenetic changes that result in variable lithification. Because of the dynamic nature of Earth forces, sedimentary rocks are subject to myriad stresses and changes in stress regimes. Rock masses respond to such stress and stress changes by deforming, with deformation taking place on scales varying from microscopic to hundreds of kilometers.

Sedimentary rocks generally show deformation by the rearrangement of mineral grains (microscopic) and the

larger-scale folding or fracturing of rock units; such folding and fracturing display variations in scale from microscopic offset of mineral grains to folds having wavelengths measured in tens to hundreds of kilometers.

These structural features of deformed sedimentary rock sequences comprise some of the most important reservoirs for hydrocarbons and water and are therefore of significant interest to petroleum geologists and geophysicists in the search for petroleum resources [3].

1. Faults are breaks in the Earth's crust along which there has been measurable movement, called *displacement*, of rock on one side of the fault relative to the other (Figure 2.5.2). Some definitions describing the most important structural features of faulted sedimentary rocks follow:

- *Dip* — the angle the fault plane makes with the horizontal, measured from the horizontal to the fault plane.
- *Strike* — a line on the horizontal surface represented by the intersection of the fault plane and the horizontal surface. The strike line is always horizontal, and since it has direction, it is measured either by azimuth or bearing. Strike is always perpendicular to the dip.
- *Heave* — the horizontal component of movement of the fault.
- *Throw* — the vertical component of movement of the fault.
- *Slip* — the actual linear movement along the fault plane.
- *Hanging wall* — the block located above and bearing down on the fault surface.
- *Footwall* — the block that occupies the position beneath the fault, regardless of whether the hanging wall has moved up or down.

FIGURE 2.5.2 Fault terminology [3].

- *Normal faulting* takes place in extensional regimes in which tension within rock masses produces slip such that the hanging wall block is displaced downward with respect to the footwall block [Figure 2.5.2](#) is an example of a normal fault.
 - *Reverse (thrust) faulting* takes place in generally compressional structural regimes, and produces displacement such that the hanging wall is thrust over footwall rocks.
 - *Strike-slip faulting* occurs in structural environments in which more or less horizontally directed forces cause structural blocks to slide laterally along the fault surface. Transform faults are special cases of strike-slip faults, occurring as differential spreading takes place along mid-ocean ridges.
2. Displacement along faults varies from almost zero to tens of kilometers for normal and reverse faults and up to hundreds of kilometers for strike-slip structures. Faults seldom consist of only single surfaces; they typically are made of myriad faulted surfaces comprising a fault zone, along which each of the faults takes up—accommodates—a portion of the overall displacement. Because fault surfaces and the zones they comprise may represent relatively low permeability zones, such structural zones may serve as effective traps for hydrocarbons and water (see [Figure 2.5.10](#)).
 3. Folds in sedimentary rocks are generated when rock mass strength and the rate at which pressure is applied to a sedimentary rock sequence are such that the rock is able to reaccommodate an applied stress, accumulating strain energy as deformed mineral grains. In some cases, because the rate of applied pressure is changed, folded rock sequences may rupture and fault, with stress being taken up by movement along the fault instead of as deformed mineral grains. Folds are generated on scales varying from millimeters to kilometers [Figure 2.5.3](#).

Fold terminology follows:

- *Anticline*—a fold with upward convexity.
- *Syncline*—a fold that is concave upward.
- *Hinge point*—the point of maximum curvature of a fold. The *hinge surface* is the locus of hinge lines within the fold.
- *Inflection point*—occurs when bed curvature in one direction changes to bed curvature in the opposite direction.
- *Limbs (or flanks) of a fold*—those portions adjacent to the inflection points of the fold.
- *Symmetrical fold*—a fold whose shape is a mirror image across the hinge point.
- *Asymmetrical fold*—a fold whose shape is not a mirror image across the hinge point.

FIGURE 2.5.3 Folding terminology [3].

- *Recumbent fold*—characterized by a horizontal or nearly horizontal hinge surface (see [Figure 2.5.4](#)).
- *Overtured fold*—when the hinge surface is depressed below the horizontal (see [Figure 2.5.4](#)).
- *Concentric (parallel) folds*—rock formations parallel to each other such that their respective thicknesses remain constant (see [Figure 2.5.5](#)).
- *Nonparallel folds*—rock formations that do not have constant thickness along the fold ([Figure 2.5.6](#)).
- *Similar folds*—folds that have the same geometric form, but where shear flow in the plastic beds has occurred ([Figure 2.5.7](#)).
- *Disharmonic folds*—folds in layered rock that have variable thickness and competence and, thereby, fold in accordance to their ability ([Figure 2.5.8](#)).

2.5.5 Traps

Traps are structural features that represent permeability contrasts such that the migration of hydrocarbons or water is attenuated to an extent that permits temporary accumulation and storage. Because traps are essentially always

FIGURE 2.5.4 Recumbent (A) and overturned (B) folds [3].

FIGURE 2.5.7 Similar folds [3].

FIGURE 2.5.5 Concentric folds [3].

FIGURE 2.5.8 Disharmonic folds [3].

FIGURE 2.5.6 Nonparallel folds [3].

of structural or stratigraphic origin, they may have finite lifetimes; if trap morphology, permeability, or size changes, the ability of a trap to store hydrocarbons and water may be altered substantially.

1. Structural traps result from deformation of rock masses, usually attributable to folding or faulting.
 - *Anticline trap*—because of the upwarping of sediments in this fold type (see Figures 2.5.1 and 2.5.8), hydrocarbons and water tend to accumulate in fold crests; as such, this type of fold represents one of

the most important productive structural traps for hydrocarbons. In some cases, faulting, especially thrust faulting, may complicate or generate anticlinal structures and the traps they may form (Figure 2.5.9). The fold-and-thrust belt of the western United States (also called the overthrust belt) represents an excellent example of composite folding and faulting, and associated hydrocarbon production.

- *Fault traps*—involve the movement of the reservoir rock formation to a position where the formation across the fault plane provides a seal preventing further migration of hydrocarbons (Figure 2.5.10).
- *Salt-related traps*—formed when the plastic salt formations deform into domelike structures under the overburden forces of the beds above the salt beds. Such plastic flowing (and bulging) of the salt

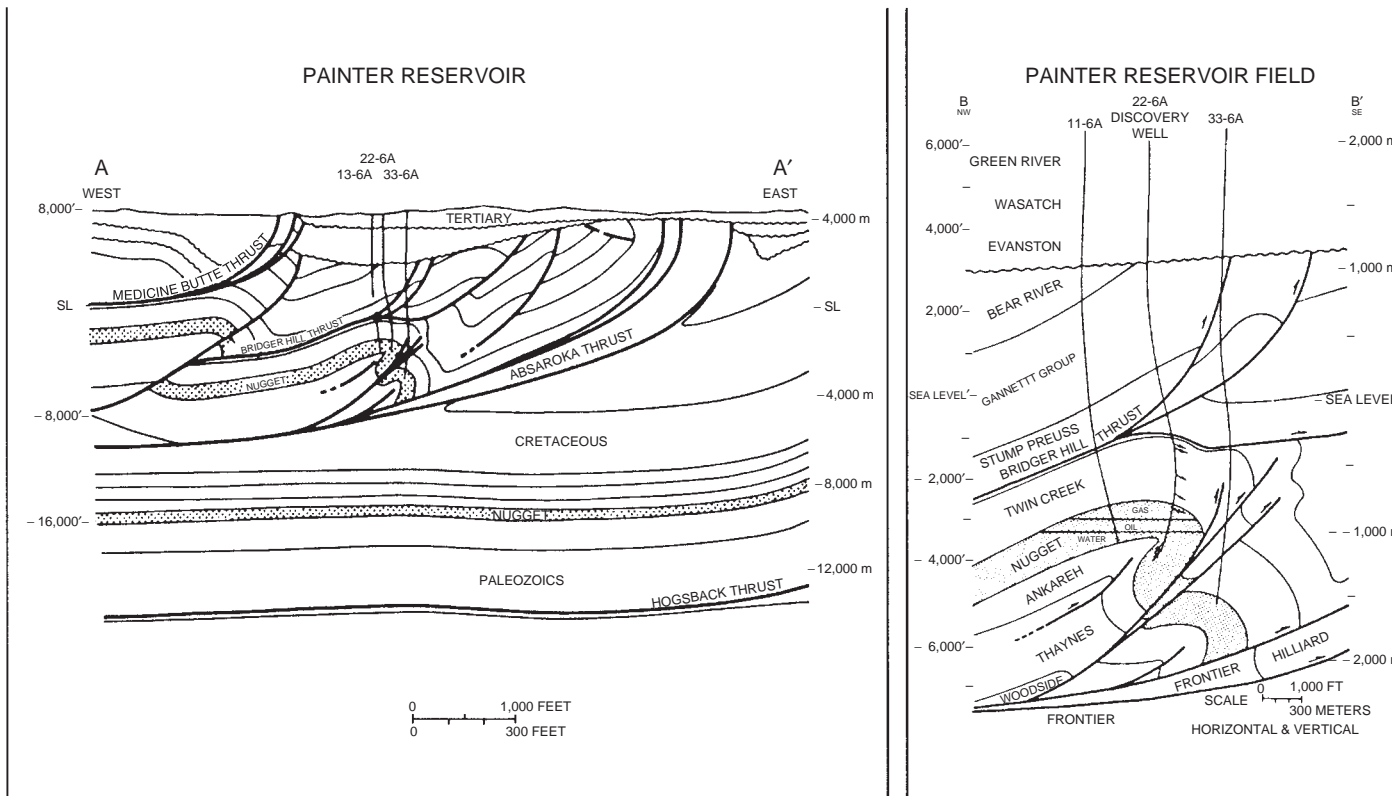

Figure 2.5.9 Overthrust structural trap (Painter Reservoir, Wyoming) [3].

FIGURE 2.5.10 Fault structural traps.

beds deforms the rock formations above producing anticline structures and faults in the rock formation astride the domelike structures (Figures 2.5.11 and 2.5.12).

2. *Stratigraphic traps* consist of permeability contrasts in sedimentary rocks. These contrasts might have been created by sedimentary processes associated with deposition of the original sediments; by post-depositional (diagenetic) processes, including lithification mechanisms; or by a combination of these processes. Biological activity also may form significant stratigraphy-related traps, such as reefs and fossiliferous carbonate banks.
 - *Sand body traps* — finite sand bodies such as channel sands, river delta sands, and sea or ocean beach or barrier bar sands. These sand body traps are deposited over well-defined regions. As deposition continues on a wider regional basis of shale-forming deposits, the sand body becomes enclosed by shale and becomes a trap for fluids, particularly hydrocarbons (Figure 2.5.13).

- *Reef traps* — important hydrocarbon-producing geological features. The porosity and permeability in reefs can be excellent. As in sand body traps, reef traps are finite bodies that are deposited over well-defined regions. Continued deposition of silt and clay materials will eventually enclose such features in shale, allowing them to trap fluids, particularly hydrocarbons (Figure 2.5.14).
- *Unconformity traps* — result from alternating periods of sedimentation and erosion; that is, the process of sediment deposition is interrupted by a period in which erosion removes some of the previously deposited sediment, creating a contrast in permeability along the erosional surface. This erosional period may occur in response to tilting of the sediment package (Figure 2.5.15) or as a consequence of climate or structural change.
- *Combination traps* — sedimentary trap features that result from both stratigraphic and structural mechanisms. There can be many combinations for stratigraphic and structural traps. An example of such a trap would be a reef feature overlaying a porous

FIGURE 2.5.11 Salt dome structural traps.

FIGURE 2.5.12 Low-relief salt pillow trap (Nancy Field, Mississippi) (from Gulf Coast Association of Geological Societies).

and permeable sandstone but in which the sequence has been faulted (Figure 2.5.16). Without the fault, which has provided an impregnable barrier, the hydrocarbons would have migrated further up dip within the sandstone.

2.5.6 Basic Engineering Properties of Rock

Because sedimentary rocks constitute the most important source and storage rocks for hydrocarbons and water, petroleum engineers emphasize the significance of understanding the nature of sedimentary rocks and the depositional environments that formed them.

Most liquid and gaseous hydrocarbons are generated from—and represent—the former remains of microscopic marine plant and animal life. Continental plant life, comprising grasses and woody materials, tends to generate coal and some low-molecular-weight gases rather than liquid hydrocarbons; this is attributable to the environment in which coal materials are accumulated, the size of the carbon molecules making up woody plants and grasses, and the nature of the sedimentary rocks with which the precursor coal organic materials are associated. Because marine life forms exist in the same aquatic environment that produces sediments and consequently sedimentary rocks, hydrocarbon genesis, migration, storage, and preservation are related closely to sedimentary processes. The two properties with which we will now be concerned are permeability and

porosity; although these are different characteristics of hydrocarbon-host rocks, they are each significant in determining whether a rock unit may serve or might have served as a source or storage media for hydrocarbons.

2.5.6.1 Porosity

Porosity is a measure of the void space within a rock, which is expressed as a fraction (or percentage) of the bulk volume of that rock [8].

The general expression for porosity ϕ is

$$\phi = \frac{V_b - V_s}{V_b} = \frac{V_p}{V_b} \quad (2.5.1)$$

where V_b is the bulk volume of the rock, V_s is the volume occupied by solids (also called grain volume), and V_p is the pore volume.

From an engineering point of view, porosity is classified as:

- *Absolute porosity*—total porosity of a rock, regardless of whether the individual voids are connected.
- *Effective porosity*—only that porosity due to voids that are interconnected.

It is the effective porosity that is of interest. All further discussion of porosity will pertain to effective porosity.

From a geologic point of view, porosity is classified as:

1. *Primary porosity*—porosity formed at the time the sediment was deposited. Sedimentary rocks that typically exhibit primary porosity are the *clastic* (also called *fragmental* or *detrital*) rocks, which are composed of erosional fragments from older beds. These particles are classified by grain size.
2. *Secondary porosity*—voids formed after the sediment was deposited. The magnitude, shape, size, and interconnection of the voids bears little or no relation to the form of the original sedimentary particles. Secondary porosity is subdivided into three classes.

- *Solution porosity* refers to voids formed by the solution of the more soluble portions of the rock in the presence of subsurface migrating (or surface percolating) waters containing carbonic and other organic acids. Solution porosity is also called *vugular porosity* where individual holes are called vugs.
- *Fractures, fissures, and joints* represent planar surfaces formed in response to applied stresses that produce local rock failure. These structures may be of tensional or compressional nature, and they may individually contribute nominal to volumetrically substantial *permeability* to a rock mass by locally enhancing the connection between pores or between porous rock units.
- *Dolomitization* is the process by which limestones, dominated by the mineral calcite, are transformed into a Ca-Mg carbonate, dolomite [Ca, Mg (CO₃)₂]. This process involves a significant change in rock density; because dolomite has a greater density than limestone, rocks undergoing dolomitization develop voids. These voids may result in very substantial increase in rock porosity (and permeability), making some dolomites excellent hydrocarbon reservoirs (e.g., the Ordovician-age Ellenberger dolomite of West Texas).

The typical value of porosity for a clean, consolidated, and reasonably uniform sand is 20%. The carbonate rocks (limestone and dolomite) normally exhibit lower values (e.g., 6–8%). These are approximate values and do not fit all situations. The principal factors that complicate intergranular porosity magnitudes are uniformity of grain size, degree of cementation, packing of the grains, and particle shape.

2.5.6.2 Permeability

Permeability is defined as a measure of the ability of a rock to permit passage of fluids. In addition to rock porosity, the permeability of a rock unit is definitive in terms of allowing the migration accumulation, and storage of hydrocarbons and water in rock media. Fluids are transmitted through rock because of differential pressures created in the normal

burial and tectonic environments of subsurface rocks. Permeability reflects the connected character of pores, fractures, joints, and faults within a rock unit; because each of these structures permits fluid flow to some extent, the overall nature of these structures to serve as interconnected passageways for fluids also represents the capacity of a rock mass to transmit fluid in response to pressure differences. The quantitative definition of permeability was first given in an empirical relationship developed by the French hydrologist Henry D'Arcy, who studied the flow of water through unconsolidated sands [8].

This law in differential form is

$$v = -\frac{k}{\mu} \frac{dp}{d\ell} \quad (2.5.2)$$

where v is the apparent flow velocity (cm/s), μ is the viscosity of the flowing fluid (centipoise), p is pressure (atmospheres), ℓ is the length (cm), k is permeability of the porous media (darcies).

Consider the linear flow system of Figure 2.5.17. The following assumptions are necessary to establish the basic flow equations:

- Steady-state flow conditions.
- Pore volume is 100% filled with flowing fluid; therefore, k is the absolute permeability.
- Viscosity of the flowing fluid is constant. In general, this is not true for most real fluids. However, the effect is negligible if μ at the average pressure is used.
- Isothermal conditions prevail.
- Flow is horizontal and linear.
- Flow is laminar.

Using the foregoing restrictions:

$$v = \frac{q}{A} \quad (2.5.3)$$

where q is the volumetric rate of fluid flow (cm³/s); A is the total cross-sectional area perpendicular to flow direction (cm²).

This further assumption concerning velocity and the volumetric rate of flow restricts flow to the pores and not

FIGURE 2.5.17 Linear flow system.

the full area. Therefore, v is an apparent velocity. The actual velocity, assuming a uniform medium, is

$$V_{\text{actual}} = \frac{V_{\text{apparent}}}{\phi} \quad (2.5.4)$$

where ϕ is porosity defined in Equation 2.5.1.

Substituting Equation 2.5.3 into Equation 2.5.2 yields

$$\frac{q}{A} = -\frac{k}{\mu} \frac{dp}{d\ell} \quad (2.5.5)$$

Separation of variables and using limits from Figure 2.5.17 gives

$$\frac{q}{A} \int_0^{\ell} d\ell = -\frac{k}{\mu} \int_{p_1}^{p_2} dp \quad (2.5.6)$$

Integrating the preceding yields

$$q = \frac{kA(p_1 - p_2)}{\mu\ell} \quad (2.5.7)$$

or

$$k = \frac{q\mu\ell}{A\Delta p} \quad (2.5.8)$$

Equations 2.5.7 and 2.5.8 are the basic forms of the permeability relationship, and the following example serves to define the darcy unit:

If $q = 1 \text{ cm}^3/\text{s}$

$$A = 1 \text{ cm}^2$$

$$\mu = 1 \text{ cp}$$

$$\Delta p/\ell = 1 \text{ atm/cm}$$

then from Equation 2.5.8,

$$k = 1 \text{ darcy}$$

A permeability of 1 darcy is much higher than that commonly found in sedimentary rock, particularly reservoir rocks. Consequently, a more common unit is the millidarcy, where

$$1 \text{ darcy} = 1,000 \text{ millidarcies}$$

Typical values for sedimentary rock permeability for the flow of hydrocarbons and other fluids are 100 millidarcies (md) or greater. Rocks exhibiting permeabilities of 50 md or less are considered tight relative to the flow of most fluids.

2.5.6.3 Subsurface Temperature

Attributable to many causes, including lithostatic and hydrostatic pressures, frictional energy, accumulated and locally released strain energy, and radioactive decay, rock temperatures show a general tendency to increase with

depth. This temperature depth relationship is commonly assumed to be a linear function.

$$t_d = t_s + \beta d \quad (2.5.9)$$

where t_d is the temperature of the rock at depth, d (°F), t_s is the average surface temperature (°F), β is the temperature gradient (°F/ft), and d is the depth (ft).

In general, there is considerable variation in the geothermal gradient throughout the United States and the world. In many regions of the world where there is evidence of rather thin crust, the relationship between temperature at depth and depth may not be approximated by the linear function given in Equation 2.5.9. The increase in temperature with depth has important consequences for drilling and production equipment that is used in the petroleum industry. The viscosity of drilling and production fluids will, in general decrease with high temperatures. The sitting time for well cement will generally decrease with increased temperature, as will the strength and fracture toughness of steels used in drilling, well completion, and production.

Temperature logs can be taken as wells are drilled and the temperature gradient determined for the particular region. These temperature logs taken at depth are used to determine the types of drilling fluids used as drilling progresses. The temperatures at depth will determine the cements used in well completion operations.

The average geothermal gradient used in most areas of the United States for initial predictions of subsurface temperatures is a value of 0.016°F/ft [9].

Example 2.5.1

Determine the temperature at 20,000 ft using the approximate geothermal gradient $\beta \approx 0.016^\circ\text{F}/\text{ft}$.

Assume $t_s \approx 60^\circ\text{F}$.

$$t_d = t_s + 0.016d$$

$$t_d = 60 + 0.016(20,000)$$

$$t_d = 380^\circ\text{F}$$

2.5.6.4 Subsurface Fluid Pressure (Pore Pressure Gradient)

In the past few decades, petroleum geologists and engineers have been successful in constructing wells in and around many of the existing active river delta basin regions around the world (e.g., Nile River delta basin, Mississippi River delta basin, the Congo River delta basin, Yellow River delta basin, Niger River delta basin, Amazon River delta basin). Many of these wells have been located offshore and have been costly to drill, complete, and produce. Since the successful wells in these basins have been very prolific hydrocarbon producers, they have been largely responsible

for the dynamic growth of offshore drilling and completion technologies. These wells have been difficult to construct relative to traditional land and earlier offshore wells because these new delta basin wells have been drilled in relatively young sediment basins. It is no coincident that these new hydrocarbon-producing delta basins were all in basins younger than approximately 65 million years. In these young sediments, the cementing process of the rock particles within the sedimentary rocks between the surface and the reservoir rock has not been completed, thus, the pore pressure reflects the portion of the overburden. In recent decades, it has been determined that drilling engineers should carefully consider this important abnormality in subsurface pore pressures when considering drilling in these young delta basins. In summary,

Immature basins: These basins have sedimentary deposits that are approximately 65 million years in age or less and river deposition continues in the basin today. Little cementing of the deposited particles has taken place as well as only minor tectonic activity in the region. These basins have high abnormal subsurface pressures due to trapped formation fluids supporting a portion of the overburden of young sedimentary deposits.

Mature basins: These basins have sedimentary deposits that are approximately 70 million years in age or greater and have no important deposition continuing today. Cementing of the deposited particles has taken place such that most of the overburden is supported by the rock structure in the formations. The basin region has experienced tectonic activity and future activity is possible. Any high abnormal subsurface pressures are due mainly to past tectonic activity. Examples of such basins are the shelf area of the Permian basin in West Texas, San Juan basin in New Mexico, Anadarko basin in Oklahoma, Piceance basin in Wyoming, Appalachian basin in Pennsylvania through West Virginia to Tennessee, Triassic basin in Algeria, and Ordos basin in China to mention a few.

The total pressure acting on a subsurface rock mass and the fluids it contains is a function of the weight of the rock (called *lithostatic pressure*) and fluid (called *hydrostatic pressure*) affecting the given subsurface rock mass. Because rocks are essentially “squeezed” by tectonic, lithostatic, and hydrostatic pressures, the fluids within rocks develop and exhibit a variable and generally substantial fluid pressure, referred to as *pore pressure*. Pore pressures represent the environmental equilibrium of a rock-fluid mass and change dramatically in response to local aberrations in applied pressure, such as the changes engendered when a surface drill hole penetrates a rock mass.

Fluids within rock pores may be inherited, such as sediments that contain original fluids from their depositional environments, called *connate waters*, or the fluids may be introduced, such as the gas-oil-water media that migrate into appropriate rock masses.

Total theoretical maximum overburden pressure, P (lb/ft^2), is

$$P_{\text{ob}} = \frac{W_r + W_{\text{sw}}}{A} \quad (2.5.10)$$

where W_r is weight of rock particle grains (lb), W_{sw} is weight of water (lb), and A is area (ft^2).

The term W_r can be approximated by

$$W = (1 - \phi)Ad\gamma_m \quad (2.5.11)$$

where ϕ is the fractional porosity, d is depth (ft), and γ_m is average mineral specific weight (lb/ft^3).

The term W can be approximated by

$$W_{\text{sw}} = \phi Ad\gamma_{\text{sw}} \quad (2.5.12)$$

where γ_{sw} is the average saltwater specific weight (lb/ft^3).

Substitution of Equations 2.5.11 and 2.5.12 into Equation 2.5.10 yields

$$P_{\text{ob}} = (1 - \phi)d\gamma_m + \phi d\gamma_{\text{sw}} \quad (2.5.13)$$

Equation 2.5.13 can be rewritten in terms of the specific gravities of average minerals S_m and salt water S_{sw} :

$$P = (1 - \phi)dS_m\gamma_w + \phi dS_{\text{sw}}\gamma_w \quad (2.5.14)$$

where γ_w is the specific weight of fresh water (i.e., $62.4 \text{ lb}/\text{ft}^3$).

The average specific gravity of minerals in the earth's crust is taken to be 2.7. The average specific gravity of saltwater is taken to be 1.07. If the average sedimentary rock porosity is assumed to be 10%, then the total theoretical maximum overburden pressure gradient ($\text{lb}/\text{ft}^2/\text{ft}$) becomes

$$\begin{aligned} \frac{P_{\text{ob}}}{d} &= (1 - 0.10)(2.7)(62.4) + 0.10(1.07)(61.4) \\ \frac{P_{\text{ob}}}{d} &= 158.3 \end{aligned} \quad (2.5.15)$$

Equation 2.5.15 can be expressed in normal gradient terms of psi/ft . Equation 2.5.15, which is the theoretical maximum overburden pressure gradient, becomes

$$\frac{P_{\text{ob}}}{d} = 1.10 \quad (2.5.16)$$

where p_{ob} is pressure in (psi).

The foregoing theoretical overburden pressure gradient assumes that the sedimentary deposits together with the saline water are a mixture of materials and fluid. Such a mixture could be considered as a fluid with a new specific weight of

$$\gamma_f = 158.3 \text{ lb}/\text{ft}$$

which in terms of drilling mud units would be

$$\bar{\gamma}_f = \frac{158.3}{7.48} = 21.1 \text{ppg}$$

where $1 \text{ ft}^3 = 7.48 \text{ gal}$.

Immediately after and during the deposition of sediments in an aqueous environment, diagenetic processes may begin to cement (or dissolve) mineral grains, depositing by means of solution newly formed minerals within the interstices of the grains composing the original sediment. The effect of adding a cementing agent to otherwise unconsolidated sediment results in a substantial reduction in pore volume and concomitant reduction in permeability. If the pore space in a rock were occupied by cementing agents and water, and if the pores were connected, the calculated minimum pressure gradient applied to that rock would be that of the overlying column of water, given as follows:

$$\frac{P}{d} = 1.07(62.4) \quad \text{or}$$

$$\frac{P}{d} = 66.8 \quad (2.5.17)$$

Equation 2.5.17 can be expressed in normal gradient terms of psi/ft. Equation 2.5.17 which is the minimum pressure gradient, becomes

$$\frac{P}{d} = 0.464 \quad (2.5.18)$$

The foregoing minimum pressure gradient assumes also that the sedimentary column pores are completely filled with saline water and that there is communication from pore to pore within the rock column from surface to depth.

Figure 2.5.18 shows a plot of the theoretical maximum overburden pressure and the theoretical minimum pressure as a function of depth. Also plotted are various bottomhole fluid pressures from actual wells drilled in the Gulf Coast region [10]. These experimentally obtained pressures are the measurements of the pressures in the fluids that result from a combination of rock overburden and the fluid hydraulic column to the surface. These data show the bottomhole fluid pressure extremes. The abnormally high pressures can be explained by the fact that the sedimentary basins in the Gulf Coast region are immature basins and are therefore unconsolidated relative to older basins. In such basins, the cementing process is by no means complete, which results

FIGURE 2.5.18 Magnitude of abnormal pressure encountered in Gulf Coast region (from Cannon and Sullins, "Problems Encountered in Drilling Abnormal Pressure Formations," in API Drilling and Production Practices, 1946).

FIGURE 2.5.19 Pressure gradients vs. depth (*Gulf Coast example*).

in pressures at depths approaching the maximum theoretical overburden pressures.

The fluid pressure in the rock at the bottom of a well is commonly defined as pore pressure (also called formation pressure, or reservoir pressure). Depending on the maturity of the sedimentary basin, the pore pressure will reflect geological column overburden that may include a portion of the rock particle weight (i.e., immature basins), or a simple hydrostatic column of fluid (i.e., mature basins). The pore pressure and therefore its gradient can be obtained from well log data as well as drilled. These pore pressure data are fundamental for the solution of engineering problems in drilling, well completions, production and reservoir engineering.

Because the geological column of sedimentary rock is usually filled with saline water, the pore pressure and pore pressure gradient can be obtained for nearly the entire column. Figure 2.5.19 shows a typical pore pressure gradient versus depth plot for a Gulf Coast region well.

2.5.6.5 Subsurface Rock Fracture Pressure (Fracture Pressure Gradient)

The Subsurface rock fracture pressure can be approximated by utilizing the known pore pressure at the same depth. The relationship between rock fracture pressure p_f (psi) and pore pressure p_p (psi) is [11]

$$p_f = (\sigma_{ob} - p_p) \left(\frac{v}{1 - v} \right) + p_p \quad (2.5.19)$$

where σ_{ob} is overburden stress (psi) and v is Poisson's ratio.

The subsurface rock fracture pressure gradient is

$$\frac{p_f}{d} = \left(\frac{\sigma_{ob}}{d} - \frac{p_p}{d} \right) \left(\frac{v}{1 - v} \right) + \frac{p_p}{d} \quad (2.5.20)$$

where d is the depth to the subsurface zone (ft).

Figure 2.5.20 shows the variation of Poisson's ratio versus depth for two general locations, the West Texas region and the Gulf Coast region.

FIGURE 2.5.20 Poisson's ratio vs. depth (from Eaton, "Fracture Gradient Prediction and Its Application in Oilfield Operations," *Journal of Petroleum Technology*, October 1969).

The constant value of 0.25 for Poisson's ratio versus depth reflects the geology and the rock mechanics of the mature sedimentary basin in the West Texas region. Since mature basins are well cemented, the rock columns of West Texas will act a compressible, brittle, elastic materials.

The Cenozoic portions of the Gulf Coast sedimentary basins are immature; therefore, little cementing of the sediments has taken place. Poisson's ratio varies with depth for such sedimentary columns, reflecting the variation of properties through the column. At great depth (i.e., approaching 20,000 ft), Poisson's ratio approaches that of incompressible, plastic materials (i.e., 0.5) [12].

Figure 2.5.21 gives typical total overburden stress gradients versus depths for several regions in North America [13].

The rock fracture pressure gradient at depth can be approximated by using Equation 2.5.20 and the variable Poisson's ratios versus depth data (Figure 2.5.20) and the variable total overburden stress gradients versus depth data (Figure 2.5.21).

FIGURE 2.5.21 Total overburden stress gradient vs. depth (from *Engineering of Modern Drilling*, Energy Publication Division of Harcourt Brace Jovanovich, New York, 1982, p. 82).

Example 2.5.2

In Figure 2.5.19 the pore pressure gradient has been given as a function of depth for a typical Gulf Coast well. Determine the approximate fracture pressure gradient for a depth of 10,000 ft. From Figure 2.5.19, the pore pressure gradient at 10,000 ft is

$$\frac{P_p}{d} = 0.066 \text{ psi/ft}$$

From Figure 2.5.20, Poisson's ratio at 10,000 ft is (i.e., Gulf Coast curve)

$$\nu = 0.45$$

From Figure 2.5.21, the total overburden stress gradient is (i.e., Gulf Coast curve)

$$\frac{\sigma_{ob}}{d} = 0.95 \text{ psi/ft}$$

Substituting the foregoing values into Equation 2.5.20 yields

$$\frac{P_f}{d} = (0.95 - 0.66) \left(\frac{0.45}{1 - 0.45} \right) + 0.66 = 0.90 \text{ psi/ft}$$

This value of 0.90 psi/ft falls on the dashed line of Figure 2.5.19. The entire dashed line (fracture pressure gradient) in Figure 2.5.19 has been determined by using Equation 2.5.20.

In general, Equation 2.5.20 can be used to approximate fracture pressure gradients. To obtain an adequate approximation for fracture pressure gradients, the pore pressure gradient must be determined from well log data. Also, the overburden stress gradient and Poisson's ratio versus depth must be known for the region.

There is a field operation method by which the fracture pressure gradient can be experimentally verified. Such tests are known as leak-off tests. The leak-off test will be discussed in Chapter 4.

2.5.7 Basic Engineering Soil Properties

The surface rock formations of the earth are continually exposed to the weathering process of the atmosphere that surrounds the earth. The weathering process through time can change the rock exposed at the surface. Such changes are both mechanical and chemical. The altered surface rock is often used by lifeforms, particularly by plant life that directly draws nourishment from minerals at the surface. As the weathering process proceeds at the surface of the earth, rock at the surface disintegrates into small separate particles and is carried off and deposited at various locations around the original rock. Some particles are carried great distances to the sea to become source sediments for new rock formations. Some particles move only a few feet or a mile or two to be deposited with fragments from other nearby rock locations. These weathered particles, once deposited on the surface of the earth in land locations, are often referred to as soil [14].

To a farmer, soil is the substance that supports plant life. To a geologist soil is an ambiguous term that refers to the

material that supports life plus the loose rock from which it was derived. To the engineer, soil has a broader meaning.

Soil, from the engineering point of view, is defined as any unconsolidated material composed of discrete solid particles that has either liquids or gases in the voids between the individual particles.

In general, soil overlays rock formations, and the soil is related to the rock since the rock was its source. Where the soil ends (in depth) and rock begins is not a well-defined interface. Basically, the depth to which soil is found is that depth where excavation by land methods can be employed. The area where the removal of material requires drilling, wedging, and blasting is believed to be the beginning of rock (in the engineering sense). The engineering properties of soil are of importance to petroleum engineering because it is soil that the drilling engineer first encounters as drilling is initiated. But, more important, it is soil that must support the loads of the drilling rig through an appropriately designed foundation. Further, the production engineer must support the well head surface equipment on soil through an appropriately designed foundation.

2.5.7.1 Soil Characteristics and Classification

The engineer visualizes a soil mass as an ideal, real, physical body incapable of resisting tensile stresses.

The ideal soil is defined as a loose, granular medium that is devoid of cohesion but possesses internal friction. In contrast, an ideal cohesive medium is one that is devoid of internal friction. Real soils generally fall between the foregoing two limiting definitions.

Soils can consist of rock, rock particles, mineral materials derived from rock formations, and organic matter.

- Bedrock is composed of competent, hard, rock formations that underlie soils. Bedrock is the foundation engineer's description of transition from soils to rock at depth. Such rock can be igneous, sedimentary, or metamorphic. Bedrock is very desirable for foundation placement.
- Weathered rock is bedrock that is deteriorating due to the weathering process. Usually, this is confined to the upper layers of the bedrock.
- Boulders are rock fragments over 10 in. in diameter found in soils.
- Cobbles are rock fragments from 2–4 in. in diameter found in soils.
- Pebbles are rock fragments from about 4 mm to 2 in. in diameter found in soils.
- Gravel denotes unconsolidated rock fragments from about 2 mm to 6 in. in size.
- Sand consists of rock particles from 0.05–2 mm in size.
- Silt and clay are fine-grained soils in which individual particle size cannot be readily distinguished with the

unaided eye. Some classification systems distinguish these particles by size, other systems use plasticity to classify these particles.

Plasticity is defined as the ability of such particle groups to deform rapidly without cracking or crumbling. It also refers to the ability of such groups to change volume with relatively small rebound when the deforming force is removed.

- Silt, in one particle classification system, consists of rock particles from 0.005 to 0.05 mm in size.
- Clay, in one particle classification system, consists of inorganic particles less than 0.005 mm in size. In another system, clay is a fine-grained inorganic soil that can be made plastic by adjusting the water content. When dried, clay exhibits considerable strength (i.e., clay loses its plasticity when dried and its strength when wetted). Also, it will shrink when dried and expand when moisture is added.

Figure 2.5.22 shows a classification system developed by the Lower Mississippi Valley Division, U.S. Corps of Engineers. Percentages are based on dry weight. A mixture with 50% or more clay is classified as clay; with 80% or more silt, as silt; and with 80% or more sand, as sand. A mixture with 40% clay and 40% sand is a sandy clay. A mixture with 25% clay and 65% silt is a clay-silt (see intersection of dashed lines in Figure 2.5.22).

2.5.7.2 Index Properties of Soils

Easily observed physical properties of soils often are useful indexes of behavior. These index properties include texture and appearance, specific weight, moisture content, consistency, permeability, compressibility, and shearing strength [14,15].

- Soil texture, or appearance, depends on particle size, shape, and gradation. Therefore, using the classification in Figure 2.5.22 the soil texture can be specified as sandy clay or clay-sand.
- Soil specific weight is the measure of the concentration of packing of particles in a soil mass. It is also an index of compressibility. Less dense, or loosely packed, soils are much more compressible under loads. Soil specific weight may be expressed numerically as soil ratio and porosity (porosity for soils being basically the same definition as that for rocks discussed earlier in this section). Soil porosity e is

$$e = \frac{V_b - V_s}{V_b} \tag{2.5.21}$$

where V_b is bulk volume of undisturbed soil (ft^3), and V_s is volume of solids in soil (ft^3).

The specific weight (unit weight) (lb/ft^3) of undisturbed soil is

$$\gamma = \frac{W_s}{W_b} \tag{2.5.22}$$

FIGURE 2.5.22 Classification chart for mixed soils (from Lower Mississippi Valley Division, U.S. Corps of Engineers).

where W_s is the weight of the soil solids relative to the undistributed soil bulk volume (lb).

Relative density D_d (a percent) is a measure of the compactness of a soil with void ratio e when the maximum void ratio is e_{max} and the minimum e_{min} . Relative density is

$$D_d = \frac{e_{max} - e}{e_{max} - e_{min}}(100) \quad (2.5.23)$$

Percentage compaction usually is used to measure soil density in a fill situation. Generally, the maximum Proctor specific weight (dry, lb/ft³), determined by a standard laboratory test, is set up as the standard for the soil. Normally, 90–100% compaction is specified.

- Moisture content, or water content, is an important influence on soil behavior. Water content w , dry-weight basis percent, is

$$W = \frac{W_w}{W_s} \quad (2.5.24)$$

where W_w is weight of water in soil (lb) and W_s is weight of solids in soil (lb).

Total net weight of soils, W (lb), is

$$W_e = W_w + W_s \quad (2.5.25)$$

Degree of saturation, S (percent) is

$$S = \frac{V_w}{V_b - V_s}(100) \quad (2.5.26)$$

where V is volume of water in soil (ft³).

Saturation, porosity, and moisture content are related by

$$S_e = WG \quad (2.5.27)$$

where G is the specific gravity of solids in the soil mass.

- Consistency describes the condition of fine-grained soils: soft, firm, or hard. Shearing strength and bearing capacity vary significantly with consistency. In consistency, there are four states: liquid, plastic, semisolid, and solid.
- Permeability is the ability of a soil to conduct or discharge water under a pressure, or hydraulic gradient (permeability for soils being basically the same definition as that for rocks discussed earlier in this section). For soils, the definition of coefficient of permeability is slightly different than that discussed earlier for petroleum reservoir rocks. Since civil engineers and hydrologists are always dealing with water, the coeffi-

cient of permeability, or more precisely, the hydraulic conductivity, k' (cm/s)¹ is

$$k' = \frac{\gamma_w}{\mu_w}k \quad (2.5.28)$$

where k is permeability as defined in Equation 2.5.8, γ_w is the specific weight of water, and μ_w is the viscosity of water.

Therefore, substituting Equation 2.5.8 into Equation 2.5.28 yields

$$k' = \frac{q}{iA} \quad (2.5.29)$$

where i (cm/cm) is the hydraulic gradient and is expressed by

$$i = \frac{\Delta p}{\ell \gamma_w} \quad (2.5.30)$$

and A (cm²) is the total cross-sectional area of soil through which flow occurs.

Table 2.5.4 gives some typical values for hydraulic conductivity and drainage characteristics for various soil types.

TABLE 2.5.4 Hydraulic Conductivity and Drainage Characteristics of Soils

Soil Type	Approximate Coefficient of Permeability k (cm/s)	Drainage Characteristic
Clean gravel	5–10	Good
Clean coarse sand	0.4–3	Good
Clean medium sand	0.05–0.15	Good
Clean fine sand	0.004–0.02	Good
Silty sand and gravel	10 ⁻⁵ –0.01	Poor to good
Silty sand	10 ⁻⁵ –10 ⁻⁴	Poor
Sandy clay	10 ⁻⁶ –10 ⁻⁵	Poor
Silty clay	10 ⁻⁶	Poor
Clay	10 ⁻⁷	Poor
Colloidal clay	10 ⁻⁹	Poor

From Reference 14.

1. Note: k' , hydraulic conductivity, is used for water flow in rocks as well as in soils.

FIGURE 2.5.23 Graphic shear strength of soils.

- Soil compressibility is important for foundation engineering because it indicates settlement. Settlement or deformation of the soil under the foundation occurs because of change of position of particles in a soil mass.
- Shearing Strength is the shear stress in a soil mass at failure of the soil mass (usually cracking), or when continuous displacement can occur at constant stress.

Shearing strength of a soil is usually important in determining bearing capacity of the soil. Shearing stress, τ (lb/in.²), of a soil is expressed as

$$\tau = c + \sigma_n \tan \theta \quad (2.5.31)$$

where C is cohesion of the soil (lb/in.²), σ_n is the normal, effective stress perpendicular to shear surface (lb/in.²), and θ is the angle of internal friction of soil.

The shear strength of coarse particle soils like gravel and sand depend on the interlocking of their particles and, thereby, on intergranular friction. The shear strength of pure clay soils depends basically on cohesion. Figure 2.5.23 gives a graphical representation of the two limits of soil types, i.e., coarse particle soils are denoted as θ soils, pure clay soils are denoted as c soils. Most real soils are a combination (i.e., $\theta - c$) soils. Some approximate friction angles for typical cohesionless soil types are as follows [14]:

Soil Type	ϕ , deg	$\tan \phi$
Silt, or uniform fine to medium sand	26–30	0.5–0.6
Well-graded sand	30–34	0.6–0.7
Sand and gravel	32–36	0.6–0.7

2.5.8 Site Investigations and Laboratory Tests

Before the construction of a foundation, field investigation should be carried out to determine surface and subsurface conditions at the site.

2.5.8.1 Site Investigations

Numerous techniques are used for site investigations. The techniques vary in cost from relatively low-cost visual investigations to costly subsurface explorations and laboratory tests [16,17].

- Visual inspection is an essential primary step. Such inspections should provide data on surface soils, surface waters, and slopes.
- Probing, driving a rod or pipe into the soil and measuring the penetration resistance, obtains initial subsurface information. This is a low-cost method, but in general it is likely to supply inadequate information about subsurface conditions, especially on the depth and nature of bedrock.
- Augers provide subsurface data by bringing up material for detailed examination. Augers disturb the soil; therefore, little or no information can be obtained on the character of the soil in its natural undisturbed state.
- Test pits permit visual examination of the soil in place. Such pits also allow manual sampling of “undisturbed” soil samples. These samples can be taken from the side walls of the pit.
- “Dry” spoon sampling is a technique that is often used in conjunction with auger drilling. At certain depths in the augered borehole a spoon is driven into the undisturbed bottom of the borehole. The spoon sampler is a specified size (usually a 2-in. OD). The number of blows per foot to the spoon samples frequently are recorded, indicating the resistance of the soil. The spoon sampler is driven into the bottom of the hole with a free-falling weight. A 140-lb weight falling 30 in. onto the 2 in. O.D. spoon sampler is the standard method of driving the sampler into the borehole bottom. Table 2.5.5 shows a system of correlation of this technique of sampling. Figure 2.5.24 shows a typical subsurface soils log that describes the soils encountered at depth and number of blows per 6 in. (instead of per foot) on the spoon sampler.

2.5.8.2 Laboratory Tests

In addition to the site investigations just described and the on-site tests which can be carried out through test pits and augering, often specific laboratory tests are required to identify soils and determine their properties. Such laboratory tests are conducted on the soil samples that are recovered from various subsurface depths. These laboratory tests are used when there are questions as to the structural supporting capabilities of the soils at a particular site. Numerous types of laboratory tests are available that can aid the engineer in designing adequate foundation support for heavy or dynamic loads. In general, however, few tests are necessary for most foundation designs [14–17].

TABLE 2.5.5 Correlation of Standard-boring-spoon Penetration with Soil Consistency and Strength (2 in OD Spoon, 140 lb)

Soil Consistency	Number of Blows per ft on Spoon	Unconfined Compressive Strength, tons/ft ²
Sand		
Loose	15	
Medium compact	16–30	
Compact	30–50	
Very compact	Over 50	
Clay		
Very soft	3 or less	0.3 or less
Soft	4–12	0.3–1.0
Stiff	12–35	1.0–4
Hard	Over 35	4 or more

 140 – LB HAMMER
 30 – IN. DROP

FIGURE 2.5.24 Typical soils boring log.

- Mechanical analyses determine the particle-size distribution in a soil sample. The distribution of coarse particles is determined by sieving, and particles finer than a 200 or 270-mesh sieve are found by sedimentation.
- Specific weight determinations measure the relative volumes of voids and solids in a soil.
- Compaction tests, such as the standard Proctor, determine the maximum specific weight or minimum void ratio that can be obtained for a soil, particularly a soil which is to be used for a fill. Specific weights of at least 95% of maximum are usually specified for compacted fills.
- In-place specific weight tests are used to correlate field compaction results with specified engineering requirements for specific weight.
- Moisture-content determinations provide data for estimating soil compaction and compressibility. If a soil is saturated, no volume change can occur without intake or discharge of water.
- Atterberg-limit tests determine the water content influence in defining liquid, plastic, semisolid and solid states of fine-grained soils. Permeability tests may be carried out in the laboratory or in the field. Such tests are used to determine the hydraulic conductivity coefficient k' .
- Confined compression tests are used to determine information pertaining to the behavior of foundations where large volume changes of soil can occur under compression but in the vertical dimension only.
- Unconfined compression tests are used to estimate the shearing strength of cohesive soils.
- Consolidation tests are made on saturated silts and clays to determine the rate of volume change under constant load.
- Direct shear tests are made in the laboratory to obtain data for determining the bearing capacity of soils and the stability of embankments.
- Triaxial compression tests are another means of determining shearing strength of a soil. A complex device is used to apply pressure along the sides of a cylindrical specimen and axially down the axis of the cylindrical specimen. In general, triaxial tests are superior to direct shear tests since there is better control over intake and discharge of water from the specimen.
- California bearing ratio tests are used to evaluate subgrades for pavements. These tests may be carried out in the field or in the laboratory. Such tests determine the resistance to penetration of a subgrade soil relative to that of a standard crushed-rock base.
- Plate bearing tests are field tests that are also used to evaluate subgrades for pavements.

Foundation Loads and Pressures. Foundations should be designed to support the weight of the structure, the live load, and the load effect on the structure and its foundation due to

such other loads as wind. In general, for foundation designs, a safety factor of 3 is used for dead loads or live loads independently. A safety factor of 2 is used for combination loads including transient loads [15, 17].

In general, a foundation is designed for settlement and for pressure distribution. In designing for settlement the usual practice is to ignore transient loads. To keep differential settlements small, foundations are designed to apportion the pressure (between the foundation and the soil) equally over the soil. The assumption is that equal intensities of pressure will produce equal settlement. The accuracy of this assumption will vary with the soil uniformity beneath the foundation, the shape of the foundation, and the distribution of the load on the foundation. Pressures used in calculating bearing capacity or settlement are those in excess of the pressure due to the weight of the soil above. Thus, one should consider pressures composed by the adjacent foundation on the region below the foundation under design. Usual practice in foundation design is to assume that bearing pressure at the bottom of a foundation or on a parallel plane below the foundation is constant for concentrically loaded foundations. This assumption may not be entirely accurate, but more accurate and more complicated theories usually are not justified because of the lack of future knowledge of loading conditions or by the present knowledge of soil conditions. The assumption of constant pressure distribution has been the basis of design of many foundations that have performed satisfactorily for decades. This is especially true for rigid foundations on soils with allowable bearing pressures of 6,000 lb/ft² or more. Another commonly used assumption in foundation design is that the pressure spreads out with depth from the bottom of the foundation at an angle of 30° from the vertical or at a slope of 1 to 2 (Figure 2.5.25). Therefore, for a total load on a foundation of P , the pressure at the base of the footing would be assumed to be $p = P/A$, where A is the area of the foundation itself. As shown in Figure 2.5.25b, the pressure at a depth h would be taken to be P/A or, for a square foundation, as $P/(b + h)^2$. When a weak layer of soil underlies a stronger layer on which the foundation is founded, this method may be used to estimate the pressure on the lower layer. This method can be adopted to determine the total pressure resulting from overlapping pressure distribution from adjacent foundations.

Approximate allowable bearing pressures on sedimentary rock and soils may be taken from Table 2.5.6 [1, 14]. Where questionable surface and subsurface soil conditions exist allowable bearing pressures can be determined with the aid of field sampling, field tests (both surface and subsurface through borings), and laboratory tests.

Spread Foundations. The purpose of the spread foundation is to distribute loads over a large enough area so that soil can support the loads safely and without excessive settlement.

FIGURE 2.5.25 Assumed pressure distribution under a foundation: (a) 30° spread; (b) 1×2 spread [14].

TABLE 2.5.6 Allowable Bearing Capacities of Sedimentary Rock and Soils [14]

Rock or Soil	Allowable Bearing Capacity lbs/ft ²
Sedimentary rock: hard shales, sitstones, sandstones, requiring blasting to remove	20,000 to 30,000
Hardpan, cemented sand and gravel, difficult to remove by picking	16,000 to 20,000
Soft rock, disintegrated ledge; in natural ledge, difficult to remove by picking	10,000 to 20,000
Compact sand and gravel, requiring picking to remove	8,000 to 12,000
Hard clay, requiring picking for removal	8,000 to 10,000
Gravel, coarse sand, in natural thick beds	8,000 to 10,000
Loose, medium and coarse sand; fine compact sand	3,000 to 8,000
Medium clay, stiff but capable of being spaded	4,000 to 8,000
Fine loose sand	2,000 to 4,000
Soft clay	2,000

Such foundations are made of steel-reinforced concrete. When concrete is used for a foundation, it should be placed on undisturbed soil. All vegetation should be removed from the surface; therefore, the upper few inches of soil should be removed before concrete is laid down. The area of the foundation must be large enough to ensure that the bearing capacity of the soil is not exceeded or that maximum settlement is within acceptable limits. If details are known of the subsurface soil conditions, the foundation must be sized to that differential settlement will not be excessive. For uniform soil condition (both horizontal and vertical), this is accomplished by designing the foundation such that the unit pressure under the foundation is uniform for the working loads (usually dead load plus normal live loads) [15,17].

Example 2.5.3

It is intended that a spread foundation be designed for a concentric load of 300,000 lb (dead load plus live load). This foundation is to be placed on the surface (brown silty sand and gravel) of the soil and bedrock column shown in Figure 2.5.23. If a square foundation can be made to support the 300,000-lb load, what should be the dimensions of this foundation?

- The surface layer of soil (i.e., brown silty sand and gravel) has a minimum number of blows per foot on the 2-in. split-barrel spoon of 8 (see Figure 2.5.24). According to Table 2.5.5, this soil would have the classification of a loose silty sand and gravel layer. Table 2.5.6 indicates the allowable bearing capacity could be as low as 3,000 lb/ft². To improve the soil conditions where the foundation is to be laid, the initial few feet of soil are to be removed to expose the subsurface layer which has a minimum number of blows per foot on the 2-in. split-barrel spoon of 16. This would require a removal of approximately 4 to 5 ft of soil. The brown silty sand and gravel in the layer at about 5 ft of depth can be classified as medium compact. Again referring to Table 2.5.6 this layer of soil should have an allowable bearing capacity above 3,000 lb/ft². The average between 3,000 and 8,000 lb/ft² is assumed, i.e., 5,500 lb/ft².
- The initial square foundation dimension that would be needed to meet the allowable bearing capacity of 5,500 lb/ft² is

$$A = \frac{300,000}{5,500} = 54.6 \text{ ft}^2$$

where A is the surface area of the foundation at the point where it contracts the soil. The dimensions of the square foundation are

$$b = (54.6)^{1/2} = 7.4 \text{ ft}$$

- There are two potentially weak subsurface soil layers in the boring log in Figure 2.5.24 that should be checked before the initial foundation design above is accepted.

1. At the depth of approximately 10 ft below the surface, or 5 ft below the intended foundation soil interface, there is a layer of clay, sand, and gravel that has a minimum number of blows per foot on the 2-in. split-barrel spoon of 18. Referring to Table 2.5.5, the compressive strength of this layer could be as low as 2,000 lb/ft². Assuming a one-by-two spread of the subsurface pressure under the foundation, the pressure at that layer would be

$$P_1 = \frac{300,000}{(7.4 + 5)^2} = 1948 \text{ lb/ft}^2$$

For further information on this subject, refer to References 15 through 17.

The subsurface pressure calculated for this layer is below the assumed compressive strength of 2,000 lb/ft²; therefore, the initial foundation dimensions are acceptable relative to the strength of this subsurface layer.

2. At the depth of approximately 40 ft below the surface or 35 ft below the intended foundation-soil interface, there is a layer of medium brown sand that has a minimum number of blows per foot in the 2-in. split-barrel spoon of 14. Referring of Tables 2.5.5 and 2.5.6, this soil could be classified as a loose sand having a compressive strength as low as 3,000 lb/ft². Assuming a one-by-two spread of the subsurface pressure under the foundation, the pressure at that layer would be

$$P_2 = \frac{300,000}{(7.4 + 35)^2} = 167 \text{ lb/ft}^2$$

The subsurface pressure calculated for this layer is well below the assumed compressive strength of 3000 lb/ft²; therefore, the initial foundation dimensions are acceptable relative to this subsurface layer also.

- Because the initial foundation dimensions result in acceptable foundation-soil interface bearing pressures and acceptable subsurface pressures on weaker underlying layers of soil, the square foundation of 7.4 ft is the final foundation design.

2.6 ELECTRICITY

2.6.1 Electrical Units

There are two principle unit systems used in electrical calculations, the centimeter-gram-second (cgs) and the meter-kilogram-second (mks) or International System (SI). [Table 2.6.1](#) is a summary of common electrical quantities and their units. The magnitude of the units in [Table 2.6.1](#) is often not conveniently sized for taking measurements or for expressing values, and [Table 2.6.2](#) presents the prefixes that modify SI units to make them more convenient.

Energy or work W is defined by

$$W = \int_{t_1}^{t_2} p \, dt \tag{2.6.1}$$

where W is work in joules, p is power in watts, and t is time in seconds.

TABLE 2.6.1 Electrical Units

Quantity	Symbol	MKS and SI Units
Current	I,i	Ampere
Charge (Quantity)	Q,q	Coulomb
Potential	V,v	Volt (V)
Electromotive Force	E,e	Volt (V)
Resistance	R,r	Ohm (Ω)
Resistivity	ℓ	Ohm-cm
Conductance	G,g	Mho, Siemens (Ω^{-1})
Conductivity	γ	Mho/cm
Capacitance	C	Farad (f)
Inductance	L	Henry (h)
Energy (work)	W	Joule (J), Watthour (Wh) Kilowatthour (KWh)
Power	P,p	Watt
Reactance, inductive	X_L	Ohm
Reactance, capacitive	X_C	Ohm
Impedance	Z	Ohm

TABLE 2.6.2 SI Unit Dimensional Prefixes

Symbol	Prefix	Multiple
T	tera	10^{12}
G	giga	10^9
M	mega	10^6
k*	kilo	10^3
h*	hecto	10^2
da*	deca	10^1
d	deci	10^{-1}
c	centi	10^{-2}
m	milli	10^{-3}
	micro	10^{-6}
n	nano	10^{-9}
p	pico	10^{-12}

*May also use capital letter for the symbol.

Relations between common units of energy are as follows:

- watt-second = 1 joule
- watt-second = 0.239 calorie
- watt-second = 0.738 foot-pound
- kilowatt-hour = 3413 Btu
- kilowatt-hour = 1.34 horsepower-hours
- kilowatt-hour = 3.6×10^6 joules
- electron-volt = 1.6×10^{-9} joule
- erg = 10^{-7} joule

Power (P,p) is the time rate of doing work. For constant current I through an electrical load having a potential drop V, the power is given by

$$P = IV \quad (2.6.2)$$

where P is power in watts, V is potential drop in volts, and I is current in amperes.

For a time-varying current i and potential drop v, the average power P_{av} is given by

$$P_{av} = \frac{1}{t} \int_0^t iv \, dt \quad (2.6.3)$$

where P_{av} is average power in watts; i is current in amperes, v is potential drop in volts, and t is time in seconds.

Relations between common units of power are as follows:

- 1 w = 1 j/s
- 0.239 c/ sec
- 9.48×10^4 Btu/s
- 1/745 hp
- 0.7375 ft-lb/s

Electric charge or quantity Q, expressed in units of coulombs, is the amount of electricity that passes any section of an electric circuit in one s by a current of one ampere. A coulomb is the charge of 6.24×10^{18} electrons.

Current (I,i) is the flow of electrons through a conductor. Two principal classes of current are:

- Direct (dc)—the current always flows in the same direction.
- Alternating (ac)—the current changes direction periodically.

The unit of current is the ampere which is defined as one coulomb per second.

Electric potential (V,v), potential difference, or electromotive force (emf, E, e) have units of volts and refer to the energy change when a charge is moved from one point to another in an electric field.

Resistance (R,r) is an element of an electric circuit that reacts to impede the flow of current. The basic unit of resistance is the ohm (Ω), which is defined in terms of

Ohm's law as the ratio of potential difference to current, i.e.,

$$R = \frac{V}{I} \quad (2.6.4)$$

The resistance of a length of conductor of uniform cross-section is given by

$$R = \frac{\rho \ell}{A} \quad (2.6.5)$$

where A is cross-section area of the conductor in square meters, ℓ is length of the conductor in meters, and ρ is resistivity of the material in ohm-meters; R is resistance in ohms.

Conductance (G,g) is the reciprocal of resistance and has units of reciprocal ohms or mhos (Ω^{-1}) or more properly in SI units, *seimens*.

Conductivity (γ) is the reciprocal of resistivity.

Capacitance (C) is the property that describes the quantity of electricity that can be stored when two conductors are separated by a dielectric material. The unit of capacitance is the farad. The capacitance of two equal-area, conducting parallel plates (see Figure 2.6.1) separated by a dielectric is given by

$$C = \frac{\epsilon_r \epsilon_v A}{d} \quad (2.6.6)$$

where ϵ_r is dielectric constant of the material between the plates, ϵ_v is dielectric constant of free space or of a vacuum, A is the area of a plate in square meters, d is distance between the plates in meters, and C is capacitance in farads.

Inductance (L) is the property of an electric circuit that produces an emf in the circuit in response to a change in the rate of current, i.e.,

$$e = L \frac{di}{dt} \quad (2.6.7a)$$

where e is emf induced in the circuit in volts, I is current in amperes, t is time in seconds, and L is coefficient of (self) inductance in henries.

FIGURE 2.6.1 Schematic of a parallel plate capacitor.

FIGURE 2.6.2 Schematic of an induction coil.

For a coil (see Figure 2.6.2), the inductance is given by

$$L = KN^2 \quad (2.6.7b)$$

where N is number of turns, K is a constant that depends on the geometry and the materials of construction, and L is coefficient of inductance in henries.

Coils are described later in the section titled “Magnetic Circuits.”

2.6.2 Electrical Circuit Elements

Electrical phenomena may generally be classified as *static* or *dynamic*. In *static* phenomena, current or charges do not flow or the flow is only momentary. Most practical uses of electricity (at least in the conventional engineering sense) involve *dynamic* systems where current flows for useful periods of time. Systems that allow current to flow for extended periods of time are termed *circuits*. As the name implies, such systems are connected in a loop so that any beginning point in the circuit has electrical continuity with the ending point through *circuit elements*.

The simplest circuit element is the *short circuit*. Figure 2.6.3a illustrates the concept of a short circuit. A source of emf (labeled v_s) produces a current that flows relatively unimpeded through the conductor resulting in a nearly zero potential drop and an infinite current.

Figure 2.6.3b illustrates an *open circuit*. The conductor of the short circuit is interrupted and current cannot flow even though the emf produces a finite potential.

2.6.3 Passive Circuit Elements

Circuit elements may be classified as *passive* or *active*. *Passive elements* may store or transform electrical energy. *Active elements* may transform other forms of energy (including electrical energy from another system) into an increase in the electrical energy of the circuit or they may

(a) SHORT CIRCUIT

(b) OPEN CIRCUIT

FIGURE 2.6.3 Schematic of the simplest circuit elements.

serve to dissipate circuit energy. In the latter case, the rate of increase or dissipation is controlled by conditions outside of the circuit. A simple example of an active element might be a generator that supplies power (emf) to the circuit. The rate of power generation depends on the mechanical shaft power input.

There are three, linear, *passive circuit elements*: resistors, capacitors, and inductors. *Resistors* dissipate energy in the circuit, i.e., electrical energy is transformed to heat energy and is lost from the circuit. *Capacitors* store electrical energy as charges on conductors separated by a dielectric material. *Inductors* store the electrical energy of current as magnetic potential in a manner analogous to the kinetic energy stored in a mass in motion. Table 2.6.3 summarizes the circuit element characteristics.

2.6.3.1 Series and Parallel Connection of Circuit Elements

Circuit elements may be connected in either a *series* or *parallel* configuration. In the *series* configuration, the same current flows through each and every element, and the circuit potential drop (or emf that is developed by the voltage source) is the algebraic sum of the potential drops of each individual element. For sources in series, the total emf developed is the algebraic sum of the emfs developed by each individual source.

In the *parallel* configuration, the same potential difference occurs across each and every element with the total current being the algebraic sum of the current flowing through each individual circuit element. Table 2.6.4 summarizes the equivalent resistance, conductance, capacitance, and inductance of series-parallel configurations of resistors, capacitors, and inductors.

TABLE 2.6.3 Circuit Element Characteristics

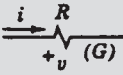

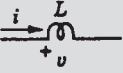

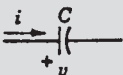

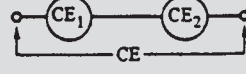

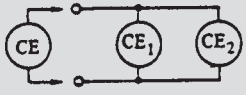

Element	Unit	Symbol	Characteristic
Resistance (Conductance)	ohm (mho)		$v = Ri$ $(i = Gv)$
Inductance	henry		$v = L \frac{di}{dt}$ $i = \frac{1}{L} \int_0^t v dt + I_0$
Capacitance	farad		$i = C \frac{dv}{dt}$ $v = \frac{1}{C} \int_0^t i dt + V_0$
Short circuit			$v = 0$ for any i
Open circuit			$i = 0$ for any v
Voltage source	volt		$v = v_s$ for any i
Current source	ampere		$i = i_s$ for any v

TABLE 2.6.4 Series-Parallel Combinations

Circuit Element	Series	Parallel
		
Resistor R_1, R_2	$R = R_1 + R_2$	$R = \frac{R_1 R_2}{R_1 + R_2}$ or $R = \left(\frac{1}{R_1} + \frac{1}{R_2} \right)^{-1}$
Inductor L_1, L_2	$L = L_1 + L_2$	$L = \frac{L_1 L_2}{L_1 + L_2}$ or $L = \left(\frac{1}{L_1} + \frac{1}{L_2} \right)^{-1}$
Capacitor C_1, C_2	$C = \frac{C_1 C_2}{C_1 + C_2}$ or $C = \left(\frac{1}{C_1} + \frac{1}{C_2} \right)^{-1}$	$C = C_1 + C_2$

2.6.3.2 Circuit Analysis

There are two fundamental laws used in circuit analysis, called Kirchhoff's laws:

1. At a branch point in an electric circuit, the sum of the currents flowing to the point equals the sum of the currents flowing from the point.
2. The electric potential measured between two points in an electric circuit is the same regardless of the path along which it is measured.

These laws apply to both DC and AC currents.

2.6.4 Transient and AC Circuits

In a transient or an AC circuit, we term the sum of resistance, inductance, and capacitance as *impedance*. Using complex notation, the energy storage properties of inductance and capacitance are represented as purely imaginary quantities, while the resistance is represented as a (+) real quantity. Capacitance is represented as the negative imaginary axis, and current through a pure capacitance is said to *lead* the potential by 90° . Inductance is represented as the positive imaginary axis, and the current through a pure inductance is said to *lag* the potential by 90° . These relationships may be expressed mathematically for an inductance and resistance in series as

$$Z = R + jX_L \quad (2.6.8)$$

and for a capacitance and resistance in series as

$$Z = R - jX_C \quad (2.6.9)$$

where Z is impedance in ohms, j is an imaginary unit, X_L is the impedance due to inductance or reactance in ohms $= 2\pi fL = \omega L$, X_C is impedance due to capacitance or *reactance* in ohms $= 1/2\pi fC = 1/\omega C$, R is resistance in *ohms*, L is coefficient of inductance in henries, C is capacitance in farads, f is frequency of the current (or voltage) in Hertz (cycles per second), and ω is angular velocity in radians per second.

For the impedance of the resistance and inductance in series, the current will lag the potential phase angle by

$$\theta = \arctan\left(\frac{X_L}{R}\right) \quad (2.6.10a)$$

For the impedance of the resistance and capacitance in series, the current will lead the potential phase angle by

$$\theta = \arctan\left(\frac{-X_C}{R}\right) \quad (2.6.10b)$$

When multiple circuit elements are involved, the resultant phase angle difference between the current and the potential will result from the contribution of each element.

2.6.5 AC Power

The power dissipated in an AC circuit with current of maximum amplitude I_m flowing through a resistance is less than the power produced by a constant DC current of magnitude I_m flowing through the same resistance. For a sinusoidal AC current, the *root mean square* (rms) value of current I is the magnitude of the DC current producing the same power as the AC current with maximum amplitude I_m . The rms value I is given by

$$I = \frac{1}{\sqrt{2}}I_m = 0.707I_m \quad (2.6.11)$$

The power dissipated in an AC circuit with only resistive elements is

$$P = I^2R = \frac{V^2}{R} \quad (2.6.12)$$

where V is rms value of the potential drop. This resistive power is termed *active power* with units of *watts*.

Reactive circuit elements (i.e., capacitors and inductors) store, not dissipate, energy. While the energy stored is periodically returned to the rest of the circuit, reactive elements do require increased potential or current to flow in the circuit. The power that must be supplied for the reactive elements is termed *reactive power*, and it is calculated as

$$Q_x = I^2X = \frac{V^2}{X} \quad (2.6.13)$$

where Q_x is reactive power in volt-amperes reactive (*VAR*), X is reactance in ohms, V is rms potential in volts, and I is current in amperes.

The reactive component of impedance is expressed as

$$X = Z\sin\theta \quad (2.6.14)$$

where Z is impedance in *ohms*, and θ is leading or lagging phase difference between current and potential.

Note that $\sin\theta$ may be either positive or negative and lies between 0 and 1 for $|\theta| \leq 90^\circ$.

The *apparent power* is the complex sum of the *active power* and the *reactive power*. By nothing that

$$R = Z\cos\theta \quad (2.6.15)$$

we may calculate

$$P_A = VI\cos\theta + jVI\sin\theta \quad (2.6.16)$$

where P_A is apparent power in volt-amperes (*VA*), V is rms potential, I is rms current, and θ is leading or lagging difference in phase angle between current and potential.

The *power factor* $\cos\theta$ is always a positive fraction between 0 and 1 (as long as $|\theta| \leq 90^\circ$). The smaller the power factor, the greater the current that must be supplied to

the circuit for a given active (useful) power output requirement. The increase in current associated with low power factors causes greater line losses or requires an increase in the capacity of the transmission equipment (wire size, transformers, etc.). As a result, for industrial applications there is often a power factor change in the rate structure for supplying electricity. The usual situation is for loads to be inductive, and the industrial consumer may add capacitance to their circuits to correct the lagging power factor.

2.6.6 Magnetism

Magnetic fields are created by the motion of electric charges. The charge motion may be a current in a conductor or, at the atomic level, the movements of orbital electrons. For certain materials, called *ferromagnetic* materials, the neighboring atoms align themselves so that the magnetic effects of their orbital electrons are additive. When the atoms of a piece of such a ferromagnetic material are aligned, the piece is called a *magnet*. Magnetic fields have north (N) and south (S) poles. When two magnets are brought together, like poles repel and unlike poles attract each other. In other (nonmagnetic) materials, the atoms are aligned randomly and the magnetic effects cancel.

Analogies exist between electric and magnetic fields. The *magnetic flux* (ϕ) is analogous to electric current and has SI units of webers (see Table 2.6.5). The *magnetic flux density* (B) is analogous to current density and has units of teslas. One tesla exists when the charge of one coulomb moving normal to the magnetic field with a velocity of one meter per second experiences a force of one newton. In vector notation this is expressed as

$$\vec{f} = q(\vec{u} \times \vec{B}) \tag{2.6.17}$$

where \vec{f} is the force vector in newtons, q is the charge in coulombs, \vec{u} is velocity vector in meters per second, and B is magnetic flux density vector in teslas.

TABLE 2.6.5 Magnetic Units			
Quantity	Symbol	Cgs Units	SI Units
Magnetomotive Force	\mathcal{F}	Gilberts	Amp-turns (NI)
Magnetic Field Intensity	H	Oersted (Oe)	Amp-turns/meter
Magnetic Flux	ϕ	Maxwell or line	Webers (Wb)
Magnetic Flux Density	B	Gauss	Teslas (Wb/m ²)

If a current flows through a conductor, the magnetic flux is oriented in a direction tangent to a circle whose plane is perpendicular to the conductor. For current flowing in an infinitely long, straight conductor, the magnetic flux density at a point in space outside the conductor is given as

$$B = \frac{\mu i}{2\pi D} \tag{2.6.18}$$

where B is magnetic flux density in teslas, i is current in amperes, D is distance from conductors to the point in space in meters, and μ is permeability in webers per amp-meter or henries per meter.

The *permeability* (μ) is a property of the material surrounding the conductor. The *permeability of free space* (μ_0) is

$$\mu_0 = 4 \times 10^{-7} \text{ henries per meter} \tag{2.6.19}$$

The ratio of the permeability of any material to the permeability of free space is termed the *relative permeability* (μ_r).

The magnetic field intensity (H) is given as

$$H = \frac{B}{\mu} \tag{2.6.20}$$

or for the magnetic field induced by current in an infinite-length straight conductor,

$$H = \frac{i}{2\pi D} \tag{2.6.21}$$

2.6.7 Magnetic Circuits

Previously the analogy between electric fields and magnetic fields was introduced. Likewise, there are analogies between magnetic circuits and electric circuits. Figure 2.6.4 illustrates these analogies and allows us to define additional terms. In the electric circuit of Figure 2.6.4a Ohm's law applies, i.e.,

$$\frac{V}{I} = R = \frac{\rho \ell}{A} = \frac{\ell}{\gamma A} \tag{2.6.22}$$

In Figure 2.6.4b, there is an analogous relationship, i.e.,

$$\mathcal{R} = \frac{\mathcal{F}}{\phi} = \frac{\ell}{\mu A} \tag{2.6.23}$$

where \mathcal{F} is magnetic magnetomotive force in ampere-turns, ϕ is magnetic flux in webers, \mathcal{R} is reluctance — the resistance to magnetic flux, and μ is magnetic permeability. The magnetic magnetomotive force (\mathcal{F}) in Figure 2.6.4 is given by

$$\mathcal{F} = Ni \tag{2.6.24}$$

FIGURE 2.6.4 Electric (a) and magnetic (b) circuits.

where \mathcal{F} is magnetomotive force in ampere-turns, N is number of turns, and i is current in amperes.

2.6.8 Transformers

Transformers are electromagnetic devices that allow electrical power supplied at one potential to be transformed into electrical power at another potential. The potential or voltage may be stepped up (increased) or stepped down (decreased). For instance, in the usual transmission of domestic power, the potential in the transmission lines is greater than the load requirements and a step down transformer is used to reduce the potential at the end use point.

Figure 2.6.5 illustrates the basics of a transformer. First there is a *core*, usually constructed of a material of high magnetic permeability to achieve a high magnetic flux density. The core has two *windings* of conductors, a *primary coil* (designated as N_1 in the figure) and a *secondary coil* (designated as N_2). Electric current through the primary coil causes a magnetic flux in the core and at the same time an impedance to the current and therefore an induced emf across the primary. The magnetic flux in the core in turn induces an emf across the secondary coil, causing a current to flow. The relation between the emf induced in the

primary coil (note that this is not the source emf) and the emf induced in the secondary coil is given by

$$\frac{e_1}{e_2} = \frac{E_1 N_1}{E_2 N_2} \tag{2.6.25}$$

where e_1, e_2 is AC-induced emfs in volts, E_1, E_2 is rms values of e_1 and e_2 , and N_1, N_2 is number of turns on the primary and secondary coils, respectively.

There will be inefficiencies within the transformer, and the voltages at the transformer terminals will vary a little from the previous relationships.

Likewise, the approximate relationship between the primary and secondary currents will be

$$\frac{I_1}{I_2} = \frac{N_2}{N_1} \tag{2.6.26}$$

2.6.9 Rotating Machines

There is a class of electromechanical equipment in which mechanical energy is converted into electrical energy (or vice versa), all of which use either the response of conductors rotating through a magnetic field or a magnetic field rotating in the presence of stationary conductors. Because the machines rotate, power is transformed in a constant mode rather than the pulsating mode as occurs in similar translational devices.

Figure 2.6.6 is a schematic of perhaps the simplest rotating machine, the elementary *dynamo*. The elementary dynamo consists of a rectangular-shaped coil, which is free to rotate about an axis. In a practical device, the coil is physically attached to a shaft at the axis of rotation but is electrically insulated from this shaft. *Slip rings* connected to the coil are also attached but insulated from the shaft. The slip rings and brushes allow electrical contact with an external circuit while the shaft turns.

Consider the effect when the coil turns in the presence of an external magnetic field. An emf will be generated in the coil given by

$$e = NBA\omega \cos \omega t \tag{2.6.27}$$

FIGURE 2.6.5 Basic transformer operation.

where e is generated emf in volts, N is number of turns of wire in the coil, B is magnetic flux density in teslas, A is area surrounded by the coil $= 2r\ell$, r is radius of rotation of the coil, ℓ is length of coil along the axis of rotation, ω is angular velocity in radians per second, and $t =$ time in seconds.

A torque will have to be overcome to maintain the rotation of the coil. This torque is given as

$$\tau_d = NBAi \cos \omega t \tag{2.6.28}$$

where N , B , A , ω , t are as previously defined, τ_d is developed torque in the elementary dynamo, and i is current.

Note that the direction of the applied torque will dictate the direction of the induced current in the elementary dynamo.

The “external” magnetic field could be due to a magnet or it could be due to the magnetomotive force induced by a current in a conductor (or another stationary coil). The relationship for torque developed when the fields of a stationary (*stator*) coil and a rotating (*rotor*) coil interact is given by

$$\tau_d = k i_s i_r \sin \delta \tag{2.6.29}$$

where τ_d is torque developed in the dynamo, k is constant term, which includes the number of coil windings, dimensions of the dynamo, velocity of rotation, etc., i_s is current in the stator coil in amperes, i_r is current in the rotor coil in amperes, and δ is angle between the fields, called the *torque* or the *power angle*.

Because the current in each coil induces a magnetic field, the torque relationship may also be given as

$$\tau_d = k' B_s B_r \sin \delta \tag{2.6.30}$$

where k' is constant, B_s is magnetic flux density associated with the stator in teslas, and B_r is magnetic flux density associated with the rotor in teslas.

Thus from Equation 2.6.30, we see that for a given dynamo geometry, the developed torque only depends on

the interaction between two magnetic fields and their orientation with respect to each other. One or both of the magnetic fields may be induced by a current. If one of the fields is the field of a magnet, then it may be either in the rotor or the stator. If the rotation results from the imposition of mechanical power on the rotor, the device is called a *generator*. If the rotation is caused by the flow of current, the device is called a *motor*, i.e., converts electric power to mechanical power.

If the rotor of the elementary dynamo is turned in a uniform magnetic field, an AC emf and current are produced. If the speed of rotation is constant, the emf and current are sinusoidal as shown in Figure 2.6.6.

Figure 2.6.7 is a schematic of another AC generator called an *alternator*. A DC current is supplied to field windings on the rotor, which are then rotated inside the stator windings, producing the AC emf.

The device of Figure 2.6.7 can also operate as a motor if a DC current is applied to the rotor windings as in the alternator and an AC current is imposed on the stator windings. As the current to the stator flows in one direction, the torque developed on the rotor causes it to turn until the rotor and stator fields are aligned ($\delta = 0^\circ$). If, at that instant, the stator current switches direction, then mechanical momentum will carry the rotor past the point of field alignment, and the opposite direction of the stator field will cause a torque in the same direction and continue the rotation.

If the slip rings of the elementary dynamo are replaced by a *split-ring commutator*, then a DC emf and current will be generated as shown in Figure 2.6.8. If the single coil of the elementary dynamo is replaced with multiple coils attached to opposing segments of a multisegment commutator, then the emf generated will be more nearly constant. There will, however, always be a momentary reduction in the emf at the times in the cycle when the spaces in the commutator pass the brushes. By the proper orientation of the rotor (called the *armature*) windings in relation to the commutator segment in contact with the brushes, the torque angle ($\delta = 90^\circ$) can be made to produce maximum torque.

FIGURE 2.6.6 Elementary dynamo construction and operation.

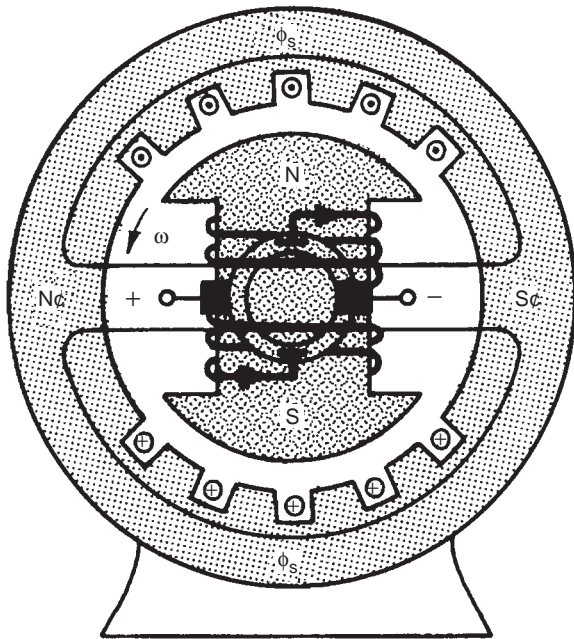

FIGURE 2.6.7 An alternator.

The DC generator can be operated as a motor by imposing a dc current on the armature.

2.6.10 Polyphase Circuits

Circuits that carry AC current employing two, three, or more sinusoidal potentials are called *polyphase* circuits. Polyphase circuits provide for more efficient generation and transmission of power than single-phase circuits. Power in a three- (or more) phase circuit is constant rather than pulsating like the single-phase circuit. As a result, three-phase motors operate more efficiently than single-phase motors.

The usual situation is to have three phases, each generated by the same generator but with a difference of 120° between each phase. Each phase of the generator could be operated independently of the other phases to supply single-phase loads, but to save wiring costs the phases are often run together. The three-phase generator may be connected in either *delta* (Δ) or *Y* configuration. Figure 2.6.9 illustrates the two types of generator connections. The coils in the figure are armature windings (see the section on “Rotating Machines”). For the *Y connection* with balanced (equal impedance and impedance phase angle on each phase) load, the *line and coil currents are equal*, but the line-to-line emfs are the square root of three times the coil emfs. In the Δ *configuration* with balanced loads, the line currents are the square root of three times the coil currents, and the *coil and line emfs are the same*.

FIGURE 2.6.8 Commutator operation (a) and generated voltage waveform (b).

FIGURE 2.6.9 Three-phase connections.

The common connection of all three armature windings in the Y connection allows a fourth, or *neutral*, conductor to be used. This neutral point is often grounded in transmission and distribution circuits. Such a circuit is termed a *three-phase, four-wire* circuit.

In a balanced three-phase circuit, the total power is three times the power in each phase, or

$$P_{total} = 3P_p = 3V_p I_p \cos \theta \quad (2.6.31)$$

where P_{total} is total circuit power, P_p is phase power, V_p is rms phase potential, I_p is rms phase current, and θ is phase angle difference between phase potential and phase current.

Regardless of whether the circuit is connected in Δ or Y, the total power is also

$$P_{total} = \sqrt{3}V_l I_l \cos \theta \quad (2.6.32)$$

where P_{total} and θ are previously defined, V_l is rms line-to-line potential, and I_l is rms line current.

Note that θ is not the phase angle difference between line potential and line current.

Just as the armature coils of a three-phase generator may be connected in a Δ or Y configuration, the circuit loads may be connected in a Δ or Y configuration. The Δ -load configuration may be supplied from a source that is connected in either Δ or Y. The Y connection may include a

neutral (fourth) wire, connected at the common connection of the circuit.

2.6.11 Power Transmission and Distribution Systems

Electric power is almost always transmitted as three-phase AC current. In domestic use, current is often distributed from a substation at voltages ranging from 4,160 to 34,500 volts, which are stepped down by a transformer close to the point of use to 600, 480, and 240 V for three-phase current for commercial power and 240 and 120 V for single-phase, three-wire current for household power and lights. If DC current is required, synchronous converters or rectifiers are used to convert the AC supply to DC.

Most devices are designed for a constant potential and, as a result, power is usually distributed to loads at constant potential. Two possible configurations for delivering a constant potential to multiple loads are illustrated in Figure 2.6.10. In the *parallel circuit*, the potential across the load decreases as the distance from the source increases. For the *loop circuit*, potentials are more nearly equal along the length of the circuit.

Transmission lines usually consist of two or more conductors separated by some form of insulation. Such a configuration exhibits a significant resistance, inductance, and capacitance. Figure 2.6.11 illustrates these effects.

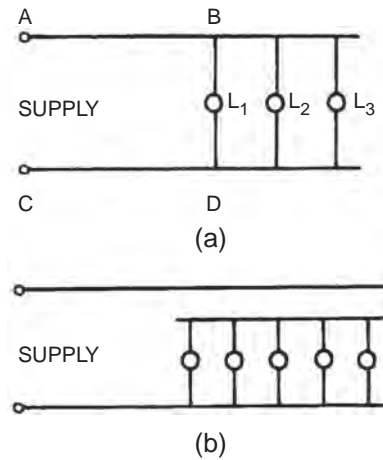

FIGURE 2.6.10 Circuits: (a) parallel; (b) loop.

FIGURE 2.6.11 Resistance, inductance, and capacitance of transmission lines.

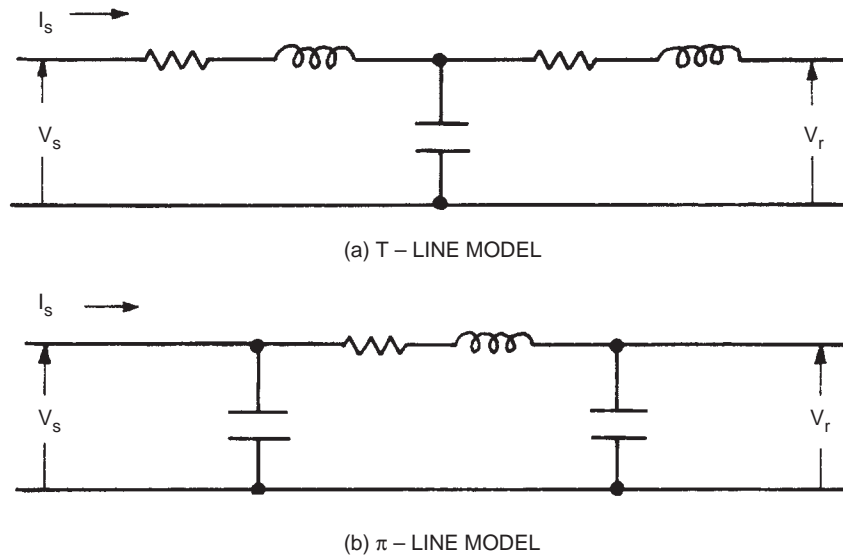

FIGURE 2.6.12 Lumped element models of transmission line electrical characteristics.

Solving the circuit of Figure 2.6.11 is quite involved, and transmission line electrical characteristics are often represented more simply as a lumped parameter model. Figure 2.6.12 depicts two common lumped models used as equivalent circuits to calculate line losses, changes in phase angle, etc.

The materials for transmission and distribution conductors are usually copper and aluminum. Copper is expensive, has a high conductivity, and has sufficient mechanical strength for many uses. Aluminum has the advantage that for a given weight of conductor, it has twice the conductance of copper. A disadvantage of aluminum is that its melting point is lower than copper, while its thermal expansion is greater and stability problems are sometimes encountered.

Conductor or wire sizes are expressed in terms of the *American Wire Gage* (AWG) system. In this system, the ratio of any wire diameter to the next smaller gage or diameter is 1.123. The AWG sizes range from 40 to 0000. Table 2.6.6 lists the AWG number, wire dimension, and resistance for solid copper wire. Wires larger than 0000 (as well as smaller wires) are stranded to maintain flexibility. Wire sizes greater than 0000 are expressed in circular mils. A circular mil is the square of the diameter of the conductor, where the diameter is expressed in milli-inches. (1000 milli-inch = 1 inch).

Interior wiring design and installation for most commercial and industrial uses should follow the *National Electrical Code* (NEC) which has been a national standard since 1970 with the passage of the Occupational Safety and Health Act (OSHA). Some localities, however, may not accept the NEC and require that their own (more stringent) standards be followed.

For further information on this subject, refer to References 1–5.

2.7 CHEMISTRY

This section discusses basic chemistry, with emphasis on the compounds found in petroleum and selected physical chemistry topics likely to arise in petroleum engineering. Examples are provided to illustrate fundamental ideas and principles. More complete treatment of these topics and others can be found in standard textbooks of general, organic, and physical chemistry.

2.7.1 Chemical Bonds and Polarity

Chemical compounds may be considered *ionic* or *covalent*. In an ionic compound, electrons are transferred from a more electropositive element, such as a metal, to a more electronegative element, such as a halide, or to a more complex structure, such as nitrate (NO_3^-). Common salt, NaCl, is an example of an ionic compound. Ionic compounds are usually soluble in water because the *cation*, in this case Na^+ , and the *anion*, Cl^- , can dissociate and become solvated by the water. Many inorganic compounds are at least partly ionic. Ionic compounds tend to be good conductors of electricity. Their melting and boiling points are higher than those of covalent compounds.

In covalent compounds, electrons are shared in the bond between two atoms, and anions and cations are not formed. Organic compounds found in petroleum are predominantly covalent. Covalent compounds are poorly soluble in water and are poor conductors of electricity.

Chemical bonds may also have mixed ionic and covalent character. As the difference in electronegativities of atoms sharing a chemical bond increases, the bond becomes more ionic. Although the molecule may be electroneutral, it can have a dipole moment, with the more electronegative atom carrying a partial negative charge.

The order of electronegativity of some elements [1] is

Examples of nonpolar molecules in which both atoms are the same are H_2 , N_2 , O_2 , I_2 , and Cl_2 . Compounds in which atoms are symmetrically arranged, such as methane (CH_4), also may be nonpolar.

Water is a covalent compound, with two bonds between oxygen and hydrogen in which the oxygen and hydrogen each contribute one electron. However, the electronegativity difference between oxygen and hydrogen is large enough that the bonds and therefore the molecule is polar:

The oxygen in water also carries an electron pair, which is attracted to the hydrogens of other water molecules (i.e., hydrogen bonding) or to other electropositive species, such as cations or electropositive hydrogens in other compounds such as acids. The hydrogen bond is much stronger than most dipole-dipole interactions and accounts for many of the distinctive properties of water.

2.7.2 Hydrocarbons

Compounds formed from carbon and hydrogen only are called *hydrocarbons*, which make up the bulk of petroleum. Carbon atoms can bond to each other to form chains and rings, and they can share one, two, or three pairs of electrons in each bond. These characteristics allow the formation of a wide variety of compounds. Chemists group these compounds into *homologous series*, families of compounds that contain a common *functional group*. Each member of a homologous series differs from the next by a one-carbon unit.

Nonpolar molecules such as H_2 , N_2 , O_2 , I_2 , and Cl_2 have zero dipole moments, because $e = 0$. On the other hand, hydrogen fluoride, HF, has a large dipole moment of 1.75 Debye and so is strongly polar. Simple carbon compounds with symmetric arrangement of like atoms (e.g., methane, CH_4 , and carbon tetrachloride, CCl_4) have zero dipole moments and so are nonpolar.

In polar compounds, the operative intermolecular forces are dipole-dipole interactions, which refer to the attraction between the positive pole of one molecule and the negative pole of another. For this reason, polar compounds are relatively more stable than nonpolar substances. A particularly strong kind of dipole-dipole attraction is hydrogen bonding, in which a hydrogen atom acts as a bridge between two electronegative atoms, holding one atom by a covalent linkage and the other by purely electrostatic forces, e.g.,

where the sequence of dots indicates the hydrogen bridge. This bond has a strength of 5 kcal/g-mole versus 50–100 kcal/g-mole for the covalent bond, but it is much stronger than other dipole-dipole interaction [21]. For hydrogen bonding to be important, both electronegative atoms must belong to the group: F, O, N.

The intermolecular forces operative in nonpolar compounds are also electrostatic in nature. These weak van der Waals forces involve attraction between nonbonded atoms and are effective over short ranges only.

The nomenclature of organic compounds is based on conventions adopted by the International Union of Pure and Applied Chemistry (IUPAC) [2]. A brief discussion of the various classes of hydrocarbons follows.

2.7.2.1 Alkanes

Alkanes are the simplest aliphatic compounds, containing only carbon and hydrogen held together by single bonds and not containing a ring. They have the general formula C_nH_{2n+2} , where n is the number of carbon atoms in the alkane molecule, and $n \geq 1$. These are also known as *paraffins* or *saturated aliphatic hydrocarbons*. Continuous or straight-chain alkanes are called normal paraffins or *n*-alkanes (e.g., methane, CH_4 ; ethane, C_2H_6 ; propane, C_3H_8 ; *n*-butane, $n-C_4H_{10}$; etc.). The corresponding *alkyl* groups, methyl, $-CH_3$; ethyl, $-C_2H_5$; *n*-propyl, $-C_3H_7$; *n*-butyl, $-C_4H_9$; etc., are generally represented by the symbol $R-$.

Branched-chain alkanes, also known as “isoparaffins” or “isoalkanes,” are possible when $n \geq 4$. The prefix “iso” is used when two methyl groups are attached to a terminal carbon atom of an otherwise straight chain and the prefix “neo” when three methyl groups are attached in that manner. Branched-chain alkanes are sometimes regarded as normal alkanes with attached substituent alkyl groups. An example is

2,2,4-trimethylpentane (isooctane)

Isomers are substances having the same molecular formula and molecular weight, but differing in physical and chemical properties. Branched and straight-chain alkanes with the same molecular formula can exist as distinct structures having different geometrical arrangement of the atoms, which are termed *structural isomers*. One example is C_4H_{10} (butane), which has two isomers:

As the carbon number increases, the number of possible structural isomers grows rapidly. For example, C_5H_{12} has only three isomers,

while $\text{C}_{10}\text{H}_{22}$ (decane) has 75, and $\text{C}_{20}\text{H}_{42}$ (eicosane) has 366,319 possible isomers.

Although n-alkanes exhibit smooth and graded variations in physical properties (Table 2.7.1), the branched members do not [3]. The structural isomers of any alkane generally show dissimilar physical and chemical characteristics. A branched-chain isomer has a lower boiling point than a straight-chain isomer, and the more numerous the branches, the lower its boiling point. Alkanes are either nonpolar or weakly polar. They are soluble in nonpolar or weakly polar solvents (e.g., benzene, chloroform, ether), and are insoluble in water and other highly polar solvents. Alkanes can dissolve compounds of low polarity. Chemically, paraffins are unreactive at ordinary conditions. At high temperatures, they can burn completely in the presence of oxygen to yield CO_2 and H_2O as products. The combustion reaction is exothermic.

At ambient temperature and pressure, the first four members of the n-alkane series (methane to n-butane) are gases, the next thirteen (n-pentane through n-heptadecane) are liquids, and the higher members from $n = 18$ on are solids.

2.7.2.2 Alkenes

These are also called “olefins” and have the general formula C_nH_{2n} , with $n \geq 2$. They contain a $\text{C}=\text{C}$ double bond (functional group) and are named in accordance with the IUPAC convention by specifying the location of the double bond from the terminal carbon atom nearest to it.

The first three members of the olefin series are ethene, propene, and butene. Structural isomers exist when $n \geq 4$, as a consequence of the positioning of the double bond in normal alkenes, or as a result of branching in branched alkenes. In addition, *geometric isomers* may be possible

owing to restricted rotation of atoms about the $\text{C}=\text{C}$ bond. For instance, C_4H_8 (butene) has four possible isomers:

This occurs because 2-butene can exist in two different structures, the *cis* or the *trans* configurations, depending on whether the methyl groups are situated on the same side or on opposite sides of the main chain.

With the inclusion of these two geometric isomers, butene has a total of four isomers.

As the carbon number increases, the number of possible isomeric structures for each member increases more rapidly than in the case of the alkane series.

The physical properties of alkenes [3] are not very different from the corresponding members of the alkane family. Alkenes are nonpolar or at most weakly polar. They are insoluble in water but are soluble in concentrated H_2SO_4 and liquid HF. Normal alkenes dissolve in nonpolar or weakly polar organic liquids such as ethers, CCl_4 , and hydrocarbons. In general, the *cis* isomer has a slightly higher polarity, a higher boiling point, and a lower melting point than the *trans* isomer, but there are exceptions.

The double bond in olefins is reactive. Halogens can be added across the double bond:

This reaction and its homologs are the basis for a common test for unsaturated compound, in which orange bromine water is shaken with a hydrocarbon. Disappearance of the orange color, caused by reaction of the bromine with double bonds, indicates the presence of unsaturated compounds.

More than one double bond may be present in a compound. The chemical behavior of compounds containing multiple double bonds is similar to that of compounds containing a single double bond.

Common *alkenyl* groups include

In *cyclic hydrocarbons*, the carbon atoms form a ring instead of an open chain. They are also called *carbocyclic* or *homocyclic* compounds. They are divided into two classes: alicyclic (or cycloaliphatic) and aromatic compounds.

Cyclic analogs of aliphatic hydrocarbons are also known as cycloalkanes, naphthenes, cycloparaffins, or saturated alicyclic hydrocarbons. They have the general formula C_nH_{2n} with $n \geq 3$. The first two members are

the next two being cyclopentane  and cyclohexane . For convenience, aliphatic rings are represented by polygons.

Their properties are similar to their open-chain aliphatic counterparts. Alicyclic hydrocarbons may have a single ring or multiple rings. Monocyclic aliphatic structures having more than 30 carbon atoms in the ring are known, but those containing 5 or 6 carbon atoms are more commonly found in nature. See, for example, the sections on steroids, prostaglandins, and terpenes in standard textbooks [3,4].

When substituent groups are present, they are identified and their positions indicated by numbers in naming the compound. As an example, dimethylcyclohexane has three structures:

Cis-trans isomerism occurs in these disubstituted cycloalkanes because the substituent groups may be located above or below the plane of the ring.

Physical properties of cycloalkanes [3] show reasonably gradual changes, but unlike most homologous series, different members may exhibit different degrees of chemical

reactivity. For example, cyclohexane is the least reactive member in this family, whereas both cyclopropane and cyclobutane are more reactive than cyclopentane because of the strain involved in forming the ring.

Cycloalkenes may have one or more double bonds in the ring. Examples are

They are chemically as reactive as their straight-chain counterparts. Compounds are added across the double bond. In scission or cleavage reactions, the ring structure opens up into a straight chain.

Hydrocarbons containing both aliphatic and alicyclic parts may be named by considering either part as the parent structure and the other part as a substituent:

Cycloalkynes have a triple bond in the carbon ring, as shown in the following example:

Although it is possible to conceive of alicyclic hydrocarbons containing more than a triple bond or two double bonds in the carbocyclic ring, such ring structures are usually unstable.

Polycyclic aliphatic hydrocarbons contain two or more rings that share two or more carbon atoms. An example of a fused-ring system is

The aliphatic rings may be saturated or partially unsaturated.

2.7.2.4 Aromatic Hydrocarbons

Aromatic hydrocarbons are unsaturated cyclic compounds, usually with benzene or its derivatives as the common building block. Benzene, the simplest aromatic hydrocarbon, has the molecular formula C_6H_6 . It is a flat and symmetrical molecule with six carbon atoms arranged in a hexagonal ring (bond angle = 120°) with a hydrogen atom attached to each carbon. Benzene is represented as having three double bonds and three single bonds between the carbon atoms, but the bonding electrons are delocalized around the ring, providing great stability. Reactions of benzene compounds usually involve substitutions of the atoms bonded to the carbon ring, rather than the ring itself. Severe conditions are required to break the ring. The molecule may be represented by

Nomenclature for benzene derivatives is a combination of the IUPAC system and traditional names. Many of the derivatives are named by the substituent group appearing as the prefix. Thus, alkylbenzenes are made up of a benzene ring and alkane units; alkenylbenzenes are composed of a benzene ring and alkene units; and alkynylbenzenes comprise a benzene ring and alkyne units. Examples of alkylbenzenes include

If several groups are attached to the benzene ring, their names as well as their relative positions are indicated. For example, dimethylbenzene or xylene, $C_6H_4(CH_3)_2$, has three geometric isomers, with prefixes *ortho*-, *meta*-, and *para*-, indicating the relative positions of the two methyl groups.

[*ortho*-xylene (*o*-xylene or 1,2-dimethylbenzene)] [*meta*-xylene (*m*-xylene or 1,3-dimethylbenzene)]

[*para*-xylene (*p*-xylene or 1,4-dimethylbenzene)]

Examples of an alkenylbenzene and an alkynylbenzene are given below:

When the benzene ring is considered a substituent group, it is called the phenyl group and is represented by

An example is

More generally, aromatic substituent groups are called *aryl* groups.

Polynuclear aromatic hydrocarbons have complex structures made up of aromatic rings, or combinations of aromatic rings with aliphatic rings and chains. One such class of compounds is biphenyl and its derivatives, in which two benzene rings are connected by a single C–C bond. The structural formula of biphenyl (or phenylbenzene) is

in which the *ortho*-, *meta*-, and *para*-positions of the carbon atoms in the α and β rings are as marked.

Condensed-ring or fused-ring systems contain two or more aromatic rings that share a pair of carbon atoms. Examples include naphthalene, anthracene, and phenanthrene.

Other polynuclear hydrocarbons include bridged hydrocarbons, spiro hydrocarbons, mixed systems containing alicyclic and aromatic rings, and aliphatic chains, etc. Examples may be found in the *CRC Handbook* [3]. Physical properties of naphthalene are discussed in Reference 1.

Although many of the aromatic compounds have pleasant odors, they are usually toxic, and some are carcinogenic. Volatile aromatic hydrocarbons are highly flammable and burn with a luminous, sooty flame. The effects of molecular size (in simple arenes as well as in substituted aromatics) and of molecular symmetry (e.g., xylene isomers) are noticeable in physical properties [1,3].

2.7.3 Other Organic Compounds

Many other functional groups are possible. Other atoms, such as O, N, S, and Cl, combine with hydrocarbon chains to form homologous series. Table 2.7.2 lists common functional groups and examples of organic compounds containing them. Compounds in a homologous series show gradual variations in physical properties as the molecular size increases.

When compounds contain more than one functional group in their structures, they are referred to as *polyfunctional* compounds. Examples include

Unlike the hydrocarbon rings (carbocyclic or homocyclic) discussed previously, *heterocyclic* compounds contain in their rings other atoms in addition to carbon. Some examples are shown below:

Other structures may be found in Reference 1. Physical properties of heterocyclic compounds are given in Reference 5.

2.7.4 Stereoisomerism

Stereoisomers contain the same atoms bonded to each other in the same ways, but they differ with respect to the orientation of the atoms in space. *Enantiomers* are stereoisomers that are mirror reflections of each other. *Diastereomers* are stereoisomers that are not mirror reflections of each other.

Enantiomers come about because of the tetrahedral arrangement of singly-bonded atoms around carbon. If four different groups are bonded to a carbon atom, that atom is a *chiral center*, and the *chiral compound* will have two enantiomeric forms. Molecules may have more than one chiral center. Sugars contain multiple chiral centers.

The Cahn-Ingold-Prelog, or R-S, system is used to name enantiomers. Groups bonded to the chiral carbon are given priority numbers from 1 to 4. Priority numbers are assigned by atomic number of the atom bonded to the chiral carbon, starting with the lowest atomic number. Thus, H would always have the priority number of 1. If a distinction cannot be made between two groups on this basis, the next atom is considered. For example, 2-butanol has a chiral center at the asterisked carbon:

The groups attached to this carbon would be assigned priority numbers 1 for H, 2 for CH₃, 3 for CH₂CH₃, and 4 for OH.

The formula or model is then rotated in space so that the lowest priority group is behind the chiral carbon. If the priority numbers of the other groups then increase counterclockwise, the enantiomer is designated R. If they increase clockwise, the enantiomer is designated S. The two enantiomers of 2-butanol are shown below.

TABLE 2.7.2 Selected Functional Groups and Representative Organic Compounds [3]

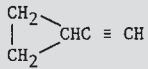

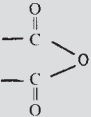

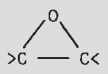

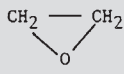

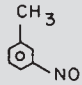

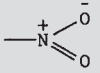

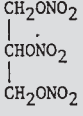

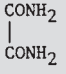

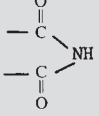

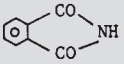

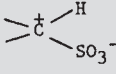

Class	Functional Group	Example	
		Molecular Formula	Compound Name
Alkene	$>C=C<$	$CH_3CH=CH_2$	Propylene
Alkyne	$-C\equiv C-$		Cyclopropylacetylene
Alcohol	$-OH$		sec-Butyl alcohol
Aldehyde		C_6H_5CHO	Benzaldehyde
Ketone		CH_3COCH_3	Acetone (Methyl ketone)
Carboxylic acid		C_6H_5COOH	Benzoic acid
Ester		$CH_3COOCH_2CH_3$	Ethyl acetate
Acid anhydride		$(CH_3CO)_2O$	Acetic anhydride
Ether	$-O-$	$CH_3OC_6H_5$	Methylphenyl ether
Epoxide (Oxirane)			Ethylene oxide
Peroxide	$-O-O-$	$(CH_3)_3COOC(CH_3)_3$	Di-tert-butyl peroxide
Halide	$-X$	$CHCl_3$	Trichloromethane (chloroform)
Acid halide		C_6H_5COCl	Benzoyl chloride
Amine	$-NH_2$	$(CH_3)_3N$	Trimethylamine
Nitrile	$-C\equiv N$	C_6H_5CN	Benzonitrile

TABLE 2.7.2 Selected Functional Groups and Representative Organic Compounds—cont'd

Class	Functional Group	Molecular Formula	Example Compound Name
Nitroso	-N=O		<i>meta</i> -Nitrosotoluene
Nitro			Nitroglycerine
Amide			Oxamide
Imide			Phthalimide
Isocyanate	-N=C=O	CH ₃ (CH ₂) ₄ NCO	<i>n</i> -Amyl isocyanate
Oxime	>C=N-OH	C ₆ H ₅ CHNOH	Benzaldoxime
Mercaptan (Thiol)	-SH	C ₆ H ₅ SH	Phenyl mercaptan (Thiophenol)
Sulfide (Thioether)	-S-	CH ₃ SCH ₂ CH ₃	Methylethyl sulfide
Disulfide	-S-S-	CH ₃ CH ₂ SSCH ₂ CH ₃	Ethyldisulfide
Sulfonate (Salt of sulfonic acid)		C ₁₂ H ₂₅ SO ₃ Na	Sodium dodecyl sulfonate (Sodium salt of dodecylsulfonic acid)
Organometallic		(CH ₃) ₄ Sn	Tetramethyltin
	R ⁻ M ⁺		Alkylmagnesium bromide

For further discussions of stereoisomerism, consult References 1, 2, and 4.

2.7.5 Petroleum Chemistry

Natural petroleum deposits are made up primarily of hydrocarbons in gaseous (*natural gas*), liquid (*crude oil* or *petroleum*), and solid (*tars* and *asphalts*) form. For general literature on the subject of petroleum chemistry consult References 6–9.

Methods of characterizing a crude oil include, among other techniques, the ultimate analysis for elemental composition and the classification, based on a standard distillation procedure, into various boiling fractions and residuum (Table 2.7.3). Selected examples of the types of compounds present in petroleum are illustrated in Tables 2.7.4 and 2.7.5.

The principal classes of hydrocarbons found in crude oils are paraffins, cycloparaffins (naphthenes), and aromatics. Compounds containing N, S, or O and metals and also found in crude oil. The molecular weight distribution of a crude oil ranges from 16 for methane to several thousands for asphaltenes. The lower boiling point fractions of most crude oils are dominated by saturated hydrocarbons (i.e., paraffins and naphthenes), whereas the higher boiling fractions and residuum contain large proportions of aromatics and N/O compounds. The sulfur content tends to increase with the boiling point.

The ratio of hydrogen to carbon in typical crude oils is approximately 1.85:1; the other elements, chiefly sulfur, nitrogen, and oxygen account for less than 3% by weight in most light crudes. Table 2.7.6 illustrates the elemental compositions of typical crude oils and asphalts. Sour crudes contain larger amounts of sulfur-containing compounds. Traces of phosphorus and heavy metals such as vanadium, nickel, and iron are also present.

In refining operations, crude oils are fractionally distilled and separated into different fractions according to the boiling point range of the compounds and their end use or application (see Table 2.7.3).

A “base” designation is given in the refining industry to classify crude oils: (i) A *paraffin-base* crude contains predominantly paraffins and small amounts of naphthenes or asphalt. Upon distillation, it yields fine lubricating oils from the gas-oil fraction and paraffin wax from the solid residue. (ii) An *asphalt-base* crude contains mostly cyclic compounds (primarily naphthenes), which, upon distillation, produce high yields of black, pitchlike, solid residue, asphalt, and heavy fuel oil. (iii) A *mixed-base* crude has characteristics intermediate between the above two categories. (iv) An *aromatic-base* crude contains large amounts of low-molecular weight aromatics together with naphthenes, and small amounts of asphalt and paraffins.

Tars and Asphalts are semisolid or solid substances. They are also referred to as bitumens, waxes, and pitch. These materials consist of mixtures of complex organic molecules of high molecular weight. As with crude oils, an exact chemical analysis for identification and composition is impractical to perform on the solid deposits of petroleum.

Gas collected at the wellhead is mostly methane with decreasing amounts of heavier hydrocarbons. Typical compositions are given in Table 2.7.7. Natural gases are primarily mixtures of normal alkanes in the C₁ to C₄ range, although other paraffins and heavier hydrocarbons may also be present. Natural gases also contain water vapor, carbon dioxide (CO₂), hydrogen sulfide (H₂S), nitrogen and helium. At conditions of high pressure and low temperature, solid hydrates may form between H₂O and the hydrocarbons.

Natural gases are classified as sweet or sour (similar to crude oils), depending on the absence or presence,

TABLE 2.7.3 Typical Crude Oil Fractions [1]

Crude fraction	Boiling point, °C	Approximate chemical composition	Uses
Hydrocarbon gas	< 30	C ₂ –C ₄	LP gas for heating
Gasoline	30–180	C ₄ –C ₉	Motor fuel
Kerosene	160–230	C ₈ –C ₁₆	Jet fuel, home heating
Diesel	200–320	C ₁₀ –C ₁₈	Motor fuel
Heavy oil	300–450	C ₁₆ –C ₃₀	Lubricating oil, bunker fuel
Petroleum	> 300 vacuum	C ₂₆ –C ₃₈	Lubricating oil, home heating
“jelly” or “wax”		> C ₂₅	Roofing compounds, paving asphalts
Residuum		> C ₃₅

TABLE 2.7.6 Elemental Composition of Natural Petroleum (Percentage by Weight) [7]

Element	Crude Oils
Carbon	84–87
Hydrogen	11–14
Sulfur	< 0.1–8
Nitrogen	< 0.1–1.8
Oxygen	< 0.1–1.8
Metals (Ni, V, etc.)	trace – 1,000 ppm

respectively, of significant amounts of hydrogen sulfide. Wet gas is capable of producing liquid hydrocarbons upon suitable treatment; dry gas does not have such ability. Processing of natural gas results in pure methane, liquefied petroleum gas (or LPG, which is mostly propane and some *n*-butane), and gasoline.

Saturated aliphatic hydrocarbons found in petroleum include normal alkanes as well as branched alkanes (isoalkanes). The paraffin content can vary widely from one crude oil to another. *n*-alkanes have been found throughout the boiling range of most crude oils, from $n = 1$ to 78. Some waxy crudes contain higher alkanes, up to $n = 200$. The pour point of a crude oil is strongly influenced by the amount and carbon-number distribution of *n*-alkanes present. For crude oils, it can range from -70 to 110°F (-57 to 43°C). Whereas *n*-alkanes tend to raise the pour point, other hydrocarbon types lower it.

All possible isoalkanes from C_4 through C_8 have been found in crude oils, along with several isomers of C_9 and some of C_{10} . Many isoprenoids (e.g., pristane and phytane) which serve as biomarkers to the genesis of petroleum have been detected in significant concentrations. The 2- and 3-methyl alkanes and pristane appear to be the dominant isoparaffins in crude oils.

Cycloalkanes occur in varying amounts in crude oils. The rings contain of five, six, or seven carbon atoms. Alkyl derivatives of cyclopentane and cyclohexane have been found, but not of cycloheptane. The most common naphthenes are methyl- and dimethyl-substituted cyclopentane and cyclohexane. The amount of naphthenes can be greater than 50 wt% of a crude oil, with the lighter boiling fractions containing less and the heavier fractions containing more. Fused polycyclic aliphatic structures such as decalin ($\text{C}_{10}\text{H}_{18}$) become prevalent in the heavier fractions. Some of these multiring compounds may contain up to seven rings.

Alkenes are found in petroleum in very low concentrations because of the reaction. Trace concentrations of multiring cycloalkenes such as hopenes and sterenes have

*Occasionally natural gases are found which are predominately carbon dioxide or hydrogen sulfide.

been reported to be present in crude oils. Alkynes and cycloalkynes are not commonly found in natural petroleum.

Aromatic hydrocarbons are frequently found in crude oils. Benzene and alkylbenzenes, ranging from methyl through decyl groups, have been found in liquid petroleum, together with several C_{11} -alkyl isomers. Indane and

tetrahydronaphthalenes as well as some of their methyl isomers have been identified. Biphenyl and its derivatives occur in lower concentrations than naphthalene and its derivatives. Polynuclear aromatics including phenanthrene, fluoranthene, pyrene, benz[a]anthracene, chrysene, triphenylene, benzopyrenes, perylene, etc., and some of their alkyl derivatives have been detected, but not anthracene. Crude oils also may contain aromatic compounds such as acenaphthene, acenaphthylene, fluorene, dibenzanthracenes, etc. Among the simpler aromatic molecules, toluene and meta-xylene are the most common; benzene, ethylbenzene, and other alkylbenzenes also occur in significant concentrations in distillates.

Aromatic content can vary considerably between crudes but rarely exceeds 15% of the total crude weight. The aromatic hydrocarbons appear throughout the boiling range but tend to be concentrated in the heavy fractions of petroleum, including the residuum. As a class, aromatics (e.g., toluene and xylenes) have the highest octane ratings among hydrocarbons and hence are used as additives to gasoline and other fuel oils. They show the largest viscosity changes with temperature and are therefore undesirable in the lubricating oil range. With rising boiling point, the heavy fractions contain increasing amounts of complex polycyclic aromatic compounds that are difficult to characterize. Some polynuclear aromatic molecules such as 3,4-benzopyrene and benz[a]anthracene are carcinogens.

Compounds containing nitrogen, sulfur, and oxygen are usually abbreviated *NSO compounds* and are sometimes referred to as *asphaltics*. The residuum contains a high percentage of NSO compounds. The strong odor of crude oil is imported by NSO compounds.

All crude oils contain sulfur in one of several forms including elemental sulfur, hydrogen sulfide, carbonyl sulfide (COS), and in aliphatic and aromatic compounds. The amount of sulfur-containing compounds increases with an increase in the boiling point of the fraction. Most of these compounds have one sulfur atom per molecule, but certain aromatic and polynuclear aromatic molecules found in low concentrations in crude oil contain two and three sulfur atoms.

Alkyl thiols (mercaptans) with normal or branched alkyl groups and with the thiol group in a primary, secondary or tertiary location have been found in petroleum, together with cycloalkyl thiols having rings of five or six carbon atoms. Continuous chain or branched alkyl sulfides and cyclic sulfides with four or five carbon atoms in their rings have been detected. Mixed alkyl cycloalkyl sulfides have also been found. Alkylpolycyclic sulfides containing one to eight cycloparaffin rings were identified in certain crudes. Aromatic compounds of sulfur include thiophenes, their benzo- and dibenzo-derivatives, and benzonaphthothiophenes. Thioindanes and alkylaryl sulfides are also present.

In general, mercaptans are more malodorous than sulfides and hydrogen sulfide. The presence of significant amounts of sulfur can poison catalyst for the refining of crude oil.

Most crude oils contain nitrogen; a large proportion of it occurs in the high boiling fractions and in the residuum. Examples of the nitrogen compounds present in petroleum include mono-, di-, and tri-alkylpyridines, quinoline and alkyl substituted quinolines, tetrahydroquinolines and dialkylbenz[h]quinolines. Carbazole and methyl- through decyl-substituted carbazoles have also been identified. The high boiling fractions from one crude oil contained a variety of nitrogen compound types (in excess of 0.1 wt% concentration) that included indoles, carbazoles, benzcarbazoles, pyridines, quinolines, and phenanthridines. Compounds containing both nitrogen and oxygen, such as amides, hydroxypyridines and hydroxyquinolines, as well as compounds containing two nitrogens such as azaindoles and azacarbazoles, were also found. Other molecular types including pyrroles, isoquinolines, benzoquinolines, and benzologues of acridine may be present in crude oil. Porphyrins are observed in the residuum, usually in association with metals. Certain aromatic nitrogen compounds (e.g., pyridines, quinolines) can cause coking on acid catalysts during petroleum processing.

Most crude oils contain only small amounts of oxygen. Oxygen compounds are mainly carboxylic acids, including straight-chain fatty acids, branched-chain acids, naphthenic acids, and dicarboxylic acids. Other molecular types observed in the higher boiling fractions include furans and their benzo-, dibenzo-, and benzonaphtho- derivatives. Oxygen may also be present in the form of phenols, alcohols, esters, and ketones and in combination with nitrogen.

Residuum is the undistilled fraction remaining at the end of distillation, which corresponds to an upper limit of -565°C (-1050°F) at atmospheric pressure, or up to -675°C (-1250°F) under vacuum. The residuum amounts to a small percentage of a very light crude oil and up to 30–40 wt% of a heavy crude. Its major constituents are resins, asphaltenes, and some high molecular weight oils and waxes. The residuum accounts for most of the total NSO content and the heavy metals. The resins and asphaltenes precipitate out when the residuum (or crude oil) is treated with liquid propane below 70°F . Additional treatment of this precipitate with n-pentane separates the soluble resins from the insoluble asphaltenes. The amount of resins always exceeds the asphaltene content of a crude oil. Resins are light to dark colored and range from thick viscous materials to amorphous solids. Asphaltenes are dark brown to black amorphous solids. Together, they may contain nearly 50% of the total nitrogen and sulfur in the crude oil, predominantly in the form of heterocyclic condensed rings structures. Asphaltenes may account for as much as 25 wt% of the residuum (up to 12% of the

crude oil). Colorless oils are the most paraffinic, while asphaltenes are the most aromatic. Dark oils and resins show similar degrees of paraffinic and aromaticity. Up to 40 wt% of saturated hydrocarbons may be present in the residuum; however, this comprises only 1–3 wt% of the total crude. The rest are aromatic and N/O-containing compounds. In the nonasphaltene fraction of the residuum, the typical aromatic structure is a highly substituted, condensed polynuclear aromatic molecule, with an average formula, $C_{100}H_{160}S$. The substituents are fused naphthenic rings, which in turn are substituted with long (C_{15} – C_{20}) alkyl side chains having intermittent methyl branches. The average structure for a N/O compound is similar in features excepting for slightly higher aromaticity and shorter (C_{10} – C_{15}) alkyl side chains. Other types of NSO compounds described previously may also be present.

In the asphaltene fraction, pure hydrocarbons become rare at molecular weights above 800, and polar functional groups become common. Asphaltenes exist as a dispersion of colloidal particles in an oily medium. Their molecular weight can be as high as 200,000. A typical asphaltene molecule has 10–20 condensed aromatic and naphthenic rings, with both alkyl and cycloalkyl substituted side chains. The observed polar functional groups in the high molecular weight compounds include carboxylic acids, amides, phenols, carbazoles and pyridines.

The *metals* present in crude oils usually exist in complexes of cyclic organic molecules—called porphyrins. The parent structure of the porphyrins is the tetramethene-tetrapyrrole ring ($C_{20}H_4N_4$). In a metalloporphyrin, the transition metal atom is held at the center of the porphyrin ring by coordination with the four pyrrole N atoms. Nickel and vanadium are present in petroleum in concentrations of less than 1 ppb to about 1000 ppm, in combined form with porphyrins. Some of the lighter metalloporphyrins are volatile, while the high molecular weight porphyrins appear in the nonvolatile residuum. When oil deposits occur together with saline water, the produced oil-water emulsions contain soluble salts of sodium, calcium, and magnesium. Other metals may be present in the inorganic state as suspended solids in the produced fluids along with any clays or mineral matter derived from the rock matrix and piping.

Figure 2.7.1 shows how the weight distributions of the different molecular types vary during the fractional distillation of a naphthenic crude oil. Saturated aliphatic hydrocarbons (i.e., paraffins and naphthenes) are the predominant constituents in the light gasoline fraction. As the

boiling point is raised, the paraffin content decreases, and the NSO content increases. About 75 wt% of the residuum is composed of aromatics and NSO compounds.

Certain properties of a liquid fuel are measured routinely for characterization purposes. Besides density and viscosity, these properties include the *pour point*, the *cloud point*, and the *flash point*. Standard ASTM (American Society for Testing Materials) procedures are available for their determination.

The *pour point* represents the lowest temperature at which the liquid fuel will pour. This is a useful consideration in the transport of fuels through pipelines. To determine the pour point, an oil sample contained in a test tube is heated up to 115°F (46°C) until the paraffin waxes have melted. The tube is then cooled in a bath kept at about 20°F (11°C) below the estimated pour point. The temperature at which the oil does not flow when the tube is horizontally positioned is termed the pour point.

The aniline *cloud point* is a measure of the paraffinic of a fuel oil. A high value denotes a highly paraffinic oil, and a low value indicates an aromatic, a naphthenic, or a highly cracked oil. The *flash point* represents the temperature to which a liquid fuel can be heated before a flash appears on its surface upon exposure to a test flame under specified conditions. A knowledge of the flash point is needed to ensure safe handling and storage without fire hazards.

The specific gravity of petroleum or petroleum products is often expressed in terms of “degrees API” on a scale defined by

$$^{\circ}\text{API} = \frac{141.5}{G} - 131.5 \quad (2.7.1)$$

where G is the specific gravity of the liquid at 60°F, with reference to water at 60°F. An *API gravity* of 10° corresponds to $G = 1$.

U.O.P. characterization factor (K) is used as a qualitative index of the paraffinic of an oil stock. By definition, $K = (T_B)^{1/3}/G$, where T_B is the average boiling point (°R) at one standard atmosphere, and G is the specific gravity at 60°F. The U.O.P. characterization factor has been found to vary within a homologous series; it is therefore not a true measure of the hydrocarbon type. Nevertheless, graphical correlations have been developed between K , API gravity, molecular weights, T_B , and critical temperatures for a number of petroleum fractions [10]. Characterization factors have also been correlated with kinematic viscosities, API gravity, and T_B .

FIGURE 2.7.1 Chemical composition of a naphthenic crude oil [9].

2.7.6 Physical Chemistry

2.7.6.1 Basic Definitions

The *formula weight* of an element (or a compound or a species) is the sum of the weights of the atoms making up its chemical formula. The formula weight of an element is its *atomic weight* and that of a compound is its *molecular weight*.

The *equivalent weight* of an ion is the ratio of its formula weight to its valence. Another definition of equivalent weight is the amount of a substance that reacts with one atomic weight of hydrogen or its chemical equivalent. Other definitions of equivalent weight may depend on the stoichiometry of a particular chemical reaction.

One *gram-atom* is the mass in grams of an element that is numerically equal to its atomic weight. Thus, the number of gram-atoms of an element is m/A , where m is its mass in grams and A , its atomic weight. Similarly, a pound-atom is the mass in grams of a given element that is numerically equal to its atomic weight. The following gram-quantities

also have analogous pound-quantities. When the quantities are not specified as gram or pound, it may be assumed they refer to grams.

One *gram-mole* is the mass in grams of a compound that is numerically equal to its molecular weight (M). Thus, the number of moles of a compound contained in a mass of m grams is m/M .

One *gram-equivalent* is the mass in grams of a material that is numerically equal to its equivalent weight.

Avogadro's number is the number of atoms (or molecules) present in one gram-atom (or gram-mole) of any elementary substance (or compound). It has a value of 6.022142×10^{23} [5].

The *density* (ρ) of a substance is defined as its mass per unit volume, expressed as g/cm^3 , lb/ft^3 , etc. The *specific volume* (\hat{V}) of a substance is the reciprocal of its density and is expressed as cm^3/g , ft^3/lb , etc.

The *specific gravity* (G) of a substance is the ratio of the density (ρ) of the substance to the density (ρ_{ref}) of a reference substance at specified conditions. That is,

$$G = \frac{\rho}{\rho_{\text{ref}}}$$

For solids and liquids, density is a weak function of pressure and, therefore, only the temperatures T and T_{ref} are usually specified. The reference substance is commonly taken as water at 4°C at which $\rho_{\text{ref}} = 1.000 \text{ g/cm}^3 = 62.43 \text{ lb/ft}^3$. If a single temperature is specified, it implies that both densities have been measured at that temperature.

In the case of gases, it is imperative that both temperature and pressure be specified for specific gravity. Air is normally chosen as the reference fluid for gaseous substances.

Many resources for unit conversion and calculation of chemical and chemical engineering problems are available on the Internet. A good place to start is Martindale's The Reference Desk (<http://www-sci.lib.uci.edu/HSG/RefCalculators3.html>), which points to an enormous number of resources of this type. Specific references to these calculators will not be made in this handbook because of the changing nature of the Internet. However, for all the calculations in this section, relevant calculators and other help can be found in Martindale's.

2.7.6.2 Compositions of Multicomponent Systems

The relative amounts of individual components (or species) making up a mixture or solution can be expressed in a variety of ways: volumetric, mass, or molar.

Volumetric Basis. The volume fraction (v_i) of component i in a mixture is the fraction of the total volume (V) of the mixture that is attributable to that component at the stated temperature and pressure. If V_i denotes the actual volume of component i present in a total volume V of the mixture, then

$$v_i = \frac{V_i}{V} \quad \sum v_i = 1 \quad (2.7.2)$$

and the volume percent of $i = 100 v_i$. If V is the volume of one mole of the mixture, then V_i is the partial molar volume of component i .

For gases in which ideal gas behavior can be assumed, these relationships hold, and the total volume of the mixture equals the sum of the volumes (V_i^0) of the pure components, or

$$V = \sum V_i^0 \quad \text{and} \quad V_i = V_i^0 \quad (2.7.3)$$

When a gas mixture contains water vapor, the volumetric analysis is stated either on a *wet* basis that includes the water vapor or on a *dry* basis (moisture-free basis) that excludes the water vapor.

For liquids and gases in which ideal gas behavior cannot be assumed, volume changes are observed on mixing of the components. For example, a mixture of ethyl alcohol and

water has a lower volume than the sums of the individual volumes before mixing. In this case, the equalities above do not hold. The temperature and pressure dependences of these volume fractions can be complex.

Weight (or Mass) Basis. The terms *weight fraction* and *weight percent* are often used interchangeably with *mass fraction* and *mass percent*, respectively. If the total mass (m) of a mixture includes an amount m_i of component i , then the mass fraction of the component is given by

$$\omega_i = \frac{m_i}{m}$$

and the mass percent of $i = 100 \omega_i$. Note that $\sum m_i = m$ and $\sum \omega_i = 1$.

This representation is ordinarily used for solid and liquid systems and rarely for gases. In the absence of chemical reactions the mass composition of a system remains unchanged. Any consistent set of units for mass (or volume) may be selected in interpreting the compositions expressed on a mass (or volumetric) basis.

Molar Basis. The mole fraction (x_i) of a component i in a multicomponent mixture is defined as

$$x_i = \frac{\text{Number of moles of } i}{\text{Number of moles of mixture}} = \frac{n_i}{n} = \frac{n_i}{\sum n_i} \quad (2.7.4)$$

The mole percent of $i = 100x_i$ and $\sum x_i = 1$.

The volume fractions and mole fractions become identical in ideal gas mixtures at fixed conditions of pressure and temperature. In an isolated, nonreactive system, the molar composition does not vary with temperature.

Mixture Properties. The *average molecular weight* (M) of a homogeneous mixture is its total mass (m) divided by the total number of moles (n) of its components. If x_i represents the mole fraction of the i th component whose molecular weight is M_i , then

$$M = \frac{m}{n} = \sum x_i M_i \quad (2.7.5)$$

In terms of mass fractions,

$$\frac{1}{M} = \sum \left(\frac{\omega_i}{M_i} \right) \quad (2.7.6)$$

The *mass density* (ρ) of the mixture is the ratio of its total mass (m) to its total volume (V), whereas the *molar density* (c) of the mixture is defined as the ratio of the total number of moles (n) to the total volume of the mixture. Thus,

$$\rho = \frac{m}{V} \quad \text{and} \quad c = \frac{n}{V} \quad (2.7.7)$$

and both are related by $\rho/c = m/n = M$.

Mass and Molar Concentrations of Components. The *mass concentration* (ρ_i) of the i th component (or species) in a homogeneous mixture is defined as the mass of that

component present per unit volume of the mixture. The *molar concentration* (c_i) of component i is defined similarly but on a molar basis. Therefore,

$$\rho_i = \frac{m_i}{V} \quad \text{and} \quad c_i = \frac{n_i}{V} \quad (2.7.8)$$

and both are related by

$$\frac{\rho_i}{c_i} = \frac{m_i}{n_i} = M_i \quad (2.7.9)$$

Also,

$$\rho = \sum \rho_i \quad \text{and} \quad c = \sum c_i \quad (2.7.10)$$

Compositions of Liquid Systems. A *solution* is a homogeneous mixture of two or more components. Petroleum is a solution, as are many of the liquids derived from it. Much of petroleum analysis and processing requires solutions of various kinds. Water is a common solvent. Because so many petroleum components are nonpolar, water is frequently not the best solvent, and organic solvents must be considered. A uniform solid mixture of two or more components is also called a solution.

There are a number of ways to quantify concentrations in solutions suited to different applications. On a weight basis, *grams of solute per gram of solvent* may be used. In the case of trace components, this may be expressed as *parts per million* (ppm), which is grams of solute per million grams of solvent. Also on a weight basis, the *molality* of a solution is the number of gram-moles of solute per 1000 grams of solvent and is usually designated by a small m .

Volumetric concentrations include

1. Grams of solute per unit volume of solution, or the *mass concentration* (e.g., grams of i/cm^3 of solution)
2. Gram-moles of solute per unit volume of solution, or the *molar concentration* (e.g., g-moles of i/cm^3 of solution), termed *molarity*
3. Gram-equivalents of solute per liter of solution, termed *normality*.

Normality and *molarity* have widespread use in volumetric analysis. If a fixed amount of reagent is present in a solution, it can be diluted to any desired normality by application of the general dilution formula $V_1N_1 = V_2N_2$. Here, subscripts 1 and 2 refer to the initial solution and the final (diluted) solution, respectively; V denotes the solution volume (in milliliters) and N the solution normality. The product V_1N_1 expresses the amount of the reagent in gram-milliequivalents present in a volume V_1 ml of a solution of normality N_1 . Numerically, it represents the volume of a one normal (1N) solution chemically equivalent to the original solution of volume V_1 and of normality N_1 . The same equation $V_1N_1 = V_2N_2$ also applies in problems involving acid-base neutralization, oxidation-reduction, precipitation, or other types of titration reactions.

Example 2.7.1

The composition of an aqueous solution of H_2SO_4 is given as 40 mole % and its mass density as 1.681 g/cm^3 at 20°C . Find the mole density of the solution and also express its composition in the following ways: (i) weight percent, (ii) lb of solute/lb of solvent, (iii) lb-moles of solute/lb of solvent, (iv) g of solute/100 ml of solution, (v) molarity, (vi) normality, and (vii) molality.

2.7.6.2.1 Solution

Choose a *basis* of 100 g-moles of solution.

MW of H_2SO_4 (solute) = 98.07; MW of H_2O (solvent) = 18.02

$$\text{Amount of solute} = 40 \text{ g-moles} = (40)(98.07) = 3922.8 \text{ g}$$

$$\text{Amount of solvent} = 60 \text{ g-moles} = (60)(18.02) = 1081.2 \text{ g}$$

$$\text{Total mass of solution} = 5004.0 \text{ g}$$

$$\text{Total volume of solution} = \frac{5004 \text{ g}}{1.681 \text{ g/cm}^3} = 2976.8 \text{ cm}^3$$

$$\text{Molar density } c = n/V = 100/2976.8 = 3.36 \times 10^{-2} \text{ g-moles/cm}^3$$

$$(i) \quad \text{weight percent of solute} = (3922.8)(100)/(5004) = 78.39\%$$

$$\text{weight percent of solvent} = 100 - 78.39 = 21.61\%$$

$$(ii) \quad \frac{\text{lb of solute}}{\text{lb of solvent}} = \frac{3922.8}{1081.2} = 3.628$$

$$(iii) \quad \frac{\text{lb-moles of solute}}{\text{lb of solvent}} = \frac{40}{1081.2} = 3.70 \times 10^{-2}$$

$$(iv) \quad \frac{\text{g of solute}}{100 \text{ ml of solution}} = \frac{(3922.8)}{(2976.8)}(100) = 131.78$$

$$(v) \quad \text{Molarity} = \frac{\text{g-moles of solute}}{1000 \text{ ml of solution}} = \frac{(40)}{(2976.8)}(1000) = 13.44 \text{ M}$$

$$(vi) \quad \text{Equivalent weight of solute} = \frac{\text{MW}}{\text{valence}} = \frac{98.07}{2} = 49.03 \text{ g/g-eq.}$$

$$\text{Normality} = \frac{\text{g-eq of solute}}{1000 \text{ ml of solution}} = 2(\text{Molarity}) = 26.87 \text{ N}$$

$$(vii) \quad \text{Molality} = \frac{\text{g-moles of solute}}{1000 \text{ g of solvent}} = \frac{(40)(1000)}{(1081.2)} = 37.00 \text{ molal}$$

The pH scale and Ionic Strength. The *pH* of a solution is defined as the logarithm of the reciprocal of the hydrogen ion concentration (or activity) $[\text{H}^+]$ of the solution:

$$\text{pH} = -\log[\text{H}^+] \quad (2.7.11)$$

Because the ion product of water $K_w = [\text{H}^+][\text{OH}^-] = 1.04 \times 10^{-14}$ at 25°C , it follows that a neutral solution (e.g., pure water at 25°C) in which $[\text{H}^+] = [\text{OH}^-]$ has a $\text{pH} = 7$. Acids have a lower pH and bases a higher pH than this neutral value of 7. Hydrogen ion concentrations can cover a wide range, from ~ 1 g-ion/liter or more in acidic solutions to $\sim 10^{-14}$ g-ion/liter or less in alkaline solutions [11]. *Buffer* action refers to the property of a solution in resisting a change of pH on addition of an acid or a base. Buffer solutions usually consist of a mixture of a weak acid and its salt (conjugate base) or of a weak base and its salt (conjugate acid).

The *ionic strength* (μ) of a solution is a measure of the intensity of the electrical field due to the ions present in the solution. It is defined by

$$\mu = \left(\frac{1}{2}\right) \sum c_i z_i^2$$

where c_i is the molal concentration of the ionic species i (g-equivalent $i/1000$ g solvent), and z_i is the valence or charge on the ion i .

Further discussion of pH and other association constants can be found in References 1, 3, and 4.

Example 2.7.2

Find the ionic strength of (i) 0.05 molal sodium sulfate (Na_2SO_4) solution, and (ii) 0.25 molal nitric acid (HNO_3) and 0.4 molal barium nitrate ($\text{Ba}(\text{NO}_3)_2$) together in one solution.

2.7.6.2.2 Solution

(i) Ions Na^+ and SO_4^{2-} are present in concentrations of 0.10 and 0.05 molal, respectively.

$$\mu = \left(\frac{1}{2}\right) [0.10(1)^2 + (0.05)(2)^2] = 0.15$$

(ii) HNO_3 contributes the ions H^+ and NO_3^- in concentrations of 0.25 molal each, and $\text{Ba}(\text{NO}_3)_2$ contributes the ions Ba^{2+} and NO_3^- in concentrations of 0.4 and 0.8 molal, respectively. The NO_3^- contributions from both sources are summed.

$$\begin{aligned} \mu &= \left(\frac{1}{2}\right) [0.25(1)^2 + (0.25 + 0.80)(1)^2 + (0.4)(2)^2] \\ &= 1.45 \end{aligned}$$

2.7.6.3 Material Balances

Chemical processes, such as petroleum refining or natural gas cleanup, transform raw materials into useful products. Matter and energy inputs and outputs must be tracked

for process control. The principle of conservation of mass provides the basis for tracking matter.

A *system* must be defined before a materials balance can be calculated. The system is all the substances contained within defined boundaries, for example, a process vessel or a system of vessels and piping.

The physical and chemical changes occurring in this system must be enumerated. The definition of the system and the degree of detail necessary for the enumeration of these changes depends on the use intended for the material balance.

Processes may be classified as batch, continuous, or semibatch depending on how materials are transferred into and out of the system. Process operation may be characterized as unsteady state (i.e., transient) or steady state, depending on whether the process variables (e.g., pressure, temperature, compositions, flowrate, etc.) change with time, respectively. In a *batch* process, the entire feed material (charge) is added instantaneously to the system at the beginning of the process, and all the contents of the system including the products are removed later, at the end of the process. In a *continuous* process, the materials enter and leave the system as continuous streams. In a *semibatch* process, the feed may be added at once and the products removed continuously, or vice versa. Batch and semibatch processes are inherently unsteady state, whereas continuous processes may be operated in a steady or unsteady-state mode. Start-up and shut-down procedures of a continuous production process are examples of transient operation.

According to the law of conservation of mass, the total mass of an isolated system is invariant, even in the presence of chemical reactions. Thus, an *overall* material balance is performed on the entire material (or contents) of the system. If a mass balance is made on a component (chemical compound or atomic species) involved in the process, it is termed a *component* (or *species*) material balance. The general mass balance equation has the following form, and it can be applied to any material in any process.

$$\begin{aligned} &\left(\begin{array}{c} \text{Mass} \\ \text{inflow} \\ \text{entering} \\ \text{the system} \end{array} \right) - \left(\begin{array}{c} \text{Mass} \\ \text{outflow} \\ \text{leaving} \\ \text{the system} \end{array} \right) \\ &+ \left(\begin{array}{c} \text{Net internal} \\ \text{mass generation} \\ \text{due to chemical} \\ \text{reactions within} \\ \text{the system} \end{array} \right) = \left(\begin{array}{c} \text{Net mass} \\ \text{accumulation} \\ \text{within the} \\ \text{system} \end{array} \right) \end{aligned}$$

or symbolically,

$$m_{\text{in}} - m_{\text{out}} + \mathcal{R} = \Delta m \quad (2.7.12)$$

The third term on the left side of the equation \mathcal{R} , has significance for components of reactive systems only. It is positive when material is produced as a net result of all chemical reactions; it is negative if material is consumed by chemical reactions. The former situation corresponds to a source and the latter to a sink for the material under consideration. Because the total mass of reactants always equals the total mass of products in a chemical reaction, this term does not appear an overall material balance.

Two types of material balances, differential and integral, are applied in analyzing chemical processes. The differential mass balance is valid at any instant in time, with each term representing a rate (i.e., mass per unit time). A *general differential material balance* may be written on any material involved in any *transient* process, including semibatch and unsteady-state continuous flow processes:

$$\left(\begin{array}{c} \text{Net rate of} \\ \text{mass accumulation} \end{array} \right) = \left(\begin{array}{c} \text{Rate of} \\ \text{mass inflow} \end{array} \right) - \left(\begin{array}{c} \text{Rate of} \\ \text{mass outflow} \end{array} \right) + \left(\begin{array}{c} \text{Net rate of internal} \\ \text{mass generation by} \\ \text{chemical reactions} \end{array} \right)$$

or symbolically

$$\frac{dm}{dt} = \dot{m}_{in}(t) - \dot{m}_{out}(t) + \dot{\mathcal{R}}(t) \quad (2.7.13)$$

where each of the rate terms on the right side of the equations can be functions of time. The solution is obtained on integration over time between the initial and final states of the transient process.

A special case of the differential material balance applies to a *continuous steady-state flow process* when all of the rate terms are independent of time and the accumulation term is zero. Thus, the differential material balance for any component i is given by

$$\left(\begin{array}{c} \text{Rate of mass} \\ \text{outflow, } \dot{m}_{out} \end{array} \right) - \left(\begin{array}{c} \text{Rate of mass} \\ \text{inflow, } \dot{m}_{in} \end{array} \right) = \left(\begin{array}{c} \text{Net rate of internal} \\ \text{mass generation, } \dot{\mathcal{R}} \end{array} \right)_i$$

and the overall material balance is $\dot{m}_{in} = \dot{m}_{out}$. When chemical reactions are absent, we have

$$(\dot{m}_{in})_i = (\dot{m}_{out})_i \quad (2.7.14)$$

for a continuous flow process at steady-state.

For a transient process that begins at time t_0 and is terminated at a later time t_f , the *general integral material balance* equation has the form

$$m(t_f) - m(t_0) = \int_{t_0}^{t_f} \dot{m}_{in} dt - \int_{t_0}^{t_f} \dot{m}_{out} dt + \int_{t_0}^{t_f} \dot{\mathcal{R}} dt \quad (2.7.15)$$

Here, $m(t_f)$ is the mass of the system contents at final time t_f and $m(t_0)$ is the mass at initial time t_0 . As before, both component and overall mass balances may be written in integral form.

A special case of Equation 2.7.15 is directly applicable to *batch* processes for which the mass flowrate terms are zero. The integral material balance for any component i in such a process is

$$\left(\begin{array}{c} \text{Net mass} \\ \text{accumulation of } i \end{array} \right) = \Delta m_i = m_i(t_f) - m_i(t_0) = \dot{\mathcal{R}}_i \quad (2.7.16)$$

and the overall mass balance is

$$\Delta m = m(t_f) - m(t_0) = 0 \quad (2.7.17)$$

It must be kept in mind that the reaction term will not occur in the overall mass balance equations of reactive systems because $\sum \dot{\mathcal{R}}_i = 0$, i.e., there is no net mass gain or loss as a result of chemical reactions.

Stoichiometry in Reactive Systems. The use of molar units is preferred in chemical process calculations since the stoichiometry of a chemical reaction is always interpreted in terms of the number of molecules or number of moles. A stoichiometric equation indicates the relative proportions of the reactants and products in a given reaction. For example, the following stoichiometric equation represents the combustion of propane in oxygen:

One molecule (or mole) of propane reacts with five molecules (or moles) of oxygen to produce three molecules (or moles) of carbon dioxide and four molecules (or moles) of water. These numbers are called *stoichiometric coefficients* (ν_i) of the reaction and are shown below each reactant and product in the equation. In a stoichiometrically balanced equation, the number of atoms of each element in the reactants must be the same as that in the products. Thus, there are three atoms of C, eight atoms of H, and ten atoms of O on either side of the equation. This is a consequence of the principle of conservation of mass. The combined mass of reactants is always equal to the combined mass of products in a chemical reaction, but the total number of moles may be different.

A *limiting reactant* is that reactant which is present in the smallest stoichiometric amount. In industrial reactions, the reactants may not be supplied in the proportions demanded by the stoichiometry of the equation. Under these circumstances, the reaction mixture at the conclusion of the process will include the products together with the unreacted reactants present in excess of their stoichiometric

requirements. By identifying a limiting reactant, the *percent excess* is calculated for any *excess reactant* as

$$\% \text{ excess} = \frac{(n - n^*)}{n^*} 100 \quad (2.7.18)$$

where n is number of available moles of excess reactant, and n^* is the stoichiometric number of moles required to react with the limiting reactant.

Conversion (or degree of conversion) is the fraction of the feed or of some reactant in the feed that is converted into products.

The *degree of completion* of a reaction is the actual fraction of the limiting reactant that is converted into products.

The yield of a product is the actual amount of product divided by the stoichiometric amount of product. These quantities may be expressed in moles or in mass units.

For combustion of fuels, pure oxygen or air is supplied in amounts greater than the stoichiometric requirements for complete combustion. The terms “theoretical air” or “theoretical oxygen” are frequently encountered in combustion problems. The molar composition of dry air at atmospheric conditions [12]:

Gas	Mole%
Nitrogen	78.03
Oxygen	20.99
Argon	0.94
Carbon dioxide	0.03
H ₂ , He, Ne, Kr, Xe	0.01
	100.00

$$\text{Average molecular weight} = 28.97$$

In summary, the procedure for material balance calculations involving reactive systems is as follows:

1. Identify the system and physical and chemical changes.
2. Examine the stoichiometry of the chemical reaction, and identify the limiting reactant and excess reactants.
3. Perform an overall material balance and the necessary component material balances so as to provide the maximum number of independent equations. In the event the balance is written in differential form, appropriate integration must be carried out over time, and the set of equations solved for the unknowns.

For a nonreactive system, the material balance may be done on either a mass or a molar basis.

Example 2.7.3

Consider the combustion of ethane (C₂H₆) in pure oxygen. If 100 lb of ethane are available and 10% excess oxygen is supplied to ensure complete combustion, calculate (1) the amount of oxygen supplied, and (2) compositions of the reactants and products on mass and molal bases.

2.7.6.3.1 Solution

Choose a *basis* of 100 lb of ethane (limiting reactant). The stoichiometric equation is

$$\begin{aligned} \text{lb-moles of C}_2\text{H}_6 \text{ available} &= 100/30.07 \\ &= 3.326 \end{aligned}$$

$$\begin{aligned} \text{Stoichiometric lb-moles of O}_2 \text{ required} &= \left(\frac{7}{2}\right) (3.326) \\ &= 11.641 \end{aligned}$$

$$\begin{aligned} \text{With 10\% excess, lb-moles of O}_2 \text{ supplied} &= 1.1(11.64) \\ &= 12.804 \end{aligned}$$

1. Amount of O₂ supplied = 12.804(32.00) = 409.7 lb
2. Calculation of the composition of the feed (reactant) mixture is shown below.

Reactant i	Mass m_i		n_i	
	(lb)	Weight %	(lb-moles)	Mole%
Ethane	100.0	19.62	3.326	20.66
Oxygen	409.7	80.38	12.804	79.34
Total	509.7	100.00	16.130	100.00

In the product mixture, amount of excess (unreacted) O₂ = 0.1(11.64) = 1.164 lb-moles = 37.25 lb.

$$\begin{aligned} \text{Amount of CO}_2 \text{ formed} \\ &= (2)(100)/30.07 = 6.651 \text{ lb-moles} = 292.7 \text{ lb} \end{aligned}$$

$$\begin{aligned} \text{Amount of H}_2\text{O formed} \\ &= (3)(100)/30.07 = 9.977 \text{ lb-moles} = 179.8 \text{ lb} \end{aligned}$$

Hence, the composition of the product gas stream can be calculated as follows:

Product j	Mass m_j (lb)	Weight %	n_j (lb-moles)	Mole %
CO ₂	292.7	57.43 (88.72)	6.651	37.38 (85.11)
H ₂ O	179.8	35.28 (—)	9.978	56.08 (—)
O ₂	37.2	7.29 (11.28)	1.164	6.54 (14.89)
Total	509.7	100.00	17.793	100.00

The values in parentheses show the product composition on a dry basis, excluding H₂O vapor.

2.7.6.4 Ideal Gas Laws

Ideal gas laws are derived from the approximation that gas molecules behave like hard spheres. This approximation is true for most gases at low pressures or elevated temperatures, for example, at atmospheric conditions. Real gas behavior at higher pressures and lower temperatures is frequently represented by modifications of the ideal gas laws. Thus, the ideal gas laws are a good starting place for calculations of gas properties.

Boyle's Law states that constant temperature (T), the volume (V) of a fixed mass of an ideal gas is inversely proportional to the absolute pressure (P). That is,

$$V \propto \frac{1}{P} \quad \text{or} \quad PV = \text{constant} \quad (T = \text{constant})$$

Charles' Law states that constant pressure (P), the volume (V) of a given mass of an ideal gas is directly proportional to the absolute temperature (T):

$$V \propto T \quad \text{or} \quad \frac{V}{T} = \text{constant} \quad (P = \text{constant})$$

These two laws may be combined to give the *ideal* (or *perfect*) *gas law*, an equation of state:

$$PV = nRT \quad \text{or} \quad P\hat{V} = \frac{RT}{M} \quad \text{or} \quad \rho = \frac{PM}{RT}$$

where n is m/M = number of moles of ideal gas, m is mass of gas present, M is molecular weight of gas in mass per mole, \hat{V} is $V/M = 1/\rho$ = specific volume of ideal gas in volume per mass, and R is universal gas constant in energy per mole per absolute degree.

Values of R in different sets of units are given below:

8.314	joules/g-mole °K
8.314	m ³ Pa/g-mole °K
82.057	cm ³ atm/g-mole °K
83.14	cm ³ bar/g-mole °K
62.36	liter mm Hg/g-mole °K
21.85	(ft) ³ (in.Hg)/lb-mole °R
0.7302	ft ³ atm/lb-mole °R
10.73	ft ³ psi/lb-mole °R
1545	(lb _f /ft ²)(ft ³)/lb-mole °R
1.987	cal/g-mole °K
1.987	Btu/lb-mole °R

When n moles of an ideal gas undergo a chemical reaction, then

$$P_1V_1 = nRT_1 \quad \text{and} \quad P_2V_2 = nRT_2$$

or

$$\frac{P_1V_1}{P_2V_2} = \frac{T_1}{T_2} \quad (2.7.19)$$

where the subscripts 1 and 2 refer to the initial state and final state, respectively.

It is a common practice to evaluate the molal volume (\tilde{V}) of an ideal gas at a set of reference conditions known as the *standard state*. If the standard state is chosen to be

$$P = 1 \text{ atm} = 760 \text{ mmHg} = 14.696 \text{ psia}$$

and

$$T = 0^\circ\text{C} = 273.16^\circ\text{K} = 32^\circ\text{F} = 491.69^\circ\text{R}$$

Then

$$\tilde{V} = \frac{V}{n} = \frac{RT}{P} \quad (2.7.20)$$

represents the volume occupied by 1 mole of any perfect gas, and has the following values at the standard conditions of temperature and pressure (abbreviated as STP):

$$\begin{aligned} \tilde{V} &= 22.414 \text{ } \ell/\text{g-mole} \\ &= 22,414.6 \text{ cm}^3/\text{g-mole} \\ &= 359.046 \text{ ft}^3/\text{lb-mole} \end{aligned}$$

The *specific gravity* (G) of an ideal gas relative to a reference gas (also assumed ideal) is given by

$$G = \frac{\rho}{\rho_{\text{ref}}} = \frac{M}{M_{\text{ref}}} \frac{P}{P_{\text{ref}}} \frac{T_{\text{ref}}}{T} \quad (2.7.21)$$

or $G = M/M_{\text{ref}}$ when $T = T_{\text{ref}}$ and $P = P_{\text{ref}}$.

Although real gases deviate from ideal gas behavior and therefore require different equations of state, the deviations are relatively small under certain conditions. An error of 1% or less should result if the ideal gas law were used for diatomic gases when $\tilde{V} \geq 5 \text{ } \ell/\text{gm-mole}$ (80 ft³/lb-mole) and for other gases and light hydrocarbon vapors when $\tilde{V} \geq 20 \text{ } \ell/\text{gm-mole}$ (320 ft³/lb-mole) [19,20].

Example 2.7.4

Analysis of a volatile compound of chlorine gives 61.23% of oxygen and 38.77% of chlorine by weight. At 1 atm and 27°C, 1000 cm³ of its vapor weighs 7.44 g. Assuming ideal gas behavior for the vapor, estimate its molecular weight and deduce its molecular formula.

2.7.6.4.1 Solution

At $T = 27^\circ\text{C} = 300.2^\circ\text{K}$ and $P = 1 \text{ atm}$,

$$\text{Mass density of the vapor} = \rho = \frac{7.44 \text{ g}}{1000 \text{ cm}^3} = \frac{PM}{RT}$$

With $R = 82.057 \text{ cm}^3\text{-atm/g-mole } ^\circ\text{K}$, the molecular weight is

$$M = \frac{\rho RT}{P} = \frac{(7.44)(82.057)(300.2)}{(1000)(1)} = 183.3 \text{ g/g-mole}$$

If the unknown compound is made up of x atoms of chlorine and y atoms of oxygen, its molecular formula will be Cl_xO_y . Because the atomic weights of Cl and O are 35.45 and 16.00 g/g-mole, respectively, we can express the weight composition of the compound as

$$\frac{\text{weight of oxygen}}{\text{weight of chlorine}} = \frac{(y)16.00}{(x)(35.45)} = \frac{0.6123}{0.3877}$$

or $y = 3.5x$. Making this substitution in the formula for the molecular weight of the substance, we have

$$183.3 = M = (x)35.45 + (y)16.00$$

or

$$183.3 = 35.45 + (16.00)(3.5)x = 91.45 \\ \therefore x = (183.3)/(91.45) \approx 2$$

With $x = 2$ and $y = 7$, the compound has molecular formula Cl_2O_7 with $M = 182.9$.

Dalton's Law of Partial Pressures states that the total pressure (P) of a gaseous mixture equals the sum of the partial pressures of its components. By definition, the *partial pressure* of any component gas is the pressure it would exert if it occupied the entire volume (V) of the mixture at the same temperature (T). That is,

$$P = P_1 + P_2 + \dots + P_N = \sum P_i \quad (2.7.22)$$

where the partial pressure of component gas i in a N -component gas mixture is

$$P_i = \frac{n_i RT}{V} \quad i = 1, 2, \dots, N \quad (2.7.23)$$

by the ideal gas law. If the mixture also behaves ideally, then

$$\frac{PV}{RT} = n = \sum n_i = \left(\sum P_i \right) \frac{V}{RT} \quad (2.7.24)$$

Thus, the mole fraction of component gas i is

$$y_i = \frac{n_i}{n} = \frac{P_i}{P} = \frac{\text{Partial pressure of } i}{\text{Total pressure of mixture}} \quad (2.7.25)$$

Amagat's Law states that the total volume of a gaseous mixture is the sum of the pure-component volumes. By definition, the *pure-component volume* of a component gas in a mixture is the volume that the component would occupy

at the same temperature and total pressure of the mixture. By Amagat's law,

$$V = \sum V_i = V_1 + V_2 + \dots$$

If each component gas as well as the mixture obeys the ideal gas law, it follows that the pure-component volume of component is

$$V_i = \frac{n_i RT}{P} = y_i \frac{n RT}{P} = y_i V \quad (2.7.26)$$

or

$$y_i = \frac{n_i}{n} = \frac{V_i}{V} \quad (2.7.27)$$

In an ideal gas mixture, the mole fraction of each component is equal to its volume fraction (by Amagat's law) or the ratio of its partial pressure to the total pressure (by Dalton's law). For both laws to be applicable simultaneously, the mixture and its components must behave ideally.

Example 2.7.5

A natural gas has the following composition by volume at a temperature of 80°F and a gauge pressure of 40 psig—87.2% methane, 4.5% ethane, 3.6% propane, 1.8% n-butane, 1.0% isobutene, and 1.9% nitrogen. Assuming the ideal-gas law is applicable, calculate (i) the average molecular weight of the mixture, (ii) density of the natural gas, (iii) specific gravity of the gas, (iv) volume occupied by 100 lb of gas at 1 atm and 60°F , (v) partial pressure of nitrogen, and (vi) pure-component volume of nitrogen per 1,000 ft^3 of gas.

2.7.6.4.2 Solution

Start with a *basis* of 1 lb-mole of the natural gas at $T = 80^\circ\text{F} = 540^\circ\text{R}$ and $P = 40 \text{ psig} = 54.7 \text{ psia}$. The volume percent and mole percent compositions are identical for a perfect-gas mixture.

- (i) The molecular weight of the gas mixture is $M = \sum y_i M_i$ and its calculation is shown below in tabular form.

Component i	M_i (lb/lb-mole)	y_i	$m_i =$ $y_i M_i$ (lb)
CH_4	16.04	0.872	13.987
C_2H_6	30.07	0.045	1.353
C_3H_8	44.10	0.036	1.588
n- C_4H_{10}	58.12	0.018	1.046
iso- C_4H_{10}	58.12	0.010	0.581
N_2	28.01	0.019	0.532
		1.000	19.087

$$\therefore M = \sum m_i = 19.09 \text{ lb/lb-mole}$$

- (ii) With $R = 10.73 \text{ ft}^3\text{-psia/lb-mole } ^\circ\text{R}$, mass density of the mixture

$$\rho = \frac{PM}{RT} = \frac{(54.7)(19.09)}{(10.73)(540)} = 0.180 \text{ lb/ft}^3$$

Molar density $c = \rho/M = 0.180/19.09 = 9.44 \times 10^{-3} \text{ lb-moles/ft}^3$

- (iii) Assuming that air (reference substance) also obeys the ideal-gas law, the specific gravity of the mixture is given by

$$G(80^\circ\text{F}, 54.7 \text{ psia}) = \frac{\rho}{\rho_{\text{air}}} = \frac{M}{M_{\text{air}}} = \frac{19.09}{28.97} = 0.659$$

- (iv) At $T_1 = 60^\circ\text{F} = 520^\circ\text{R}$ and $P_1 = 1 \text{ atm} = 14.696 \text{ psia}$, the volume occupied by

$$n_1 = \frac{100}{19.09} \text{ lb-moles of the gas}$$

is

$$V_1 = \frac{n_1RT}{P_1} = \frac{(100)(10.73)(520)}{(19.09)(14.696)} = 1,988.3 \text{ ft}^3$$

- (v) At $P = 40 \text{ psig}$ and $T = 80^\circ\text{F}$, by Dalton's law of partial pressures, $P_i = y_iP$ for any component i in the mixture. Therefore, partial pressure of nitrogen = $(0.019)(54.7) = 1.039 \text{ psia}$.
- (vi) Applying Amagat's law at the same conditions, the pure component volume $V_i = y_iV$ for any i . For nitrogen, $V_i = (0.019)(1,000) = 19.0 \text{ ft}^3$.

2.7.6.5 Phase Rule and Phase Behavior

The phase rule derived by W.J. Gibbs applies to multiphase equilibria in multicomponent systems, in the absence of chemical reactions. It is written as

$$\mathcal{F} = \mathcal{C} - \mathcal{P} + 2 \quad (2.7.28)$$

where \mathcal{F} is number of degrees of freedom or variance of the system, \mathcal{C} is the number of independent chemical components, and \mathcal{P} is number of phases.

The term \mathcal{F} is the number of intensive variables that must be specified to describe the system. The intensive variables are temperature (T), pressure (P), and the composition of the mixtures (e.g., mole fractions, x_i). As an example, consider the triple point of water at which all three phases—ice, liquid water, and water vapor—coexist in equilibrium. According to the phase rule,

$$\mathcal{F} = \mathcal{C} - \mathcal{P} + 2 = 1 - 3 + 2 = 0 \quad (2.7.29)$$

The absence of any degrees of freedom implies that the triple point is a unique state that represents an *invariant*

system, i.e., one in which any change in the state variables T or P will reduce the number of coexisting phases.

A pure substance can have at most three coexisting phases at equilibrium. At temperatures and pressures over than the triple point, a pure substance may exist as a single phase (solid, liquid, or vapor) or as a two-phase system. For the single-phase region ($\mathcal{P} = 1$),

$$\mathcal{F} = \mathcal{C} - \mathcal{P} + 2 = 1 - 1 + 2 = 2. \quad (2.7.30)$$

indicating that P and T can vary simultaneously. In the two-phase region ($\mathcal{P} = 2$), $\mathcal{F} = 1 - 2 + 2 = 1$, so that either P to T can vary, but not both.

It is possible to graph the equilibrium phase behavior of a pure substance in three dimensions with pressure (P), specific volume* (V), and temperature (T) as coordinates. This is called a phase or P - V - T diagram (Figure 2.7.2). Orthogonal projections onto the P - V , V - T , and P - T planes give two-dimensional plots suited for determining phase properties for those combinations of variables. Isotherms ($T = \text{constant}$), isobars ($P = \text{constant}$), and isochors ($V = \text{constant}$) may be drawn as necessary to highlight aspects of phase behavior.

The *vapor pressure* (P^2) of a pure liquid at a given temperature (T) is the pressure exerted by its vapor in equilibrium with the liquid phase in a closed system. All liquids and solids exist in equilibrium with vapor. For instance, in Figure 2.7.3, lines BA and AC represent the equilibrium vapor pressure curves of the solid and liquid phases, respectively.

Phase transitions are equilibrium transformations from one phase to another. Examples are sublimation (solid to vapor), boiling or vaporization (liquid to vapor), and freezing (liquid to solid). On a P - T diagram (see Figure 2.7.3) the phase transformations take place on the sublimation curve BA, vaporization curve AC, and melting curve AD, which separate the single-phase regions. Two phases coexist in equilibrium on each of these phase-boundary curves, with the exception of the triple point, A. The vaporization curve terminates at the critical point C, at which the distinction between liquid and vapor phases disappears and the latent heat of vaporization becomes zero. The single phase that exists above the critical point (P_c, T_c) is variously described as gas, dense fluid, or supercritical fluid. When $T > T_c$, it is impossible to liquefy a dense fluid by varying the pressure alone.

Because a phase change is usually accompanied by a change in volume the two-phase systems of a pure substance appear on a P - V (or a T - V) diagram as regions with distinct boundaries. On a P - V plot, the triple point appears as a horizontal line, and the critical point becomes a point of

2. The intensive variable for volume (V) can be either the specific volume (\hat{V} , volume/mass) or the specific molal volume (\bar{V} , volume/mole).

FIGURE 2.7.2 Typical phase diagram for a pure substance showing P-V-T surface and its projections [18].

inflection of the critical isotherm, $T = T_c$ (see Figure 2.7.2 and Figure 2.7.4).

The vapor-liquid region of a pure substance is contained within the *phase* or *saturation envelope* on a P-V diagram (see Figure 2.7.4). A vapor, whether it exists alone or in a mixture of gases, is said to be *saturated* if its partial pressure equals its equilibrium vapor pressure at the system temperature T . This temperature is called the *saturation temperature* or *dew point* T_{dp} of the vapor because any decrease in system temperature will result in condensation. For a pure substance, saturated vapor coexists in equilibrium with saturated liquid at every point on the vaporization

curve AC (see Figure 2.7.3) of the P-T diagram. Its coordinates are given by P (system pressure) = P^* (vapor pressure at temperature T), and T (system temperature) = T_b (boiling point of the substance at pressure P). The *normal boiling point* (nbp) refers to the value of T_b attained at a total pressure of 1 standard atmosphere.

A *superheated vapor* refers to a vapor that exists under conditions such that $P_i < P_i^*(T)$. The difference between its existing temperature (T) and its dew point (T_{dp}) is termed the *degrees of superheat* of the vapor. The region of superheated vapor for a pure substance is shown on the T-P diagram (see Figure 2.7.3) by the area lying to the

FIGURE 2.7.3 Typical P–T diagram for a pure substance (A is the triple point and C is the critical point).

right of the vaporization curve AC. The term *bubble point* (T_{bp}) of a liquid is the temperature above which boiling will take place. For a pure component system, the bubble point and dew point temperatures are identical to the boiling point of the substance at that pressure. For binary and multicomponent systems of a given composition, $T_{dp} > T_{bp}$ at fixed P or, alternatively, P_{bp} (bubble point pressure) $> P_{dp}$ (dew-point pressure) at fixed T. The saturated liquid curve is thus equivalent to the bubble point curve, and the saturated vapor curve is the same as the dew point curve (see Figure 2.7.4). Although the isotherms on a P–V plot are horizontal lines in the vapor-liquid region of a pure substance, they become curves having negative slopes in system containing more than one component. A liquid is termed *subcooled* if its temperature (T) is less than the bubble-point temperature (T_{bp}) at given pressure (P). The *degrees of subcooling* are then given by the difference ($T_{bp} - T$). In the case of a pure substance, the area DAC lying to the left of the curve AC in the subcooled liquid region (see Figure 2.7.3).

In the vapor-liquid region of a pure substance, the composition of a two-phase system (at given T and P) varies from pure saturated liquid at the bubble point M to pure saturated vapor at the dew point N along the line MQN on the P–V diagram (Figure 2.7.4). For a *wet vapor* represented by an intermediate point Q, the *quality* (q) refers to the mass

fraction of saturated vapor present in the two-phase mixture. If m_ℓ and m_g indicate the masses of saturated liquid and saturated vapor comprising the wet vapor at point Q, then its quality may be calculated by the application of the lever rule as

$$q \equiv \frac{m_g}{m_\ell + m_g} = \frac{\hat{V} - \hat{V}_\ell}{\hat{V}_g - \hat{V}_\ell} = \frac{\text{length MQ}}{\text{length MN}} \quad (2.7.31)$$

The origin of this rule lies in the expression for the specific volume of the wet vapor, $\hat{V} = q\hat{V}_g + (1 - q)\hat{V}_\ell$. The intensive properties of the wet vapor are obtained readily from the individual properties of its component phases by an analogous equation:

$$\mathcal{M} = q\mathcal{M}_g + (1 - q)\mathcal{M}_\ell \quad (2.7.32)$$

where the symbols \mathcal{M}_g , \mathcal{M}_ℓ and \mathcal{M} refer to the specific properties of the saturated vapor, saturated liquid, and the two-phase mixture, respectively.

The *Clausius-Clapeyron Equation* was originally derived to describe the vaporization process of a pure liquid, but it can also be applied to other two-phase transitions of a pure substance. The Clausius-Clapeyron equation relates the variation of vapor pressure (P^*) with absolute temperature (T) to the molar latent heat of vaporization, λ_v ,

FIGURE 2.7.4 Typical P–V diagram for a pure substance showing isotherms and saturation (phases) envelope.

i.e., the thermal energy required to vaporize one mole of the pure liquid:

$$\frac{dP^*}{dT} = \frac{\lambda_v}{T(\tilde{V}_g - \tilde{V}_l)} \approx \frac{\lambda_v}{T\tilde{V}_g} \quad (2.7.33)$$

By neglecting the specific molar volume of the saturated liquid \tilde{V}_l in relation to that of the saturated vapor \tilde{V}_g , and by assuming the vapor phase to behave as an ideal gas, i.e., $P^*\tilde{V}_g = RT$, the above equation may be arranged into

$$\frac{d(\ln P^*)}{d(1/T)} = -\frac{\lambda_v}{R} \quad (2.7.34)$$

This suggests that a plot of $\ln P^*$ against $1/T$ should yield a line having a local slope of $(-\lambda_v/R)$. A straight line is obtained only when λ_v is nearly constant, i.e., over a narrow range of temperatures. An integrated version of the Clausius-Clapeyron equation finds use in correlation of vapor pressure data:

$$P^*(T) \approx P_0^* \exp \left[-\frac{\bar{\lambda}_v}{R} \left(\frac{1}{T} - \frac{1}{T_0} \right) \right] \quad (2.7.35)$$

where P_0^* is the known vapor pressure at reference temperature T_0 , and $\bar{\lambda}_v$ is the average value of λ_v between T_0 and T . The above equation is reasonably valid when the range $|T_0 - T|$ is small and when the two-phase region of interest is far away from the critical point.

2.7.6.6 Vapor–Liquid Equilibria in Binary and Multicomponent Systems

Multicomponent systems do not exhibit a single boiling point at a given pressure as a pure substance does. Instead, at a constant pressure, a liquid mixture undergoes a change of phase to vapor over a range of temperatures lying between the bubble point and the dew point. Three different approaches — Raoult's law, Henry's law, and the concept of the equilibrium ratio or K factor — are available for computations involving vapor–liquid equilibria.

Raoult's Law. The molar composition of a liquid phase (ideal solution) in equilibrium with its vapor at any temperature T is given by

$$x_i = P_i/P_i^*(T) \quad i = 1, 2, \dots, N \quad (2.7.36)$$

If the vapor phase behaves as an ideal gas mixture, then by Dalton's law of partial pressures,

$$y_i = P_i/P = x_i P_i^*(T)/P \quad i = 1, 2, \dots, N \quad (2.7.37)$$

where x_i and y_i are the respective mole fractions of component i in the liquid and vapor phases, $P_i^*(T)$ is the equilibrium vapor pressure of pure liquid i at system temperature T , P_i is the partial pressure of i in the vapor phase, and P is the total pressure of the vapor phase. Each component i is distributed between the two phases to an extent dictated by the relative volatilities of the components at the system temperature. Note that $\sum x_i = 1$, $\sum y_i = 1$, and $P = \sum x_i P_i^*$.

Raoult's law is strictly applicable to ideal liquid solutions at all compositions, pressures, and temperatures. In an ideal of perfect solution, the components are mutually miscible in all proportions and there are no volume or thermal changes on mixing. Solutions that approach ideality include mixtures of nonpolar hydrocarbons belonging to a homologous family (e.g., paraffins). Whereas binary mixtures of propane-butane, n-hexane-n-heptane, benzene-toluene, etc., show ideal behavior over a range of compositions, nonideal solutions comprising a solvent (1) and a solute (2) obey Raoult's law only in the limit of $x_1 \rightarrow 1$ (i.e., in dilute solutions). Raoult's law finds use in molecular weight determination of nonvolatile solutes in dilute solutions, in estimation of equilibrium solubilities of noncondensable gases in nonpolar liquids, and in vapor-liquid equilibria calculations.

Molecular Weight Determination by Application of Raoult's Law. If a small amount (m_2 in grams) of a nonvolatile, nonionized substance (solute, 2) is dissolved in m_1 grams of a volatile liquid (solvent, 1), the vapor pressure is lower from the pure solvent value (P_1^*) to the solution value (P) at the system temperature. This is a consequence of Raoult's law because the total vapor pressure of the dilute solution ($x_2 \ll 1$) is given by $P^* = x_1 P_1^* + x_2 P_2^* \approx x_1 P_1^*$.

(a) The *relative lowering of vapor pressure* of the solvent is then

$$\frac{P_1^* - P^*}{P_1^*} = \frac{\Delta P^*}{P_1^*} \approx x_2 = \frac{(m_2/M_2)}{(m_1/M_1) + (m_2/M_2)} \approx \frac{m_2 M_1}{M_2 m_1} \quad (2.7.38)$$

Measurement of P^* and P_1^* at one temperature allows determination of unknown M_2 .

(b) The presence of the nonvolatile solute also causes an *elevation of the boiling point* of the liquid from pure solvent value T_b to solution value T . The above equation is coupled with Clausius-Clapeyron equation to yield

$$\Delta T_b = T - T_b = \frac{-RT_b^2}{\lambda_v} \ln(1 - x_2) \approx \frac{RT_b^2}{\lambda_v} x_2 \approx \frac{RT_b^2}{\lambda_v} \frac{M_1 m_2}{M_2 m_1}$$

where λ_v is the molal latent heat of vaporization of pure solvent at its boiling point (T_b) and R is the universal gas constant. By measuring ΔT_b and T_b at the same total pressure, x_2 can be computed and hence M_2 .

(c) The presence of the solute also causes a *depression in the freezing point* of the solvent from the pure liquid value T_f to the solution value T . Application of Raoult's law together with Clausius-Clapeyron equation gives a similar result:

$$\Delta T_f = T_f - T \approx \frac{RT_f^2 x_2}{\lambda_f} \approx \frac{RT_f^2}{\lambda_f} \frac{M_1 m_2}{M_2 m_1} \quad (2.7.39)$$

where λ_f is the molal latent heat of fusion of the solvent at T_f . Techniques (b) and (c) provide more accurate data and therefore better estimates for M_2 than method (a).

Example 2.7.6

A solution is prepared by dissolving 0.911 g of carbon tetrachloride in 50.00 g of benzene. (i) Calculate the freezing point depression of the solution if pure benzene has a T_f of 5.53°C and a latent heat of fusion of 30.45 cal/g. (ii) What will be the elevation in boiling point of the solution if pure benzene has a T_b of 80.1°C and a latent heat of vaporization of 7,700 cal/g-mole [5].

2.7.6.6.1 Solution

$$\text{MW of solute (CCl}_4\text{)} = M_2 = 153.82 \quad m_2 = 0.911 \text{ g}$$

$$\text{MW of solvent (C}_6\text{H}_6\text{)} = M_1 = 78.11 \quad m_1 = 50.00 \text{ g}$$

$$x_2 = \frac{(m_2/M_2)}{(m_1/M_1) + (m_2/M_2)} = 0.917 \times 10^{-2}$$

(i) Because $x_2 \ll 1$, the solution is dilute and Raoult's law may be applied

$$\Delta T_f = T_f - T \approx \frac{RT_f^2}{\lambda_f} x_2$$

With $R = 1.987$ cal/g-mole, $T_f = 273.2 + 5.53 = 278.73^\circ\text{K}$, and $\lambda_f = (30.45)(78.11)$ cal/g-mole, we obtain $\Delta T_f = 0.595^\circ\text{C}$, which compares well with an experimental observation of 0.603°C .

- (ii) With $T_b = 273.2 + 80.1 = 353.3^\circ\text{K}$, $\lambda_v = 7,700$ cal/g-mole, we get

$$\Delta T_b = T - T_b = \frac{RT_b^2 x_2}{\lambda_v} = 0.295^\circ\text{C}$$

Henry's Law is an empirical formulation that describes equilibrium solubilities of noncondensable gases in a liquid when Raoult's law fails. It states that the mole fraction of a gas (solute i) dissolved in a liquid (solvent) is proportional to the partial pressure of the gas above the liquid surface at given temperature. That is,

$$x_i = P_i/H_i(T) \quad (2.7.40)$$

where the constant of proportionality $H_i(T)$ is known as Henry's law constant, with units of pressure per mole fraction. It is a characteristic of the gas-liquid system and increases with T . Experimentally determined values of H_i are available in the standard references for various gas-liquid systems [13-16]. If the gas phase is assumed to be ideal, then the equilibrium mole fraction of component i in the gas phase is

$$y_i = P_i/P = x_i H_i(T)/P \quad (2.7.41)$$

Henry's law is a reasonable approximation in the absence of gas-liquid reactions when total pressure is low to moderate. Deviations are usually manifested in the form of H_i dependence on P and phase compositions.

Example 2.7.7

A gas mixture has a molal composition of 20% H_2S , 30% CO_2 and 50% N_2 at 20°C and a total pressure of 1 atm. Use Henry's law to calculate the volumes of these gases that may be dissolved in 1,000 lb of water at equilibrium.

2.7.6.6.2 Solution

By Henry's law, the partial pressure of solute i in the gas phase is $P_i = H_i(T)x_i$, where x_i is the mole fraction of i in solution. Data on Henry's law constant are obtained from Chapter 14 of Perry and Chilton's *Chemical Engineers' Handbook* [14] for gas-water systems at 20°C .

Gas i :	H_2S	CO_2	N_2
$H_i(\text{atm/mole fraction})$:	4.83×10^2	1.42×10^3	8.04×10^4

Assuming ideal-gas law to hold, $P_i = y_i P$, where $P = 1$ atm and $y_i =$ mole fraction of i in the gas phase. The equilibrium mole fraction x_i of gas i in solution is then given by

$$x_i = P_i/H_i = y_i P/H_i$$

Gas	P_i		n_i		
i	y_i	(atm)	x_i	(lb-moles)	V_i (ft ³)
H_2S	0.20	0.20	4.14×10^{-4}	2.30×10^{-2}	8.86
CO_2	0.30	0.30	2.11×10^{-4}	1.17×10^{-2}	4.51
N_2	0.50	0.50	6.22×10^{-5}	3.45×10^{-3}	1.33

The table shows the rest of the required results for the number of moles n_i of each gas i present in the aqueous phase and the corresponding gas volume V_i dissolved in it. Since $x_i \ll 1$, the total moles of liquid is $n \approx (1000/18.01)$ lb-moles in 1000 lb of water and so $n_i = x_i n$ can be calculated. At $T = 20^\circ\text{C} = 68^\circ\text{F} = 528^\circ\text{R}$ and $P = 1$ atm, the molal volume of the gas mixture is

$$\tilde{V} = \frac{RT}{P} = \frac{(0.7302)(528)}{(1)} = 385.55 \text{ ft}^3/\text{lb-mole}$$

The volume of each gas dissolved in 1,000 lb of water is then $V_i = n_i \tilde{V}$.

Equilibrium Distribution Ratio or K factor. This is also termed *distribution coefficient* in the literature; it is a widely accepted method of describing vapor-liquid equilibria in nonideal systems. For any component i distributed between the vapor phase and liquid phase at equilibrium, the distribution coefficient or K factor is defined by

$$K_i = y_i/x_i = K_i(T, P) \quad (2.7.42)$$

The dimensionless K_i is regarded as a function of system T and P only and not of phase compositions. It must be experimentally determined. Reference 64 provides charts of $K_i(T, P)$ for a number of paraffinic hydrocarbons. K_i increases with an increase in system T and decreases with an increase in P . Away from the critical point, it is assumed that the K_i values of component i are independent of the other components present in the system. In the absence of experimental data, caution must be exercised in the use of K -factor charts for a given application. The term *distribution coefficient* is also used in the context of a solute (solid or liquid) distributed between two immiscible liquid phases; y_i and x_i are then the equilibrium mole fractions of solute i in each liquid phase.

Example 2.7.8

The distribution coefficient for n -heptane (solute i) distributed between ethylene glycol (solvent 1) and benzene (solvent 2) at 25°C is given as the ratio of mass fractions $(\omega_{i,1}/\omega_{i,2})=K_i=0.30$. Suppose 60 g of n -heptane are added to a solvent mixture of 600 g of ethylene glycol and 400 g of benzene. Assuming that the solvents are immiscible, determine the amount of n -heptane dissolved in each liquid phase at equilibrium.

2.7.6.6.3 Solution

Consider the equilibrium state of the system assuming that m grams of n -heptane are dissolved in the benzene phase. The mass fraction of n -heptane in this phase is $\omega_{i,2} = m/(400 + m)$.

Because $(60 - m)$ g of i are present in the glycol phase, the equilibrium mass fraction of i in this phase is $\omega_{i,1} = (60 - m)/(600 + 60 - m)$. Thus,

$$\frac{\omega_{i,1}}{\omega_{i,2}} = K_i = 0.30 = \frac{(60 - m)(400 + m)}{(660 - m)m}$$

which must be solved for m . A quadratic equation in m is obtained by cross-multiplication and rearrangement of terms:

$$0.30m(660 - m) - (60 - m)(400 + m) = 0$$

or

$$0.70m^2 + 538m - 24,000 = 0$$

Its roots are

$$m = \frac{-538 \pm \sqrt{(538)^2 - 4(0.70)(-24,000)}}{2(0.70)}$$

Only the positive root is the physically meaningful value and so

$$m = (-538 + 597.197)/1.4 = 42.28 \text{ g}$$

$$\therefore \omega_{i,2} = 42.28/442.28 = 0.0956 \text{ in benzene phase}$$

and

$$\omega_{i,1} = (60 - 42.28)/617.72 = 0.0287 \text{ in glycol phase}$$

Note that $w_{i,1}/w_{i,2} = 0.0287/0.0956 = 0.3$

2.7.7 Thermochemistry

Thermochemistry is the study of thermal effects associated with phase changes, formation of chemical compounds or solutions, and chemical reactions in general. The amount of heat (Q) liberated (or absorbed) is usually measured in a batch-type bomb calorimeter at fixed volume or in a steady-flow calorimeter at constant pressure. Under these operating conditions, $Q = Q_v = \Delta U$ (net change in the internal energy of the system) for the bomb calorimeter, while $Q = Q_p = \Delta H$ (net change in the enthalpy of the system) for the flow calorimeter. For a pure substance, the thermodynamic properties U and H are functions of the state variables, temperature (T) and pressure (P), and its state of aggregation [e.g., liquid (ℓ), gas or vapor (g), solid (s)]. We briefly review basic definitions and terminology employed in the area of thermochemistry and consider some applications pertaining to combustion of fuels.

Heat of Reaction (ΔH_r). The heat of a chemical reaction carried out at constant pressure (P) is given by the difference between the total enthalpies of the reactants and products.

$$\Delta H_r = H_{\text{products}} - H_{\text{reactants}} = \sum_P n_j H_j - \sum_R n_i H_i \quad (2.7.43)$$

where the subscripts i and j refer to reactant i and product j , n is the number of moles, and symbols \sum_R and \sum_P imply summations over all reactants ($i = 1, 2, \dots$) and all products ($j = 1, 2, \dots$), respectively. ΔH_r has units of calories or BTUs; its value depends on the amounts and physical states of the reactants and products as well as on the reaction conditions. Note that ΔH_r is *negative* for an *exothermic* reaction in which heat is spontaneously liberated and is *positive* for an *endothermic* reaction in which heat is absorbed from the surroundings.

Standard-state enthalpy changes (ΔH^0). To expedite calculations, thermochemical data are ordinarily presented in the form of standard-state enthalpy changes of the system $\Delta H^0(T, P)$, with the requirement that materials start and end at the same temperature (T) and pressure (P) and in their standard states of aggregation, i.e.,

$$\Delta H^0(T, P) = H_{\text{final}}^0(T, P) - H_{\text{initial}}^0(T, P) \quad (2.7.44)$$

The reference state is usually chosen as $P = 1$ standard atmosphere and $T = 25^\circ\text{C}$ (77°F). Examples include standard heats of reaction ΔH_r^0 , heats of formation ΔH_f^0 , heats of combustion ΔH_c^0 , heats of vaporization ΔH_v^0 or λ_v , heats of solution ΔH_s^0 , etc. To avoid confusion, the standard state of aggregation of each substance taking part in the thermochemical process must be specified by an appropriate letter symbol adjoining its chemical formula. The standard state for a gas is the ideal gas at 1 atm and specified T . The standard state for a solid is its stable crystalline form (e.g., rhombic sulfur) or amorphous form existing at the specified P and T . In the absence of such information, the normal state of aggregation of the material at given P and T is assumed. Tabulated values of standard-state enthalpy changes (ΔH^0) are readily available from a number of sources including handbooks and textbooks [13–18].

Standard Heat of Reaction. This is the standard enthalpy change accompanying a chemical reaction under the assumptions that the reactants and products exist in their standard states of aggregation at the same T and P , and stoichiometric amounts of reactants take part in the reaction to completion at constant P . With $P = 1$ atm and $T = 25^\circ\text{C}$ as the standard state, $\Delta H_r^0(T, P)$ can be written as

$$\Delta H_r^0(25^\circ\text{C}, 1 \text{ atm}) = \sum_P \nu_i H_j^0(25^\circ\text{C}, 1 \text{ atm}) - \sum_R \nu_i H_i^0(25^\circ\text{C}, 1 \text{ atm}) \quad (2.7.45)$$

Because ν represents the stoichiometric coefficient of a given species, the value of ΔH_r^0 clearly depends on the way the stoichiometric equation is written for the reaction. It is conventional to express the above equation in a simplified form as

$$\Delta H_r^0(25^\circ\text{C}, 1 \text{ atm}) = \sum_P \nu_j H_j^0 - \sum_R \nu_i H_i^0 \quad (2.7.46)$$

where it is understood that H_i^0 and H_j^0 are to be evaluated at the reaction conditions of 1 atm and 25°C . Another common practice is to use the number of moles n_i (or n_j) in place of the stoichiometric coefficient ν_i (or ν_j). Further discussion of heats of reaction can be found in Reference 11.

Relation between Q_p and Q_v . The heats of reaction measured at constant pressure and at constant volume are $Q_p = \Delta H_r(T, P)$ and $Q_v = \Delta U_r(T, P)$. Since $H = U + PV$, it follows that Q_p and Q_v are related by

$$\Delta H_r = \Delta U_r + P\Delta V \quad (2.7.47)$$

where $\Delta V = \text{total volume of products} - \text{total volume of reactants}$.

If all the species are gaseous and obey the ideal gas law, then

$$\Delta H_r = \Delta U_r + RT\Delta n$$

where $\Delta n = \sum_p n_j - \sum_r n_i = \text{net change in the number of moles of the system}$.

The *standard heat of formation* (ΔH_f^0) of a chemical compound is the standard heat of reaction corresponding to the chemical combination of its constituent elements to form one mole of the compound, each existing in its standard state at 1 atm and 25°C . It has units of cal/g-mole.

$$\Delta H_f^0(1 \text{ atm}, 25^\circ\text{C}) = H_{\text{compound}}^0 - H_{\text{elements}}^0 \quad (2.7.48)$$

By convention, the standard-state enthalpies of the elements (H_i^0) are taken to be zero at 1 atm and 25°C so that $\Delta H_f^0 = H_{\text{compound}}^0$.

The *standard heat of combustion* (ΔH_c^0) of a chemical substance (usually an organic compound) is the standard heat of reaction for complete oxidation of 1 mole of the substance in pure oxygen to yield $\text{CO}_2(\text{g})$ and $\text{H}_2\text{O}(\ell)$ as products. A reference state of 25°C and 1 atm is assumed in quoting standard heats of combustion in cal/g-mole. The value of ΔH_c^0 is always negative because combustion is an exothermic reaction. Note that the standard heats of combustion for carbon and hydrogen are the same as the heats of formation for $\text{CO}_2(\text{g})$ and $\text{H}_2\text{O}(\ell)$, respectively.

Laws of Thermochemistry. Lavoisier and Laplace (1780) found that the heat required to decompose a chemical compound into its elements was numerically equal to the heat generated in its formation under the same conditions of

T and P. That is $\Delta H_d = -\Delta H_f$, where the subscript d refers to decomposition reaction [11, 19].

An important corollary of this postulate is known as *Hess's law of constant heat summation* (1840): The overall heat of a chemical reaction is the same whether the reaction occurs in a single step or multiple steps.

The two basic principles permit the algebraic manipulation of chemical reactions for thermochemical calculations.

Applications. (1) Heats of formation of reactants and products can be used to calculate the standard heat of a chemical reaction by applying Hess's law:

$$\Delta H_r^0 = \sum_P \nu_j \Delta H_{f,j}^0 - \sum_R \nu_i \Delta H_{f,i}^0 \quad (2.7.49)$$

where $\Delta H_{f,i}^0$ and $\Delta H_{f,j}^0$ are the standard heats of formation of reactant i and product j, respectively.

(2) For reactions involving only organic compounds as reactants, ΔH_r^0 can be determined using heats of combustion data.

$$\Delta H_r^0 = \sum_R \nu_i \Delta H_{c,i}^0 - \sum_P \nu_j \Delta H_{c,j}^0 \quad (2.7.50)$$

These two approaches are useful when a direct measurement of ΔH_r^0 is not possible because of experimental difficulties.

Example 2.7.9

Calculate the heat of reaction at the standard reference state (1 atm, 25°C) for

using heat of formation data. Also check results using heat of combustion data.

2.7.7.0.4 Solution

The required data are tabulated below in units of kJ/g-mole [5].

	$-\Delta H_f^0$	$-\Delta H_c^0$
n-C ₄ H ₁₀ (g)	125.7	2877.6
C ₂ H ₄ (g)	-52.4	1411.2
C ₂ H ₆ (g)	84.0	1560.7
CO ₂ (g)	393.5	-
CO(g)	110.5	283.0
H ₂ (g)	0	285.8
H ₂ O(ℓ)	285.8	-

Using heat of formation data, by Hess' law

- (i) $\Delta H_r^0 = \Delta H_f^0(\text{C}_2\text{H}_4) + \Delta H_f^0(\text{C}_2\text{H}_6) - \Delta H_f^0(\text{C}_4\text{H}_{10})$
 $= 52.4 - 84.0 - (-125.7)$
 $= +94.1 \text{ kJ}$
- (ii) $\Delta H_r^0 = \Delta H_f^0(\text{CO}) + \Delta H_f^0(\text{H}_2\text{O}) - \Delta H_f^0(\text{CO}_2)$
 $- \Delta H_f^0(\text{H}_2)$
 $= -110.5 - 285.8 - (-393.5)$
 $= -2.8 \text{ kJ}$

Using heat of combustion data,

- (i) $\Delta H_r^0 = \Delta H_c^0(\text{C}_4\text{H}_{10}) - \Delta H_c^0(\text{C}_2\text{H}_4) - \Delta H_c^0(\text{C}_2\text{H}_6)$
 $= -2877.6 - (-1411.2) - (-1560)$
 $= +94.3 \text{ kJ for first reaction}$
- (ii) $\Delta H_r^0 = \Delta H_c^0(\text{CO}_2) + \Delta H_c^0(\text{H}_2) - \Delta H_c^0(\text{CO})$
 $- \Delta H_c^0(\text{H}_2\text{O})$
 $= 0 - 285.8 - (-283.0) - 0$
 $= -2.8 \text{ kJ for second reaction}$

Both methods yield identical results for the heats of reaction.

Very frequently ΔH_f^0 data are available for inorganic substances but not for organic compounds for which ΔH_c^0 values are more readily available. Because ΔH_f^0 of hydrocarbons are not easily measurable, they are often deduced by Hess's law from known ΔH_c^0 of the hydrocarbon and known ΔH_c^0 values of the products of combustion.

Example 2.7.10

Find the standard heat of formation of benzene (ℓ) given the following heats of combustion data (in kcal/g-mole) at 1 atm and 25°C:

- (i) $\text{C}(\text{s}) + \text{O}_2(\text{g}) \rightarrow \text{CO}_2(\text{g}) \quad \Delta H_c^0 = -94.05$
- (ii) $\text{H}_2(\text{g}) + 1/2 \text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\ell) \quad \Delta H_c^0 = -68.32$
- (iii) $\text{C}_6\text{H}_6(\ell) + 15/2 \text{O}_2(\text{g}) \rightarrow 6\text{CO}_2(\text{g}) + 3\text{H}_2\text{O}(\ell) \quad \Delta H_c^0 = -780.98$

2.7.7.0.5 Solution

The desired formation reaction is

which is equivalent to [6 Equation (i) + 3 Equation (ii) - Equation (iii)]. By Hess' law,

$$\begin{aligned} \Delta H_r^0 &= \sum_R \nu_i \Delta H_{c,i}^0 - \sum_P \nu_j \Delta H_{c,j}^0 \\ &= 6(-94.05) + 3(-68.32) - 1(-780.98) \\ &= -564.30 - 204.96 + 780.98 \\ &= 11.72 \text{ kcal/g-mole} \end{aligned}$$

Effect of Temperature on the Heat of Reaction. It is possible to calculate the heat of a chemical reaction $\Delta H_r(T_1)$ at any temperature T_1 and pressure P , provided we know the standard heat of reaction $\Delta H_r^0(T_0)$ at reference conditions of T_0 and P (e.g., 25°C and 1 atm).

Temperature effects are incorporated into the calculation by a thermal cycle as shown in Figure 2.7.5. The terms ΔH_R and ΔH_P represent the sensible heats necessary to change the temperatures of reactants and products from T_0 to T_1 . Thus,

$$\Delta H_r^0(T_0) + \Delta H_P = \Delta H_R + \Delta H_r(T_1) \quad (2.7.51)$$

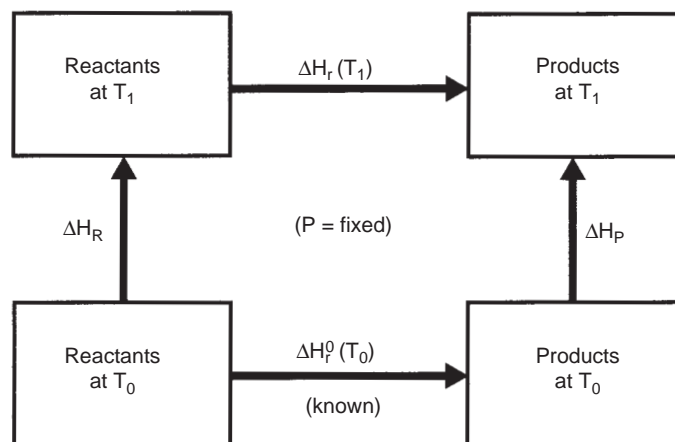

FIGURE 2.7.5 Schematic representation to calculate the heat of reaction at temperature T_1 .

or

$$\begin{aligned}\Delta H_r(T_1) &= \Delta H_r^0(T_0) + \Delta H_P - \Delta H_R \\ &= \Delta H_r^0(T_0) + \sum_P \int_{T_0}^{T_1} \nu_j C_{p,j} dT \\ &\quad - \sum_R \int_{T_0}^{T_1} \nu_i C_{p,i} dT\end{aligned}$$

The integral terms representing ΔH_P and ΔH_R can be computed from molal heat capacity data $C_p(T)$ for the reactants (i) and products (j). When phase transitions occur between T_0 and T_1 for any species, the appropriate latent heats of phase transformations for those species must be included in the evaluation of ΔH_R and ΔH_P . In the absence of phase changes, let $C_p(T) = a + bT + cT^2$ describe the variation of C_p (cal/g-mole °K) with absolute temperature T (°K). Assuming that constants a , b , and c are known for each species involved in the reaction, we can write

$$\begin{aligned}\Delta H_r(T_1) &= \Delta H_r^0(T_0) + \alpha(T_1 - T_0) \\ &\quad + \beta \frac{(T_1^2 - T_0^2)}{2} + \gamma \frac{(T_1^3 - T_0^3)}{3}\end{aligned}\quad (2.7.52)$$

where the coefficient, α , β , and γ are defined by

$$\begin{aligned}\alpha &\equiv \sum_P \nu_j a_j - \sum_R \nu_i a_i \\ \beta &\equiv \sum_P \nu_j b_j - \sum_R \nu_i b_i \\ \gamma &\equiv \sum_P \nu_j c_j - \sum_R \nu_i c_i\end{aligned}\quad (2.7.53)$$

In a more compact notation, the same result becomes

$$\Delta H_r(T_1) = H_0 + \alpha T_1 + \frac{\beta T_1^2}{2} + \frac{\gamma T_1^3}{3}\quad (2.7.54)$$

where

$$H_0 \equiv \Delta H_r^0(T_0) - \left(\alpha T_0 + \frac{\beta T_0^2}{2} + \frac{\gamma T_0^3}{3} \right)\quad (2.7.55)$$

is a function of T_0 only.

Sometimes tabulated values of the *mean molal heat capacities* $\bar{C}_p(T)$ are more easily accessible than $C_p(T)$ data, with respect to a reference temperature of $T_0 = 25^\circ\text{C}$ (see [Table 2.7.8](#)). Since \bar{C}_p is defined over the range T_0 and T_1 by

$$\bar{C}_p = \frac{1}{(T_1 - T_0)} \int_{T_0}^{T_1} C_p(T) dT\quad (2.7.56)$$

we can rewrite the expression for $\Delta H_r(T_1)$ as

$$\Delta H_r(T_1) = \Delta H_r^0(T_0) + \left[\sum_P \nu_j \bar{C}_{p,j} - \sum_R \nu_i \bar{C}_{p,i} \right] (T_1 - T_0)\quad (2.7.57)$$

If mean molal heat capacity data are available with a reference temperature T_r other than $T_0 = 25^\circ\text{C}$ (see [Table 2.7.9](#) for data with $T_r = 0^\circ\text{C}$), the following equation can be used to calculate $\Delta H_r(T_1)$:

$$\Delta H_r(T_1) = \Delta H_r^0(T_0) + (T_1 - T_r)A - (T_0 - T_r)B\quad (2.7.58)$$

where

$$A, B = \sum_P \nu_j \bar{C}_{p,j} - \sum_R \nu_i \bar{C}_{p,i}$$

excepting that the mean heat capacities are evaluated between T_r and T_1 for term A and between T_r and T_0 for term B.

Effects of Pressure on ΔH_r . Consider a reaction carried out at reference temperature $T = 25^\circ\text{C}$ but at a constant pressure P_1 different from the initial standard-state pressure $P_0 = 1$ atm. The value of $\Delta H_r(P_1)$ can be found from an energy balance similar to the previous analysis:

$$\Delta H_r(P_1) = \Delta H_r^0(P_0) + \Delta H_P - \Delta H_R\quad (2.7.59)$$

The terms ΔH_P and ΔH_R now denote the enthalpy changes associated with the change of pressure from P_0 to P_1 . Thus

$$\begin{aligned}\Delta H_r(P_1) &= \Delta H_r^0(P_0) + \sum_P \int_{P_0}^{P_1} \left(\frac{\partial H_j}{\partial P} \right)_T dP \\ &\quad - \sum_R \int_{P_0}^{P_1} \left(\frac{\partial H_i}{\partial P} \right)_T dP\end{aligned}\quad (2.7.60)$$

where $\partial/\partial P$ denotes partial differentiation with respect to pressure. For solids and liquids away from the critical point, the variation in enthalpy with pressure at constant T is quite small and, therefore, $\Delta H_r(P_1) \approx \Delta H_r^0(P_0)$ is assumed. For gaseous reactants and products that follow the ideal-gas law, $H = H(T)$ only, and the effect of pressure is zero, i.e., $\Delta H_r(P_1) = \Delta H_r^0(P_0)$. In nonideal gas systems, the enthalpy changes are nonzero, but the effect is usually small up to moderate pressures.

Heating Values of Combustion Fuels. The calorific value or heating value (HV) of a fuel (usually a hydrocarbon) is the negative of its standard heat of combustion at 1 atm and 25°C , expressed in cal/g or Btu/lb. It is termed *higher heating value* (HHV) if $\text{H}_2\text{O}(\ell)$ is a combustion product and is calculated as $\text{HHV} = (-\Delta H_c^0)/M$, where M is the molecular weight of the fuel. An appropriate ΔH_c^0 value must be used in referring to the *lower heating value* (LHV)

TABLE 2.7.8 Mean Molal Heat Capacities of Gases Between 25°C and T°C (Reference pressure = 0) (cal/(g-mole) (°C)) [13]

based on H₂O (g) as a combustion product. Both are related by

$$\text{HHV} = \text{LHV} + (\nu_w \lambda_v) / M \quad (2.7.61)$$

where ν_w is the stoichiometric coefficient for water in the combustion reaction of 1 mole of fuel, and λ_v is the molal latent heat of vaporization for water at 25°C and 1 atm = 10,519 cal/g-mole = 18,934 Btu/lb-mole.

For a fuel mixture composed of combustible substances $i = 1, 2, \dots$, the heating value is calculated as $\text{HV} = \sum \omega_i (\text{HV})_i$, where ω_i is the mass fraction of the i^{th} substance having a heating value of $(\text{HV})_i$.

Adiabatic reaction temperature (T_{ad}). The concept of adiabatic or theoretical reaction temperature (T_{ad}), at which

all of the heat liberated goes to heat the reaction products, plays an important role in the design of chemical reactors, gas furnaces, and other process equipment to handle highly exothermic reactions such as combustion. T_{ad} is defined as the final temperature attained by the reaction mixture at the completion of a chemical reaction carried out under adiabatic conditions in a closed system at constant pressure. Theoretically, this is the maximum temperature achieved by the products when stoichiometric quantities of reactants are completely converted into products in an adiabatic reactor. In general, T_{ad} is a function of the initial temperature (T_i) of the reactants and their relative amounts as well as the presence of any nonreactive (inert) materials. T_{ad} is also dependent on the extent of completion of the reaction. In actual experiments, it is very unlikely that the theoretical

TABLE 2.7.9 Mean Molal Heat Capacities of Combustion Gases Between 0°C and T°C (Reference temperature = 0°C; pressure = 1 atm) [12] (\bar{C}_p in cal/(gm-mole) (°C) (To convert to J/kg mole) (°K), multiply by 4184.)

T(°C)	N ₂	O ₂	Air	H ₂	CO	CO ₂	H ₂ O
0	6.959	6.989	6.946	6.838	6.960	8.595	8.001

maximum values of T_{ad} will be realized, but the calculated results provide a basis for comparison of the thermal effects resulting from exothermic reactions. Lower feed temperatures (T_i), presence of inerts and excess reactants, and incomplete conversion tend to reduce the value of T_{ad} . The term *theoretical* or *adiabatic flame temperature* (T_{fl}) is preferred over T_{ad} in dealing with the combustion of fuels.

Calculation of T_{ad} . To calculate T_{ad} (or T_{fl} for a combustible fuel), we refer to Figure 2.7.6 and note that $Q = \Delta H = 0$ for the adiabatic reaction process. Taking 25°C (=298.2°K) and 1 atm as the reference state, the energy balance can be expressed as

$$\begin{aligned} \Delta H = 0 &= H_{\text{products}}(T_{ad}) - H_{\text{reactants}}(T_i) \\ &= -\Delta H_R + \Delta H_r^0(25^\circ\text{C}) + \Delta H_P \end{aligned} \quad (2.7.62)$$

or

$$\Delta H_P = -\Delta H_r^0 + \Delta H_R \quad (2.7.63)$$

where

$$\Delta H_R = \sum_R \int_{298}^{T_{ad}} n_i C_{p,i} dT \quad (2.7.64)$$

and

$$\Delta H_P = \sum_P \int_{298}^{T_{ad}} n_j C_{p,j} dT + \sum_P n_j \lambda_{v,j} \quad (2.7.65)$$

The second term on the right side of the expression for ΔH_P accounts for *any* phase changes that may occur between 25°C and T_{ad} for the final products; it should be deleted if not applicable. Using molal heat capacity data $C_p(T)$ for all the species present, the following equality is solved for T_{ad} .

$$\sum_P \int_{298}^{T_{ad}} n_j C_{p,j} dT = -\Delta H_r^0 - \sum_P n_j \lambda_{v,j} + \sum_R \int_{298}^{T_i} n_i C_{p,i} dT \quad (2.7.66)$$

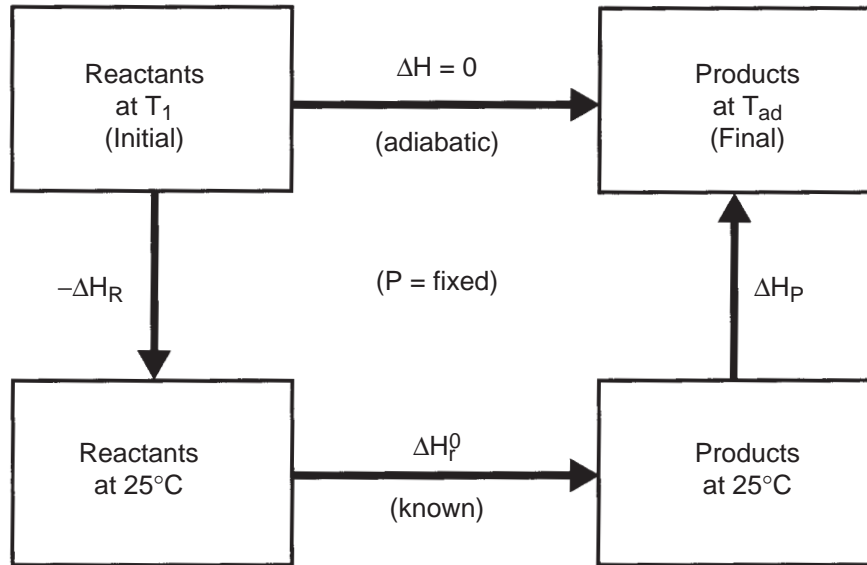

FIGURE 2.7.6 Schematic representation to calculate the adiabatic reaction temperature (T_{ad}).

An alternative representation is useful when data on mean molal heat capacities $\bar{C}_p(T)$ are available with 25°C as the reference temperature (T_0). Then the equation

$$\sum_P n_j \bar{C}_{p,j}(T_{ad} - 298) = -\Delta H_r^0 - \sum_P n_j \lambda_{v,j} + \sum_R \bar{C}_{p,i}(T_i - 298) \quad (2.7.67)$$

can be solved for T_{ad} , though it still requires a trial-and-error procedure.

Example 2.7.11

A natural gas having the volumetric composition 90% methane, 8% ethane, and 2% nitrogen at 1 atm and 25°C is used as fuel in a power plant. To ensure complete combustion 75% excess air is also supplied at 1 atm and 25°C . Calculate (i) the lower and higher heating values of the fuel at 25°C and (ii) the theoretical maximum temperature in the boiler assuming adiabatic operation and gaseous state for all products.

2.7.7.0.6 Solution

For ideal gas behavior, the volume composition is identical with the mole composition. Choose a *basis* of 1 g-mole of natural gas (at 1 atm and 25°C) which contains 0.90 g-mole of CH_4 (MW = 16.04), 0.08 g-mole of C_2H_6 (MW = 30.07), and 0.02 g-moles of N_2 (MW = 28.01). Then the molecular weight of the natural gas is

$$M = \sum y_i M_i = 0.90(16.04) + 0.08(30.07) + 0.02(28.01) = 17.40 \text{ g/g-mole}$$

- (i) The combustion reactions of interest are

where the standard heat of combustion ΔH_C^0 at 1 atm and 25°C are stated in kcal/g-mole.

With $\text{H}_2\text{O}(\ell)$ as a product, the higher heating value (HHV) of the fuel is calculated as

$$\begin{aligned} \text{HHV} &= 0.9 \left[-\Delta H_C^0(\text{CH}_4) \right] + 0.08 \left[-\Delta H_C^0(\text{C}_2\text{H}_6) \right] \\ &= 0.9(212.80) + 0.08(372.82) \\ &= 221.35 \text{ kcal/g-mole} \\ &= \frac{221.35}{17.40} = 12.72 \text{ kcal/g} \end{aligned}$$

Note that $\text{H}_2\text{O}(\ell) \rightarrow \text{H}_2\text{O}(\text{g})$ at 1 atm and 25°C has $\lambda_v = \Delta H_v^0 = 10.519$ kcal/g-mole. With $\text{H}_2\text{O}(\text{g})$ as a combustion product, the lower heating value (LHV) of the fuel is

$$\begin{aligned} \text{LHV} &= \text{HHV} - n_w \lambda_v \\ &= 221.35 - [0.9(2) + 0.08(3)](10.519) \\ &\quad \text{kcal/g-mole} \\ &= 199.89 \text{ kcal/g-mole} = 11.49 \text{ kcal/g} \end{aligned}$$

(ii) The adiabatic flame temperature T_{fl} must be calculated with all products in the gaseous state. So the appropriate standard heat of reaction at 1 atm and 25°C is the heat of combustion of the fuel with $H_2O(g)$ as a product, i.e., the negative of LHV.

$$\therefore \Delta H_r^0 = -(\text{LHV}) = -199.89 \text{ kcal/g-mole}$$

$$\begin{aligned} \text{Stoichiometric amount of } O_2 \text{ required} &= 2(0.9) + \frac{7}{2}(0.08) \\ &= 2.08 \text{ g-moles} \end{aligned}$$

Because 75% excess air is supplied, amount of O_2 supplied = $1.75(2.08) = 3.64$ g-moles.

Assuming dry air to contain 79 mole% N_2 and 21 mole% O_2 , N_2 supplied = $(3.64)(0.79)/0.21 = 13.693$ g-moles.

The mole compositions of the feed gases entering (reactants i) at 25°C and of the products leaving the boiler at T_{fl} are tabulated:

Feed at 25°C			
Gas i	n_i (g-moles)		
CH ₄	0.90		
C ₂ H ₆	0.08		
N ₂	0.02	}	13.713
N ₂ in air	13.693		
Stoich. O ₂	2.08	}	3.64
Excess O ₂	1.56		
Total	18.333		
Products at T_{fl}			
Gas j	n_j (g-moles)		
CO ₂	$0.9(1) + 0.08(2) =$	1.06	
H ₂ O	$0.9(2) + 0.08(3) =$	2.04	
N ₂		13.373	
O ₂		1.56	
Total		18.373	

Applying the heat balance equation, $\Delta H = 0 = \Delta H_r^0 - \Delta H_R + \Delta H_P$, we realize that $\Delta H_R = 0$ because the feed gases are supplied at the reference temperature of 25°C = 298°K.

$$\therefore \Delta H_P = \sum_P \int_{298}^{T_{fl}} n_j C_{p,j} dT = -\Delta H_r^0 = 199,890 \text{ cal} \quad (2.7.68)$$

must be solved for unknown T_{fl} .

Method 1. Use $C_p(T)$ data for product gases from Tables 2.7.8 and 2.7.9. The equation is $C_p = a + bT + cT^2$, with T in °K and C_p in cal/g-mole °K.

Gas	a	$b \times 10^2$	$c \times 10^5$	Applicable range (°K)
CO ₂ (g)	6.393	1.0100	-0.3405	273-3700
H ₂ O(g)	6.970	0.3464	-0.0483	
N ₂ (g)	6.529	0.1488	-0.02271	273-3700
O ₂ (g)	6.732	0.1505	-0.01791	273-3700

The equation for T_{fl} now becomes

$$\begin{aligned} 199,890 &= \alpha(T_{fl} - 298) + \frac{\beta}{2}(T_{fl}^2 - 298^2) \\ &+ \frac{\gamma}{3}(T_{fl}^3 - 298^3) \end{aligned} \quad (2.7.69)$$

where

$$\begin{aligned} \alpha &= \sum_P n_j a_j \\ &= 1.06(6.393) + 2.04(6.970) + 13.713(6.529) \\ &+ 1.56(6.732) \\ &= 6.777 + 14.219 + 89.532 + 10.502 = 121.029 \end{aligned} \quad (2.7.70)$$

Similar calculations yield

$$\beta = \sum_P n_j b_j = 4.053 \times 10^{-2} \quad (2.7.71)$$

and

$$\gamma = \sum_P n_j c_j = -0.799 \times 10^{-5} \quad (2.7.72)$$

A trial-and-error procedure is needed to solve the cubic equation in T_{fl} :

$$\begin{aligned} 199,890 &= 121.029(T_{fl} - 298) \\ &+ 2.027 \times 10^{-2}(T_{fl}^2 - 298^2) \\ &- 0.266 \times 10^{-5}(T_{fl}^3 - 298^3) \end{aligned}$$

As a first trial let $T_{fl} = 1,500^\circ\text{C} = 1773^\circ\text{K}$. Then

$$\begin{aligned} \text{RHS} &= 178,518 + 61,909 - 14,774 \\ &= 225,652 \text{ cal (too high)} \end{aligned}$$

Try $T_{fl} = 1,400^\circ\text{C} = 1,673^\circ\text{K}$ as a second trial value. Then

$$\begin{aligned} \text{RHS} &= 166,415 + 54,925 - 12,402 \\ &= 206,566 \text{ (high)} \end{aligned}$$

Similar calculations show that with $T_{fl} = 1345^\circ\text{C} = 1618^\circ\text{K}$, the $\text{RHS} = 159,759 + 51,257 - 11,212 = 199,804$ which is very close to $\text{LHS} = 199,890$.

$$\therefore \text{The solution is } T_{fl} \approx 1345^\circ\text{C}.$$

Method 2. Use mean heat capacity data from Table 2-45 with reference conditions of $P = 0$ and $T = 25^\circ\text{C}$ for the combustion gases. Then the equation for T_{fl} becomes

$$\begin{aligned} 199,890 &= \sum_P n_j \bar{C}_{p,j}(T_n - 25) \\ &= [1.06\bar{C}_p(\text{CO}_2) + 2.04\bar{C}_p(\text{H}_2\text{O}) \\ &\quad + 13.713\bar{C}_p(\text{N}_2) + 1.56\bar{C}_p(\text{O}_2)] \\ &\quad \times (T_n - 25) \end{aligned}$$

With a first trial value of $T_{fl} = 1400^\circ\text{C}$, we have

$$\begin{aligned} \text{RHS} &= [1.06(12.50) + 2.04(9.77) + 13.713(7.738) \\ &\quad + 1.56(8.166)](1400 - 25) \\ &= (152.031)(1375) = 209,043 \text{ cal (high)} \end{aligned}$$

For the second trial, try $T_{fl} = 1350^\circ\text{C}$. Then

$$\begin{aligned} \text{RHS} &= [1.06(12.445) + 2.04(9.715) + 13.713(7.715) \\ &\quad + 1.56(8.145)](1325) = 200,754 \text{ cal.} \end{aligned}$$

which is nearer to the LHS. Thus, using interpolated values of \bar{C}_p between the temperatures 1300°C and 1400°C , we find good agreement between $\text{RHS} = 199,927$ and $\text{LHS} = 199,890$ at $T_{fl} = 1345^\circ\text{C}$.

Method 3. Use mean molal heat capacity data from Table 2.7.9 with reference conditions of 0°C and 1 atm. Then the equation for T_{fl} is

$$199,890 = \sum_P n_j \bar{C}_{p,j}(T_{fl} - 0) - \sum_P n_j \bar{C}_{p,j}(25 - 0)$$

or

$$\begin{aligned} \sum_P n_j \bar{C}_{p,j} T_{fl} &= 199,890 + [1.06(8.716) + 2.04(8.012) \\ &\quad + 13.713(6.960) + 1.56(7.002)](25) \\ &= 199,890 + 3,299 = 203,189 \text{ cal} \end{aligned}$$

which can be written as

$$\begin{aligned} 203,189 &= [1.06\bar{C}_p(\text{CO}_2) + 2.04\bar{C}_p(\text{H}_2\text{O}) \\ &\quad + 13.713\bar{C}_p(\text{N}_2) + 1.56\bar{C}_p(\text{O}_2)]T_{fl} \end{aligned}$$

Assume a trial value of $T_{fl} = 1400^\circ\text{C}$ for which

$$\begin{aligned} \text{RHS} &= [1.06(12.44) + 2.04(9.74) + 13.713(7.718) \\ &\quad + 1.56(8.146)](1400) \\ &= 212,240 \text{ (high)} \end{aligned}$$

The results obtained with other trial values are shown below:

$$\text{2nd trial: } T_{fl} = 1350^\circ\text{C} \quad \text{RHS} = 203,855$$

$$\text{3rd trial: } T_{fl} = 1345^\circ\text{C} \quad \text{RHS} = 203,034$$

Because the last trial gives a close agreement with the LHS value of 203,189 cal, we take the solution to be $T_{fl} \approx 1,345^\circ\text{C}$. It is concluded that all of the three methods of calculations provide the same final answer.

For further information on this subject, refer to References 1–2.

2.8 ENGINEERING DESIGN

2.8.1 Introduction

2.8.1.1 *The Petroleum Engineer*

Petroleum engineers are traditionally involved in activities known in the oil industry as the “front end” of the petroleum fuel cycle (petroleum is either liquid or gaseous hydrocarbons derived from natural deposits—reservoirs—in the earth). These front end activities are namely exploration (locating and proving out the new geological provinces with petroleum reservoirs that may be exploited in the future), and development (the systematic drilling, well completion, and production of economically producible reservoirs). Once the raw petroleum fluids (e.g., crude oil and natural gas) have been produced from the earth, the “back end” of the fuel cycle takes the produced raw petroleum fluids and refines these fluids into useful products.

Because of the complex interdisciplinary nature of the engineering activities of exploration and development, the petroleum engineer must be conversant with fundamentals of designing devices and systems particular to the petroleum industry [1, 2]. The petroleum engineer must be competent in skills related to engineering design. Design involves planning, development, assembly and implementation of plans to achieve a prescribed and specified result.

2.8.1.2 *Multidisciplinary Team*

The exploration activities directed at locating new petroleum-producing provinces are cost-intensive operations. The capital expended in the search for new petroleum-producing provinces is always at risk because there are no guarantee that such searches will be economically successful. There is no way to actually “know” if crude oil or natural gas is present in a particular geologic formation except to drill into the formation and physically test it. Highly sophisticated geologic and geophysical methods can be used to identify the possible subsurface geological conditions that might contain crude oil and/or natural gas. However, the final test is to drill a well to the rock formation (reservoir) in question and physically ascertain whether it contains petroleum, and if it does, ascertain if the petroleum can be produced economically. Thus, in the early part of the

exploration phase geologists, geochemists, geophysicists and petroleum engineers must form teams in order to carry out effective investigations of possible petroleum producing prospects [2]. In general, such teams are initially driven by the geologic, geochemical and geophysical sciences that are to be used to infer possible subsurface locations for new deposits of petroleum. However, once the subsurface locations have been identified, the process of discovery becomes driven by the necessity to drill and complete a test well to the prospective reservoir. The skills of the exploration geologist are important for successful drilling. These exploration (wildcat) wells are usually drilled in remote locations where little or no previous subsurface engineering experience is available, thus, they are inherently risky operations.

Development of new proven petroleum resources are also cost-intensive operations, but generally lack the high risk of nearly total capital loss that exists in exploration activities. Development operations begin after the exploration test wells have proven that crude oil and/or natural gas can be economically recovered from a new reservoir. These operations require that numerous development (or production) wells be drilled and completed into proven resources. Production equipment are placed in these wells and the crude oil and/or natural gas is recovered and transported to refineries (in the back of the fuel cycle). The placement of these wells and the selection of their respective production rates within a particular reservoir or field must be planned carefully. The pattern of well locations and production rates should be designed so that the largest fraction of the in-place petroleum can eventually be recovered even though the maximum recoverable fraction of the oil or natural gas in place will not reach 100 percent. As developmental wells are drilled and completed, the production geologists ensure that wells are drilled to correct subsurface targets.

The development effort is largely a engineering activity requiring a great deal of planning. This planning requires increased interaction of multiple engineering disciplines to assure that the wells are drilled, completed and produced in a safe, efficient and economical manner.

2.8.1.3 *Engineering Arts and Sciences*

There are three basic engineering fields of knowledge. These are called the engineering arts and sciences. They are the mechanical arts and sciences, the chemical arts and science, and the electrical arts and sciences. Every specific engineering discipline, such as petroleum engineering, utilizes one of the basic engineering fields of knowledge as their scholarly foundation.

The mechanical arts and sciences are based on classical physics (or Newtonian mechanics). The chemical arts and sciences are based on classical and modern chemistry. The

electrical arts and sciences are based on modern particle physics. Table 2.8.1 gives a listing of the engineering disciplines that usually have the mechanical arts and sciences as their foundation. Table 2.8.2 gives a listing of the engineering disciplines that usually have the chemical arts and sciences as their foundation. And Table 2.8.3 gives a listing of the engineering disciplines that usually have the electrical arts and sciences as their foundation.

Note that a few disciplines such as petroleum engineering, environmental engineering and nuclear engineering are listed under two of these general engineering fields. At one engineering university, for example, the petroleum engineering curriculum may have a mechanical arts and sciences foundation. At another university, the petroleum

engineering curriculum could have a chemical arts and sciences foundation. However, most petroleum engineering curricula are based on the mechanical arts and sciences. Petroleum engineering curricula that are based on the mechanical arts and sciences usually have a balanced emphasis regarding drilling and completions, production and reservoir engineering subjects. Curricula that are based on the chemical arts and sciences generally concentrate on reservoir engineering subjects.

Similar situations occur with curricula in environmental engineering and in nuclear engineering.

2.8.2 Scientific and Engineering Philosophies

2.8.2.1 Scientific Method

The foundation philosophies of science and engineering are quite different. In the historical sense, it is obvious that scientific inquiry came first. In order for humans to “engineer,” they had to be able to predict certain potentially useful physical phenomena. Thus, the scientific method evolved to aid humans in systematically discovering and understanding natural phenomena. The scientific method is a set of prescribed steps that are used to assist in understanding hitherto unknown natural phenomena. Table 2.8.4 gives a listing of the basic steps of the scientific method. The scientific method is an iterative procedure and in modern settings requires the development of a carefully devised plan of work. Such a plan requires both experimentation and analysis. It is necessary for the scientist to keep careful records in order to assure that little will be missed and that other investigators will be able to carry out any follow-on work. It is important to understand that the act of seeking pure knowledge in mutually exclusive of any desire to apply the gained knowledge to anything useful. In essence, the scientist seeks a unique and comprehensive understanding (or solution) of phenomena.

• Iterate the above steps and continue to refine theory

2.8.2.2 Engineering Method

The scientific method has been successfully used throughout human history to enlighten us to our natural world and beyond. Since the earliest days there have been individuals who desired to use scientific knowledge for practical use within their respective societies. The modern engineer would have little trouble recognizing these individuals as our forerunners.

Modern engineering has its formal roots in France where, in 1675, Louis XIV established a school for a corps of military engineers. Shortly afterward, early in the reign of Louis XV, a similar school was created for civilian engineers [2]. These original engineering schools were created to provide trained individuals who could improve the well-being of French society by creating an economical infrastructure of water, sewer and transportation systems. By the time modern engineering was established in the United States, the idea of the dependence of engineering practice on scientific knowledge was well established. This is illustrated by the original charter of the Institution of Civil Engineers in 1828 (the first professional engineering society in the United States, now known as the American Society of Civil Engineers) by the following statement. . .

“...the art of directing the great sources of power in Nature for the use and convenience of man. . .”

In recent years there has been a greater appreciation of the word “use.” As society and engineers have become more aware of the systems or process aspects of nature, it has become clear that the use of natural resources must stop short of abuse.

In early engineering practice, products (devices or systems) evolved slowly with step-by-step improvements made after studying the results of actual usage. In those early days, engineering judgments were made by intuition (i.e., parts are strong enough, etc.), and engineering design was the same as engineering drawing. As society’s needs for new products expanded and as each product became more complicated, it also became necessary to develop an engineering methodology that would assure economic and systematic development of products. In time, the engineering community developed the engineering method. Table 2.8.5 lists the basic steps of the engineering method.

The unique characteristics of the engineering method are:

1. The engineering method is initiated by the desire to create a product that will meet the needs of society, and
2. The created product will be economically affordable and “safe” for use by society.

However, like the scientific method, the engineering method is an interactive process and embedded in the

TABLE 2.8.5 Engineering Method

- A problem is recognized or a need is identified.
- Establish performance specifications (based on the details of the need stated above)
- Describe the preliminary characteristics of the life-cycle that the product design** should have (i.e., relative to production, distribution, consumption and retirement)
- Create first prototype design
- Evaluate feasibility of first prototype design from both the technical and economic point-of-view and modify first prototype design appropriately
- Evaluate performance characteristics of first prototype using models (usually both analytic and physical) and using the results, modify first prototype design appropriately
- Fabricate first prototype
- Test first prototype
- Iterate the above process until society is satisfied and accepts the product
- Plan for the maintenance and retirement of the product through its life-cycle

***The product in petroleum engineering may be as large and as inclusive as an entire oil field or it may be as small as a component of a machine or a process used in production.*

engineering method is the systematic use of the scientific method itself to predict behavior of a prototype device or process. This means both methods require the use of trial and error. The interdependency of trial and error was explained by someone who said. One cannot have trial and error without error.

Since the desire of society³ to improve its condition will likely always exceed its complete scientific and economic knowledge to do so, the engineer must learn to deal with ambiguity—physical as well as societal. Ambiguities in engineering will always result in several useful engineering solutions (or alternative solutions) that can meet a perceived need. Thus, the engineering method, by its very nature, will yield alternative solutions. Society is then required to select one or more of those solutions to meet its need. However, society may decline all of the alternative solutions if the long term results of applying these solutions are unknown or if they have known detrimental outcomes. This was the situation in the United States and in other

3. “Society” is used in a generic sense here. Depending on context, society may mean society at large. It may mean a local community, corporation, operating division of a company or corporation, or it may mean the immediate association of employees or personnel.

countries regarding the commercial application of nuclear energy.

2.8.3 The “Art” of Engineering Design

Engineering design is a creative act in much the same way that the creation of fine art is a creative act. This is why the three general fields of knowledge are described as “arts and sciences.” This description acknowledges that engineering activity is a combination of creative “art” and knowledge in science. The act of design is directed at the creation of a product (for society’s use) which can be, in broad terms, either a device or a system.

Probably the most difficult part of engineering design is the “definition of the problem.” This part of engineering design is described by the first three steps of Table 2.8.5 (i.e., the engineering method). To define a problem for which the engineer may design several alternative solutions requires extensive study of society’s need and the analysis of applicable technologies that may be brought to bear. The most important aspect of engineering design is the assessment of whether society will accept or reject the engineer’s proposed designs. Modern engineering practice is littered with engineered “solutions” to the wrong problem. Such situations emphasize the need for engineers to assure the correct problem is being solved.

2.8.3.1 Device Design

A device is a product having all major parts are essentially made by a single manufacture. Thus, the device design and its manufacturing operation are under the complete control of the designer. This definition does not dictate a particular product size or complexity, but does infer that such a product will have limited size and complexity.

The creation of these device designs is somewhat abstract with regards to providing products for the “needs of society.” The device designs are in support of an industry which is vital to society’s operation. Thus, the designer of a device for the petroleum industry designs, in a sense, for society’s needs. In the petroleum industry, suppliers of hardware and services for operating companies function more in the area of designing devices than in the design and supply of systems (or processes) that produce natural petroleum resources.

2.8.3.2 System Design

A system design is a product that is made up of a combination of devices and components. As described above the devices within a system are under the control of the designer and are designed specifically for the system. Components, on the other hand, are other devices and/or subsystems which are not made to the specification of the system designer. Usually these components are manufactured for a

number of applications in various systems. Thus, the system design and the fabrication of the system are under the control of the system designer. The definition of a system infer complexity in design and operation.

In the petroleum industry, the term system and process are often considered synonymous. This is basically because engineering designers in the industry create “systems” that will carry out needed operational “processes” (e.g., water-flood project).

2.8.3.3 Role of Models

Once the problem has been defined and the decision has been made to proceed with a design effort (device or system), the conceptual designs and/or parts of the device or system are modeled, both mathematically and physically. Engineers design by creating models that they can visualize, think about, and rearrange until they believe they have an adequate design concept for practical application. Therefore, modeling is fundamental to successful engineering design efforts and is used to predict the operating characteristics of a particular design concept in many operational situations.

Mathematical Models. In modern engineering practice it is usually possible to develop mathematical models that will allow engineers to understand the operational characteristics of a design concept without actually fabricating or testing the device or system itself. Thus, analysis (using mathematical models) usually allows for great economic savings during the development of a device or system. To carry out such analyses, it is necessary to separate a particular design concept into parts — each of which being tractable to mathematical modeling. Each of these parts can be analyzed to obtain needed data regarding the operating characteristics of a design concept. Although repetitive analyses of models are exceedingly powerful design tools, there is always the risk that some important physical aspect of a design will be overlooked by the designer. This could be a hitherto unknown phenomenon, or an ignored phenomenon, or simply an interaction of physical phenomenon that the separate analysis models can not adequately treat.

Physical Models. At some point in the design process it is usually necessary to create physical models. Often these physical models are of separate parts of the design concept that have defined adequate mathematical modeling. But most often physical models are created to assist in understanding groups or parts of a design concept that are known to have important interactions. As in mathematical modeling, physical modeling usually requires that the design concept be separated into parts that are easily modeled. Physical modeling (like mathematical modeling) allows the engineer to carry out economic small scale experiments that give insight into the operational characteristics of the design concept. Physical modeling must be

carried out in accordance to certain established rules. These rules are based on principals given in the technique known as dimensional analysis (also known as Lord Rayleigh's method) or in a related technique known as the Buckingham Π theorem [4–6].

Dimensional Analysis. In the design of rather simple devices or systems, dimensional analysis can be used in conjunction with physical model experimental investigations to gain insight into the performance of a particular design concept. It is usually possible to define the performance of a simple device or system with a certain number of well chosen geometric and performance related variables that describe the device or system. Once these variables have been selected, dimensional analysis can be used to:

1. Reduce the number of variables by combining the variables into a few dimensionless terms. These dimensionless terms can be used to assist in the design of a physical model that, in turn, can be used for experimentation (on an economic scale) that will yield insight into the prototype device or system.
2. Develop descriptive governing relationships (in equation or graphical form) utilizing the dimensionless terms (with the variables) and the model experimental results that describe the performance of the physical model.
3. Develop device or system designs utilizing the descriptive governing relationships between the dimensionless terms (and subsequently between the variables) that are similar to those of the tested physical model, but are the dimensional scale of the desired device or system.

Dimensional analysis techniques are especially useful for manufacturers that make families of products that vary in size and performance specifications. Often it is not economic to make full-scale prototypes of a final product (e.g., dams, bridges, communication antennas, etc.). Thus, the solution to many of these design problems is to create small scale physical models that can be tested in similar operational environments. The dimensional analysis terms combined with results of physical modeling form the basis for interpreting data and development of full-scale prototype devices or systems. Use of dimensional analysis in fluid mechanics is given in the following example.

Example 2.8.1

To describe laminar flow of a fluid, the unit shear stress τ is some function of the dynamic viscosity μ (lb/ft²), and the velocity difference dV (ft/s) between adjacent laminae that are separated by the distance dy (ft). Develop a relationship for τ in terms of the variables μ , dV and dy .

The functional relationship between τ and μ , dV and dy can be written as

$$\tau = K(\mu^a dV^b dy^c)$$

Using Table 2.8.6, the dimensional form of the above is

$$(FL^{-2}) = K(FL^{-2}T)^a(LT^{-1})^b(L)^c$$

The equations for determining the dimensional exponents a , b and c are

$$\begin{aligned} \text{Force } F : \quad 1 &= a + 0 + 0 \\ \text{Length } L : \quad -2 &= -2a + b + c \\ \text{Time } T : \quad 0 &= a - b + c \end{aligned}$$

Solving the above equations for a , b and c yields

$$\begin{aligned} a &= 1 \\ b &= 1 \\ c &= 1 \end{aligned}$$

Thus, inserting the exponent values gives

$$\tau = K(\mu^1 dV^1 dy^{-1})$$

which can be written as

$$\tau = K[\mu(dV/dy)]$$

where the constant K can be determined experimentally for the particular design application.

Buckingham Π . The Buckingham Π theorem is somewhat more sophisticated than the dimensional analysis technique. Although directly related to the dimensional analysis technique, Buckingham Π is usually used in design situations where there is less understanding of exactly which performance characteristics are ultimately important for prototype design. The Buckingham Π theorem is generally more applicable to the design of complex devices or systems. In particular, Buckingham Π is usually used when the number of dimensionless terms needed to describe a device or system exceeds four. The fundamental theorem is . . .

“if an equation is dimensionally homogeneous (and contains all the essential geometry and performance variables) it can be reduced to a relationship among a complete set of dimensionless terms of the variables.”

Applications of the Buckingham Π theorem results in the formulation of dimensionless terms called Π ratios. These Π ratios have no relation to the number 3.1416.

Example 2.8.2

Consider the rather complicated phenomenon of the helical buckling of drill pipe or production tubing inside a casing. This is a highly complicated situation that must be considered in many petroleum engineering drilling and production operations. In general, this involves the torsional post-buckling behavior of a thin walled elastic pipe. The mathematical model for this situation is very complicated

TABLE 2.8.6 Dimensions and Units of Common Variables

Symbol	Variable	Dimensions		Units	
		MLT	FLT	USCU*	SI

*United States customary units.

and dependable closed-form solutions of this problem do not exist. But still the designer must obtain some insight into this phenomena before an engineering design can be completed. The problem can be approached by utilizing the principals of physical modeling based on the Buckingham Π theorem. What is sought is a set of dimensional relationships (the Π ratios) that are made up of the important variables of the problem. These Π ratios may then be used to created a small-scale experiment that will yield data that can be used to assist in the design the prototype (or full-scale pipe system). The important variables in this problem are EI (lb-in² or lb-ft²) the flexural rigidity of the thin-walled elastic pipe (which is directly related to the torsional rigidity GJ through known material constants), the length of the pipe L(ft), the shortening of the pipe δ (ft) (as it helically twists in the casing), the annular distance between the outside of the pipe and the inside of the casing $(d_2 - d_1)$ (ft) (where d_1 is the outside diameter of the pipe and d_2 is the inside diameter of the casing), the applied torque to the pipe T(ft-lbs), and the applied tension in the pipe P(lbs).

Using Table 2.8.6 the variables are EI(FL²), L(L), d(L), $(d_2 - d_1)$ (L), T(FL), and P(F). Note that this I is moment-area which is in the units of ft⁴ (not to be confused with I given in Table 2.8.6 which is moment of inertia, see Chapter 2, Strength of Materials, for clarification). The number of Π ratios that will describe the problem is equal to the number of variables (6) minus the number of fundamental dimensions (F and L, or 2). Thus, there will be four Π ratios (i.e., $6 - 2 = 4$), Π_1 , Π_2 , Π_3 , and Π_4 . The selection of the combination of variables to be included in each n ratio must be carefully done in order not to create a complicated system of ratios. This is done by recognizing which variables will have the fundamental dimensions needed to cancel with the fundamental dimensions in the other included variables to have a truly dimensionless ratio. With this in mind, Π_1 is

$$\prod_1 = EI^a T^b L^c$$

and Π_2 is

$$\prod_2 = T^d P^e L^f$$

and Π_3 is

$$\prod_3 = L^g (d_2 - d_1)^h$$

and Π_4 is

$$\prod_4 = (d_2 - d_1)^i \delta^j$$

In dimensional form Π_1 and each variable of Π_1 becomes

$$(F^0 L^0) = (FL^2)^a (FL)^b (L)^c$$

and for Π_2

$$(F^0 L^0) = (FL)^d (F)^e (L)^f$$

and for Π_3

$$(F^0 L^0) = (L)^g (L)^h$$

and for Π_4

$$(F^0 L^0) = (L)^i (L)^j$$

For Π_1 the equations for a, b and c are

$$\text{Force F: } 0 = a + b$$

$$\text{Length L: } 0 = 2a + b + c$$

This yields $b = -a$ and $c = a$, which is

$$\prod_1 = EI^a T^{-1} L^a$$

or

$$\prod_1 = [EI/TL]^a$$

and since Π_1 is a dimensionless ratio, then the actual value of a is not important. Therefore, the above becomes simply

$$\prod_1 = EI/TL$$

Similarly it is found that

$$\prod_2 = T/PL$$

$$\prod_3 = L/(d_2 - d_1)$$

and

$$\prod_4 = (d_2 - d_1)/\delta$$

These Π ratios allow the following relationships to be made between the performance characteristics found for a small-scale experimental model and a full-scale prototype:

$$\left[\prod_1 \right]_m = \left[\prod_1 \right]_p$$

$$\left[\prod_2 \right]_m = \left[\prod_2 \right]_p$$

$$\left[\prod_3 \right]_m = \left[\prod_3 \right]_p$$

and

$$\left[\Pi_4 \right]_m = \left[\Pi_4 \right]_p$$

The Π ratios can be used as the basis for a small-scale experiment to obtain data that might allow an investigator to determine the number of helices N , and the shortening δ , that will occur in a full-scale tubing string under particular torsional post-buckling conditions. The small-scale experiment will yield experimental data that can be related through the Π ratios to the full-scale prototype. The use of Π ratios and experimental data in engineering design requires extensive statistical and deterministic analyses.

2.8.3.4 Analysis, Synthesis and the Creative Art of Design

Evolution was an early engineering design methodology. This methodology (basically trial and error) is a primitive form of physical modeling. Prior to the development of more sophisticated engineering design methodologies, the only method to develop a useful device or system was to fabricate a conceptual design and put it into operation. If the design failed to meet the desired specifications, then the failure was analyzed and the appropriate changes made to the design and another product fabricated and placed into operation. However, design by evolution was not very economical and as engineering design methodologies were developed that would allow for design choices to be made without resorting to costly fabrication, design engineers were driven to accept these new methodologies. Modern engineering design methodologies are based on the design engineer's ability to appropriately utilize analysis and synthesis to create the desired device or system [7–10].

Nearly all modern engineering design situations require the use of models, both mathematical and physical. Once societal needs are defined, the designer specifies the performance characteristics required for a design. Also, at this point, the designer can often sketch or otherwise define the various initial alternative design concepts. The designer then separates each alternative design concept into parts that are tractable to either mathematical or physical modeling (or both). The designer utilizes a wide variety of analysis techniques (inherit in mathematical models but also part of the assessment of test data from physical models) to attempt to predict the performance characteristics of the various proposed alternative design concepts. This usually requires repeated analysis and the development of numerous sketches and fabrication drawings for the separate parts of each proposed alternative design concept. Thus, the design of a device or system is a lengthy iterative process.

Once the designer has developed confidence in the analysis techniques pertaining to the various parts of a design concept (whether derived from mathematical models or from physical models), the designer can begin the process of synthesis. Synthesis is basically the combining of the analyses (and any other pertinent information) to allow for the design concept to be viewed as a whole. In general, it is during the process of synthesis that the creative capabilities of the individual designer are utilized the most. The designer utilizes knowledge of the performance specifications, results from modeling, economics, experience with other similar projects, aesthetics (if needed), and intuition to create many easy-to-make choices concerning the design. Thus, the synthesis process often allows the designer to proceed to the final design of a device or system with little iteration.

Creativity in engineering is the art portion of engineering. It is a unique sum of an individual design engineer's experience, practice and intuition with a flair for the aesthetic. Creativity can be found in any part of the engineering design process, but it is usually in the synthesis portion of the process that a designer's aptitude for creativity can make the difference between a mediocre design and a truly successful design. Thus, creativity is an essential part of the engineering method.

2.8.3.5 Feasibility Studies and Economics

Once an engineering design has been identified (that will meet the performance specifications) it is necessary to ask a very important question, "Can and should the device or system be made?" In general, this question can be divided into three corollary questions [7]:

1. Can the design of the anticipated alternative devices or systems be physically realized?
2. Is the production of alternative devices or systems compatible with the capabilities and goals of the producing company?
3. Can the alternative devices or systems be economically produced and economically operated?

Only if all of the above three questions are answered in the affirmative can and should the device or system be made. The gathering of information to answer these questions is called the feasibility study.

Physical realizability is often the most difficult of the above three corollary questions to answer. In general, to answer this question it is necessary to know; 1) whether the materials and components required by the engineering design are available; and 2) whether the manufacturing (and/or fabrication) techniques and skilled craftsmen needed to fabricate the product are also available. These two assessments are difficult to make because they often involve the projection of future technological developments.

Technological developments usually do not occur according to schedule.

Company compatibility requires the analysis of the engineering, manufacturing (with quality assurance), distribution, and sales capabilities of an organization to produce and realize a profit from a given engineering design or product. Often, an engineering department within a company may be capable of designing a particular device or system, but the production and sales departments are not capable of carrying out their respective tasks. Also, a new product line under consideration may be beyond the scope of the overall business goals and objectives of the company.

As in all business situations, the economics of the development of a newly designed device or system is of paramount importance. In order to fully understand the economic feasibility of a new design, the engineer must make the following economic assessments:

1. Evaluate two or more manufacturing techniques.
2. If components of a new system design are available from sources outside the company, then an evaluation must be made as to whether it is more economic to buy these components from outside or to manufacture them within.
3. Engineers will constantly seek ways of reducing manufacturing costs. As these design modifications are made, economic evaluations of changes must be made.
4. An overall economic evaluation must be made to ensure that the contemplated project for petroleum development will recover sufficient capital to pay for the total cost of development, installation and assembly effort of the company. Further, the capital return must yield a financial return consistent with the overall company risk involved. Thus, it is very important that the petroleum engineer designing a recovery system understand the company's evaluation criteria that will be used by management in judging whether a new project is to go forward. Chapter 7 (Petroleum Economics) has detailed discussions of general engineering economics and product (or project) evaluation criteria.

2.8.4 Design in the Petroleum Industry

2.8.4.1 Producing and Service Companies

The petroleum industry is a highly complex primary industry. Its function in society is to provide a reliable supply of liquid and gaseous hydrocarbon fuels and lubricants (and well as other related products) for both industrial and private customers. The industry is composed of two basic business elements 1) producing companies (often called operating companies 2) service companies.

Producing companies locate the subsurface petroleum resources; recover the oil, gas or condensate; and then market the recovered resource to customers. These activities involves planning and carrying out exploration, drilling and well completion, and the production activities.

The service companies provide a supporting role to the producing companies. They supply the products and services that allow the producing companies to explore, drill and complete wells, and produce the petroleum from the earth. Once the petroleum has been brought to the surface, the service companies also assist in providing safe transportation of the petroleum to refining facilities. There is a great variety of service companies. Many service companies are dedicated only to supporting the producing companies (e.g., geophysical surveying) while other service companies supply products and services to a number of primary industries.

2.8.4.2 Service Company Product Design

In general, engineering design of devices or systems takes place throughout the petroleum industry. However, service industries are responsible for supplying (thus, designing and manufacturing/fabricating) the vast majority of the devices and systems (and often the personnel to operate them) that are utilized by the producing companies. Therefore, the service companies do for more traditional device and system engineering design than the producing companies (e.g., geophysical survey tool design, drilling fluid design, drill bit design, cement design and placement system design, production pump design, etc.). Because of the complexity of the petroleum industry, these engineering design activities cover all three of the basic engineering fields (e.g., mechanical arts and sciences, the chemical arts and sciences, and the electrical arts and sciences).

2.8.4.3 Producing Company Project Design

The producing companies are responsible for carrying out the complex operations of exploration, drilling and completion, and production. These projects vary from the seeking oil and gas deposits at 15,000 ft of depth in the continental U.S. to seeking similar deposits at 15,000 ft below some remote ocean floor. The engineering planning and design of these complex projects is a special class of systems engineering design. Although dealing with quite different technologies, production operations have similar concerns related to overall system outcome as do large mining projects or large civil engineering projects (such as the construction of a dam or large transportation system). Thus, the engineering projects design and management aspects of systems engineering are of primary interest to the engineering staffs of the producing companies [12].

2.8.5 Engineering Ethics

2.8.5.1 The Profession of Engineering

An engineer is a professional in exactly the same context as a medical doctor, a lawyer, clergy, teacher, etc. The dictionary defines a “profession” as

“an occupation requiring advanced education.”

In this context, an advanced education means an academic education beyond secondary education. The term ‘professional’ is defined as

“connected with, or engaged in a profession.”

The professional should not be confused with the other occupations that make up the economic doers in modern society, namely craftsmen, tradesmen, and laborers. The difference between these other occupations and the professional is in the definition of the profession and professional. Very few occupations *require* an advanced education to be employed in that occupation. A plumber does not have to have an advanced academic education to be in the plumbing business. But the plumber does have to have certain manual skills in order to be successful in that occupation. Thus, the plumber is a craftsman. A banker does not have to have an advanced education to be in the banking business. Also, the banker does not have to have any particular manual skills to be a banker. Thus, the banker is considered to be a tradesman. It should be noted that the definition of the term “professional” does not depend upon whether the engineer (or medical doctor, etc.) is legally registered (with a state board) as a licensed professional engineer (or registered as a licensed medical doctor, etc.) [13].

There are certain unwritten accepted societal ideals that also separate professionals from the other occupations. The most important of these is that professionals, in carrying out the duties of their respective professions, usually are doing work that can affect society. This is particularly true of the engineering profession. The engineering profession designs many devices and systems that if not designed correctly and fail can have catastrophic effects on society as a whole. For example, when a civil engineer does not correctly design a community water supply and sewer system and the community becomes sick from contaminated drinking water, then society as a whole suffers from the civil engineer’s incompetence. Likewise, when a petroleum engineer does not correctly design the reserve pits at the drilling location and drilling mud contaminated with crude oil is washed into a nearby stream, society as a whole suffers from the petroleum engineer’s incompetence. Also, when a petroleum engineer plans and operates a drilling location that is quite near a high voltage power line and fails to get the local power company to either provide a by-pass line or rubber boot the line, and subsequently a crane operator on location is electrocuted, society as a whole suffers from the

petroleum engineer’s incompetence. In this case, “society” is represented by the craftsmen and laborers working at the location [14, 15].

2.8.5.2 NSPE Code of Ethics

All professional groups in society have a code of ethics to guide their respective members as they carry out their professional duties for society. There is a general code of ethics of the National Society of Professional Engineers (NSPE) which basically covers all registered professional engineers regardless of specific discipline. The preamble and fundamental canons of the NSPE Code of Ethics is given below [16].

Preamble. Engineering is an important and learned profession. As members of this profession, engineers are expected to exhibit the highest standards of honesty and integrity. Engineering has a direct and vital impact on the quality of life for all people. Accordingly, the services provided by engineers require honesty, impartiality, fairness, and equity, and engineers must be dedicated to the protection of the public health, safety, and welfare. Engineers must perform under a standard of professional behavior that requires adherence to the highest principles of ethical conduct.

Fundamental canons. Engineers, in the fulfillment of their professional duties, shall

1. Hold paramount the safety, health and welfare of the public.
2. Perform services only in areas of their competence.
3. Issue public statements only in an objective and truthful manner.
4. Act for each employer or client as faithful agents or trustees.
5. Avoid deceptive acts.
6. Conduct themselves honorably, responsibly, ethically, and lawfully so as to enhance the honor, reputation, and usefulness of the profession.

2.8.5.3 SPE Code of Ethics

Each specific engineering discipline has developed its own code of ethics. These discipline specific codes of ethics generally reflect the working situations that are relevant that discipline. This can be seen in the Society of Petroleum Engineers (SPE), Guide for Professional Conduct. Because the devices and systems that petroleum engineers design are usually in operational locations that are remote from most of general public, the issue concerning the “safety, health and welfare of the public” is not as immediate to the petroleum engineer as it is to other disciplines (e.g., civil engineers). Thus, the “safety, health and welfare of the public” is found further down in this list of canons than in the NSPE Code of Ethics. The preamble, the fundamental principle, and

the canons of professional conduct of the SPE Guide for Professional Conduct is given below [17].

Preamble. Engineers recognize that the practice of engineering has a direct and vital influence on the quality of life of all people. Therefore, engineers should exhibit high standards of competency, honesty, and impartiality; be fair and equitable; and accept a personal responsibility for adherence to applicable laws, the protection of the public health, and maintenance of safety in their professional actions and behavior. These principles govern professional conduct in serving the interests of the public, clients, employers, colleagues, and the profession.

The Fundamental Principle. The engineer as a professional is dedicated to improving competence, service, fairness, and the exercise of well-founded judgment in the practice of engineering for the public, employers, and clients with fundamental concern for the public health and safety in the pursuit of this practice.

Canons of Professional Conduct.

1. Engineers offer services in the areas of their competence affording full disclosure of their qualifications.
2. Engineers consider the consequences of their work and societal issues pertinent to it and seek to extend public understanding of those relationships.
3. Engineers are honest, truthful, and fair in presenting information and in making public statements reflecting on professional matters and their professional role.
4. Engineers engage in professional relationships without bias because of race, religion, sex, age, national origin, or handicap.
5. Engineers act in professional matters for each employer or client as faithful agents or trustees disclosing nothing of a proprietary nature concerning the business affairs or technical processes of any present or former client or employer without specific consent.
6. Engineers disclose to affected parties known or potential conflicts of interest or other circumstances which might influence or appear to influence judgment or impair the fairness or quality of their performance.
7. Engineers are responsible for enhancing their professional competence throughout their careers and for encouraging similar actions by their colleagues.
8. Engineers accept responsibility for their actions; seek and acknowledge criticism of their work; offer honest criticism of the work of others; properly credit the contributions of others; and do not accept credit for work not theirs.
9. Engineers, perceiving a consequence of their professional duties to adversely affect the present or future public health and safety, shall formally advise their employers of clients and, if warranted, consider further disclosure.
10. Engineers act in accordance with all applicable laws and the canons of ethics as applicable to the practice of engineering as stated in the laws and regulations governing the practice of engineering in their country, territory, or state, and lend support to others who strive to do likewise.

2.8.6 Intellectual Property

Since one of the main focuses of the engineer is to provide technological solutions for the needs of society, then creative invention is a major part of the engineer's design activity. Therefore, the engineer must be familiar with the current laws (and any imminent future changes in the laws) for the protections of intellectual property. Intellectual property is composed of four separate legal entities. These are trade secrets, patents, trademarks, and copyrights.

2.8.6.1 Trade Secrets

Trade secrets are creative works (usually methods, processes, or designs) that are not covered by the strict definition of "an invention" required for a legal patent, or they are actual inventions that a company or individual does not want to expose to public scrutiny through the patent process (since the published patent must contain a written description of the invention).

Companies and individuals have the legal right to protect and maintain trade secrets. The key point, however, is that trade secrets must be something that can be kept secret. Anyone who discovers a trade secret via his or her own efforts may use it. The only legal protection for trade secrets is against persons who obtain these secrets by stealing them and then using them, or after having been entrusted with these secrets as a necessary part of their job and then using them [7, 18].

The term trade secret is well understood by U.S. courts and is a legal term. In general, the U.S. courts have strongly upheld the protection of company- or individual-owned trade secrets. Cases against ex-employees or others who have obtained trade secrets by stealth are relatively easy to prosecute (compared to patent, trademark, or copyright infringement cases).

2.8.6.2 Patents

When the U.S. Constitution was framed in 1789 it contained this provision (Article 1, Section 8) [18–22]:

"The Congress shall have power to promote the progress of science and useful arts by securing for limited times to authors and inventors the exclusive right to their respective writings and discoveries."

In 1790 the formal U.S. Patent system was founded. Since that time the U.S. Patent Office has undergone numerous changes that have generally improved legal protection for intellectual property owned by individual citizens.

A U.S. Patent is a legal document granted only to the individual inventor that allows the inventor to have the exclusive right for a limited time to exclude all others from making, using or selling his or her invention in the U.S. There are restrictions to this statement. An inventor does not have an absolute right to use his or her patented invention, if doing so would also involve making, using or selling another invention patented by someone else. The time limits for the exclusive use of an invention by the inventor are fixed by law and can only be extended in special circumstances. After this time limit expires, anyone may make and sell the invention without permission of the inventor. There are three legal categories of patents; utility patents, design patents, and plant patents.

Utility Patents. Utility patents are granted to individuals only who have invented or discovered any new and useful method, process, machine, manufacture, or matter composition. These patents must be useful to society (have utility). A utility patent has a total time limit for exclusive use by the inventor of 17 years.

Design Patents. Design patents are granted to individuals who have invented new, original and ornamental designs for an article of manufacture. A design patent has a total time limit for exclusive use by the inventor of 14 years.

Plant Patents. Plant patents are granted to individuals who have invented or discovered and a sexually reproduced a new and distinct variety of plant. This includes mutants, hybrids, and newly found seedlings. A plant patent has a total time limit for exclusive use by the inventor of 17 years.

Only the actual inventor may apply for a patent (utility, design, or plant patent). Once a patent has been obtained, the patent can be sold or mortgaged. Also, the owner of a patent may assign part or all interest in the patent to another individual or a company or other business entity. The owner of a patent may also grant licenses to others (either individuals or business entities), to make, use or sell the invention.

In addition to each of the above patent's unique characteristic (i.e., utility, ornamental or original design, be a plant), an invention, in order to be granted a U.S. Patent, must demonstrate two additional characteristics: the invention must be novel, and the invention must not be obvious. The steps to pursue to obtain a patent are as follows:

1. Make sure the invention is new and practical and is not already in use. This requires a preliminary search of the industrial literature to determine if the invention is practical and is not already in use in the public domain.

2. Keep records that document when and what was invented. It is important that accurate records are kept showing your original sketches with a disclosure statement describing what and how your invention works. It is useful to have someone witness this disclosure document and verify the date that this invention took place. It is often during this step that the invention concept is either modeled (mathematical or physical or both) and tested. Thus, accurate records of these analyzes or test results should also be kept. In the U.S. it is the first to invent that will obtain a patent in the event of two individuals inventing the same thing. Keep the disclosure document secret until the patent application is submitted to the patent office.

3. Search the existing patents relating to the invention. Carry out an extensive patent search of existing patents to find patents that are related to the new invention. Make sure the new invention is novel and unobvious and is not in conflict with existing patents. A search of U.S. patents can be made in the Search Room of the U.S. Patent and Trademark Office in Crystal Plaza, 2021 Jefferson Davis Highway, Arlington Virginia. An individual inventor or a patent attorney may hire agents that will carry out thorough patent searches. In addition, every state in the U.S. has a U.S. Patent Depository Library where patent searches may be conducted by private individuals.

4. Prepare and file the patent application documents. This document is called a "specification." The specification must be clear enough so that anyone skilled in the subject matter of the invention could recreate your invention and use it. In the written portion of the specifications the inventor must state the claims of the invention. These claims must show that the invention is novel and unobvious. Also, where applicable, illustrations must accompany the specification. There are filing fees for patent applications and if the application is successful there are maintenance fees to keep the patent in force. Literature describing patent applications and how they are to be submitted can be obtained from the Commissioner of Patents and Trademarks, Washington, D. C., 20231. This is also the address to submit properly prepared patent applications.

Infringement of a patent occurs when an individual or company makes, uses, or sells an invention without the permission of the inventor, assignee, owner, or licensee. The U.S. courts will award damages and place penalties on the infringer. But patent infringement cases are very costly and time consuming.

Any inventor may apply for a patent regardless of age, sex, or citizenship. Once a U.S. Patent has been granted most other countries allow the inventor up to one year to submit a patent application for a foreign patent. The

exception is Japan which requires nearly immediate submission of a patent application to the Japanese patent office at nearly the same time the inventor is submitting to the U.S. Patent office.

It should be noted that all other countries grant patents to inventors that are the first to submit patent applications to their respective patent offices. We are the only country that grants a patent to the first to invent (not the first to the patent office). However, in 2003 the U.S. may change to the “first to the patent office” method of granting patents.

2.8.6.3 Trademarks

A trademark is any work, name, symbol, or device or any combination of these adopted and used by manufacturers or merchants to identify their goods and distinguish them from those manufactured or sold by others. A service mark is a mark used in the sale or advertising of services to identify the services of one individual or company and distinguish them from the services of others [23,24].

Unlike a patent, but like a copyright, ownership of a trademark or service mark is acquired by use. An individual or company using the mark within a state may register the mark in that state. The Secretary of State within each state has the forms for the registration of a trademark or service mark. Once a mark has been used in interstate or foreign commerce, the mark may be registered in the U.S. Patent and Trademark Office. This is accomplished by filing an application to that office (see Reference 87). Prior to receiving federal registration of the mark, the symbols TM and SM may be used (these symbols give notice that the marks have been filed with the state). After the mark has received federal registration the symbol ® should be used.

There are two classes of registration for a mark. The Principal Register is for unique and distinctive marks that when applied to products and services are not likely to cause confusion or deception. To be registered on the Principal Register a mark must be in continuous, exclusive interstate use. Marks not registrable on the Principal Register may be registered on the Supplemental Register.

The term of a federal registered trademark and service mark is 20 years. In order to secure the mark for the full 20 years, an affidavit must be filed with the Commissioner of Patents and Trademarks in the sixth year showing the mark is still in use. It is advisable to conduct a search in the U.S. Patent and Trademark Office to determine whether a mark under consideration might conflict with existing registered marks. Trademarks and service mark registrations may be assigned after registration.

Once federal certification of a mark has been issued, the mark is protected nationwide. Any infringement by an individual or company of a mark after federal registration

can be subject to damage claims by the mark owner in U.S. District Courts.

Foreign countries require registration of a mark in compliance with local laws. The local laws vary a great deal; thus, it is necessary to consult a local attorney or a U.S. attorney familiar with foreign patent and trademark law in order to register a mark in a foreign country.

Information concerning the registration of marks in the U.S. may be obtained from the Commissioner of Patents and Trademarks, Washington, D. C., 20231.

2.8.6.4 Copyrights

The copyright protects creative works such as literary works, musical works, dramatic works, pictorial, graphic, sculptural, motion pictures and other audio-visual works, and computer software. It is the latter that is of most concern to the engineer [25,26].

Registration for copyright protection may be obtained by application to the Register of Copyrights, Library of Congress, Washington, D. C., 20540. This registration must take place on or about the time of the first sale of the creative work. The forms for application are obtained from the address above (the application fee is \$10).

The notice of copyright is given by “copyright” or the abbreviation “Copr” or by the symbol ©. The notice must be accompanied by the name of the copyright owner and the year of the first publication. Like a patent, only the author of the creative work can be the copyright owner. However, an assignee may file for the copyright on behalf of the author of a creative work. In general, the term of a copyright is for the life of the author (of the creative work) plus 50 years. Any infringement by an individual or company of a registered copyright can be subject to damage claims by the creative work owner or assignee in U.S. District Courts.

Under the Universal Copyright Convention, a U.S. citizen may obtain a copyright in most countries of the world by simply publishing within the U.S. using the © symbol and the appropriate author and date of publication notices (only the © symbol is recognized worldwide).

Auxiliary Equipment

This chapter describes the various auxiliary equipment that are important to the function of oil field activities. This equipment is used in drilling, well completion, production, and related operations. The discussions that follow will concentrate on the basic operation characteristics and specifications required by a user. The aim is to give the user the information needed to ascertain whether the equipment available for a particular field operation is adequate, or if the equipment available is not adequate, how to specify what equipment will be necessary.

3.1 PRIME MOVERS

Section reviewed by T. Wayne Brewster

The prime mover is the unit that first converts an energy source into a mechanical force. Typical prime movers are internal combustion motors, gas turbines, water turbines, steam engines and electrical motors. The discussion will be limited to the prime movers that are most used in modern well drilling and production operations. These are internal combustion motors, gas turbine motors and electric motors.

3.1.1 Internal Combustion Engines

The internal combustion engines considered in this section are four-stroke engines. The combustion process in such engines are assumed to be constant volume, constant pressure, or some combination of both. Piston-type internal combustion engines are made up of a series of pistons that can move in enclosed chambers called cylinders. These engines can be designed in a variety of configurations. The most widely used configurations are the following [1]:

- An in-line type engine has all cylinders aligned and on one side of the crankshaft (Figure 3.1.1). These engines are found in sizes from 4 pistons (or cylinders) to as many as 16.
- A V-type engine has an equal number of cylinders aligned on two banks of the engine. These banks form

a V shape (see Figure 3.1.2). These engines are found in sizes from 4 cylinders to as many as 12.

- An opposed-type engine has an equal number of cylinders aligned on two banks of the engine. These banks are horizontally opposed to one another on opposite sides of the crankshaft (see Figure 3.1.3). These engines are found in sizes from 4 cylinders to as many as 8.

One of the more important specifications of an internal combustion engine is its displacement volume. The displacement volume, $V_d(\text{in}^3)$, is (per revolution)

$$V_d (\text{in}^3) = \frac{\pi}{4} d^2 l n \quad (3.1.1)$$

FIGURE 3.1.1 In-line type engine [1].

FIGURE 3.1.2 V-type engine [1].

FIGURE 3.1.3 Opposed type engine [1].

where d is the outside diameter of the piston (or bore of cylinder in in.), l is the stroke (or length of movement) of the piston within the cylinder in in., and n is the number of cylinders.

The nominal compression ratio (which is usually specified) is the displacement volume plus the clearance volume divided by the clearance volume. Because of the mechanics of intake valve closing, the actual compression ratio r_a is less than the nominal. Thus, the compression pressure p (psia) may be estimated by

$$p = r_a \cdot p_m \quad (3.1.2)$$

where p_m is the intake manifold pressure in psia.

There are two basic combustion cycles. These are

1. Spark-ignition, or otto cycle, engine which is fueled by a gas and air mixture.
2. Compression-ignition, or diesel cycle engine, which is fueled by a diesel oil and air mixture.

There can also be a combination of the two cycles in an engine. Such an engine is called a mixed, combination, or limited pressure cycle.

The spark-ignition cycle engine uses volatile liquids or gases as fuel. Such engines have compression ratios from 6:1 to 12:1. liquid gasoline is the most common fuel for this cycle, especially for automobile, truck, and airplane engines. Large stationery engines usually use commercial gases such as natural gas, produces gas, or coal gas. All engines operating on this cycle use carburetors, gas-mixing valves, or fuel injection systems to mix the volatile fuel with the appropriate volume of air for subsequent combustion. This mixing can be carried out prior to the mixture being placed in the cylinder of the engine, or mixed directly in the cylinder.

The compression-ignition cycle engine uses low volatile fuel. These are typically fuel oils. The compression ratios for these engine are from 11.5:1 to 22:1. These engines are used to power large trucks and buses. They are also used for large engines. The compression-ignition cycle engine usually is equipped with a fuel injection system which allows the fuel to be mixed with air directly in the cylinders of the engine.

The internal combustion four-stroke engine, which is the predominant engine in oilfield applications, requires four piston strokes (or two crankshaft revolutions) for each cycle. In a downward stroke, the intake valve is opened and the combustible mixture is brought into the cylinder. In an upward stroke the fuel-air mixture is compressed and ignited near the top of the stroke. This forces the piston downward (to provide power). In the next upward stroke the exhaust valve is opened and the spent gases are forced from the cylinder. In the following downward stroke, the cycle is repeated with the opening of the intake valve.

The standards for internal combustion engines have been established by the American Petroleum Institute (API), the Diesel Engine Manufacturers Association (DEMA), and the Internal Combustion Engine Institute (ICEI). In addition, some of the engine manufacturers have their own rating procedures. It is important to know which standards have been applied for the rating of an engine. A consistent set of standards should be used by the engineer when comparing the ratings of various engines for the purpose of selecting the appropriate design for field applications.

The API standards describe the method used in rating engines and the recommended practice for engine installation, maintenance, and operation [2, 3]. In oil field operations the API rating standards are most frequently used.

The important definitions are

1. *Bare engine.* A bare engine shall be an engine less all accessories except those (built in or attached) absolutely required for running. All accessories normally required for operation of the engine, such as ignition, water pump, air cleaner, oil pump, governor, etc., shall be included.
2. *Power unit.* A power unit shall consist of a bare engine, plus other equipment such as a fan for air cooling, special water pumps, and so forth. When included, specific information must be given as to design factors such as ambient temperature and power consumption.
3. *Maximum standard brake horsepower.* At any rotational speed, maximum standard brake horsepower shall be the greatest horsepower, corrected to standard conditions, that can be sustained continuously under conditions as outlined under test procedure. The unit of horsepower is 33,000 ft-lb/min or 550 ft-lb/s. Standard conditions for the purpose of internal combustion engine testing and rating is 85°F(29.4°C) and 29.38 in. of mercury (99 kPa). Note these values are different from standard conditions for gas and air volume specifications.
4. *Maximum standard torque.* The maximum standard torque at any given rotational speed shall be that corresponding to the maximum standard brake horsepower at that speed.

Test engines shall be of exactly the same design and equipped with the same components and accessories as engines delivered to the purchaser [2]. The observed brake horsepower H_0 obtained during the testing of a bare engine or a power unit is converted to standard brake horsepower using

$$H_s = H_0 \frac{29.38}{P_0 - E_0} \frac{460 + t_0}{520} \quad (3.1.3)$$

where P_0 is observed barometric pressure in in. Hg, E_0 is pressure of water vapor in air (from relative humidity data) in in. Hg, t_0 is observed air temperature in °F.

When an internal combustion engine is to be used at different operating conditions (altitude) other than the standard conditions that the engine was rated at, it is necessary to derate the engine specifications. The brake horsepower H at pressure and temperature conditions other than standard can be obtained from the following:

$$H = \frac{H_s (P - E)}{29.38} \frac{520}{t + 460} \quad (3.1.4)$$

where P is the local barometric pressure in in. Hg, E is pressure of water vapor in air (from relative humidity data) in in. Hg, t is the local air temperature in °F.

At any given set of ambient conditions, the horsepower H is related to the torque the engine produces at a given speed from the following:

$$H = \frac{TN}{5,252} \quad (3.1.5)$$

where T is the torque in ft-lb, N is the speed in rpms.

For the various transmission speed ratios, and the engine speed, the maximum available torque may be found using the maximum brake horsepower which can be produced by the engine.

Figures 3.1.4 and 3.1.5 are examples of a typical manufacturer's report of test results.

There is a reduction in the power available from an internal combustion engine when there is a decrease in ambient air pressure, an increase in ambient temperature, or an increase in relative vapor pressure. Such changes reduce the mass of oxygen available for combustion inside the engine

FIGURE 3.1.4 Example of test data for internal-combustion bare engines [3].

FIGURE 3.1.5 Example of test data for internal combustion power units [3].

cylinder. This reduction is standard brake horsepower as a function of altitude increase and temperature increase (or decrease) can be approximated by Table 3.1.1 [4]. This table gives the approximate percentage of power reduction for naturally aspirated and turbocharger internal combustion engines.

Internal combustion engines can be operated by a number of liquid and gaseous fuels. Table 3.1.2 gives the high value heat of combustion for various field available liquid and gaseous fuels [5].

The gas-powered drilling and production internal combustion engines can be set up at the manufacturer to operate on gasoline, natural gas, or liquified petroleum gas (LPG). The manufacturer can also set up the engine to operate on all three types of gas fuels. This is accomplished by providing

engines with conversion kits that can be used to convert the engine in the field.

Power unit manufacture also produce diesel engines that can be converted to operate on a dual fuel carburation of

about 10% diesel and natural gas. Such conversions are more difficult than converting spark-ignition engines to various gas fuels.

Actual fuel consumption data are available from the bare engine or power unit manufacturer. Conversion kits and alternate fuel consumption data are also usually available. However, often the field engineer does not have the time to obtain the needed data directly from the manufacturer regarding the various power units that are to be used for a particular field operation. [Table 3.1.3](#) gives the approximate liquid fuel consumption for multicylinder engines for various fuels. [Table 3.1.4](#) gives the approximate gaseous fuel consumption for multicylinder engines for various fuels.

[Figure 3.1.6](#) shows average vacuum-load curves for several engine models with four-cycle engines of two or more cylinders constructed by six representative engine manufacturers [3]. These curves cannot be used for supercharged or turbocharger engines. Vacuum readings are obtained with a conventional vacuum gauge, containing a dial graduated in inches of mercury. The intake manifold vacuum reading is taken first with the engine running at normal speed with no load and then with the engine running at normal speed with normal load. The curve selected is the one which, at no load, most closely corresponds to the no-load intake manifold

vacuum reading. The point on the curve is then located with the ordinate corresponding to the reading taken at normal loading. The abscissa of this point gives the percentage of

TABLE 3.1.3 Approximate Liquid Fuel Consumption for Multicylinder Internal Combustion [4,5]

Fuel	100% Load (lb/hp-hr)	75% Load (lb/hp-hr)	50% Load (lb/hp-hr)
Motor Gasoline	0.62	0.67	0.76
Propane/Butane	0.5	0.56	0.64
Diesel	0.5	0.53	0.63

TABLE 3.1.4 Approximate Gaseous Fuel Consumption for Multicylinder Internal Combustion Engines [4,5]

Fuel	100% Load (SCF/hp-hr)	75% Load (SCF/hp-hr)	50% Load (SCF/hp-hr)
Natural Gas	9.3	10.0	11.1

FIGURE 3.1.6 Intake vacuum vs. load curves [3].

full load at which the engine is operating. For instance, if the no-load reading is 17 in. Hg and the normal reading is 10 in. Hg, the curve selected in Figure 3.1.4 would be the one which shows 17 in. Hg at 0% of full load. This curve would be followed down to its intersection with the horizontal line of 10 in. The abscissa of this point indicates that the engine is operating at 48% of full power.

The above method is useful in determining internal combustion engine loading conditions. Failure to duplicate former readings at no load and at normal speed indicates that the engine is in poor condition. Failure to duplicate former readings at normal load and normal speed indicates a change in either engine efficiency or load conditions.

3.1.2 Gas Turbine

Gas turbines are essentially constant speed machines and, therefore, generally not suited to be used for the mechanical driving of most equipment in the oil field. Gas turbines

are used in combination electrical generating systems and electrical motors to power drilling rigs and other auxiliary drilling and production equipment. In general, gas turbine are used where a constant power source is needed [1,5,6].

There are some rare situations where the gas turbine is used to power, through direct linkage, a mechanical unit, e.g., a hydraulic fracture pump.

The most common use of the gas turbine power system in the oil and gas industry is in combination with an electrical system (i.e., electric generators and electric motors). In 1965 such a system was used to power a rotary rig. This was a 3,000-hp rig developed by Continental-Ensco. The rig used three 1,100-hp Solar Saturn single-shaft gas turbines. These gas turbines operated at 22,300 rpm and were connected through double reduction gear transmissions to DC generators.

Gas turbines can be fueled by either gas or liquid hydrocarbons. The gas turbine is often used as a means of utilizing what would otherwise be waste hydrocarbons gases and liquids to generate local electric power via the gas turbine power unit. This is called cogeneration.

The basic concept of the gas turbine is to inject the fuel into a steady flow of compressed air (see Figure 3.1.7). The compressed air is ignited and the expanding exhaust is forced to pass through a series of stationary and rotating turbine blades. These expanding gases force the turbine shaft to rotate. This shaft power is either directly connected or connected through speed reducers to an electric generator and the compressor used to initially compress the air entering the turbine combustor.

As shown in Figure 3.1.7, a small electrical (or other type of motor) is needed to start the gas turbine. This is usually accomplished by disconnecting the generator load from the gas turbine (usually via a clutch mechanism on gear shaft in the transmission). The starter motor is actuated, which brings the gas turbine shaft up to a speed where the compressor is providing compressed air at the

FIGURE 3.1.7 Gas turbine (open-cycle) and electric generator.

pressure and weight rate of flow that can sustain the gas turbine operation. Once the gas turbine is up to its critical start speed (usually about one-fourth to one-third of operating speed), fuel is injected into the combustor and ignited. The fuel is then regulated to the desired operating speed for the system and the generator or other power take off re-engaged to the gas turbine shaft.

The gas turbine shown in Figure 3.1.7 is an open-cycle type. An open-cycle type gas turbine uses the same air that passes through the combustion process to operate the compressor. This is the type most often used for stationary power unit applications. A typical example of power requirements for an open-cycle type gas turbine would be for the unit to develop a total of 3,000 hp. However, about 2,000 hp of this would be needed to operate its compressor. This would leave 1,000 hp to operate the generator (or other systems connected to the gas turbine). Thus, such a gas turbine power unit would be rated as a 1,000-hp unit because this is the power that can be utilized to do external work.

Due to increased availability/lower costs of natural gas as well as environmental awareness, natural gas internal combustion engines have gained in popularity with respect to drilling contractor prime movers over the past decade. An important consideration when utilizing natural gas engines is to understand the relationship of transient loading effects to a natural gas combustion engine efficiency. Sudden power demands that are often seen in drilling operations due to sudden torque, drag, or hydraulic loadings can have an adverse effect on these types of engines.

3.1.3 Electric Motors

There are a number of electric motor types available. These motors are classified by the National Electrical Manufacturers Association (NEMA). These electric motor classifications are presented in the NEMA standards [7].

Figure 3.1.8 shows a graphic breakdown of the various electric motors available [8]. The outline in Figure 3.1.8 is based on an electrical classification. Besides their classification, NEMA also classified electric motors according to

- Size
 - Fractional horsepower
 - Integral horsepower
- Application
 - General purpose
 - Definite purpose (e.g., shell type)
 - Special purpose
 - Part-winding
- Mechanical protection and cooling
 - Open machine (with subclasses)
 - Totally enclosed machine (with subclasses)

- Variability of speed
 - Constant speed
 - Varying speed
 - Adjustable speed
 - Multispeed

In what follows, electric motors are described in accordance with their electric type as shown in Figure 3.1.8 [7,8].

3.1.3.1 Alternating-Current Motors

Alternating-current motors are of three general types, induction, synchronous, and series, and are defined as follows:

Induction Motors. An induction motor is an alternating-current motor in which a primary winding on one member (usually the stator) is connected to the power source and a polyphase secondary winding or a squirrel-cage secondary winding on the other member (usually the rotor) carries induced current. There are two types:

Squirrel-Cage Induction Motor. A squirrel-cage induction motor is one in which the secondary circuit consists of a squirrel-cage winding suitably disposed in slots in the secondary core.

Wound-Rotor Induction Motor. A wound-rotor induction motor is an induction motor in which the secondary circuit consists of a polyphase winding or coils whose terminals are either short circuited or closed through suitable circuits.

Synchronous Motor. A synchronous motor is a synchronous machine which transforms electrical power into mechanical power.

Series-Wound Motor. A series-wound motor is a motor in which the field circuit and armature circuit are connected in series.

Polyphase Motors. Alternating-current polyphase motors are of the squirrel-cage, wound-rotor, or synchronous types.

Design Letters. Polyphase squirrel-cage integral-horsepower induction motors may be one of the following:

Design A. A Design A motor is a squirrel-cage motor designed to withstand full-voltage starting and to develop locked-rotor torque as shown in MG 1-12.37, pull-up torque as shown in MG 1-12.39, breakdown torque as shown in MG 1-12.38 with locked-rotor current higher than the values shown in MG 1-12.34 for 60 Hz and MG 1-12.25 for 50 Hz and having a slip at rated load of less than 5%. Motors with 10 or more poles may have slip slightly greater than 5%.

Design B. A Design B motor is a squirrel-cage motor designed to withstand full-voltage starting and to develop locked-rotor, breakdown and pull-up torques adequate for general application as specified in MG 1-12.37, MG 1-12.38, and MG 1-12.39, drawing locked-rotor current not to exceed the values shown in MG 1-12.34 for 60 Hz and MG 1-12.35 for 50 Hz, and having a slip at rated load of less than 5%. Motors with 10 and more poles may have slip slightly greater than 5%.

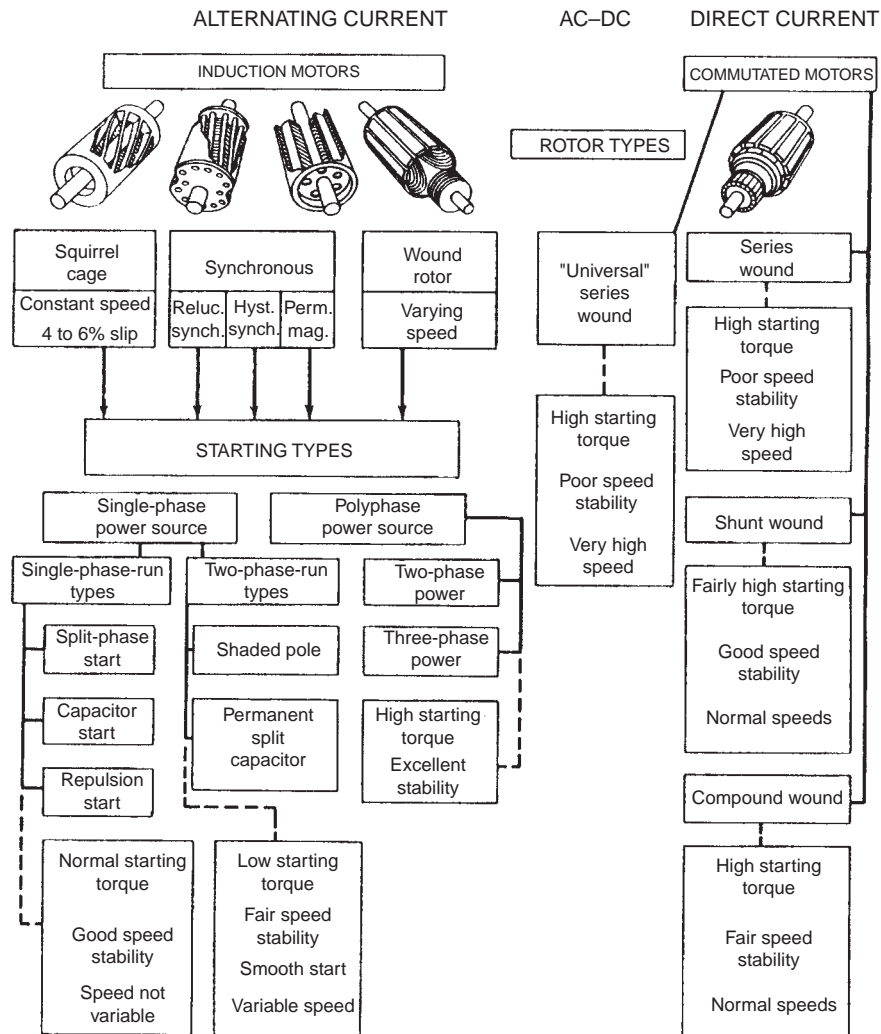

FIGURE 3.1.8 Electric motor classification.

Design C. A Design C motor is a squirrel-cage motor designed to withstand full-voltage starting and develop locked-rotor torque for special high-torque application up to the values shown in MG 1-12.37, pull-up torque as shown in MG 1-12.39, breakdown torque up to the values shown in MG 1-12.38, with locked-rotor current not to exceed the values shown in MG 1-12.34 for 60 Hz and MG 1-12.35 for 50 Hz, and having a slip at rated load of less than 5%.

Design D. A Design D motor is a squirrel-cage motor designed to withstand full-voltage starting and to develop high locked-rotor torque as shown in MG 1-1.37 with locked-rotor current not greater than shown in MG 1-12.34 for 60 Hz and MG 1-12.35 for 50 Hz, and having a slip at rated load of 5% or more.

Single-phase Motors. Alternating-current single-phase motors are usually induction or series motors, although single-phase synchronous motors are available in the smaller ratings.

Design Letters. Single-phase integral-horsepower motors may be one of the following:

Design L. A Design L motor is a single-phase integral-horsepower motor designed to withstand full-voltage starting and to develop a breakdown torque as shown in MG 1-10.33 with a locked-rotor current not to exceed the values shown in MG 1-12.33.

Design M. A Design M motor is a single-phase integral-horsepower motor designed to withstand full-voltage starting and to develop a breakdown torque as shown in MG 1-10.33 with a locked-rotor current not to exceed the values shown in MG 1-12.33.

Single-Phase Squirrel-cage Motors. Single-phase squirrel-cage induction motors are classified and defined as follows:

Split-Phase Motor. A split-phase motor is a single-phase induction motor equipped with an auxiliary winding, displaced in magnetic position from, and connected in parallel

with, the main winding. *Note:* Unless otherwise specified, the auxiliary circuit is assumed to be opened when the motor has attained a predetermined speed. The term “split-phase motor,” used without qualification, described a motor to be used without impedance other than that offered by the motor windings themselves, other types being separately defined.

Resistance-Start Motor. A resistance-start motor is a form of split-phase motor having a resistance connected in series with the auxiliary winding. The auxiliary circuit is opened when the motor has attained a predetermined speed.

Capacitor Motor. A capacitor motor is a single-phase induction motor with a main winding arranged for a direct connection to a source of power and an auxiliary winding connected in series with a capacitor. There are three types of capacitor motors, as follows:

Capacitor-start motor. A capacitor-start motor is a capacitor motor in which the capacitor phase is in the circuit only during the starting period.

Permanent-split capacitor motor. A permanent-split capacitor motor is a capacitor motor having the same value of capacitance for both starting and running conditions.

Two-value capacitor motor. A two-value capacitor motor is a capacitor motor using different values of effective capacitance for the starting and running conditions.

Shaded-Pole Motor. A shaded-pole motor is a single-phase induction motor provided with an auxiliary short-circuited winding or windings displaced in magnetic position from the main winding. This makes the motor self-starting.

Single-Phase Wound-Rotor Motors. Single wound-rotor motors are defined and classified as follows:

Repulsion Motor. A repulsion motor is a single-phase motor that has a stator winding arranged for connection to a commutator. Brushes on the commutator are short circuited and are so placed that the magnetic axis of the stator winding. This type of motor has a varying-speed characteristic.

Repulsion-Start Induction Motor. A repulsion-start induction motor is a single-phase motor having the same windings as a repulsion motor, but at a predetermined speed the rotor winding is short circuited or otherwise connected to give the equivalent of a squirrel-cage winding. This type of motor starts as a repulsion motor but operates as an induction motor with constant-speed characteristics.

Repulsion-Induction Motor. A repulsion-induction motor is a form of repulsion motor that has a squirrel-cage winding in the rotor in addition to the repulsion motor winding. A motor of this type may have either a constant-speed (see MG1-1.30) or varying-speed (see MG 1-1.31) characteristic.

Universal Motors. A universal motor is a series-wound motor designed to operate at approximately the same speed and output on either direct current or single-phase alternating current of a frequency not greater than 60 cycles/s and approximately the same rms voltage. There are two types:

Series-Wound Motors. A series-wound motor is a commutator motor in which the field circuit and armature circuit are connected in series.

Compensated Series Motor. A compensated series motor is a series motor with a compensating field winding. (The compensating field winding and the series field winding may be combined into one field winding.)

3.1.3.2 Direct-Current Motors

Direct-current motors are of three general types, shunt wound, series wound, and compound wound, and are defined as follows:

Shunt-Wound Motor. A shunt-wound motor is a direct-current motor in which the field circuit and armature circuit are connected in parallel.

Straight Shunt-Wound Motor. A straight shunt-wound motor is a direct-current motor in which the field circuit is connected either in parallel with the armature circuit or to a separate source of excitation voltage. The shunt field is the only winding supplying field excitation.

Stabilized Shunt-Wound Motor. A stabilized shunt-wound motor is a direct-current motor in which the shunt field circuit is connected either in parallel with the armature circuit or to a separate source of excitation voltage, and which also has a light series winding added to prevent a rise in speed or to obtain a slight reduction in speed with increase in load.

Series-Wound Motor. A series-wound motor is a motor in which the field circuit and armature circuit are connected in series.

Compound-Wound Motor. A compound-wound motor is a direct-current motor which has two separate field windings. One, usually the predominating field, is connected in parallel with the armature circuit. The other is connected in series with the armature circuit.

Permanent Magnet Motor. A permanent magnet motor is a direct-current motor in which the field excitation is supplied by permanent magnets.

3.1.3.3 Rating, Performance, and Testing

The following defines and describes the commonly used terms of electric motor rating, performance, and testing [7]:

Rating of a Machine. The rating of a machine shall consist of the output power together with any other characteristics, such as speed, voltage, and current, assigned to it by the manufacturer. For machines that are designed for absorbing power, the rating shall be the input power.

Continuous Rating. The continuous rating defines the load that can be carried for an indefinitely long period of time.

Short-Time Rating. The short-time rating defines the load that can be carried for a short and definitely specified time.

Efficiency. The efficiency of a motor or generator is the ratio of its useful power output to its total power input and is usually expressed in percentage.

Power Factor. The power factor of an alternating-current motor or generator is the ratio of the kilowatt input (or output) to the kVA input (or output) to the kVA input (or output) and is usually expressed as a percentage.

Service Factor of Alternating-current Motors. The service factor of an alternating-current motor is a multiplier that, when applied to the rated horsepower, indicates a permissible horsepower loading that may be carried under the conditions specified for the service factor (see MG 1-14.35).

Speed Regulation of Direct-Current Motors. The speed regulation of a direct-current motor is the difference between the steady no-load speed and the steady rated-load speed, expressed in percent of rated-load speed.

Secondary Voltage of Wound-Rotor Motors. The secondary voltage of wound-rotor motors is the open-circuit voltage at standstill, measured across the slip rings, with rated voltage applied on the primary winding.

Full-Load Torque. The full-load torque of a motor is the torque necessary to produce its rated horsepower at full-load speed. In pounds at a 1-ft radius, it is equal to the horsepower multiplied by 5,252 divided by the full-load speed.

Locked-Rotor Torque (Static Torque). The locked-rotor torque of a motor is the minimum torque that it will develop at rest for all angular positions of the rotor, with rated voltage applied at rated frequency.

Pull-Up Torque. The pull-up torque of an alternating-current motor is the minimum torque developed by the motor during the period of acceleration from rest to the speed at which breakdown torque occurs. For motors that do not have a definite breakdown torque, the pull-up torque is the minimum torque developed up to rated speed.

Breakdown Torque. The breakdown torque of a motor is the maximum torque that it will develop with rated voltage applied at rated frequency, without an abrupt drop in speed.

Pull-Out Torque. The pull-out torque of a synchronous motor is the maximum sustained torque that the motor will develop at synchronous speed with rated voltage applied at rated frequency and with normal excitation.

Pull-In Torque. The pull-in torque of a synchronous motor is the maximum constant torque under which the motor will pull its connected inertia load into synchronism, at rated voltage and frequency, when its field excitation is applied. The speed to which a motor will bring its load depends on the power required to drive it. Whether the motor can pull the load into step from this speed depends on the inertia of the revolving parts, so that the pull-in torque cannot be determined without having the Wk^2 as well as the torque of the load.

Locked-Rotor Current. The locked-rotor current of a motor is the steady-state current taken from the line with the rotor locked and with rated voltage (and rated frequency in the case of alternating-current motors) applied to the motor.

Temperature Tests. Temperature tests are tests taken to determine the temperature rise of certain parts of the machine above the ambient temperature, when running under a specified load.

Ambient Temperature. Ambient temperature is the temperature of the surrounding cooling medium, such as gas or liquid, which comes into contact with the heated parts of the apparatus. *Note:* Ambient temperature is commonly known as “room temperature” in connection with air-cooled apparatus not provided with artificial ventilation.

High-Potential Test. High-potential tests are tests that consists of the application of a voltage higher than the rated voltage for a specified time for the purpose of determining the adequacy against breakdown of insulating materials and spacings under normal conditions (see MG 1, Part 3).

Starting Capacitance for a Capacitor Motor. The starting capacitance for a capacitor motor is the total effective capacitance in series with the starting winding under locked-rotor conditions.

Radial Magnetic Pull and Axial Centering Force

Radial Magnetic Pull. The radial magnetic pull of a motor or generator is the magnetic force on the rotor resulting from its radial (air gap) displacement from magnetic center.

Axial Centering Force. The axial centering force of a motor or generator is the magnetic force on the rotor resulting from its axial displacement from magnetic center. *Note:* Unless other conditions are specified, the value of radial magnetic pull and axial centering force will be for no load, with rated voltage, rated field current, and rated frequency applied, as applicable.

Induction Motor Time Constants. When a polyphase induction motor is open circuited or short circuited while running at rated speed, the rotor flux linkages generate a voltage in the stator winding. The decay of the rotor flux linkages, and the resultant open-circuit terminal voltage or short-circuit current, is determined by the various motor time constants defined by the following equations:

Open-circuit AC time constant:

$$T''_{do} = \frac{X_M + X_2}{2\pi f r_2} \quad (\text{s}) \quad (3.1.6)$$

Short-circuit AC time constant:

$$T''_d = \frac{X_S}{X_1 + X_M} T''_{do} \quad (\text{s}) \quad (3.1.7)$$

Short-circuit DC time constant:

$$T_a = \frac{X_S}{2\pi f r_1 \left(1 + \frac{L L_s}{k W_1}\right)} \quad (\text{s}) \quad (3.1.8)$$

FIGURE 3.1.9 Motor circuit [7].

X/R ratio:

$$X/R = \frac{X_s}{r_1 \left(1 + \frac{LL_s}{kW_1}\right)} \quad (\text{rad}) \quad (3.1.9)$$

Terms (Figure 3.1.9):

- r_1 = Stator DC resistance per phase corrected to operating temperature.
- r_2 = Rotor resistance per phase at rated speed and operating temperature referred to stator.
- X_1 = Stator leakage reactance per phase at rated current.
- X_2 = Rotor leakage reactance per phase at rated speed and rated current referred to stator.
- X_s = Total starting reactance (stator and rotor) per phase at zero speed and locked-rotor current.
- X_M = Magnetizing reactance per phase.
- LL_s = Fundamental-frequency component of stray-load loss in kilowatts at rated current.
- kW_1 = Stator I^2R loss in kilowatts at rated current and operating temperature.
- f = Rated frequency in hertz.
- s = Slip in per unit of synchronous speed.

3.1.3.4 AC Performance Examples

In general, the typical electric motor applications in the oil and gas industry are polyphase motors (either squirrel-cage or wound-rotor motors).

Squirrel-Cage Motor. This type of motor finds a broader application and a more extensive and general use than any other type of motor. This is because it is, inherently, the simplest type of electric motor and, also, has excellent characteristics and operates essentially at constant speed. It has greater reliability and low maintenance requirements and thus meets a broad range of applications.

Torque, horsepower, and speed requirements demanded in drives for most machines can be met with one of four designs of squirrel-cage polyphase induction motors. Each design offers a different combination of torque, speed, and

current characteristics to meet the operating requirements of various industrial applications.

All four designs can withstand full-voltage starting directly across the power lines, that is, the motors are strong enough mechanically to withstand magnetic stresses and the locked-rotor torques developed at the time the switch is closed.

Design A produces exceptionally high breakdown torques but at the expense of high locked rotor currents that normally require provision for starting with reduced voltage. This motor is suitable for machines in which the friction and inertia loads are small.

Design B has normal starting torque adequate for a wide variety of industrial machine drives and a starting current usually acceptable on power systems. This design is suitable where slightly more than full load torque and low slip is required, also where relatively high breakdown torque is needed to sustain occasional emergency overloads, or where a low locked-rotor current is needed. These motors are for use in driving machine tools, blowers, centrifugal pumps, and textile machines.

Design C has high starting torque and a normal breakdown torque. Applications for this design are machines in which inertia loads are high at starting, but normally run at rated full load and are not subjected to high overload demands after running speed has been reached. Conveyors, plunger pumps, compressors that are not unloaded at starting, and over chain conveyors, also hoists, cranes, and machine tools where a quick start and reversal are required are typical examples of such machines.

Design D develops extremely high starting torque with moderate starting current. This design uses a high-resistance-type rotor to obtain variation of speed with load and has no sharply defined breakdown torque. This motor eases off in speed when surge loads are encountered and also develops high torque to recover speed rapidly. Typical applications for this motor are machines in which heavy loads are suddenly applied and removed at frequent intervals, such as hoists, machines with large flywheels, conventional punch presses, and centrifuges.

Slip ratings of the four designs are

Design	Slip, %
A	Less than 5
B	Less than 5
C	Less than 5
D	5 or more

Note that motors with 10 or more poles may have slip slightly greater than 5%.

Figure 3.1.10 shows the typical torque-speed performance curves for various designs of polyphase squirrel-cage induction motors [9].

FIGURE 3.1.10 Torque-speed curves for various designs of polyphase squirrel-cage induction motors [9].

25 and larger	200	200	200

*Values are expressed in per cent of full-load torque and represent the upper limit of the range of application.
Values are based on rated voltage and frequency.*

Tables 3.1.5 and 3.1.6 give the typical locked-rotor torque developed by Designs A, B, and C motors [8].

Table 3.1.7 gives the typical breakdown torque for Design B and C motors with continuous ratings [8]. Breakdown torques for Design A motors are in excess of the values given for Design B motors.

It is usually good practice to apply motors at momentary loads at least 20% below the values given for maximum torque in order to offset that much torque drop caused by an allowable 10% voltage drop.

Wound Rotor. Characteristics of wound-rotor motors are such that the slip depends almost entirely upon the load on the motor. The speed returns practically to maximum when the load is removed. This characteristic limits the use of these motors on applications where reduced speeds at light loads are described.

Wound-rotor motors are suitable for constant-speed applications that require frequent starting or reversing under load or where starting duty is severe and exceptionally high starting torque is required.

A second major type of application is where speed adjustment is required. Controllers are used with these motors to obtain adjustable speed over a considerable range. But at any point of adjustment the speed will vary with a change in load. It is usually not practicable to operate at less than 50% of full speed by introducing external resistance in the secondary circuit of the motor. Horsepower output at 50% of normal speed is approximately 40% of rated horsepower.

Use of wound-rotor induction motors has been largely in continuous-duty constant-speed applications where

particularly high starting torques and low starting currents are required simultaneously, such as in reciprocating pumps and compressors. These motors are also used where only alternating current is available to drive machines that require speed adjustment, such as types of fans and conveyors.

Typical torque-speed characteristics of wound-rotor motors are shown in the curves in Figure 3.1.11 for full voltage and for reduced voltage that are obtained with different values of secondary resistance.

3.1.3.5 DC Performance Examples

Important advantages of direct-current motors for machine drives are the adjustable speed over a wide range, the fact that speeds are not limited to synchronous speeds, and the variation of speed-torque characteristics [8].

Shunt-Wound Motors. These motors operate at approximately constant speed regardless of variations in load when connected to a constant supply voltage and with fixed field excitation. Maximum decrease in speed as load varies from no load to full load is about 10–12%.

Constant-speed motors are usually suited for a speed range of less than 3 to 1 by field control, but mechanical and electrical characteristics govern maximum safe speeds. With constant voltage on the armature, as the field is weakened the speed increases and the motor develops constant horsepower.

For speed ranges 3 to 1 or greater, adjustable-voltage operation is recommended. The adjustable-voltage drive usually includes a motor-generator set to supply an adjustable voltage supply to the armature of the drive motor. With this method of operation, a speed range of 10 to 1 readily obtained.

Regenerative braking can also be obtained with the variable-voltage drive. This system permits deceleration of the driven load by causing the motor to operate as a generator to drive the motor-generator set, thereby returning power to the alternating-current power supply.

With an adjustable voltage supply to the armature, at speeds below basic, the motor is suitable for a constant-torque drive. Minimum speeds are limited by temperature rise, because the motor carries full-load current at the lower speeds and at low speeds the ventilation is reduced. Adjustable voltage drives are used for paper mills, rubber mill machinery, winders, machine-tool drives, and hoists.

Adjustable-speed shunt-wound motors with field control are designed for operation over speed ranges of 3 to 1 or greater. Standard adjustable-speed motors are rated in three ways: tapered horsepower, continuous, 40°C rise; constant horsepower, continuous, 40°C rise; and constant horsepower, 1 hr, 50°C rise, of the next larger horsepower rating than for continuous duty.

TABLE 3.1.7 Breakdown Torque of Design B and C, 60 and 50-cycle Motors with Continuous Ratings [8]

Hp	Synchronous speed, rpm	Design B	Design C	Hp	Synchronous speed, rpm	Design B	Design C
1/2	900–750	250		3	1800–1500	275	
	Lower than 750	200			1200–1000	250	225

	Lower than 750	200			Lower than 750	200	
2	3600–3000	275		10	3600–3000	200	
	1800–1500	275			1800–1500	200	190
	1200–1000	250			1200–1000	200	190
	900–750	225			900–750	200	190
	Lower than 750	200			Lower than 750	200	
3	3600–3000	250		15 and larger	All speeds	200	190

Values are expressed in per cent of full-load torque and represent the upper limit of the range of application. Values are based on rated voltage and frequency.

The 1 hr, 50°C open motors develop constant horsepower over the entire speed range. Semienclosing covers can be added without changing the rating.

The 40°C continuous-rated open motors develop the rated horsepower from 150% of minimum speed to the maximum speed. From minimum speed to 15% of minimum speed, the rated horsepower will be developed continuously without exceeding safe temperature limits.

Tapered horsepower motors develop the maximum rated horsepower at three times the minimum speed, the horsepower decreasing in direct proportion to the decrease in speed down to the horsepower rating at 150% of the minimum speed. Figure 3.1.12 plots characteristics of shunt, series, and compound-wound direct-current motors.

Series-Wound Motors. These motors are inherently varying-speed motors with changes in load. On light or no loads, the speed may become dangerously high. These motors should be employed only where the load is never entirely removed from the motor. They should never be connected to the driven machine by belt.

Series motors are used on loads that require very high starting torques or severe accelerating duty or where the high-speed characteristics may be advantageous, such as in hoists.

Compound-Wound Motors. These motors are used to drive machines that require high starting torque or in which the loads have a pulsating torque. Changes in load usually produce wide speed regulation. This motor is not suited for adjustable speed by field control.

FIGURE 3.1.11 Typical torque-speed characteristics of wound-rotor motors [8].

FIGURE 3.1.12 Direct-current motor performance curves [8].

The relative strength of the shunt and series fields of the motor determines to what extent the motor approaches the shunt or series characteristics.

From no load to full load, the drop in speed of compound-wound motors is approximately 25%. Compound-wound motors are used where reasonably constant speed is required and for loads where high starting torque is needed to accelerate the drive machine.

Compound-wound motors should be used on machines having flywheel or high inertia loads, wherein the dropping

speed characteristics of the motor causes the flywheel to give up its energy as the shock load comes on, thereby cutting down the power peaks taken from the line and resulting in less heating of the motor.

3.1.3.6 Industry Applications

The oil and gas industry utilizes electric motors as prime movers in a number of industry operations. The motor applications and the electric motors typically utilized are now described [8,10].

Well Drilling and Completions. In the past, most drilling and completion rigs utilized direct drive diesel engines as prime movers. This was especially so of the large (deeper drilling) land rigs. The smaller land rigs utilize direct drive gas (including LPG and natural gas) engines. However, over the past decade, there has been an increasing trend to utilize diesel-engine-driven generators, which in turn operate direct-current motors for large land rigs and especially offshore drilling rigs. These direct-current electric motors are used for the drawworks and rotary table drives because of high starting-torque requirements for these operations.

Production. Torque requirements vary widely during the production pumping cycle, and peaks occur when the sucker-rod string and fluid load are lifted and when the counterweight is lifted. NEMA Design D motors, although relatively expensive, are well suited to this service, since they minimize current peaks and provide adequate torque under all service conditions, including automatic operation by time control. NEMA Design C motors may be used where operating conditions are less severe. NEMA Design B motors must be used with care in this service to avoid high cyclic current peaks, which may be objectionable on a small system, particularly if several wells should “get in step.” The use of Design B motors can also lead to oversizing of motors in an attempt to obtain sufficient starting torque. This results in the operation of the motor at a relatively low load factor, with consequent low power factor.

Double or Triple-Rated Motors. There are special motors developed for oil-well pumping. They are totally enclosed, fan-cooled NEMA Design D motors that can be reconnected for 2–3-hp ratings at a common speed of 1,200r/min. Typical horsepower ratings are 20/15/10 and 50/40/30. They provide flexibility in the field since they permit the selection of the horsepower rating at which the motor may be operated most efficiently. They also permit changing the pumping speed by changing the motor pulley and reconnecting the motor.

Single-Phase Operation. If single-phase power only is available, it is advisable to consider the use of single-phase to three-phase converters and three-phases motors. This

avoids the use of large single-phase capacitor start motors, which are relatively expensive and contain a starting switch that could be a source of trouble due to failure or to the presence of flammable gas in the vicinity of the well.

Oil-Well Control. A packaged control unit is available to control individual oil-well pumps. It contains, in a weatherproof enclosure, a combination magnetic starter, a time switch that can start and stop the motor according to a predetermined program, a timing relay that delays the start of the motor following a power failure, and lightning arresters. Pushbutton control is also provided.

Power-Factor Correction. The induction motors used for oil-well pumping have high starting torques with relatively low power factors. Also, the average load on these motors is fairly low. Therefore, it is advisable to consider the installation of capacitors to avoid paying the penalty imposed by most power companies for low-power factor. They will be installed at the individual motors and switched with them, if voltage drop in the distribution system is to be corrected as well as power factor. Otherwise they may be installed in large banks at the distribution center, if it is more economical to do so.

Oil Pipelines. The main pumps for an oil pipeline usually driven by 3,600 rpm induction electric motors having NEMA Design B characteristics. Full-voltage starting is used. Figure 3.1.13 shows a typical pumping station diagram. Such pumping stations are located at the beginning of the pipeline and at intervals along the line. Intermediate or booster stations must be capable of operating under varying conditions due to differences in liquid gravity, withdrawals at intermediate points, and the shutting down of other booster stations. Pumping stations often contain two or three pumps connected in series, with bypass arrangements using check valves across each pump. The pumps may all be of the same capacity, or one of them may be half size. By operating the pumps singly or together, a range of pumping capacities can be achieved.

Throttling of pump discharge may also be used to provide finer control and to permit operation when pump suction pressure may be inadequate for full flow operation.

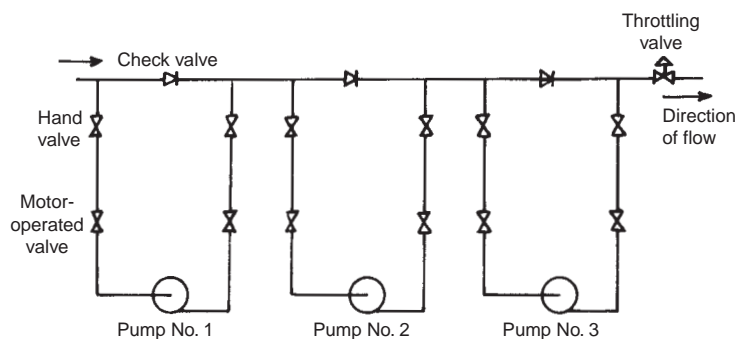

FIGURE 3.1.13 Typical oil pipeline pump station [3].

Pumping stations are often unattended and may be remotely controlled by radio or telephone circuits.

Motor enclosures for outdoor use are NEMA weather-protected Type II, totally enclosed, fan-cooled, or drip-proof with weather protection. Motors of the latter type are widely used. Not only are they less expensive than the other types, but they also have a service factor of 1.15. The above enclosure types are all suitable for the Class I, Group D, Division 2 classifications usually encountered.

If the pumps are located indoors, a Division 1 classification is likely to apply. Motors must be Class I, Group D, explosion-proof, or they may be separately ventilated with clean outside air brought to the motor by fans. Auxiliary devices such as alarm contacts on the motor must be suitable for the area classification. The installed costs, overall efficiencies, and service factors associated with the enclosures that are available will influence the selection.

Natural Gas Pipelines. Compressor drivers are usually reciprocating gas engines or gas turbines, to make use of the energy available in the pipeline. Electric motor drives use slow-speed synchronous motors for reciprocating compressors and four or six-pole induction motors with gear increases for high-speed centrifugal compressors. Motor voltages, types, and enclosures are selected as for oil pipeline pumps. Motors used with centrifugal compressors must develop sufficient torque at the voltage available under in-rush conditions to accelerate the high inertia load. They must also have adequate thermal capacity for the long starting time required, which may be 20 or 30 s.

3.1.3.7 Motor Control

Efficient use of electric motors requires appropriate control systems. Typical control systems for AC and DC electric motor operations are now discussed [10].

Inverter-AC Motor Drives. An adjustable-frequency control of AC motors provide efficient operation with the use of brushless, high-performance induction, and synchronous motors. A typical system is shown in Figure 3.1.14. Such a system consists of a rectifier (which provides DC power from the AC line) and an inverter (which converts the DC power to adjustable-frequency AC power for the motor). Inverter cost per kilowatt is about twice that of controller rectifiers; thus the power convertor for an AC drive can approach three times the cost of a DC drive.

These AC drive systems require the inverters to operate with either low-slip induction motors or reluctance-type synchronous-induction motors. Such systems are used where DC commutator motors are not acceptable. Examples of such applications are motor operations in hazardous atmospheres and high motor velocities.

The power convertor must provide the AC motor with low-harmonic voltage waveform and simultaneously allow the amplitude to be adjusted. This avoids magnetic saturation of the motor as the frequency is adjusted. For constant torque, from maximum speed to base speed, the voltage is adjusted proportional to frequency. Above base speed, the motor is usually operated at constant horsepower. In this region the voltage is held constant and the flux density declines. Also, the convertor must limit the starting current, ensure operation at favorable slip, and provide a path for reverse power flow during motor slowdown.

Inverters are designed with various power semiconductor arrangements. Power semiconductor elements of the inverter operate like switches by synthesizing the motor voltage waveform from segments of the DC bus voltage. For power ranges up to about 5 hp, convertors can use power transistors to synthesize six-step (per cycle), three-phase voltage for frequency ranges from 10 to 120 Hz for standard motors and from 240 to 1,200 Hz for high-frequency motors. For the conventional drive range from 5 to 500 hp, thyristor inverters are used to develop either six-step per cycle, twelve-step per cycle, or pulse-width modulated (pwm) voltages over typical frequency ranges from 10 to 120 Hz.

The voltage control of the six-step thyristor inverter can be accomplished in the rectifier, or the inverter. The output voltage of a six-step inverter is directly proportional to the DC bus voltage. Thus, control of the rectifier is usually sufficient provided that the inverter commutation capacitors are charged from a fixed-voltage bus. Another method that can be used in dealing with a fixed DC bus voltage is to operate two inverter bridges in series with adjustable relative phase shift to control the motor voltage. An additional method is to use an adjustable-ratio output transformer (Variac).

In general, the usage of the voltage control methods is being replaced by pulse-width-modulation (pwm) techniques. These techniques allow the DC bus voltage to remain fixed, and, thus, lower-cost systems with motor

FIGURE 3.1.14 Typical inverter AC motor drive consisting of rectifier-DC link, adjustable-frequency inverter, and induction or synchronous motor [10]

voltages of potentially lower harmonic content can be obtained. A variety of PWM techniques are now used in inverters. One technique requires that each half-cycle or motor voltage waveform be divided into a fixed number of pulses, (typically four or six) and the pulse width modulated to control the voltage. In another technique, the pulse number is increased with pulse period and the width modulated for voltage control. An additional technique requires that the pulse number be fixed, but the width is graded over the half-cycle as a sine function, and the relative widths are controlled.

The inverter drive system that uses a current-controlled rectifier and parallel-capacitor commutation operates to both improve reliability and reduce cost. Such systems are built commercially for the ranges from 20 to 500 hp for the typical 20:1 constant-torque speed range.

Primary-Voltage-Control-AC Motor Driver. Induction motor torque at any slip s is proportional to primary V^2 . Rotor-power dissipation is equal to s times the air-gap power. These two relationships define the boundary of operation of an induction motor with primary voltage control of speed. As the speed is reduced (s increased) at constant torque, the air-gap power remains fixed, but the power divides between rotor circuit dissipation and mechanical shaft power.

Solid-state primary voltage controllers are built with phase-controlled thyristors in each AC circuit and are used with high-slip NEMA Design D motors. The thyristors are either placed in the three supply lines (as shown in Figure 3.1.15) in the star ends of a wye motor winding or in the arms of a delta motor winding. Commercial systems are built to 100 hp or more for pumps and related applications. Such systems have the inherent limitation of thyristor rating and rotor heating.

Wound-Rotor Motor Drives. The wound-rotor induction motor, using adjustable rotor-circuit resistance, is rarely used. However, two versions that use solid-state auxiliary equipment are finding limited application.

Just as for the primary-voltage control system, the air-gap power at slip s divides between mechanical power and rotor-circuit power in the wound-rotor drive. Except for the losses in the rotor windings, the rotor-circuit power is

FIGURE 3.1.15 Primary voltage central system [10].

extracted from the slip rings and is disposed of external to the machine. One type of solid-state system is shown in Figure 3.1.16a. In this system the power to a resistor is controlled by thyristors. Another type of solid-state system is shown in Figure 3.1.16b. In this system the slip-ring power is rectified and returned to the supply line through a line-commutated convertor. The first system is wasteful of power. The second system uses power in an economical manner.

The rating of the solid-state equipment depends upon the torque requirement as a function of speed. For a constant-torque drive, the auxiliary system at starting must handle the full motor rated power. For pump drives, the auxiliary system ratings are reduced considerably. The convertor operates with phase-controlled firing signals from the supply line, such as for a DC drive rectifier and develops relatively constant-speed characteristics. The stator-rotor winding ratio is made slightly larger than unity to ensure that power flow is toward the supply line at the lowest speed (e.g., at stall).

Solid-State DC Drives. The controlled-thyristor rectifier and separate-field DC motor is the solid-state motor drive in greatest use. The combination provides control over at least a 10:1 speed range, plus an additional two to three times by field weakening. Depending upon the power level, the rectifier is operated directly from the AC supply lines, or via a transformer. Typical speed regulation of $\pm 2\%$ can be accomplished with a single control system. The horsepower and speed limitations are set by the DC motor, not by the semiconductor rectifiers. The DC motor and rectifier can be combined to any required power level.

Commercial solid-state DC motor drives fall into three general groups. Drives operating from single-phase lines are available in fractional horsepower sizes up to about 3 hp. Three-phase drives are available in horsepower sizes from 5 to 500 hp. Drivers above 500 hp are generally classed as special.

Speed adjustment from base speed downward is obtained by armature voltage control. The armature current and torque in this range is limited by the thyristor ratings or motor temperature rise. Control above base speed at constant horsepower is obtained by field weakening. An example system is shown in Figure 3.1.17a. In this example three or six thyristors are used in the rectifier. Reversible operation requires either the use of two rectifiers connected as shown in Figure 3.1.17b, a reversing armature contactor, or a field-reversing technique.

Speed adjustment, current limiting, and regulation against load, temperature, and line-voltage disturbances require a control system for the armature and field rectifier thyristors. For typical $\pm 2\%$ regulation, the speed signal is derived from the armature voltage, corrected for IR drop. For regulation to $\pm 0.1\%$, the speed signal is obtained from analog or digital tachometers and processed in solid-state

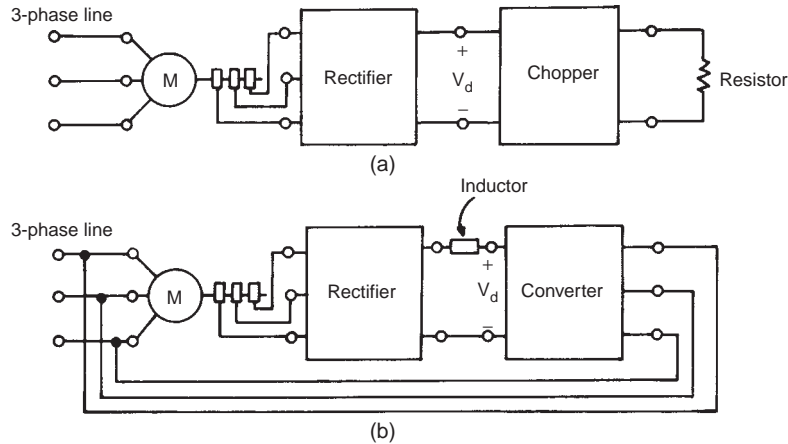

FIGURE 3.1.16 Wound-rotor systems: (a) rotor power dissipated in resistance; (b) rotor power retirement to supply line [10].

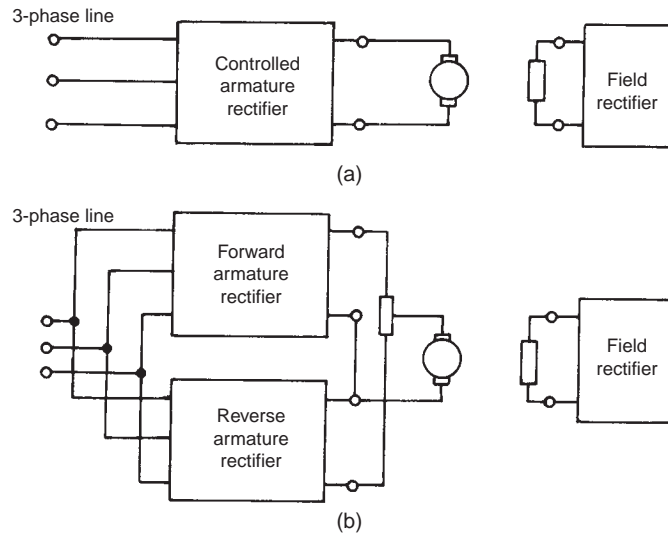

FIGURE 3.1.17 Rectifier-DC motor driver: (a) unidirectional or field-reversing; (b) bidirectional operation with armature voltage reversing [10].

digital or analog circuits. Signals that override the constant-speed control system limit armature current during speed changes, acceleration, and reversal.

3.2 POWER TRANSMISSION

Section reviewed by T. Wayne Brewster

In nearly all mechanical power applications in the oil and gas industry, it is necessary to transmit the power generated by a prime mover to an operation (e.g., drawworks of a drilling rig, a production pumping system). The transmission of rotary power to such operation elements is carried out by a power transmission system. Mechanical power transmission is typically carried out by belting systems, chain systems, gear systems, hydraulic systems, or some combination of these four [1].

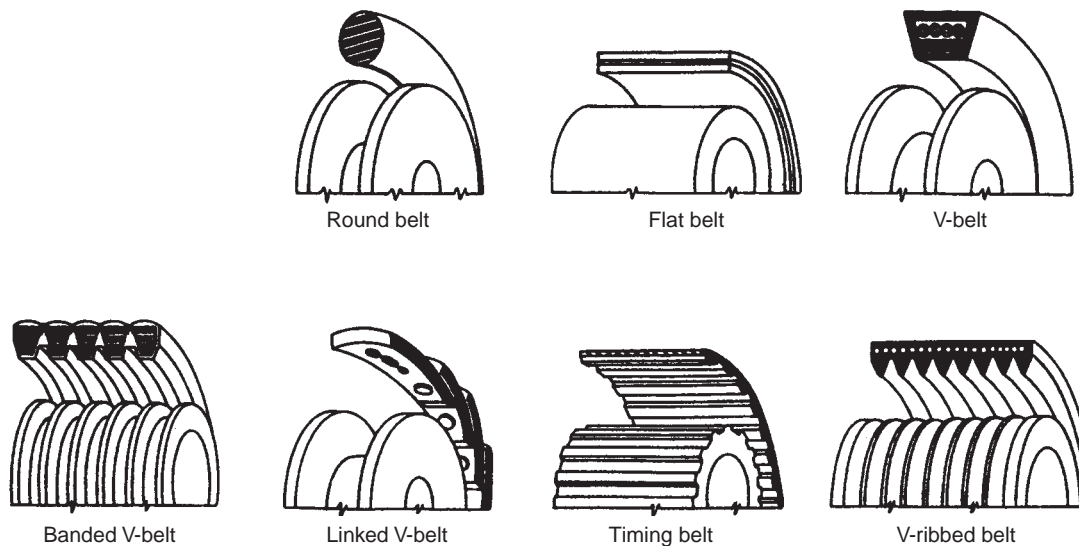

FIGURE 3.2.1 Types of belts [2].

3.2.1 Power Belting

There are three basic types of power belting. They are round, flat, and V, as shown in Figure 3.2.1. In general, the choice of a power belt drive depends on factors such as speed, reduction ratio, positive-drive requirements, center distances, and shaft relationship (i.e., magnitude of skew and load).

3.2.1.1 Round-Belt Drives

Round belts, modern versions of the now obsolete rope drive are available in endless and spliced variations. Round belts can operate satisfactorily over pulleys in several different planes and are thus well suited for serpentine drives, reverse bends and 90° twists [2].

3.2.1.2 Flat-Belt Drives

Flat belts are used chiefly for conveyor belt systems rather than power transmission. Synchronous belt are generally used for control of critically timed rotating elements of a mechanical system and are not used in power transmission applications. V-ribbed belts are typically used in light-duty applications requiring high speed ratios.

3.2.1.3 V-Belt Drives

V belts were developed from the older rope drive systems. The grooved sheaves required for ropes became V shaped, and the belt itself was contoured to fit the groove. The reason V belts are able to transmit higher torque at smaller widths and tension than other types of belts is because of the wedging action of the V belts in the sheave groove.

FIGURE 3.2.2 Element of a V belt in a sheave [2].

Figure 3.2.2 shows this wedging action. Figure 3.2.3 shows typical sheave designs for single and multiple V belts.

3.2.1.3.1 V Belt Types

There are several different configurations of V belts for power transmission applications. Cross-sections for standard or classic V belts and narrow V belts are shown in Figure 3.2.4 and Table 3.2.1. The narrow or superpower V belts were specifically designed to have a higher horsepower capacity than standard V belts. These superpower V belts allow shorter center distances and narrower sheaves without imposing any extra total bearing stresses. Such belts can carry up to three times the horsepower than standard V belts. In addition, speeds can be increased up to 6500 ft/min without dynamic balancing of the sheaves because the sheaves are smaller.

FIGURE 3.2.3 Types of sheaves for V belts [2].

FIGURE 3.2.4 V belt cross-sections [3].

TABLE 3.2.1 Nominal Dimensions of Cross-Sections, in Inches [3]

Belt Type	Cross-section	b_b	h_b	h_{bb}	S_g^*
Classic V-belts	A, AX	0.50	0.31	0.41	0.625
	B, BX	0.66	0.41	0.50	0.750
	C, CX	0.88	0.53	0.66	1.000
	D	1.25	0.75	0.84	1.438
Narrow V-belts	3V, 3VX	0.38	0.31	0.38	0.406
	5V, 5VX	0.62	0.53	0.62	0.688
	8V	1.00	0.91	1.00	1.125

* S_g is sheave groove spacing.

3.2.1.3.2 V Belt Terminology

- **Belt length (L):** V belts are of closed loop construction and come in standard lengths. V belt length is based on the pitch diameter of the sheaves and the center distance and is termed *pitch length*.

- **Center distance (C):** The distance between the center of the drive sheave to the center of the driven sheave.
- **Classic:** V belts with cross-sections including A, AX, B, BX, C, CX, and D.
- **Contact angle (θ):** The angle of belt wrap on the smaller sheave.
- **Creep:** Loss in speed of the driven sheave compared with the theoretical speed based on the speed ratio. It is caused by the alternate lengthening and shortening of the belt as it passes between the taut side and slack side of the drive.
- **Drive sheave:** This sheave is mounted on the motor or prime mover. It is usually the smaller of the two sheaves and has the higher rotational speed.
- **Driven sheave:** This sheave is located on the equipment being driven by the motor or prime mover. It is usually the larger of the two sheaves and thus has the lower rotational speed.
- **Narrow:** V belts with cross-sections including 3V, 3VX, 5V, 5VX, and 8V.
- **Pitch diameter (d, D):** The diameter at the point where the neutral axis of the belt contacts the sheave.
- **Service factor:** A value that is multiplied times the required horsepower to determine the design horsepower. This value compensates for those drives which intermittently operate above the required horsepower.
- **Speed ratio (i):** The ratio of the pitch diameter of the larger sheave to the pitch diameter of the smaller sheave. It can also be expressed as the speed of the faster sheave divided by the speed of the slower sheave.

3.2.1.3.3 V Belt Drive General Dimensions

Figure 3.2.5 shows the general dimensions of an open-belt drive. For V belt drives, the sheave diameters D and d are pitch diameters [2]. The quantity C is the center distance, θ is the contact angle for the smaller sheave, and $2x$ is the angular deviation from a 180° angle of contact.

From Figure 3.2.5, θ (radians) is approximately

$$\theta \approx \pi - \frac{D - d}{c} \quad (3.2.1)$$

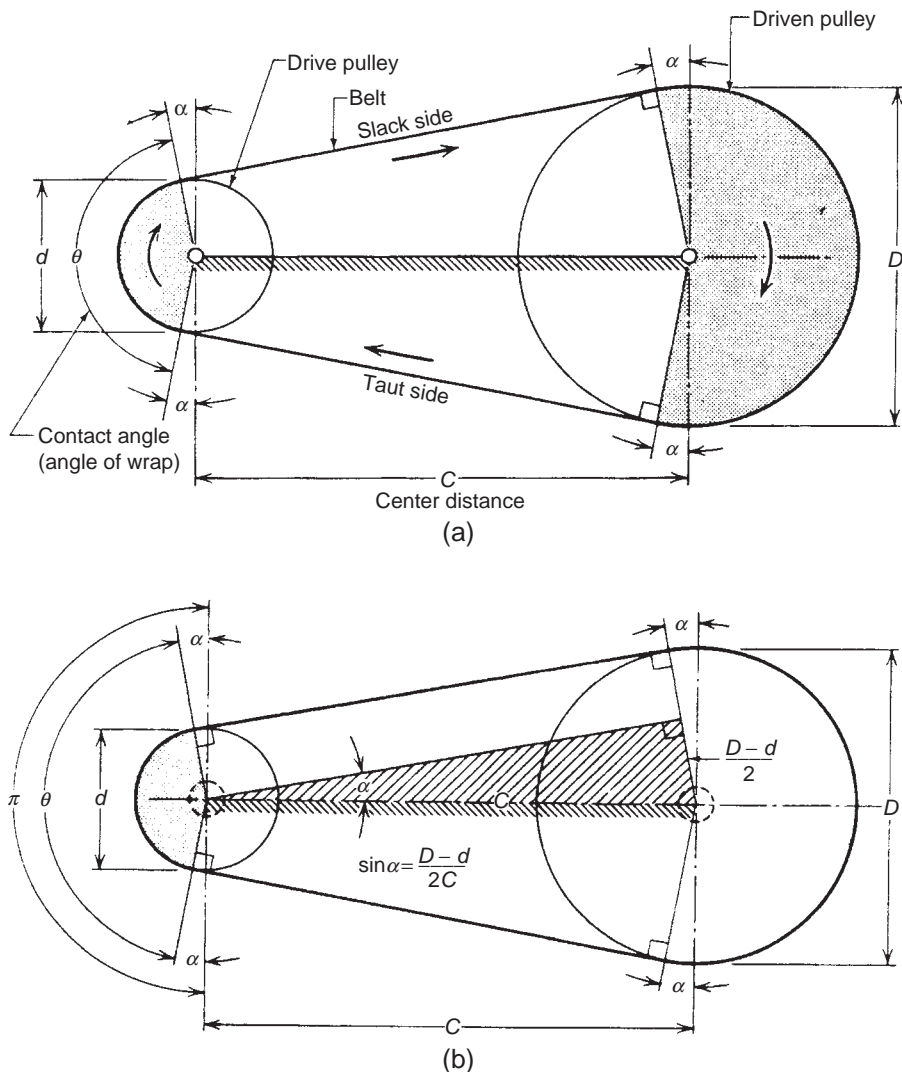

FIGURE 3.2.5 V-belt geometry [2].

For V-belt applications, D and d are sheave pitch diameters. From the geometry of Figure 3.2.5, θ is always less than or equal to 180° or π radians. The lower guideline for θ is approximately 150° . Below this values, there will be increasing tension and slip, which will result in decreased life of the V belts. This limit on θ imposes a lower limit on the center distance and thus a practical limit on the speed ratio attainable is a given V-belt design.

3.2.1.3.4 Drive Center Distance and V-Belt Length

Shorter center distance is a very practical design objective. Such a design uses space economically and allows for a stable operation. In general, center distances are limited by the physical dimensions of the sheaves, or the minimum

angle of θ (i.e., 150°). Maximum drive centers are limited only by available V-belt stocked lengths.

The center distance is

$$C = \frac{b + \sqrt{b^2 - 32(D - d)^2}}{16} \tag{3.2.2}$$

where D is the pitch diameter of the larger sheave (usually the driven sheave) in in., d is the pitch diameter of the smaller sheave (usually the drive sheave) in in., and the quantity b is

$$b = 4L - 6.28(D + d) \tag{3.2.3}$$

where L is the V-belt pitch length in inches.

From the above, L is

$$L = 2C + 1.57(D + d) + \frac{(D - d)^2}{4C} \quad (3.2.4)$$

Modern V belts are nearly all of the closed-loop continuous type which come in standard lengths.

For V-belt drives with more than two sheaves, belt length is calculated from sheave coordinates and drive dimensions in layout drawings.

3.2.1.3.5 Speed Ratio

Most prime movers rotate at a higher speed than the operational driven equipment. Therefore, speed reduction is necessary for most belt drive systems. The speed ratio i between the prime mover drive shaft and the drive shaft is

$$i = \frac{\text{speed of drive shaft (rpm or ft/s)}}{\text{speed of driven shaft (rpm or ft/s)}} \quad (3.2.5)$$

This can also be expressed in terms of sheave pitch diameter. This is

$$i = \frac{\text{pitch diam. of larger sheave (in.)}}{\text{pitch diam. of smaller sheave (in.)}} \quad (3.2.6)$$

3.2.1.3.6 V-Belt Speed

Under normal operating conditions, speed reduction due to creep of the V-belt material is usually quite small. Neglecting these effects, the velocity v (in./s) of the V belt is

$$v = \frac{\pi D n_D}{60} = \frac{\pi d n_d}{60} \quad (3.2.7)$$

where n_D is the large sheave speed and n_d is the small sheave speed, both in rpm.

In general, modern V-belt speeds are limited to about 6,500 ft/min ($v = 108$ ft/s), and the relationship between D , d , n_D , n_d , and i is

$$n_D = \frac{d}{D} n_d = \frac{n_d}{i} \quad (3.2.8)$$

3.2.1.3.7 Creep and Slip

As a belt turns on a pulley, it tends to stretch on the contact arc of the driving pulley and shorten on the driven pulley. This local movement of the belt is known as *creep*. The loss in speed is about 0.5% and is neglected in sizing and speed calculations. Creep should not be confused with slip, which is an undesirable difference in speed between the belt and pulley.

From Figure 3.2.2, the relationship between the forces N (lb) normal to the V-belt sides and the force F_n (lb) can be obtained. This is

$$2N = \frac{F_n}{\sin \beta} \quad (3.2.9)$$

The total friction force, F_f (lb) acting tangent to the sheave is

$$F_f = \frac{f F_n}{\sin \beta} \quad (3.2.10)$$

where f is the coefficient of friction between the V belt and the sheave surface. The typical value for 2β is $32\text{--}40^\circ$ (average value 36°). The typical value of f is about 0.30 (rubber against cast iron or steel).

Figure 3.2.6 shows the constant speed forces in the V belts with drive sheave transferring power via the V belt to the large driven sheave [2]. If centrifugal forces and slippage are neglected, then taut side tension force F_1 (lb) is

$$F_1 = F_2 e^{f\theta / \sin \beta} \quad (3.2.11)$$

where F_2 (lb) is the slack side tension.

3.2.1.3.8 Power

The power P (hp) transmitted by the drive sheave to the drive sheave is

$$P = \frac{F_1(1 - e^{-(f\theta / \sin \beta)})v}{550} \quad (3.2.12)$$

The force F_1 is the taut side of the V belt. In practice this force cannot exceed the allowable V-belt load F_{\max} (lb). Equation 3.2.12 is valid only for rather slow speeds where centrifugal force can be neglected.

If centrifugal force is not neglected, then the power P transmitted is

$$P = \frac{(F_{\max} - F_c)(1 - e^{-(f\theta / \sin \beta)})v}{550} \quad (3.2.13)$$

where F_c (lb) is the centrifugal force created by the high speed of the V belt. The force F_c is

$$F_c = mv^2 \quad (3.2.14)$$

where m is the mass per unit length of the V belt ($\text{lb}\cdot\text{s}^2/\text{ft}^2$).

FIGURE 3.2.6 Equilibrium forces [2].

From Equations 3.2.13 and 3.2.14, an optimum velocity may be found for higher speed V-belt applications. This optimum velocity V_{op} (ft/s) is

$$V_{op} = \left(\frac{F_{max}}{3m} \right)^{1/2} \quad (3.2.15)$$

and the optimum power P_{op} (hp) is

$$P_{op} = \frac{(F_{max} - mV_{op}^2)(1 - e^{-(f\theta/\sin\beta)})V_{op}}{550} \quad (3.2.16)$$

3.2.1.3.9 Belt Power Rating

The horsepower rating for a belt of average length with 180° of contact is

$$P_r = d_p \cdot r \left[K_1 - \frac{K_2}{d_p} - K_3 \cdot (d_p \cdot r)^2 - K_4 \cdot \text{LOG}(d_p \cdot r) \right] + K_2 \cdot r \cdot \left(1 - \frac{1}{K_{sr}} \right) \quad (3.2.17)$$

where d_p is the pitch diameter of the small sheave in inches, r is the RPM of the faster shaft divided by 1000, constants K_1 through K_4 are taken from Table 3.2.2, and the speed ratio correction factor K_{sr} is taken from Table 3.2.3.

For other lengths and arcs of contact, the power rating obtained from Equation 3.2.17 should be modified. The corrected horsepower rating per belt is

$$P_c = P_r \cdot K_\theta \cdot K_1 \quad (3.2.18)$$

where K_θ is the arc of contact correction factor from Table 3.2.4, and K_1 is the length correction factor taken from Table 3.2.5 or 3.2.6.

3.2.1.3.10 Service Factors

Design horsepower equals the horsepower transmitted multiplied by the service factor. *Transmitted horsepower* is usually the nameplate rating of the motor. The service factor compensates for load fluctuations that cause the rating of the motor to be exceeded. Service factors for various types of oil field applications are given in Table 3.2.7.

3.2.1.3.11 Sizing a V Belt

API has developed specifications for V belting in oil-field power transmission applications [3]. Reference 3 is used to carry out detailed design calculations. Although this is an API publication, the specifications contained are consistent with specifications of other industrial groups. The basic calculation techniques above have been carried out for the stock V belts available. These data are tabulated in the API publication to simplify the design effect for V-belt power transmission systems.

Using the data contained in the API specifications for V belting the following steps can be used to find V-belt drive system dimensions.

1. The following information is required to size a V-belt drive.
 - a. Average horsepower transmitted
 - b. The rpm of the faster shaft
 - c. The rpm of the slower shaft
 - d. Approximate desired center distance

*Standard length designation is the effective length multiplied by 10.

2. Determine the design horsepower by multiplying the average horsepower transmitted by the service factor. Use [Table 3.2.7](#) to select a service factor.
3. Select the proper V-belt cross-section from [Figure 3.2.7](#) or [3.2.8](#) using the design horsepower (Step 2) and the speed of the faster shaft.
4. Calculate the speed ratio using [Equation 3.2.5](#).
5. Select sheave diameters. [Tables 3.2.8](#) and [3.2.9](#) show generally available sheave sizes for classic and narrow V belts. Select a set of sheaves that best match the desired speed ratio (Step 4) using [Equation 3.2.6](#). Care should be taken such that the faster sheave is not smaller than the minimum recommended values given in [Table 3.2.10](#).

TABLE 3.2.7 V-Belt Service Factors [3]

Types of Service	Service Factor
Compressors, reciprocating	1.6
Fans, propeller	1.5
Pumps, centrifugal	1.4
Pumps, rotary or vane	1.4
Pumps, duplex piston, except slush pumps	1.6
Pumps, duplex piston slush pumps	1.0*
Pumps, triplex plunger	1.5
Generators serving beam-pumping units	1.8
Generators with no beam-pumping load	1.5

* Consult manufacturer.

- Find the V-belt speed using Equation 3.2.7. The rim speed of the sheaves should not exceed 6,500 ft/min.
- A desirable center distance should not be less than the diameter of the large sheave and preferably the sum of the diameters of the large and small sheaves. Using the approximate desired center distance, calculate the belt length using Equation 3.2.4, and then select a standard belt length that is the closest match to the calculated

belt length. The actual center distance can be calculated using Equations 3.2.2 and 3.2.3.

- Find the horsepower capability per V belt using Equations 3.2.17 and 3.2.18.
- Determine the number of belts required by dividing the design horsepower (Step 2) by the horsepower capability per V belt (Step 7). If the number of V belts is a whole number and a fraction, the next higher whole number of belts should be used.
- The V-belt drive can now be tabulated using
 - V-belt type (Step 3)
 - Number of V belts (Step 9)
 - Drive sheave design (Steps 5 & 9)
 - Driven sheave design (Steps 5 & 9)
 - Center distance and V-belt length (Step 7)

3.2.2 Chains

Power transmission chains provide a positive drive even when operated under very adverse temperatures (−60 to 600°F) and other environmental conditions. These power transmission systems are very flexible with regards to their field applications. In general, chain drives are primarily selected for low-speed and medium-speed service. Some silent chain designs may be used in high-speed service [5,6].

There are six types of chains used for power transmission. These are roller, silent (inverted tooth), offset link (Ewart with bushing), detachable (open Ewart), pintle (closed Ewart), and bead.

25.00	2-6, 8, 10	28.00	3-6, 8, 10		
33.50	3-6, 8, 10	31.50	3-6, 8, 10		
		37.50	3-6, 8, 10		
		50.00	3-6, 8, 10		

Some of these are shown in [Figure 3.2.9](#). Because most modern power transmissions use roller chains, silent chains or the offset link (Ewart) chains, these will be the only chain types discussed since they are quite important in oil field applications.

The term *chain drive* denotes a combination of chain and sprockets, with the sprockets mounted on rotating shafts.

Standardization of chains is under the jurisdiction of the American National Standards Institute [7,8].

3.2.2.1 Chain Terminology

These are basic terminology terms that aid in the description of chains. These are (see [Figure 3.2.10](#) [2]) the following:

- *Pitch* is the distance between any point on a link and the same point on the next link in a straight (unarticulated) chain.
- *Drive sprocket* is usually the sprocket that is provided with the shaft input power (usually the smaller diameter sprocket).

TABLE 3.2.10 Minimum Recommended Sheave Sizes [3]

Classic		Narrow	
Section	Minimum Pitch Diameter, Inch	Section	Minimum Pitch Diameter, Inch
A	3.00	3V	2.65
AX	2.20	3VX	2.20
B	5.40	5V	7.10
BX	4.00	5VX	4.40
C	9.00	8V	12.50
CX	6.80		
D	13.0		

- *Driven sprocket* is the sprocket and shaft that the chain is transferring power to (usually the larger diameter sprocket).
- *Center distance* is the length between the centers of the drive and drive sprocket shafts.
- *Chain length* is the total length of the chain (usually measured in pitches).
- *Pitch diameter* (of either the drive sprocket or driven sprocket) is generally on a theoretical circle described by the centerline of the chain as it passes over the sprocket.

- *Chain rating* is the load that a chain will satisfactorily handle over extended periods of time.
- *Angle of wrap* or *angle of contact* is the angular section of a sprocket that is in contact with the chain.

3.2.2.2 Roller Chain

Where accurate and higher-speed chain drives are required, roller chains are used. Roller chains are fundamentally a development of the block chain in which rollers have been inserted. The addition of the rollers increases the overall efficiency of the chain and permits it, in its ordinary form, to be operated at high speeds; a rate of 600–800 ft/min is usually recommended. The links can be furnished in a multitude of shapes, one common form being the “offset” shown in Figure 3.2.11. This type of chain is furnished in pitches (i.e., center distance between rollers) from $\frac{1}{8}$ up to $2\frac{1}{2}$ in. and in breaking strengths, dependent upon the materials and the construction used, from about 10,000 to 20,000 lb [5].

Precision tools are used in the manufacture of roller chains, and a high degree of accuracy is maintained. The chain is made up of links, pins, and bushings, all fabricated from a high grade of steel, with the pins and the bushings ground to ensure accuracy of pitch.

Extreme care is used in the manufacture of some of the highest grades of roller chains, with the result that they can be operated at speeds as high as 4,000 ft/min. In general use, however, unless the chain is fully enclosed and well lubricated, the upper speed limit should be kept at about

FIGURE 3.2.9 Commonly used chain types [5].

FIGURE 3.2.10 Chain drive terminology and geometry [2].

FIGURE 3.2.11 Steel offset link [5]

FIGURE 3.2.12 Standard roller chain configuration [5].

1,400 ft/min. The chains operated at these high speeds must be fabricated from accurately ground rollers, bushings, and pins and be run over cast-iron or steel sprockets having accurately machined teeth. The general structure of a roller chain for this type of high-speed service is illustrated in Figures 3.2.12 and 3.2.13.

Roller chains can generally be furnished not only in single but in multiple widths as well. The use of the multiple roller chain makes possible a shorter pitch without sacrificing high-power capacity. Because the shorter pitch permits a greater number of teeth for an allowable sprocket diameter and a reduction in drive weight, quieter and smoother operation are obtained. The multiple chains may be operated at the same speed as a single chain of the same pitch. Theoretically, the power that can be transmitted by them is equal to the capacity of the single chain multiplied by the number of stands, but actually this quantity is usually reduced about 10%.

Sprockets. To secure full advantage of the modern roller chain, it should be operated on sprockets having accurately machined teeth, the profile of which has been specified or approved by the ANSI [7]. This profile, which is made up of circular arcs, is designed to compensate for the increase in pitch due to natural wear and thereby provides maximum efficiency throughout the life of the sprocket.

FIGURE 3.2.13 Roller chain details [5].

The shape (Figure 3.2.14) of the standard form of tooth used on the roller-chain sprockets permits the rollers to ride farther out on the teeth as the chain is stretched under load or the pitch is increased by wear. A further effect of the particular design is an apparent slight increase in pitch diameter as the chain and sprockets wear, thus distributing the load over a larger number of teeth and the wear over a larger portion of the tooth surfaces.

Although as few as five or six teeth and as many as 250 have been used on sprockets with roller chains, experience and research have proved that, if speed and efficiency are to be considered, the number of teeth should be neither too few nor too many. It has been generally conceded by all chain manufacturers that 17-tooth sprockets are the minimum to

FIGURE 3.2.14 ANSI roller chain sprocket tooth [5].

FIGURE 3.2.15 Double-strand roller chain (courtesy of Borg Warner Corp.).

be used at high speeds and that 19 or 21-tooth sprockets are even better. The upper limit should be kept at about 125. It is considered good practice to use an odd number of teeth on the smaller sprocket. For a speed ratio of 7:1 or larger, a double-reduction drive often may be actually cheaper and undoubtedly will give longer life.

If the number of teeth is reduced below the recommended minimum, the increased shock or hammer action of the rollers engaging the teeth will increase wear and materially shorten the life of the chain. If more than 125 teeth are used, a small amount of pitch elongation will cause the chain to ride the sprocket long before it is actually worn out. Figure 3.2.15 shows a typical double-strand roller chain and its sprockets [2].

In general, four types of sprockets are available for roller chains. They are steel plate without hubs, cast iron or steel with hubs on one or both sides, split type, double-duty type.

The type of sprocket to be used depends entirely upon local or load conditions. The steel plate without hubs is the cheapest and is furnished for bolting to suitable hubs or flanges. The cast-iron or steel type fitted with hubs is made for direct mounting upon shaft and is fastened in place by either keys or setscrews or a combination of both. The split type is almost a necessity when the hub is mounted on a shaft with other pulleys or sheaves. Its construction facilitates installation and removal, but because of its extra cost it is usually not recommended except when

solid hubs cannot be installed. The double-duty sprockets are made with steel rims or plates that may be removed or replaced without disturbing the hub, shaft, bearing, etc. Plates and hubs can be obtained either solid or split. They are particularly adapted for jobs requiring changing of drive ratios or where replacements must be made quickly.

Shaft Centers. It can be readily seen that on any chain drive the minimum center distances must be more than one-half the sum of the diameters of the two sprocket wheels. Experience has shown that best results are usually obtained when the center distance between shafts is 30 to 50 times the chain pitch. Forty times the chain pitch is about normal, and 80 times the pitch is maximum. In highly pulsating loads, 20 to 30 times the pitch is more nearly the correct center distance. Center distances of 10–12 ft are permissible with finished steel roller chains operated at moderate speeds without the use of idlers. On distances greater than this, an idler should be used to eliminate the possibility of swaying or flopping, which may cause the chain to jump the sprocket. When idlers are used, they should be placed on the slack strand of the chain. The number of teeth in the idler should be the largest possible and preferably not less than the number in the smaller sprocket of the drive.

3.2.2.3 Silent Chain

The expression “silent chain” may be somewhat misleading, for the type of chain which it is used to describe is not exactly silent, but it is much quieter in operation than the roller chain. The essential features of the silent chain are the straight-sided working jaws of the links, meshing with the straight-sided teeth of the sprocket, and the method of joining the links to form the chain. Figure 3.2.16 illustrates the principles of this chain, and shows that as the chain rides on the sprocket a rolling rather than a surface contact occurs. The construction tends to prevent undue vibration of the parts of the chain between sprockets [5].

In the silent chain the greatest wear occurs at the joint, and a number of developments and improvements have been made to reduce this to a minimum. In the first chain of this type (Figure 3.2.17a), the joint was made by means of a solid round pin that passed through circular holes punched

FIGURE 3.2.16 Silent chain and differential-type sprocket teeth [5].

FIGURE 3.2.17 Types of silent chain joints [5].

in the links. The individual links bore directly upon the pins, and considerable wear resulted both in the links and the pins from the rubbing action produced by the wrapping of the chain around the sprockets. The first major improvement of this joint consisted of the placing of a bushing over the solid pin (Fig. 3.2.17b), thus producing a larger surface on which to distribute the load and a consequent reduction of the wear. This improvement was followed by still another one in which the solid bushing was replaced with a split or segmented one (Figure 3.2.17c). In still another design of joint (Figure 3.2.17d) the single round pin was replaced with two hardened alloy-steel specially shaped pins forming what is known as the “rocker-pin” joint. In this design the pin at one end of the link is the “seat pin” and that at the other is the “rocker,” each securely held in their respective holes in the link and prevented from turning. Facing these pins in an individual link are the pins in the adjoining link, with the seat pin in contact with the rocker and the rocker turning on a seat pin. The rocker is shaped and located to provide a flat surface against the seat, while the chain is pulling in a straight line and yet rolls over its cylindrical section as the chain flexes and passes on the sprocket. In this way a rolling contact occurs as the joint parts turn; the wearing qualities are improved, and vibration is reduced to a minimum.

To guide silent chains on their sprockets, a number of arrangements are used. They can, however, all be grouped under one of two heads: flanged links as part of the chain, or flanged jaws of the sprockets.

In the flanged-link type of guide, there are again two general classes: the “middle guide” and the “side flange” (Figure 3.2.18a,b). This method of guiding is particularly satisfactory when the drive is an integral part

of the machine, and it is very reasonable at first cost. The choice between the two classes depends almost entirely upon the structural details of the sprockets. The middle guide is generally considered standard and is the one usually carried in stock by the chain manufacturer.

The “wire-flange” sprockets (Figure 3.2.18c) are assembled by simply inserting a preformed, crimped wire of the proper number of teeth and pitch along the edges of the teeth of the sprocket. This type of guide is recommended particularly in the case of independently mounted electric motors that are not likely to stay in accurate alignment.

The plate flange is used on the drive sprocket in those cases where heavy guiding action is expected such as is sometimes encountered in high-power devices.

Silent chains are furnished in pitches varying from $\frac{3}{16}$ to 3 in. and in weights capable of transmitting from a fraction of a horsepower up to several thousand. They can be operated at speeds up to 3,500 ft/min, but where long life and low maintenance are desired, they should be held between 1,200 and 1,500 ft/min. Although they can be successfully operated at speeds below 1,200 ft/min, when extremely low speeds are required, it is usually more economical to use the roller chain.

Sprockets. Since the silent chain has not had the same wide usage as roller chains and because of the different types of construction that have been employed, there has been but little standardization of specializations. Each manufacturer has more or less carried out its own design and ratings, with the result that the sprockets to be used with this type of chain vary accordingly.

Practically all sprockets used with silent chain are made with cut teeth. Those with up to 25 teeth are usually cut from a steel forging and are furnished with a solid hub. For

FIGURE 3.2.18 Guides for silent chain sprockets [5].

sprockets with more than 25 teeth, a semisteel is used, and the sprockets are available in either solid or split form.

Differential-Cut Wheels. When a wheel has 81 or more teeth, a patented differential-cut construction is available that assures maximum drive life. The object is to cut the teeth of a wheel having a relatively large number of teeth so that two or more chain pitches, which are pivotally connected, act as a single unit to secure a greater angle of bend at the points of articulation and a corresponding larger component force acting toward the center of the wheel. For example, a 141-tooth, $\frac{1}{2}$ -in. pitch wheel cut to a differential of 3 will have the same operating characteristics as a 47-tooth $1\frac{1}{2}$ -in. pitch wheel and will provide better chain action and longer chain life than a 141-tooth single-cut wheel. Figure 3.2.16 shows this type of wheel.

As a protection for equipment against overload, sprockets are sometimes provided for silent chains with a “shearing pin” or a “break-pin hub.” A pin of a known strength is used, and an overload of sufficient magnitude shears the pin and leaves the plate free to turn on the hub. After the overload condition is remedied, a new pin may be easily inserted and the drive again made ready to operate.

Shaft Centers. As in roller chains, the minimum distance between shaft centers for silent chains must, in order to provide tooth clearance, be greater than half the sum of the two sprocket diameters. On large-speed reductions, experience has shown that the center distance should not be less than eight-tenths the difference in diameters of the two sprockets.

3.2.2.4 Offset Link (Ewart with Bushing)

The offset link is used principally in conveying and elevating equipment, although it is also frequently employed to transmit very little loads at comparatively low speeds. This chain was originally patented over 60 years ago and has given a good account of itself ever since. It is furnished in either the open or closed type of link and is so designed as to permit ease of assembly and disassembly. The open-type link is illustrated in Figure 3.2.19 and the closed type in Figure 3.2.20. The use of the closed link results in greater strength and at the same time overcomes some objections by the exclusion of dust and grit.

The Ewart links are usually cast in one piece with no separate bushings or pins. The material used is generally malleable iron, although steel is also extensively employed. As a general rule the maximum speed at which this type of chain is operated is about 400 ft/min, and even at that speed it is apt to be quite noisy. Because the links used in this chain are not machined and the pitch is not very uniform, the teeth of the sprockets used with them are, in turn, generally not machined.

The offset link type of chain can be further improved by the use of a bushing, as shown in Figure 3.2.21. The

FIGURE 3.2.19 Open Ewart link [5].

FIGURE 3.2.20 Closed Ewart link or pintle link [5].

FIGURE 3.2.21 Ewart link with bushing (API chain) [5].

improved or modified offset link can be used for more severe service conditions, but its safe maximum speed should, however, not exceed 400 ft/min. The offset link chain with bushing is known as the API chain. These chains are in only three nominal sizes, 3 in., $3\frac{1}{8}$ in., and 4 in. In general, the use of this older type of chain is not recommended.

3.2.2.5 Design Consideration

There are design considerations for the various chain power transmission applications that are common to nearly all chain types [5]. These are discussed in the following.

Roller Chains. These chains are primarily selected for low and medium-speed service and for conveyor work, although roller chains are sometimes used for higher speeds because they operate more smoothly and quietly.

The factors that will be discussed are often overlooked or misunderstood when applying chain. Other factors to be considered are found in chain manufacturers' catalogs along with chain sizes, sprocket types, and engineering examples.

Number of Teeth in Wheel. For roller chains, pinions should have 17 teeth or more for moderate-speed drives and 21 teeth or more for high-speed drives. Fewer teeth may be used for low-speed drives, with 12 teeth a recommended minimum.

For silent chain drives, pinions with 21 teeth or more are recommended for general applications and at least 25 teeth are recommended for high-speed applications. The recommended minimum is 17 teeth.

When space limits the diameter of the larger wheel, it may be necessary to select a wider chain with a smaller pitch to obtain a desirable number of teeth in the pinion.

Small roller-chain wheels should be hardened when used on moderate and high-speed drives, very low-speed heavily loaded drives, and when operating under abrasive conditions or when the drive ratio is greater than 4:1. Steel silent chain pinions should be hardened.

For 1:1 and 2:1 ratio drives, wheels of relatively large diameter should be selected. Large diameters assure that the distance between the two spans of chain is great enough to prevent them from striking after slack from normal joint wear has accumulated. This is of particular importance for

drives operating on long fixed centers with the slack span on the chain on top.

Chordal Action. The chordal rise and fall of each chain pitch as it contacts a sprocket tooth is known as chordal action and results in repeated variations in linear chain speed. As shown in Figure 3.2.22, the amount of chordal movement and chain-speed variation becomes progressively smaller as the number of teeth in the pinion is increased. Smoother operation and longer chain life may be obtained by selecting pinions with 21 teeth or more because chain-joint articulation is reduced. Chordal action becomes negligible when a sprocket has 25 teeth or more.

Drive Ratio. Ratios in excess of 7:1 are generally not recommended for roller chains. If greater speed reduction is required, it is desirable and usually more economical to compound two or more drives.

Properly engineered silent chain drives having ratios as great as 12:1 will perform satisfactorily. However, it might be more economical to consider a compound drive where the ratio is 8:1 or larger.

Large reduction drives on minimum wheel centers are more economical if small-pitch, wide chains are being

FIGURE 3.2.22 Chordal action of a roller chain (courtesy of Link-Belt Co.).

FIGURE 3.2.23 Typical roller chain tensioning methods [5].

considered. Small reduction drives on long wheel centers are cheaper when larger pitch, narrow chains are used.

Wheel Centers. To avoid interference, wheel centers must be more than one-half the sum of the wheel outside diameters. Where ratios are 2:1 to 7:1, a center distance equal to the diameter of the large wheel plus one-half the diameter of the small wheel is recommended. Drives so proportioned will have ample chain wrap on the small wheel. A chain wrap of 90° is regarded as an absolute minimum for load-carrying sprocket wheels, and 120° or more of wrap is considered desirable.

Chain Tension. All chain drives should have some means of controlling the chain sag caused by normal joint wear. This is of utmost importance when the drive is subject to shock or pulsating loads or to reversals in direction of rotation. The most common methods taking up chain slack are (1) drive units mounted on adjustable base plat, slide rails, or similar units; these are used extensive in motor-driven applications; and (2) the use of adjustable idlers (Figure 3.2.23) and chain tensioners.

An adjustable idler is recommended for drives having fixed centers, particularly if the line of centers is vertical or near vertical. With such idlers, the required chain tension can be maintained for correct chain and sprocket-wheel contact.

An adjustable idler on relatively long-center drives that are subject to pulsating loads will eliminate whipping or thrashing of the chain. Such whipping action results in additional chain loading and joint wear, thereby reducing chain life. Also, an adjustable idler will provide sufficient chain wrap on the smaller sprocket wheel of large ratio, short-center drives.

Where maintenance service is infrequent, a counterweighted, spring-loaded, or automatic idler adjustment is best suited to promote long chain life. Manually adjusted idlers, if not periodically checked for proper chain tensioning, may become a destructive source in the drive system.

Adjustable-idler sprocket wheels must be securely mounted and should engage the slack or nonload carrying side of the chain. At least three teeth of the idler must be in full engagement with the chain. To take up the slack of accumulative wear of the chain, an idler needs only to be

adjustable for slightly more than two chain pitches. Finally, idler sprocket wheels should have at least 17 teeth.

A hardened-steel or hardwood shoe bearing against the back of the chain is another method of controlling chain tension. The method is satisfactory for small horsepower drives operating on fixed centers at slow or moderate speed with ample lubrication.

Offset couplers may be used to adjust chain tension or chain length when other methods are not feasible. This is done by removing a section of chain having one more pitch than the offset coupler and inserting the coupler in its place.

Drive Types. Variable-speed drives may be selected on a chain-strength basis when operating with infrequent high chain loads such as from a torque converter, variable-speed motor, or multispeed transmission.

Speed-increasing drives should have at least 23 teeth in the smaller, faster running wheel. If possible, the taut span of the chain should be on top.

Vertical center drives require some form of chain tensioning or means for center adjustment to assure satisfactory operation and normal life. This is particularly important when the small wheel is in the lower position.

Fixed center drives should be selected on a conservative basis.

If an adjustable idler is not used, chain elongation may be retarded by using (1) a chain pitch larger than speed and horsepower indicate; (2) a larger service factor, thereby reducing the rate of wear in the chain joint; (3) as many teeth in the small sprocket wheel as the ratio will permit without exceeding 120 teeth in the larger wheel; and (4) good lubrication.

Lubrication. The primary purpose of chain lubrication is to maintain a film of oil between the bearing surfaces in the joints, thus assuring maximum operating efficiency. This clean oil film must be maintained at all load-carrying points where relative motion occurs, that is, between the pin and bushing on the chain, and the chain and wheel sprocket teeth. Table 3.2.11 gives some recommended methods for various speeds.

The method of application is primarily dictated by chain speed and the relative shaft positions. Some recommended methods are given below.

TABLE 3.2.11 Recommended Methods of Chain Lubrication [9]

Chain Pitch, inch	Chain Speed, ft/min		
	Manual or Drip	Oil Bath or Slinger Disc	Oil Stream
0.500	up to 290	up to 2200	over 2200
0.625	240	1930	1930
0.750	210	1740	1740
1.000	170	1480	1480
1.250	145	1300	1300
1.500	125	1170	1170
1.750	110	1080	1080
2.000	100	1000	1000
2.250	90	930	930
2.500	85	880	880
3.000	75	790	790

**FIGURE 3.2.24** Splash lubrication drive arrangements [5].

Manual Lubrication. This method is recommended for small horsepower drives with low chain speeds. Open running chains should not be exposed to abrasive dirt.

Drip-Cup Lubrication. This semiautomatic method is also suitable for small horsepower drives with low chain speeds. Cups should be located so that oil will drop to the center of the lower span at about 4 to 10 drops per minute.

Splash Lubrication. This is the simplest method of lubricating enclosed drives and is highly satisfactory for low and moderate-speed drives. In Figure 3.3.24 are shown a few arrangements for splash lubrication of different types of drives.

Oil-Disk Lubrication. This method is frequently used when a drive is not suitable for splash lubrication. It is highly satisfactory for moderate and semihigh-speed drives. The chain is kept above the oil level, and a circular disk,

**FIGURE 3.2.25** Disk lubrication (courtesy of Link-Belt Co.).

mounted to the lower wheel or shaft, dips into the oil about $\frac{1}{2}$ in. Figure 3.2.25 shows relative shaft positions best suited for oil-disk lubrication.

There must be sufficient disk speed to throw the oil. Figure 3.2.26 indicates the amount of oil delivered at various shaft speeds.

Forced lubrication is recommended for large-horsepower drives, heavily loaded drives, high-speed drives, or where splash and disk lubrication cannot be used. An oil pump—capacity about 1 gal/min—supplies a continuous spray of oil to the inside of the lower span of chain. The circulation of the lubricant aids in the dissipation of heat and results in a well-lubricated, cooler operating device.

Trial Chain Sizes. To aid in the selection of an approximate chain size, Figure 3.2.27 gives chains of various pitches for horsepower from 1 to 300. More precise values for chain capacity can be obtained in the various manufacturers catalogs.

Calculations. For a simple two-sprocket drive, the following guidelines for the initial design may be used [2].

Center Distance.

1. Minimum center distance is limited to the distance at which the two sprockets contact each other, or slightly more than half the sum of the outer diameters of the sprockets (Figure 3.2.28a).
2. Based on experience, a center distance equal to the diameter of the large sprocket plus half the diameter of the small sprocket is a good compromise with regard to angle of wrap, wear, and initial cost (see Figure 3.2.28b). The center distance $C(n)$ is

$$C = D + 0.5d \text{ for } D \gg d \quad (3.2.19)$$

where d is the driven sprocket diameter in inches D is the driven sprocket diameter in inches.

3. With large ratios, the angle of contact becomes smaller and the number of teeth engaged with the chain decreases. For angles less than 120° , θ increasingly becomes a critical factor in the design of chain drives.
4. For maximum life and minimum wear, the center distance should be chosen so as to provide an even number of links in the chain. This arrangement, coupled

FIGURE 3.2.26 Oil delivered to a chain by forward (a) and reverse (b) shafts [5].

FIGURE 3.2.27 Trial-chain chart enables an approximate to be chosen (courtesy of Link-Belt Co.).

with an odd number of teeth in each sprocket, will minimize wear.

5. A short center distance provides a compact design (desirable) and allows for a shorter, less expensive chain. But wear is more rapid on a drive with a short center

distance because the chain has fewer links and each joint must therefore articulate more often.

6. When the center distance exceeds 60 pitches, a long chain will be needed and a manufacturer's representative should be consulted.

FIGURE 3.2.28 Shaft center distance (courtesy of American Chain Association).

Angle of Wrap. The angle of wrap, θ (rad), is approximately

$$\theta = \pi - 2\alpha = \pi - \frac{D - d}{C} \quad (3.2.20)$$

The chain length is generally measured in pitches because it consists of a whole number of links, each being of length p . Chain length is a function of the number of teeth in the two sprockets and the distance between sprocket centers. Thus, the chain length L (pitches) is

$$L = \frac{N + n}{2} + \frac{2C}{p} + \frac{p(N - n)^2}{39.5C} \quad (3.2.21)$$

where n is the number of teeth in the drive sprocket, N is the number of teeth in the driven sprocket, C is the center distance in inches, p is pitch in inches.

Equation 3.2.21 does not often result in an even number of pitches. Thus, the results must be rounded off to a whole number, preferably an even whole number to avoid the specification of an offset link chain.

When several sprockets are used, center distances and chain lengths are best found by means of accurate engineering layouts and calculations.

TABLE 3.2.12 Service Factors for Roller Chain Drives [7]

Type of Driven Load	Type of Input Power		
	Internal Combustion Engine with Hydraulic Drive	Electric Motor or Turbine	Internal Combustion Engine with Mechanical Drive
Smooth	1.0	1.0	1.2
Moderate shock	1.2	1.3	1.4
Heavy shock	1.4	1.5	1.7

Chain Speed. The chain speed v (ft/min) is

$$v = \pi n_s \frac{d}{12} \quad (3.2.22)$$

where n_s is the drive shaft speed in rpm.

3.2.2.6 Design Data

In what follows, the pertinent design data are given for the roller chain, silent chain, and the offset link chain (API chain).

Roller Chain. Table 3.2.12 gives the typical service factor for roller chain drives [7]. Table 3.2.13 gives the basic roller chain design dimensions for ANSI standard roller chains by ANSI chain number [7].

Table 3.2.14a,b gives the horsepower ratings for single-strand roller chain drives. These data are given for each ANSI chain number [7].

Silent Chain. Table 3.2.15 gives the typical service factors for silent chain drives [10]. Tables 3.2.16 and 3.2.17 give the horsepower ratings per inch width for silent chain drives [10].

Drilling Applications. Drilling equipment utilizes chain drives in various applications on the drilling rig itself and its auxiliary equipment. The drives for this type of equipment are called compound drives. Such drive equipment are subject to very severe operational loads. Table 3.2.18 gives the typical service factors for these chain drives [9].

TABLE 3.2.13 Roller Chain Data and Dimensions, in Inches [10]

ANSI Chain no.	ISO Chain no.	Roller				Roller Link Plate		Dimension			Tensile Strength per Strand, lb	Recommended Max Speed r/min

TABLE 3.2.18 Drilling Equipment Service Factor [9]

1	2	3
Typical Service Factor		
Compound drives		
For hoisting service	12 —	16
For pump driving service	16 —	21
Pump final drive	20 —	25
Pump countershaft drive ¹	20 —	25
Drawworks input drive type A ²	9 —	12
Drawworks input drive type B ²	5 —	7
Drawworks transmission drives ³	— —	—
Drawworks low drum drive	2 —	3
Drawworks high drum drive	3.5 —	5
Rotary countershaft drive ⁴	5 —	10
Rotary final drive ⁴	5 —	10
Auxiliary brake drive ⁵	— —	—

¹Pump countershaft drives are frequently very short centered, which reduces the heat liberating surface and for high horsepower they may require supplementary cooling.

²Drawworks input drives are of two types. The type A drive is located between the prime movers and drawworks transmission. The type B drive is located between the transmission and drawworks. Drawworks input drives have smaller service factors than compound drives, based on experience. Among the reasons for this are the fewer horsepower hours logged in a given period and the fact that they are somewhat removed from the influence of engine impulses.

³Service factors on drawworks transmission drives have been omitted from the Recommended Practices for two basic reasons. First, the recommended practices are basically intended for field design guides, and it is not expected that such designs will be made in the field. Second, transmission designs cover a wide range of conditions such as shaft speeds, number of ratios, and methods of obtaining ratios, so that no one family of service factors could be made to apply.

⁴Rotary countershaft and final drives have benefited only slightly from experience because too little has been known about rotary horsepowers through the years.

⁵Auxiliary brake chain drives have been omitted because of the indefinite nature of the load. Each manufacturer has established successful drives, but these are suited to specific conditions which cannot be reduced to simple terms. Most such drives violate the rules of chain speeds and loads and are successful only because of the short duration of use and deviation from calculated loads. It is recommended that the drawworks manufacturer be consulted.

3.3 PUMPS

Section reviewed by T. Wayne Brewster

Pumps are a mechanical device that forces a fluid to move from one position to another. Usually a pump refers to the mechanical means to move incompressible (or nearly incompressible) fluid or liquid. Pumps are our earliest machine and are to this day one of our most numerous mechanical devices.

Pumps are a very essential part of the oil and gas industry. They are used throughout the industry, from drilling operations through to final delivery to the customer.

3.3.1 Classifications

Pumps are classified into two basic classes, displacement and dynamics. Figures 3.3.1/3.3.2 show the subclasses of pumps under each of these basic classes [1–3].

The most widely used pumps in the oil and gas industry are reciprocating displacement pumps (in particular piston plunger type), the rotary displacement pump, and the centrifugal dynamic pump. Only these pumps will be discussed in detail.

The reciprocating and rotary positive displacement pumps primary characteristic is that they have a nearly direct relationship between the motion of the pumping elements and the quantity of liquid pumped. Thus, in positive displacement pumps liquid displacement (or discharge from the device) is theoretically equal to the swept volume of the pumping element. Figure 3.3.3 shows the typical positive displacement plot of discharge rate Q (ft³/s) versus pressure P (lbs/ft²) [3]. The discharge rate remains the same (assuming a constant rate of rotation for the system) regardless of the pressure in the flow. The pressure in the flow is, of course, the result of resistance in the flow system the pump discharges to. If the resistance increases, rotation

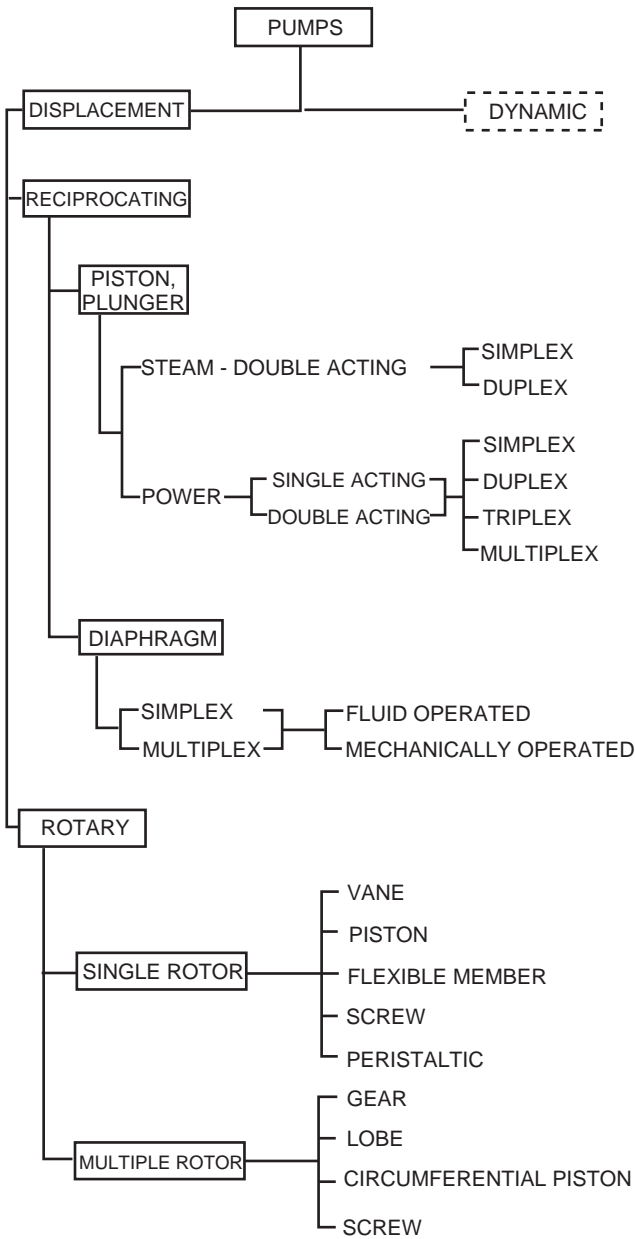

FIGURE 3.3.1 Classification of displacement pumps.

can be maintained and more force applied to each stroke of the pump (i.e., power). This is why the reciprocating piston plunger pump is also called a power pump. In practice, pressure does have some influence on the capacity of these pumps. This is because as the pressure increases, there is some leakage of the seals in the system. This leakage is somewhat proportional to the pressure, particularly beyond some characteristic pressure related to the seals. The difference between theoretical flow and the actual flow of a pump is often referred to as slip. This slip is shown in Figure 3.3.3.

In the dynamic pump, in particular, the centrifugal pump, the discharge rate Q is determined by the resistance

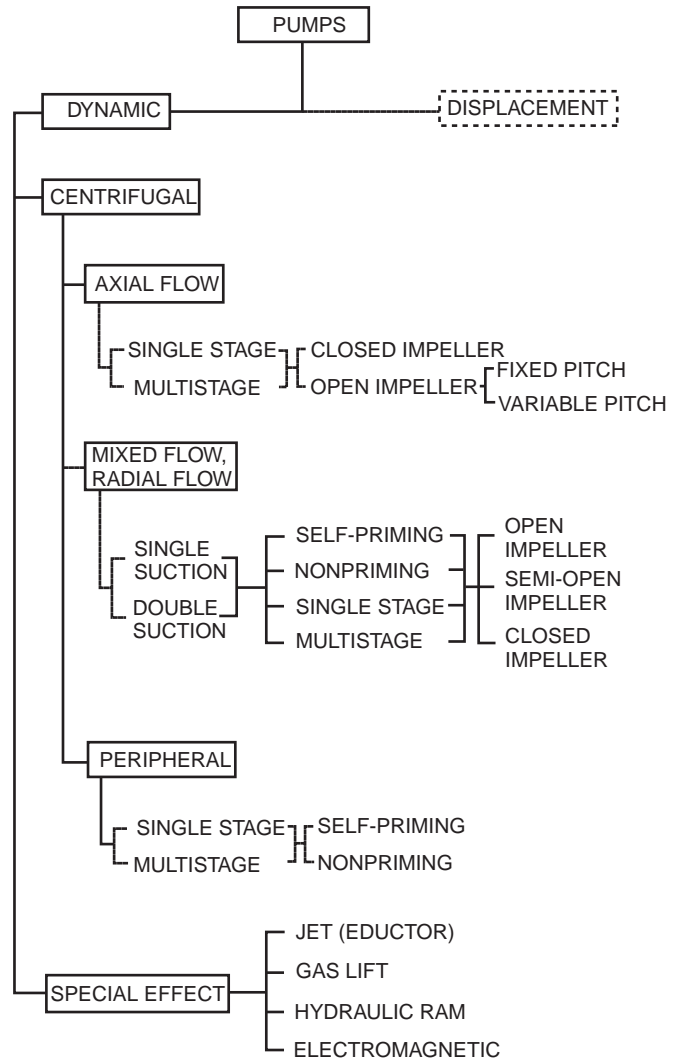

FIGURE 3.3.2 Classification of dynamic pumps [1].

FIGURE 3.3.3 Positive displacement pump [1]

FIGURE 3.3.4 Dynamic (centrifugal) pumps [1].

pressure P in the flow system the pump discharges to (assuming some given speed of the pump). This is illustrated in Figure 3.3.4.

3.3.2 General Calculations

There are several important calculations that are needed to properly evaluate and select the appropriate positive displacement pump [1, 4–7].

The theoretical power P (hp), which is the power actually important to the fluid by the pump, is

$$P = \frac{qp}{1,714} \quad (3.3.1)$$

where q is the discharge rate in gpm and p is the differential pressure in psi (usually the actual gauge discharge pressure).

The total pump power input P_{pi} is the net power delivered to the pump drive shaft by the prime mover system. This is

$$P_{pi} = P + P_{pl} \quad (3.3.2)$$

where P_{pl} is the pump power loss.

The total power input P_{ti} is the net power delivered by the prime mover. This is

$$P_{ti} = P_{pi} + P_{pml} \quad (3.3.3)$$

where P_{pml} is the prime mover loss.

Overall efficiency e_0 is

$$e_0 = \frac{P}{P_{ti}} \quad (3.3.4)$$

usually multiplied by 100 and expressed as a percentage.

Pump efficiency e_p is

$$e_p = \frac{P}{P_{pi}} \quad (3.3.5)$$

(usually expressed as a percentage).

Mechanical efficiency e_m (which usually refers to the efficiency of the prime mover to supply power to the pump) is

$$e_m = \frac{P_{pi}}{P_{ti}} \quad (3.3.6)$$

(usually expressed as a percentage).

3.3.3 Reciprocating Pumps

The piston plunger pump is the simplest form of a positive displacement pump. These pumps can be powered by a variety of prime movers, internal combustion engines, and electric motors (and in some cases, powered by a gas turbine motor). In such applications, the separate pump unit is connected to the prime mover by a power transmission.

The capacity of a pump is determined by the number of plungers or pistons and the size of these elements (bore and stroke). A reciprocating pump is usually designed for a specific volumetric rate capacity and pressure capability. These factors are set by the application. Once the volumetric rate capacity and pressure capability are known, a designer can determine the plunger piston bore and stroke the rotation speed range and the power of the prime mover needed to complete the system.

Reciprocating pumps are fabricated in both horizontal and vertical configurations.

3.3.3.1 Single-Acting Pump

A single-acting pump has only one power (and discharge) stroke for its pistons. Such a pump brings fluid into its chamber through the inlet or suction valve or the piston is drawn backward to open the chamber. To discharge the fluid, the inlet valve is closed and the outlet valve opened as the piston is forced forward to push the fluid from the chamber into the discharge line. The piston motion is accomplished by a rotating crankshaft that is connected to the piston by a piston rod much like an internal combustion piston engine. The rotating crankshaft of the pump is rotated by the rotational power of the prime mover (through a transmission) [7].

The single-action pump is usually available with three, five and even seven pistons. The odd number of pistons allows the pump to be rotationally balanced, and the use of at least three pistons reduces the discharge pulsation of these single-acting pumps. A three piston pump single-action pump is called a triplex pump. A five piston, or seven piston single-acting pump is called a multiplex pump.

3.3.3.2 Double-Acting Pump

Double-acting pumps have two power strokes. As a piston of the pump is pushed forward, the fluid is discharged from

FIGURE 3.3.5 Schematic of valve operation of single and double-acting pumps [7].

the forward chamber into the discharge line (much like a single-action piston). But during this same stroke, the chamber behind the piston (which contains the connecting rod) is being filled via that chamber's inlet valve (Figure 3.3.5). When the forward power stroke is complete and the fluid discharged from the chamber in front of the piston, the chamber behind the piston is filled. The crankshaft continues to rotate, requiring the piston to begin a rearward stroke. During this stroke the fluid behind the piston is forced from its chamber into the discharge line via the outlet valve and the chamber in front of the piston refills via its inlet valve [7].

Double-acting pumps are usually available with one or two pistons.

A one-piston double-action pump is called a *double-acting simplex* (since there are older single-action steam and pneumatic driven simplex pumps).

A two piston double-action pump is called a *duplex* pump.

FIGURE 3.3.6 Simplex (double-acting), duplex (double-acting), triplex (single-acting), pressure-time curves [7].

3.3.3.3 Flow Characteristics

All reciprocating pumps have a pulsating discharge. This is the result of the piston motion as it stops and reverses. At this moment, the flow from that piston theoretically drops to zero. Thus, the discharge curves as a function of time are those illustrated in Figure 3.3.6. By having two or more pistons the pulsation of the discharge from the pump can be smoothed out and the magnitude of the pulsation reduced if the pistons motions are timed for proper dynamic balancing of the pump (Figure 3.3.7). For those pumps that have large pulsations, a cushion change (or accumulator) may be used in the discharge line to reduce or eliminate the pulsations (Figure 3.3.8).

3.3.3.4 Calculations

There are several important calculations that are needed in order to properly evaluate and select the appropriate reciprocating piston pump [1]. These calculations are used in conjunction with Equations 3.3.1–3.3.6.

FIGURE 3.3.7 Example pulsation dampener [7].

FIGURE 3.3.8 Typical power-pump performance (courtesy of Ingersoll-Rand Co.).

The capacity of a reciprocating piston pump, q (in³/min), is

$$q = V_d(1 - S)N \tag{3.3.7}$$

where V_d is the displacement of the pumps piston in in.³, S is the slip fraction, and N is the speed of the pump in rpm.

The displacement V_d (gals) of a single-acting pump is

$$V_d = \frac{nA_pL_s}{231} \tag{3.3.8}$$

where n is the number of pistons, A_p is the cross-sectioned area of the piston in in.², and L_s is the length of the piston stroke in in.

The displacement V_d of a double-acting pump is

$$V_d = \frac{n(2A_p - a)L_s}{231} \tag{3.3.9}$$

where a is the cross-sectioned area of the piston rod in in.².

The pressure p used in Equation 3.3.1 is the differential developed pressure (across the pump inlet and outlet). Since the inlet suction pressure is usually small compared to the discharge pressure, the discharge pressure is used. Thus, this is the application resistance pressure in most cases. Figure 3.3.8 shows a typical reciprocating pump performance.

The slip S is the fraction of suction capacity loss. It consists of the volumetric efficiency loss fraction l_e , the stuffing box loss fraction l_s , and the valve loss fraction l_v . The slip S is

$$S = l_e + l_b + l_v \tag{3.3.10}$$

The volumetric efficiency loss l_e is

$$l_e = 1 - e_v \tag{3.3.11}$$

where e_v is the volumetric efficiency. The volumetric efficiency is the ratio of discharge volume to suction volume and is expressed as a percentage. It is proportional to the ratio r and the developed pressure (Figure 3.3.9). The ratio r is the ratio of internal volume of fluid between valves when the piston is at the top of its back stroke to the piston displacement (Figure 3.3.10). Because volume cannot readily be measured at discharge pressure, it is taken at suction pressure. This will result in a higher e_v due to fluid compressibility which is neglected.

The stuffing box loss l_b is usually negligible.

The valve loss l_v is the loss due to the flow of fluid back through the valve during closing. This is of the order of 0.02 to 0.10 depending on the valve design.

The mechanical efficiency e_m of a power pump at full load of pressure and speed is 0.90 to 0.95. When the pump has a single built in gear as part of the power frame, the mechanical efficiency is 0.80 to 0.95. Table 3.3.1 shows the typical effects of speed and pressure on the mechanical efficiency of a power pump [1].

3.3.4 Rotary Pumps

Another important positive displacement pump is the rotary pump. This type of pump is usually of rather simple construction, having no valves and being lightweight. Such pumps can be constructed to handle small fluid capacities (i.e., less than a gal/min) to very large fluid capacities (i.e., 5,000 gal/min or greater). Rotary pumps are designed to operate at 1,000 psi discharge pressure, but the normal rotary pump design is for pressure of 25 to about 500 psi with mechanical efficiencies of 0.80 to 0.85.

Rotary pumps are classified in two basic groups and several subgroups:

Single-rotor pumps

- vane
- piston
- flexible vane
- screw

Multiple-rotor pumps

- lobe
- gear
- circumferential piston
- screw

These pumps require the maintenance of very close clearances between rubbing surfaces for continual volumetric efficiency. Some of the important pumps are discussed.

In general, rotary pumps with discharge pressure of up to 100 psi are considered low-pressure pumps. Rotary pumps with pressure between 100 and 500 psi are considered moderate-pressure pumps. Pumps with pressure beyond 500 psi are considered to be high-pressure pumps.

FIGURE 3.3.9 Volumetric efficiency (courtesy of Ingersoll-Rand Co.).

FIGURE 3.3.10 Ratio r (courtesy Ingersoll-Rand Co.).

Rotary pumps with volume capacities up to 50 gal/min are considered to be small-volume capacity pumps. Pumps with volume capacities from 50 to 500 gal/min are moderate-volume capacity pumps. And pumps with volume capacities beyond 500 gal/min are large-volume capacity pumps.

3.3.4.1 Gear Pumps

Gear pumps are rotary pumps in which two or more gears mesh to provide the pumping action. Usually one of the gears is capable of driving the other(s). The simplest form of this type of rotary pump is the gerotor pump. Figure 3.3.11 shows a typical gerotor pump configuration. These pumps are often used for small-volume capacity applications where space is quite limited [4]. Such gear pumps can be used on a rotating shaft such as a crankshaft to provide oil lubrication of critical moving machine parts.

Figures 3.3.12 shows an external gear pump. This is an example of a double- (multiple) rotor pump. Such a gear

TABLE 3.3.1 Effects of Speed and Pressure on Mechanical Efficiency [1, 7, 8]

Constant Speed	
% full-load developed pressure	Mechanical efficiency
20	82

50	92.5
73	92.5
100	92.5

pump has a drive gear and a driven gear that are encased in housing with minimum clearance between the housing and the tips of the gears. The

simplest type of this pump uses spur gears. The large number of gear teeth in contact with the casing minimizes

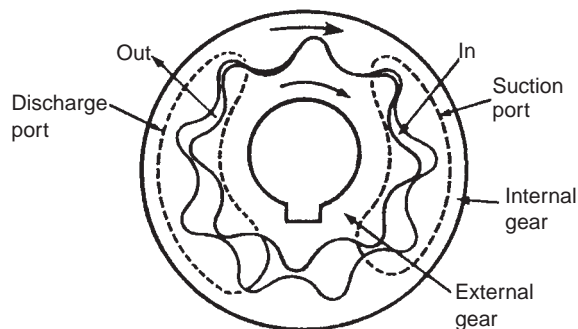

FIGURE 3.3.11 Gerotor type pump [1].

FIGURE 3.3.12 Gear pump (double rotor type) [1].

leakage around the periphery. The spur-gear type of pump is limited by its characteristics of trapping liquid. This occurs on the discharge side at the point of gear intermesh. This results in a noisy operation and low mechanical efficiency, particularly at high rotary speeds. Gear pumps can also be constructed with single or double-helical gears with 15–30° angles (0.26–0.52 rad). Such a helical (or even a herringbone) gear construction will nearly eliminate the problems of liquid trapping but increase the leakage.

One-Tooth Difference. These pumps are commonly known as gerotor pumps (see Figure 3.3.11). An outlet gear is mounted eccentrically with the outlet casing actuated by an internal gear rotating under the action of the central shaft (keyway connected). The internal gear has one less tooth than the outside ring gear. There is clearance between the outside impeller gear and its casing and the inner gear fixed to the shaft. As the shaft rotates, the inner gear forces the outer gear to progress around the shaft at a rate slower than the shaft rotation. The liquid trapped between the two gears is forced from the space between the two gears as the rotation takes place.

Two-Teeth Difference. In this type of pump an abutment on one side plate is used to fill the clearance between the external and internal gear. This construction reduces

leakage but involves the use of an overhung internal gear. Such a gear arrangement limits the application of these pumps to small and moderate-volume capacity pumps.

3.3.4.2 Circumferential Piston

Figure 3.3.13 shows the typical cross-section of this type of pump. In this pump liquid is pumped by the action of the rotation of the two eccentrically located piston surfaces. There is no contact between the piston surfaces.

3.3.4.3 Vane Pump

This example of a single-rotor type pump makes use of an eccentric shaft on which are mounted several sliding vanes (Figure 3.3.14). The vanes are forced against the bore of the housing by springs and the centrifugal force of the rotor rotation. The vanes are usually made of materials that will not damage the surface of the bore (e.g., bronze and bakelite). This type of pump is useful for small and moderate-volume capacities and low pressure. This is due to the rather low speeds such pumps must be operated at. High speeds result in rapid wear of the vanes.

3.3.4.4 Screw Pumps

Screw pumps are available in single or double-rotor (multiple) types.

Figure 3.3.15 shows the cross-section of the typical single-rotor screw pump. In this pump there is a single helical threaded rotating element. As the screw rotates

FIGURE 3.3.13 Circumferential-piston pump (double rotor) [1].

FIGURE 3.3.14 Sliding vane pump (single rotor) [1].

FIGURE 3.3.15 Single screen pump (single rotor) [1].

FIGURE 3.3.16 Two-screw pump (double rotor) [1].

the liquid progresses axially down the pump. This pump produces continuous flow with relatively little pulsation or agitation of the fluid. Screw pumps of this type are quiet and efficient. They are available with high-speed, high-pressure, and large-volume capacities.

Figure 3.3.16 shows the cross-section of the typical multiple-rotor screw pump. This screw pump incorporates right-hand and left-hand intermeshing helices on parallel shafts with timing gears. Such pumps are available with high-speed, high-pressure, and large-volume capacities.

For all screw pumps, flow is continuous.

3.3.4.5 Calculations

There are several important calculations which are needed to properly evaluate and select the appropriate rotary pump [1]. These calculations are used in conjunction with Equations 3.3.1–3.3.6.

The capacity of a rotary pump operating with zero slip is called displacement capacity, q_d (gpm). Thus, the actual capacity of a rotary pump q (gpm) is

$$q = q_d - q_1 \quad (3.3.12)$$

or

$$q = \frac{V_d N}{231} - q_1 \quad (3.3.13)$$

where V_d is the pump displacement per revolution in in.³, N is the pump speed in rpm, and q_1 is the pump loss in gpm.

Pump horsepower P is the power actually imparted to the fluid by the rotary pump in Equation 3.3.1.

The definitions for the various power terms and efficiencies for the rotary pumps are the same as those discussed above for the reciprocating pump; namely, Equations 3.3.2–3.3.6.

The volumetric efficiency e_v for the rotary pump is

$$e_v = \frac{q}{q_d} \quad (3.3.14)$$

or

$$e_v = 1 - \frac{231q_e}{V_d N} \quad (3.3.15)$$

(usually expressed as a percentage).

3.3.5 Centrifugal Pumps

The centrifugal pump is the most important pump of the dynamic class of pumps for the oil and gas industry. Other pumps in this class are covered in other references [1,4].

In its simplest form, a centrifugal pump consists of a rotating impeller (with radial vanes) rotating at a rather high speed. The rotating impeller is encased in a rigid housing that directs the liquid within the pump (see Figure 3.3.17) [1]. Liquid is supplied to the inlet that feeds the liquid to the center section of the rotating impeller. The rotational motion of the impeller forces the liquid, via the centrifugal forces, to move radially outward with the aid of the stationary diffuser. The rigid housing around the impeller guides the high-velocity fluid around the inside of the housing and out of the outlet of the pump.

The capacity of this type of pump depends on the pressure head against which the pump must act (see Figure 3.3.4).

When the liquid within the impeller is forced radially outward to the diffuser, a major portion of the velocity energy is converted into pressure energy by the stationary diffuser vanes (see Figure 3.3.17). This can also

FIGURE 3.3.17 Typical diffuser-type pump [1].

FIGURE 3.3.18 Typical volute-type pump [1].

be accomplished by means of a volute, which is a part of the casing design (Figure 3.3.18) [1].

3.3.5.1 Centrifugal Pump Classifications

Centrifugal pumps with diffusion vanes are called *diffusion pumps* or, more recently, *vertical turbine pumps*. Those pumps with volute casings are called *volute pumps*.

Centrifugal pumps can also be classified by the design of the impeller. Centrifugal pumps may have radial-flow impellers, axial-flow impellers, and mixed-flow impellers (both radial-flow and axial-flow).

Pump impellers are further classified as to the inlet flow arrangement such as single suction (which has a single inlet on one side) and double suction (which has a double inlet on each side of the impeller).

Impellers can be further classified with regard to their physical design: a closed impeller has shrouds or sidewalls enclosing the fluid flow, an open impeller has no shrouds or sidewalls, and a semiopen impeller is a mix of the closed and open design.

Another centrifugal pump classification is whether the pump is a single-stage pump (the pressure head is developed by a single impeller) or a multistage pump (the pressure head is developed by two or more impellers).

Centrifugal pumps can be further classified by physical design or axially split, radially split and whether the axis of rotation of the impeller(s) is vertical or horizontal. Horizontal pumps can be classified according as end suction, side suction, bottom suction, and top suction.

In applications, centrifugal pumps can be supplied with liquid via piping, or the pump may be submerged. Vertical pumps are called dry-pit or wet-pit types. The wet-pit pump (submerged) discharges up through a pipe system to some point above the pump.

3.3.5.2 Calculations

There are important calculations that are needed to properly evaluate and select the appropriate centrifugal pump [6].

There are several similar relationships for centrifugal pumps that can be used if the effects of viscosity of the pumped fluid can be neglected. These relate the operating performance of any centrifugal pump for one set of operating conditions to the pump at another set of operating conditions, say conditions, and conditions 2.

The volumetric flow rate q (gpm) is related to rate q_2 (gpm) and the impeller speeds N_1 (rpm) and N_2 (rpm) by

$$\frac{q_1}{q_2} = \frac{N_1}{N_2} \tag{3.3.16}$$

The pressure head H_1 (ft) related to the head H_2 (ft) and impeller speeds N_1 and N_2 by

$$\frac{H_1}{H_2} = \left(\frac{N_1}{N_2}\right)^{1/2} \tag{3.3.17}$$

The pump input power P_1 (Lp) is related to the pump input power P_2 (hp) and impeller speed N_1 and N_2 by

$$\frac{P_1}{P_2} = \left(\frac{N_1}{N_2}\right)^3 \quad (3.3.18)$$

The centrifugal pump specific speed N_{ds} (rpm) (or discharge specific speed) is

$$N_{ds} = \frac{Nq^{0.5}}{H^{0.75}} \quad (3.3.22)$$

For a constant impeller speed, the relationship between q_1 , q_2 , and impeller diameter D_1 (ft) and D_2 (ft) is

$$\frac{q_1}{q_2} = \frac{D_1}{D_2} \quad (3.3.19)$$

The centrifugal pump suction specific speed N_{ss} (rpm) is

$$N_{ss} = \frac{Nq^{0.5}}{H_{nps}^{0.75}} \quad (3.3.23)$$

The heads are related by

$$\frac{H_1}{H_2} = \left(\frac{D_1}{D_2}\right)^2 \quad (3.3.20)$$

where H_{nps} is the net positive suction head (ft).

Figure 3.3.19 gives the upper limits of specific speeds of single-stage, single- and double-suction centrifugal pumps handling clear water at 85°F at sea level [8].

and the power related by

$$\frac{P_1}{P_2} = \left(\frac{D_1}{D_2}\right)^3 \quad (3.3.21)$$

Figure 3.3.20 gives the upper limits of specific speeds of single-suction mixed-flow and axial-flow centrifugal pumps handling clear water at 85°F at sea level [8].

Figure 3.3.21 gives the approximate relative impeller shapes and efficiency variations for various specific speeds of centrifugal pumps.

TABLE 3.3.2 Pump Types Listed by Specific Speed

Specific speed range	Type of pump
Below 2,000	Volute, diffuser
2,000–5,000	Turbine
4,000–10,000	Mixed-flow
9,000–15,000	Axial-flow

TABLE 3.3.3 Suction Specific-Speed Ratings

Single-suction pump	Double-suction pump	Rating
Below 11,000	Above 14,000	Excellent
9,000–11,000	11,000–14,000	Good
7,000–9,000	9,000–11,000	Average
5,000–7,000	7,000–9,000	Poor
Below 5,000	Below 7,000	Very poor

Table 3.3.2 gives the specific speeds for various centrifugal pump types. Table 3.3.3 gives the suction specific speed ratings for single-suction and double-suction centrifugal pumps. These tables are for pumps handling clear water.

3.4 COMPRESSORS

Section reviewed by T. Wayne Brewster

Compressors of various designs and manufacturers are used in many operations throughout the oil and gas industry.

Compressors are used in some drilling operations, in many production operations, and extensively used in surface transportation of oil and gas via pipelines.

Air or gas compressors are very similar in design and operation to liquid pumps discussed earlier. The air and gas compressor is a mover of compressed fluids; the pumps are movers of basically incompressible fluids (i.e., liquids).

3.4.1 Classifications

In much the same manner as pumps, compressors are classified as one of two general classes: positive displacement or dynamic (Figure 3.4.1) [1]. These two general classes of compressors are the same as that for pumps. The positive displacement class of compressors is an intermittent flow device, which is usually a reciprocating piston compressor or a rotary compressor (e.g., sliding vane, screws). The dynamic class of compressor is a continuous flow device, which is usually an axial-flow or centrifugal compressor (or mix of the two).

Each of the two general classes of compressors and their subclass types have certain advantages and disadvantages regarding their respective volumetric flow capabilities and the pressure ratios they can obtain. Figure 3.4.2 shows the typical application range in volumetric flow rate (actual cfm) and pressure ratio several of the most important compressor types can obtain [1].

In general, positive displacement compressors are best suited for handling high-pressure ratios (i.e., about 200), but with only moderate volumetric flow rates (i.e., up to about 10^3 actual cfm). Dynamic compressors are best suited for handling large volumetric flow rates (i.e., up to about 10^6 actual cfm), but with only moderate pressure ratios (i.e., about 20).

This is not the complete view of these two compressor classes. Figure 3.4.3 gives the general performance curves for various positive displacement and dynamic compressors. The positive displacement compressors, particularly the multistage reciprocating compressors, are very insensitive to pressure ratio changes. These compressors will produce their rated volumetric flow rate even when the pressure ratio approaches the design limit of the machine. This is less so for the rotary compressor. The dynamic compressors, however, are quite sensitive to pressure ratio changes. The volumetric rate of flow will change drastically with changes in the pressure ratio around the pressure ratio the machine has been designed.

Thus, the positive displacement compressors are normally applied to industrial operations where the volumetric flow rate is critical and the pressure ratio is a variable. The dynamic compressors are generally applied to industrial operations where both the volumetric flow rate and pressure ratio requirements are relatively constant.

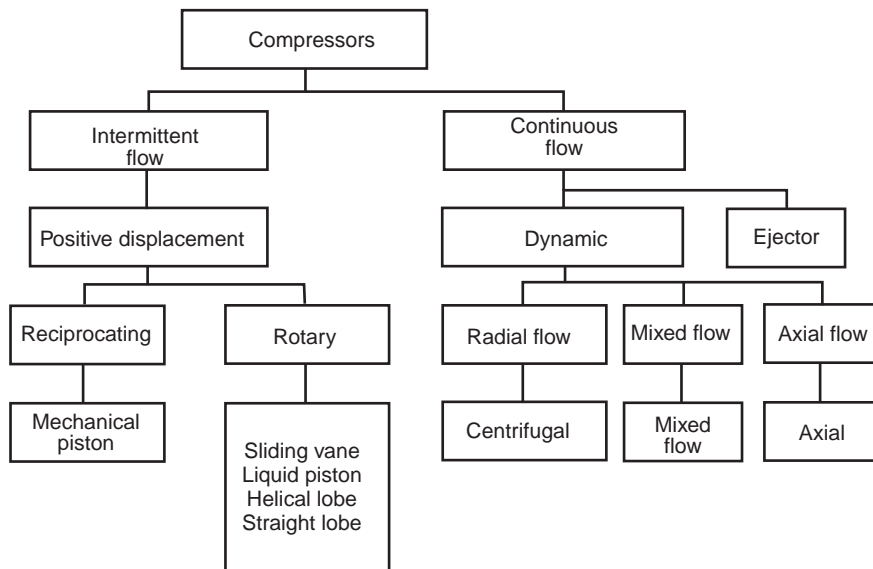

FIGURE 3.4.1 Classification of compressor [1].

FIGURE 3.4.2 Typical application ranges of various compressor types [1].

In general, only the reciprocating compressor allows for reliable flexibility in applying variable volumetric flow rate and variable pressure ratio in an operation. The rotary compressor does not allow for variation in either (except that of pressure through the decompression of the air or gas if the system back pressure is below the design pressure of the machine). The dynamic compressors are designed for specific volumetric flow rates and pressure ratios and are not very useful when these design limits are altered. The positive displacement class of compressors is the most useful group for the oil and gas exploration, drilling and completion and production industry. This section will focus on this class of compressors.

3.4.2 Standard Units

In the United States, the unit of air or any gas if referenced to the standard cubic foot of dry air. The API Mechanical Equipment Standards standard atmospheric conditions for dry air is fixed at a temperature of 60°F (which is 459.67 + 60 = 519.67°R) and a pressure of 14.696 psia (760 mm, or 29.92 in. Hg) [2]. The equation of state for the perfect gas can be written as

$$\frac{P}{\gamma} = \frac{R_u T}{m_w} \tag{3.4.1}$$

FIGURE 3.4.3 General performance curve for various compressor types [1].

where P is the pressure in lb/ft^2 absolute, γ is the specific weight in lb/ft^3 , R_u is the universal gas constant in $1,545.4 \text{ ft}\cdot\text{lb}/\text{lb}\cdot\text{mole}\cdot^\circ\text{R}$, T is the temperature in $^\circ\text{R}$, and m_w is the molecular weight of the gas in $\text{lb}/\text{lb}\cdot\text{mole}$.

Thus, the specific weight γ or the weight of 1 ft^3 of dry air will be

$$\gamma = \frac{14.696 (144) (28.96)}{1,545.4 (519.67)} = 0.0763 \text{ lb}/\text{ft}^3$$

where for dry air $m_w = 28.96 \text{ lb}/\text{lb}\cdot\text{mole}$. Thus, a dry cubic foot of air at the API Mechanical Equipment Standards standard atmosphere condition weighs 0.0763 lb and has a specific gravity of 1.000 .

An alternate calculation method for obtaining the properties of gas is an expression commonly known as the gas engineering equation:

$$\frac{P}{\gamma} = \frac{RT}{S_g} \quad (3.4.2)$$

where P is the pressure in lb/ft^2 absolute (or in absolute N/m^2), γ is the specific weight in lb/ft^3 (or in N/m^3), R is the engineering gas constant $53.36 \text{ lb}\cdot\text{ft}/\text{lb}\cdot^\circ\text{R}$ (or $29.28 \text{ N}\cdot\text{m}/\text{N}\cdot\text{K}$), T is the temperature in $^\circ\text{R}$ (or in $^\circ\text{K}$), and S_g is the specific gravity of the gas (for API standard conditions air $S_g = 1.0$).

There are other organizations within the United States and regions around the world that have established different standards. The ASME standard atmosphere is at a temperature of 68°F , a pressure of 14.7 psia , and a relative humidity of 36% . The British use a standard atmosphere with a temperature of 60°F and a pressure of 30.00 in.Hg . The Europeans use a standard atmosphere with a temperature of 15°C (59°F) and pressure of 750 mmHg (14.5 psia) [3,4].

When selecting and sizing compressors, care should be taken in determining which standard has been used to rate a compressor under consideration, particularly if the compressor has been produced abroad. All further discussions in this section will utilize only the API Mechanical Equipment Standards standard atmosphere.

Compressors are rated as to their maximum input volumetric flow rate, and their maximum pressure output. These ratings are usually specified as *standard cubic feet per minute* (scfm) and psig (or standard cubic meters per minute and N/m^2 gage). The scfm of volumetric flow rate refers to the compressor intake. The pressure rating refers to the output pressure capability.

3.4.3 General Calculations

There are several important calculations needed to properly evaluate and select the appropriate compressors [1,3,4].

Compressors have nearly equal ratios of compression in each of the stages. Thus, the total pressure ratio r_t across the compressor (i.e., input pressure to output pressure prior to after cooling) is

$$r_t = \frac{P_{\text{out}}}{P_{\text{in}}} \quad (3.4.3)$$

where p_{out} is the output pressure in psia, p_{in} is the input pressure in psia, and the pressure ratio for each stage r_s is

$$r_s = r_t^{1/n} \quad (3.4.4)$$

where n is the number of equal compression stages in the compressor.

Thus, for a four-stage compressor, if $p_1 = p_{\text{in}}$, then p_2 would be the pressure exiting the first stage compression.

The pressure p_2 would be

$$p_2 = r_s p_1 \quad (3.4.5)$$

The pressure entering the second stage would be p_2 and the pressure exiting would be p_3 , which is

$$p_3 = r_s p_2 \quad (3.4.6)$$

or

$$p_3 = r_s^2 p_1 \quad (3.4.7)$$

The pressure entering the third stage would be p_3 and the pressure exiting would be p_4 , which is

$$p_4 = r_s p_3 \quad (3.4.8)$$

or

$$p_4 = r_s^3 p_1 \quad (3.4.9)$$

The pressure entering the fourth stage would be p_4 and the pressure exiting would be p_5 , which is

$$p_5 = r_s p_4 \quad (3.4.10)$$

or

$$p_5 = r_s^4 p_1 \quad (3.4.11)$$

The above pressure calculations assume intercooling between the first and second stages of compression, between the second and third stages of compression, and between the third and fourth stages of compression. The intercooling system in a multistage compressor ideally reduced the temperature of the gas leaving first stage (or the other stages) to ambient temperature, or at least the input temperature. This cooling of the gas moving from one stage to another is necessary for an efficient and economical design of the compressors. Further, if the gas moving to progressive stages were to get too hot, the machine could be severely damaged. This intercooling is normally accomplished using either a water-jacket, oil-jacket, or air-cooled finned pipes between the stages.

Assuming efficient intercooling between stages, then $T_1 = T_2 = T_3$. The temperature T_4 is

$$T_4 = T_1 \frac{P_4^{\frac{k-1}{k}}}{P_3} \quad (3.4.12)$$

where k is ratio of specific heats.

Flow rate is often given in field units (e.g., g(cfm)). These field units are usually converted to consistent units Q (ft³/s) (or in m³/s).

The temperature T_4 at the exit of the compressor is cooled with an adjustable cooling system called an after-cooler. Such a system is useful in adjusting the output air for specific application purposes. The after cooling process is assumed to be a constant pressure process. The volumetric flow rate from the fourth stage is Q_4 (ft³/s), then the volumetric flow rate after the flow or passed through the after cooler Q'_4 (ft³/s) will be

$$Q'_4 = Q_4 \frac{T_4}{T'_4} \quad (3.4.13)$$

where T'_4 is the final temperature the after-cooler is to cool the output (°R).

If the compressor has a capability to compress a volumetric flow rate of Q_{in} (ft³/s) then for the multistage compressor

$$Q_1 = Q_{in} \quad (3.4.14)$$

This compressor design capability is usually stated in scfm, which means that this is the capability of the compressor when at a sea level location. If the compressor is moved to a higher elevation, then the compressor will have to be derated and the scfm capability of the machine reduced, or the actual cfm term used to describe capability of the compressor. This derating can be carried using [Table 3.4.1](#).

If a compressor is rated as having a volumetric flow capability of q_{in} (scfm) and is to be used at surface location of 6,000 ft, then the compressor still has the capability of its rated volumetric flow rate, but it is now written as q_{in} (actual cfm). Thus the actual weight rate of flow through the compressor w (lb/s), will be (see [Table 3.4.1](#))

$$\dot{w} = \frac{0.0639q_{in}}{60} \quad (3.4.15)$$

TABLE 3.4.1 Atmosphere at Elevation (Mid-Latitudes) above Sea Level

Surface Location Above Sea Level (ft)	Pressure (psi)	Temperature (°F)	Specific Weight (lb/ft ³)
0	14.696	60.00	0.0763
2,000	13.662	51.87	0.0721
4,000	12.685	44.74	0.0679
6,000	11.769	37.60	0.0639
8,000	10.911	30.47	0.0601
10,000	10.108	23.36	0.0565

The equivalent derated standard volumetric flow rate $q_{in dr}$ (scfm) is

$$q_{in dr} = \frac{\dot{w}}{0.0763} \quad (60) \quad (3.4.16)$$

The theoretical power \dot{W}_s (hp), which is actual power imparted to the gas by the multistage compressor shaft, is approximated as

$$\dot{W}_s = \frac{n_s k}{k-1} \frac{\dot{w}_g}{550} \left(\frac{RT_{in}}{S_g} \right) \left[r_t^{\frac{k-1}{n_s k}} - 1 \right] \quad (3.4.17)$$

where T_{in} is the actual average temperature of the input air (or gas) ($^{\circ}R$).

Mechanical efficiency e_m (which usually refers to the efficiency of the prime mover to supply power to the compressor) is

$$e_m = \frac{\dot{W}_s}{\dot{W}_{as}} \quad (3.4.18)$$

where \dot{W}_{as} (hp) is the actual shaft power required.

For the SI system, the theoretical power W_s (watts), is approximated by

$$\dot{W}_s = \frac{n_s k}{k-1} \dot{w}_g \left(\frac{RT_{in}}{S_g} \right) \left[r_t^{\frac{k-1}{n_s k}} - 1 \right] \quad (3.4.19)$$

In the preceding equation,

$$r_t = \frac{P_{out}}{P_{in}}$$

and pressure is in the units of N/m^2 absolute.

Mechanical efficiency, e_m , is

$$e_m = \frac{\dot{W}_s}{\dot{W}_{as}} \quad (3.4.20)$$

where W_{as} (watts) is the actual shaft power required.

3.4.4 Reciprocating Compressors

The reciprocating compressor is the simplest example of the positive displacement class of compressors. This type of compressor is also the oldest. Like reciprocating pumps, reciprocating compressors can also be either single acting or double acting. Single-acting compressors are usually of the trunk type (Figure 3.4.4). Double-acting compressors are usually of the crosshead type (Figure 3.4.5) [4].

Reciprocating compressors are available in both lubricated and nonlubricated versions. The lubricated versions provide lubrication for the piston, moving pistons either through an oil lubricated intake air or gas stream, or via an oil pump and injection of oil to the piston sleeve. There are some applications where oil must be completely omitted from the compressed air or gas exiting the machine. For such applications where a reciprocating piston type of compressor is required, there are nonlubricated compressors. These compressors have piston rings and wear bands around the periphery of each piston. These wear bands are made of special wear-resistant dry lubricating materials such as polytetrafluorethylene. Trunk type nonlubricated compressors have dry crankcases with permanently lubricated bearings. Crosshead type compressors usually have lengthened piston rods to ensure that no oil wet parts enter the compression space [4,5].

Most reciprocating compressors have inlet and outlet valves (on the piston heads) that are actuated by a pressure difference. These are called *self-acting valves*. There are

FIGURE 3.4.4 Single-acting (trunk-type) reciprocating piston compressor [1].

FIGURE 3.4.5 Double-acting (crosshead-type) reciprocating piston compressor [5].

some larger multistage reciprocating piston compressors that do have camshaft-controlled valves with rotary slide valves.

The main advantage of the multistage reciprocating piston compressor is that there is nearly total positive control of the volumetric flow rate which can be put through the machine and the pressure of the output. Many reciprocating piston compressors allow for the rotation to be adjusted, thus, changing the throughput of air or gas. Also, providing adequate power from the prime mover, reciprocating piston compressors will automatically adjust to back pressure changes and maintain proper rotation speed. These compressors are capable of extremely high output pressure (see Figure 3.4.1).

The main disadvantages to multistage reciprocating piston compressors is that they cannot be practically constructed in machines capable of volumetric flow rates much beyond 1,000 actual cfm. Also, the higher-capacity compressors are rather large and bulky and generally require more maintenance than similar capacity rotary compressors.

In a compressor, like a liquid pump, the real volume flow rate is smaller than the displacement volume. This is due to several factors:

- pressure drop on the suction side
- heating up of the intake air
- internal and external leakage
- expansion of the gas trapped in the clearance volume (reciprocating piston compressors only)

The first three factors are present in compressors, but they are small and on the whole can be neglected. The clearance volume problem, however, is unique to reciprocating piston compressors. The volumetric efficiency e_v estimates the effect of clearance. The volumetric efficiency can be approximated as

$$e_v = 0.96 \left[1 - \epsilon \left(r_t^{1/k} - 1 \right) \right] \quad (3.4.21)$$

FIGURE 3.4.6 Volumetric efficiency for reciprocating piston compressors (with clearance) [4].

where $\epsilon = 0.04-0.12$. Figure 3.4.6 gives values of the term in the brackets for various values of ϵ and the r_t .

For a reciprocating piston compressor, Equation 3.4.18 becomes

$$\dot{W}_{as} = \frac{\dot{W}_s}{e_m e_v} \quad (3.4.22)$$

3.4.5 Rotary Compressors

Another important positive displacement compressor is the rotary compressor. This type of compressor is usually of rather simple construction, having no valves and being lightweight. These compressors are constructed to handle volumetric flow rates up to around 2,000 actual cfm and pressure ratios up to around 15 (Figure 3.4.2). Rotary

compressors are available in a variety of designs. The most widely used rotary compressors are sliding vane, rotary screw, rotary lobe, and liquid-piston.

The most important characteristic of this type of compressors is that all have a fixed built-in pressure compression ratio for each stage of compression (as well as a fixed built-in volume displacement) [4]. Thus, at a given rate of rotational speed provided by the prime mover, there will be a predetermined volumetric flow rate through the compressor, and the pressure exiting the machine at the outlet will be equal to the design pressure ratio times the inlet pressure.

If the back pressure on the outlet side of the compressor is below the fixed output pressure, the compressed gas will simply expand in an expansion tank or in the initial portion of the pipeline attached to the outlet side of the compressor. Figure 3.4.7 shows the pressure versus volume plot for a typical rotary compressor operating against a back pressure below the design pressure of the compressor.

If the back pressure on the outlet side of the compressor is equal to the fixed output pressure, then there is no expansion of the output gas in the initial portion of the expansion tank or the initial portion of the pipeline.

Figure 3.4.8 shows the pressure versus volume plot for a typical rotary compressor operating against a back pressure equal to the design's pressure of the compressor.

If the back pressure in the outlet side of the compressor is above the fixed output pressure, then the compressor must match this higher pressure at the outlet. In so doing the compressor cannot expel the compressed volume within the compressor efficiently. Thus, the fixed volumetric flow rate (at a given rotation speed) will be reduced from what it

FIGURE 3.4.7 Rotary compressor with back pressure less than fixed pressure output [4].

FIGURE 3.4.8 Rotary compressor with back pressure equal to fixed pressure output [4].

FIGURE 3.4.9 Rotary compressor with back pressure greater than fixed pressure output.

would be if the back pressure were equal to or less than the fixed output pressure. Figure 3.4.9 shows the pressure versus volume plot for a typical rotary compressor operating against a back pressure greater than the design pressure of the compressor.

Nearly all rotary compressors can be designed with multiple stages. Such multistage compressors are designed with nearly equal compression ratios for each stage. Thus, since the volumetric flow rate (in actual cfm) is smaller from one stage to the next, the volume displacement of each stage is progressively smaller.

3.4.5.1 Sliding Vane Compressor

The typical sliding vane compressor stage is a rotating cylinder located eccentrically in the bore of a cylindrical housing (Figure 3.4.10). The vanes are in slots in the rotating cylinder, and are allowed to move in and out of these slots to adjust to the changing clearance between the outside surface of the rotating cylinder and the inside bore surface of the housing. The vanes are always in contact with the inside bore due to either air pressure under the vane, or spring force under the vane. The top of the vanes slide

FIGURE 3.4.10 Sliding vane compressor [4].

over the inside surface of the bore of the housing as the inside cylinder rotates. Gas is brought into the compression stage through the inlet suction port. The gas is then trapped between the vanes, and as the inside cylinder rotates the gas is compressed to a smaller volume as the clearance is reduced. When the clearance is the smallest, the gas has rotated to the outlet port. The compressed gas is discharged to the pipeline system connected to the outlet side of the compressor. As each set of vanes reaches the outlet port, the gas trapped between the vanes is discharged. The clearance between the rotating cylinder and the housing is fixed, and thus the pressure ratio of compression for the stage is fixed, or built-in. The geometry (e.g., cylinder length, diameter) of the inside of each compressor stage determines the displacement volume and compression ratio of the compressor.

The principal seals within the sliding vane compressor are provided by the interface between the end of the vane and the inside surface of the cylindrical housing. The sliding vanes must be made of a material that will not damage the inside surface of the housing. Therefore, most vane material is phenolic resin-impregnated laminated fabrics (such as asbestos or cotton cloth). Also, some metals other than one that would gall with the housing can be used such as aluminum. Usually, vane compressors utilize oil lubricants in the compression cavity to allow for smooth action of the sliding vanes against the inside of the housing. There are, however, some sliding vane compressors that may be operated oil-free. These utilize bronze, or carbon/graphite vanes [4].

The volumetric flow rate for a sliding vane compression stage q_s (ft³/min) is approximately

$$q_s = 2al(d_2 - mt)N \quad (3.4.23)$$

where a is the eccentricity in ft, l is the length of the cylinder in ft, d_1 is the outer diameter of the rotary cylinder in ft, d_2 is the inside diameter of the cylindrical housing in ft, t is the vane thickness in ft, m is the number of vanes, and N is the speed of the rotating cylinder in rpm.

The eccentricity a is

$$a = \frac{d_2 - d_1}{2} \quad (3.4.24)$$

Some typical values of a vane compressor stage geometry are $d_1/d_2 = 0.88$, $a = 0.06d_2$, and $l/d_2 = 2.00$ to 3.00. Typical vane up speed usually does not exceed 50 ft/s.

There is no clearance in a rotary compressor. However, there is leakage of air within the internal seal system and around the vanes. Thus, the typical volumetric efficiency for the sliding vane compression is of the order of 0.82 to 0.90. The heavier the gas, the greater the volumetric efficiency. The higher the pressure ratio through the stage, the lower the volumetric efficiency.

3.4.5.2 Rotary Screw Compressor

The typical rotary screw compressor stage is made up of two rotating shafts, or screws. One is a female rotor and the other a male rotor. These two rotating components turn counter to one another (counterrotating). The two rotating elements are designed so that as they rotate opposite to one another; their respective helix forms intermesh (Figure 3.4.11). As will all

FIGURE 3.4.11 Screw compressor working principle [5].

rotary compressors, there are no valves. The gas is sucked into the inlet port and is squeezed between the male and female portion of the rotating intermeshing screw elements and their housing. The compression ratio of the stage and its volumetric flow rate are determined by the geometry of the two rotating screw elements and the speed at which they are rotated.

Screw compressors operate at rather high speeds. Thus, they are rather high volumetric flow rate compressors with relatively small exterior dimensions.

Most rotary screw compressors use lubricating oil within the compression space. This oil is injected into the compression space and recovered, cooled, and recirculated. The lubricating oil has several functions

- seal the internal clearances
- cool the gas (usually air) during compression
- lubricate the rotors
- eliminate the need for timing gears

There are versions of the rotary screw compressor that utilize water injection (rather than oil). The water accomplishes the same purposes as the oil, but the air delivered in these machines is oil-free.

Some screw compressors have been designed to operate with an entirely oil-free compression space. Since the rotating elements of the compressor need not touch each other or the housing, lubrication can be eliminated. However, such rotary screw compressor designs require timing gears. These machines can deliver totally oil-free, water-free dry air (or gas).

The screw compressor can be staged. Often screw compressors are utilized in three- or four-stage versions.

Detailed calculations regarding the design of the rotary screw compressor are beyond the scope of this handbook. Additional details can be found in other references [4-7].

3.4.5.3 Rotary Lobe Compressor

The rotary lobe compressor stage is a rather low-pressure machine. These compressors do not compress gas internally in a fixed sealed volume as in other rotaries. The straight lobe compressor uses two rotors that intermesh as they rotate (Figure 3.4.12). The rotors are timed by a set of timing gears. The lobe shapes may be involute or cycloidal in form. The rotors may also have two or three lobes. As the rotors turn and pass the intake port, a volume of gas is trapped and carried between the lobes and the housing of the compressor. When the lobe pushes the gas toward the outlet port, the gas is compressed by the back pressure in the gas discharge line.

Volumetric efficiency is determined by the leakage at tips of the lobes. The leakage is referred to as slip. Slippage is a function of rotor diameter, differential pressure, and the gas being compressed.

For details concerning this low pressure compressor see other references [4-7].

3.4.5.4 Liquid Piston Compressor

The liquid piston compressor utilizes a liquid ring as a piston to perform gas compression within the compression space. The liquid piston compressor stage uses a single rotating element that is located eccentrically inside a housing (Figure 3.4.13). The rotor has a series of vanes extending radially from it with a slight curvature toward the

FIGURE 3.4.12 Straight lobe rotary compressor operating cycle [4,23].

FIGURE 3.4.13 Liquid piston compressor [1,5].

direction of rotation. A liquid, such as oil, partially fills the compression space between the rotor and the housing walls. As rotation takes place, the liquid forms a ring as centrifugal forces and the vanes force the liquid to the outer boundary of the housing. Since the element is located eccentrically in the housing, the liquid ring (or piston) moves in an oscillatory manner. The compression space in the center of the stage communicates with the gas inlet and outlet parts and allows a gas pocket. The liquid ring alternately uncovers the inlet part and the outlet part. As the system rotates, gas is brought into the pocket, compressed, and released to the outlet port.

The liquid compressor has rather low efficiency, about 50%. The liquid piston compressor may be staged. The main advantage to this type of compressor is that it can be used to compress gases with significant liquid content in the stream.

3.4.6 Summary of Positive Displacement Compressors

The main advantages of reciprocating piston compressors are dependable, near constant volumetric flow rate, and variable pressure capability (up to the maximum pressure capacity of the compressor). The disadvantages are bulky construction, high initial capital costs (relative to rotary

compressors of similar capabilities), and relatively high maintenance costs due to a great number of moving parts (relative to rotary compressors).

The advantages of rotary compressors are low initial capital costs, less bulky construction, and general ease of maintenance. The main disadvantages are an inability to adjust to flow line back pressure (i.e., fixed compression ratios), the need for frequent specific maintenance for rotating wear surfaces to prevent slippage, and the requirement of most rotary compressors must operate with some oil lubrication in the compression chambers [4,5].

Drilling and Well Completions

4.1 DRILLING AND WELL SERVICING STRUCTURES

Section reviewed by Bill Lyons and Tom Mangum

Structures for drilling and well servicing provide the clearance and structural support necessary for handling tubulars such as drill pipe and casing that are used in these operations and for handling and use of blowout preventors and well intervention equipment. Drilling structures are generally classified as derricks, masts, and substructures, but because they are used in a broad range of operational, environmental, and transportation conditions, there is a considerable blurring of additional characterizations.

Derricks are structural towers commonly used where disassembly is seldom or never required, such as on offshore floating vessels and fixed platforms, and they are rarely guyed. They are generally characterized by

- Having semi-permanent structures of square or rectangular cross-section
- Having members that are latticed or trussed on all four sides
- Using bolted connections
- Being designed to be assembled vertically in a member-by-member fashion

Masts are structural towers typically used in applications where the structure must be partially disassembled for transportation between well locations. They may be guyed or unguyed. They are more commonly used for onshore applications but are used offshore where occasional disassembly is required. They are characterized by

- Having a rectangular cross-section with at least one open face to facilitate handling of tubulars into well center
- Consisting of transportable sections that are assembled in a horizontal position near the ground

- Raising to the vertical operating position through an incorporated erection system

A *substructure* is a structural arrangement designed to support and elevate the working floor to allow the handling of blowout preventors below the floor and through which some or all drilling loads are transmitted.

Drilling and well servicing structures must be designed to safely carry all loads that are likely to be imposed during the structure's life [1]. For derricks and masts, the largest vertical dead load that will likely be applied to the structure is the heaviest casing string run into the borehole. The casing string may be floated in by plugging the lower end of the casing; the applied load at the hook is the weight of the casing string in air, reduced by the weight of displaced mud from the casing annulus. For substructures, casing loads can be applied simultaneously with the weight of the drill pipe string racked back on the drill floor.

These loads can be amplified by acceleration and impact while hoisting or setting the casing in the rotary slips. If the casing or drill string becomes stuck in the well bore, it may be necessary to apply an overpull to dislodge the string. For these reasons, it is customary for users to specify a required structural capacity somewhat higher than the maximum expected static drilling loads.

Drilling structures must also be designed to withstand environmental loads caused by wind, ice accumulation, vessel motion, and earthquake acting on the structures and racked tubulars. Because these loads can occur during operations, the designer and user must consider carefully combinations of loads that will limit the safe capacities of the structures. The designer must also consider dead weights and environmental loads on ancillary equipment that will be installed in the structures such as top drives, pipe handling equipment, BOP handling equipment, casing baskets, piping, cabling, and the like,

because they will further reduce the capacity of the structures.

Improper design of foundations or failure to properly interface foundation design with design of the drilling structures is a leading cause of failures of drilling structures due to rig overturning. Freestanding drilling structures used onshore and some offshore structures during skidding are potentially subject to overturning under excessive wind and dynamic conditions. Overturning is also a concern for masts and substructures during erection. The designer must ensure that adequate stability against overturning is provided at all times, and such consideration should include the allowable bearing loading of the foundation. Weights of nonstructural equipment and other items used to stabilize the rig against overturning should be conservatively evaluated; caution should be used in considering weights of items that may be inadvertently left out or that cannot be in place at the time of erection. The rig operating instructions provided by the manufacturer must clearly state the requirements for such items, and the user must refer to and adhere to these instructions.

The API Standard 4F, Fourth Edition, January, 2013, "Specification for Drilling and Well Servicing Structures," was written to provide suitable steel structures for drilling and well servicing operations and to provide a uniform method of rating the structures for the petroleum industry [1,2].

Drilling and well servicing structures that meet the requirements of API Standard 4F are identified by a nameplate securely affixed to the structure in a conspicuous place. The nameplate markings convey at least the following information:

4.1.1 Mast and Derrick Nameplate Information

- a. Manufacturer's name
- b. Manufacturer's address
- c. Date of manufacture, including month and year
- d. Serial number
- e. Height in feet
- f. Maximum rated static hook load in pounds, with guy lines if applicable, for stated number of lines to traveling block
- g. Maximum rated wind velocity in knots, with guy lines if applicable, with rated capacity of pipe racked
- h. The API specification and edition of the API specification under which the structure was designed and manufactured
- i. Manufacturer's guying diagram—for structures as applicable
- j. The following note: "Caution: Acceleration or impact, as well as setback and wind loads, will reduce the maximum rated static hook load capacity."
- k. Manufacturer's load distribution diagram (which may be placed in mast instructions)
- l. Graph of maximum allowable static hook load versus wind velocity
- m. Mast setup distance for mast with guy lines

4.1.2 Substructure Nameplate Information

- a. Manufacturer's name
- b. Manufacturer's address
- c. Date of manufacture, including month and year
- d. Serial number
- e. Maximum rated static rotary capacity
- f. Maximum rated pipe setback capacity
- g. Maximum combined rated static rotary and rated setback capacity
- h. API specification and edition under which the structure was designed and manufactured

The manufacturer of structures that satisfy API Standard 4F must also furnish the purchaser with one set of instructions that covers operational features, block reeving diagram, and lubrication points for each drilling or well servicing structure. Instructions should include the raising and lowering of the mast and a facsimile of the API nameplate.

4.1.3 Definitions and Abbreviations

4.1.3.1 Definitions

The following terms are commonly used in discussing drilling structures:

Crown block assembly: The stationary sheave or block assembly installed at the top of a derrick or mast.

Design load: The force or combination of forces that a structure is designed to withstand without exceeding the allowable stress in any member.

Dynamic loading: The loading imposed upon a structure as a result of motion as opposed to static loading.

Dynamic stress: The varying or fluctuating stress occurring in a structural member as a result of dynamic loading.

Erection load: The load produced in the mast and its supporting structure during the raising and lowering operation.

Gin pole: An auxiliary structure typically mounted atop a derrick for use in maintenance and repair of crown components.

Guy line: A wire rope with one end attached to the derrick or mast assembly and the other end attached to a suitable anchor.

Guying pattern: A plane view showing the manufacturer's recommended locations and distance to the anchors with respect to the wellhead.

Height of derrick and mast without guy lines: The minimum clear vertical distance from the top of the working floor to the bottom of the crown block support beams.

Height of mast with guy lines: The minimum vertical distance from the ground to the bottom of the crown block support beams.

Impact loading: The loading resulting from sudden changes in the motion state of rig components.

Mast setup distance: The distance from the centerline of the well to a designated point on the mast structure defined by a manufacturer to assist in the setup of the rig.

Maximum rated static hook load: The sum of the weight applied at the hook and the traveling equipment for the designated location of the dead line anchor and the specified number of drilling lines without any pipe setback, sucker rod, or wind loadings.

Pipe lean: The angle between the vertical and a typical stand of pipe with the setback.

Racking platform: A platform located at a distance above the working floor for laterally supporting the upper end of racked pipe.

Rated static rotary load: The maximum weight being supported by the rotary table support beams.

Rated setback load: The maximum weight of tubular goods that the substructure can withstand in the setback area.

Rod board: A platform located at a distance above the working floor for supporting rods.

Static hook load: see *Maximum rated static hook load*.

4.1.3.2 Abbreviations

The following standard abbreviations are used throughout this section.

- ABS — American Bureau of Shipping
- AISC — American Institute of Steel Construction
- AISI — American Iron and Steel Institute
- ANSI — American National Standard Institute
- API — American Petroleum Institute
- ASA — American Standards Association
- ASTM — American Society for Testing and Materials
- AWS — American Welding Society
- IADC — International Association of Drilling Contractors
- SAE — Society of Automotive Engineers
- USAS — United States of America Standard (ANSI)
- RP — recommended practice

4.1.4 Load Capacities

All derricks and masts will fail under an excessively large load. Thus API makes it a practice to provide standard ratings for derricks and masts that meet its specifications. The method for specifying standard ratings has changed over the years; therefore, old structures may fail under one rating scheme and new structures may fail under another.

API Standard 4F provides rating of derrick capacities in terms of gross nominal capacity (GNC) as follows:

$$GNC = [(N + 4)/N] \times \text{Maximum Static Rated Hook Load} \tag{4.1.1}$$

where N is the number of lines strung between traveling block and crown block [3].

GNC served the purpose of providing a single capacity rating regardless of the number of drill lines strung to the block. Given a drill floor arrangement similar to that shown in Figure 4.1.1, statics gives the maximum leg load to be approximately equal to one fourth of the hook load plus the dead line load. Designing the legs for this load would make the derrick “capacity” four times the single leg capacity and thus numerically equal to GNC.

Most structures produced have different structural and floor arrangements for which the use of GNC could be highly inaccurate in establishing an allowable hook load for a given number of lines to the block, and the term was dropped in subsequent revisions of API Standard 4.

API Standard 4F provides rating of portable masts as follows: For each mast, the manufacturer shall designate a maximum rated static hook load for each of the designated line reevings to the traveling block. Each load shall be the maximum static load that may be applied at the hook, for the designated location of deadline anchor and in the absence of any pipe-setback, sucker-rod, or wind loadings. The rated static hook load includes the weight of the traveling block and hook. The angle of mast lean and the specified minimum load guy line pattern shall be considered for guyed masts.

Under the rigging conditions given on the nameplate and in the absence of setback or wind loads, the static hook load

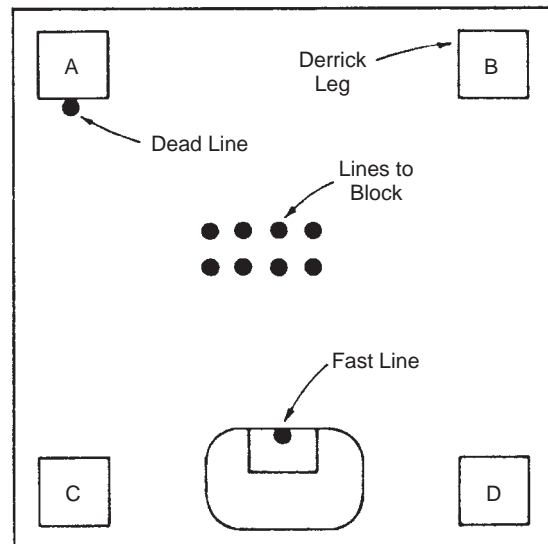

FIGURE 4.1.1 Projection of fast-line and deadline locations on rig floor.

under which failure may occur in masts conforming to this specification can be given as only approximately twice the maximum rated static hook load capacity.

The manufacturer shall establish the reduced rated static hook loads for the same conditions under which the maximum rated static hook loads apply, but with the addition of the pipe-setback and sucker-rod loadings. The reduced rated static hook loads shall be expressed as percentages of the maximum rated static hook loads.

4.1.4.1 Standard Ratings

Each structure shall be rated for the following applicable loading conditions. The structures shall be designed to meet or exceed these conditions in accordance with the applicable specifications set forth herein. The following ratings do not include any allowance for impact. Acceleration, impact, setback, and wind loads will reduce the rated static hook load capacity.

4.1.4.2 Derrick — Stationary Base

1. Maximum rated static hook load for a specified number of lines to the traveling block.
2. Maximum rated wind velocity (knots) without pipe setback.
3. Maximum rated wind velocity (knots) with full pipe setback.
4. Maximum number of stands and size of pipe in full setback.
5. Maximum rated gin pole capacity.
6. Rated static hook load for wind velocities varying from zero to maximum rated wind velocity with full rated setback and with maximum number of lines to the traveling block.

4.1.4.3 Mast with Guy Lines

1. Maximum rated static hook load capacity for a specified number of lines strung to the traveling block and the manufacturer's specified guying.
2. Maximum rated wind velocity (knots) without pipe setback.
3. Maximum rated wind velocity (knots) with full pipe setback.
4. Maximum number of stands and size of pipe in full setback.

4.1.4.4 Mast without Guy Lines

1. Maximum rated static hook load for a specified number of lines to the traveling block.
2. Maximum rated wind velocity (knots) without pipe setback.

3. Maximum rated wind velocity (knots) with full pipe setback.
4. Maximum number of stands and size of pipe in full setback.
5. Rated static hook load for wind velocities varying from zero to maximum rated wind velocity with full rated setback and with maximum number of lines to the traveling block.

4.1.4.5 Mast and Derricks under Dynamic Conditions

1. Maximum rated static hook load for a specified number of lines to the traveling block.
2. Hook load, wind load, vessel motions, and pipe setback in combination with each other for the following:
 - a. Operating with partial setback.
 - b. Running casing.
 - c. Waiting on weather.
 - d. Survival.
 - e. Transit.

4.1.4.6 Substructures

1. Maximum rated static hook load, if applicable.
2. Maximum rated pipe setback load.
3. Maximum rated static load on rotary table beams.
4. Maximum rated combined load of setback and rotary table beams.

4.1.4.7 Substructure under Dynamic Conditions

1. Maximum rated static hook load.
2. Maximum rated pipe setback load.
3. Maximum rated load on rotary table beams.
4. Maximum rated combined load of setback and rotary table beams.
5. All ratings in the section titled "Mast and Derricks under Dynamic Conditions."

4.1.5 Design Loadings

Derricks and masts are designed to withstand some minimum loads or set of loads without failure. Each structure shall be designed for the following applicable loading conditions. The structure shall be designed to meet or exceed these conditions in accordance with the applicable specifications set forth herein.

4.1.5.1 Derrick — Stationary Base

1. Operating loads (no wind loads) composed of the following loads in combination:
 - a. Maximum rated static hook load for each applicable string up condition.
 - b. Dead load of derrick assembly.
2. Wind load without pipe setback composed of the following loads in combination:
 - a. Wind load on derrick, derived from maximum rated wind velocity without setback (minimum wind velocity for API standard derrick sizes 10 through 18A is 93 knots, and for sizes 19 through 25 is 107 knots).
 - b. Dead load of derrick assembly.
3. Wind load with rated pipe setback composed of the following loads in combination:
 - a. Wind load on derrick derived from maximum rated wind velocity with setback of not less than 93 knots.
 - b. Dead load of derrick assembly.
 - c. Horizontal load at racking platform, derived from maximum rated wind velocity with setback of not less than 93 knots acting on full pipe setback.
 - d. Horizontal load at racking platform from pipe lean.

4.1.5.2 Mast with Guy Lines

1. Operating loads (no wind load) composed of the following loads in combination:
 - a. Maximum rated static hook load for each applicable string up condition.
 - b. Dead load of mast assembly.
 - c. Horizontal and vertical components of guy line loading.
2. Wind loads composed of the following loads in combination:
 - a. Wind load on mast, derived from a maximum rated wind velocity with setback of not less than 60 knots.
 - b. Dead load of mast assembly.
 - c. Horizontal loading at racking board, derived from a maximum rated wind velocity with setback of not less than 60 knots, acting on full pipe setback.
 - d. Horizontal and vertical components of guy line loading.
 - e. Horizontal and vertical loading at rod board, derived from a maximum rated wind velocity with setback of not less than 60 knots, acting on rods in conjunction with dead weight of rods.
3. Wind loads composed of the following loads in combination:
 - a. Wind load on mast, derived from a maximum rated wind velocity with setback of not less than 60 knots.
 - b. Dead load of mast assembly.

- c. Horizontal loading at racking platform, derived from a maximum rated wind velocity with setback of not less than 60 knots, acting on full pipe setback.
 - d. Horizontal and vertical components of guy line loading.
4. Wind loads composed of the following loads in combination:
 - a. Wind load on mast derived from a maximum rated wind velocity without setback of not less than 60 knots.
 - b. Dead load of mast assembly.
 - c. Horizontal and vertical components of guy line loading.
 5. Erection loads (zero wind load) composed of the following loads in combination:
 - a. Forces applied to mast and supporting structure created by raising or lowering mast.
 - b. Dead load of mast assembly.
 6. Guy line loading (assume ground anchor pattern consistent with manufacturer's guying diagram shown on the nameplate).
 - a. Maximum horizontal and vertical reactions from conditions of loading applied to guy line.
 - b. Dead load of guy line.
 - c. Initial tension in guy line specified by mast manufacturer.

4.1.5.3 Mast without Guy Lines

1. Operating loads composed of the following loads in combination:
 - a. Maximum rated static hook load for each applicable string up condition.
 - b. Dead load of mast assembly.
2. Wind load without pipe setback composed of the following loads in combination:
 - a. Wind loading on mast, derived from a maximum rated wind velocity without setback of not less than 93 knots.
 - b. Dead load of mast assembly.
3. Wind load with pipe setback composed of the following loads in combination:
 - a. Wind loading on mast, derived from a maximum rated wind velocity with setback of not less than 70 knots.
 - b. Dead load of mast assembly.
 - c. Horizontal load at racking platform derived from a maximum rated wind velocity with setback of not less than 70 knots acting on pipe setback.
 - d. Horizontal load at racking platform from pipe lean.
4. Mast erection loads (zero wind load) composed of the following loads in combination:

- a. Forces applied to mast and supporting structure created by raising or lowering mast.
 - b. Dead load of mast assembly.
5. Mast handling loads (mast assembly supported at its extreme ends).

When specifying masts for use offshore, it is recommended that the user specify the higher wind velocity requirements of derricks.

4.1.5.4 Derricks and Mast under Dynamic Conditions

All conditions listed in the section titled "Load Capacities," subsection titled "Mast and Derricks under Dynamic Conditions," are to be specified by the user.

4.1.5.5 Substructures

1. Erection of mast, if applicable.
2. Moving or skidding, if applicable.
3. Substructure shall be designed for the following conditions:
 - a. Maximum rated static rotary load.
 - b. Maximum rated setback load.
 - c. Maximum rated static hook load (where applicable).
 - d. Maximum combined rated static hook and rated setback loads (where applicable).
 - e. Maximum combined rated static rotary and rated setback loads.
 - f. Wind loads resulting from maximum rated wind velocity acting from any direction on all exposed elements. Wind pressures and resultant forces are to be calculated in accordance with the equations and tables in the section titled "Design Specifications," paragraph titled "Wind." When a substructure is utilized to react guy lines to the mast, these reactions from the guy lines must be designed into the substructure.
 - g. Dead load of all components in combination with all of the above.

4.1.5.6 Substructure under Dynamic Conditions

All conditions listed in the section titled "Load Capacities," paragraph titled "Structure under Dynamic Conditions," are to be specified by the user. Forces resulting from wind and vessel motion are to be calculated in accordance with formulas from the section titled "Design Specifications," paragraphs titled "Wind" and "Dynamic Loading (Induced by Floating Hull Motion)."

4.1.6 Design Specifications

4.1.6.1 Allowable Stresses

AISC specifications for the design fabrication and erection of structural steel for buildings shall govern the design of these steel structures (for AISC specifications, see the current edition of Steel Construction Manual of the American Institute of Steel Construction). Only Part I of the AISC manual, the portion commonly referred to as elastic design, shall be used in determining allowable unit stresses; use of Part II, which is commonly referred to as plastic design, is not allowed. The AISC shall be the final authority for determination of allowable unit stresses, except that current practice and experience do not dictate the need to follow the AISC for members and connections subject to design, is not allowed. The AISC shall be the final authority for determination of allowable unit stresses, except that current practice and experience do not dictate the need to follow the AISC for members and connections subject to repeated variations of stress, and for the consideration of secondary stresses.

For purposes of this specification, stresses in the individual members of a latticed or trussed structure resulting from elastic deformation and rigidity of joints are defined as secondary stresses. These secondary stresses may be taken to be the difference between stresses from an analysis assuming fully rigid joints, with loads applied only at the joints, and stresses from a similar analysis with pinned joints. Stresses arising from eccentric joint connections, or from transverse loading of members between joints, or from applied moments, must be considered primary stresses.

Allowable unit stresses may be increased 20% from the basic allowable stress when secondary stresses are computed and added to the primary stresses in individual members. However, primary stresses shall not exceed the basic allowable stresses.

Wind and Dynamic Stresses (Induced by Floating Hull Motion)

Allowable unit stresses may be increased one-third over basic allowable stresses when produced by wind or dynamic loading, acting alone, or in combination with the design dead load and live loads, provided the required section computed on this basis is not less than required for the design dead and live loads and impact (if any), computed without the one-third increase.

Wire Rope

The size and type of wire rope shall be as specified in API Specification 9A and by API RP 9B (see section titled "Hoisting System") [5,6].

1. A mast raised and lowered by wire rope shall have the wire rope sized to have a nominal strength of at least $2\frac{1}{2}$ times the maximum load on the line during erection.
2. A mast or derrick guyed by means of a wire rope shall have the wire rope sized so as to have a nominal strength of at least $2\frac{1}{2}$ times the maximum guy load resulting from a loading condition.

Wire ropes subjected to bending exhibit reduced breaking strengths compared with straight pull tests, and extensive testing has shown that the smaller a sheave is in relation to the diameter of the rope, the larger is the reduction in strength [5, 7, 8]. Figure 4.1.2 shows this relationship for 6×19 and 6×37 constructions, where D is the sheave tread diameter and d is the wire rope diameter. For example, a wire rope designed to the API 4F minimum design factor of 2.5 and bent over a sheave with tread diameter less than 7.5 times the rope diameter will have an actual factor of safety to breaking of less than 2.0.

Ropes loaded to more than 50% of breaking strength suffer core damage, which can lead to premature and often catastrophic failure; the designer should carefully consider the effects of small-diameter erection and crown sheaves used with drilling structures. It is recommended that the minimum factors of safety required by API 4F (and API RP 9B for drilling lines) be increased by the inverse of the reduction factor from Figure 4.1.2.

Crown Shafting

Crown shafts, including fastline and deadline sheave support shafts, shall be designed to AISC specifications except

FIGURE 4.1.2

that the safety factor in bending shall be a minimum of 1.67 to yield. Wire rope sheaves and bearings shall be designed in accordance with “API Specification 8A: Drilling and Production Hoisting Equipment [7,8].”

4.1.6.2 Wind

Wind forces shall be applied to the entire structure.* The wind directions that result in the highest stresses for each component of the structure must be determined and considered. Wind forces for the various wind speeds shall be calculated according to

$$F = (P) (A) \tag{4.1.2}$$

where F = Force in lb

P = Pressure in lb/ft²

A = Total area, in ft², projected on a plane, perpendicular to the direction of the wind, except that the exposed areas of two opposite sides of the mast or derrick shall be used.

Although the API 4F specification does not specifically address the wind areas of accessories and equipment, it seems obvious that calculations of wind loads must also include these areas.

When pipe or tubing is racked in more than one area, the minimum area of setback shall be no less than 120% of the area on one side; when rods are racked on more than one area, the minimum area of rods shall be no less than 150% of the area of one side to account for the effect of wind on the leeward area (Figure 4.1.3).

The pressure due to wind is

$$P = 0.00338 (V_k^2)(C_h)(C_s) \tag{4.1.3}$$

where P = pressure in lb/ft²

V_k = wind velocity in knots

C_h = height coefficient (per Table 4.1.1).

For convenience, Table 4.1.2 tabulates wind pressures for various wind speeds with C_s = 1.25 and C_h = 1.0.

Height is the vertical distance from ground or water surface to the center of area. The shape coefficient C_s for a derrick is assumed as 1.25. C_s, and C_h were obtained from ABS, “Rules for Building and Classing Offshore Drilling Units, 1968 [9].”

4.1.6.3 Earthquake

Earthquake is a special loading condition to be addressed when requested by the user. The user is responsible for furnishing the design criteria that includes design loading, design analysis method, and allowable response.

The design criteria for land units may be in accordance with local building codes using equivalent static design methods.

FIGURE 4.1.3 Diagram of projected area [9].

TABLE 4.1.1 Height Coefficients, C_h

Height, feet (meters)				C_h
Over	Not Exceeding			
0 (0)	50 (15.2)			1.00
50 (15.2)	100 (30.5)			1.10
100 (30.5)	150 (45.7)			1.20
150 (45.7)	200 (61.0)			1.30
200 (61.0)	250 (76.2)			1.37
250 (76.2)	300 (91.4)			1.43
300 (91.4)	350 (106.7)			1.48
350 (106.7)	400 (121.9)			1.52
400 (121.9)	450 (137.2)			1.56
450 (137.2)	500 (152.4)			1.60
500 (152.4)	550 (167.6)			1.63
550 (167.6)	600 (182.9)			1.67
600 (182.9)	650 (198.1)			1.70
650 (198.1)	700 (213.4)			1.72
700 (213.4)	750 (228.6)			1.75
750 (228.6)	800 (243.8)			1.77
800 (243.8)	850 (259.1)			1.79
850 (259.1)				1.80

TABLE 4.1.2 Conversion Values (for 0–50 ft. height)

Pressure		Wind Velocity		
Lb/Sq	Ft (kPa)	V_k Knots	Miles/ Hour	Meters/ Second
10	(68.9)	49	56	25.2
15	(103.4)	60	69	30.9
20	(137.9)	69	79	35.5
25	(172.4)	77	89	39.6
30	(206.8)	84	97	43.2
35	(241.3)	91	105	46.8
40	(275.8)	97	112	49.9
45	(310.3)	103	119	53.0
50	(344.7)	109	125	56.1
55	(379.2)	114	131	58.6

For fixed offshore platform units, the design method should follow the strength level analysis guidelines in API RP 2A. The drilling and well servicing units should be able to resist the deck movement, i.e., the response of the deck to the ground motion prescribed for the design of the offshore platform. The allowable stresses for the combination of earthquake, gravity and operational loading

should be limited to those basic allowables with the one-third increase as specified in AISC Part I. The computed stresses should include the primary and the secondary stress components.

Guidance for the seismic assessment and design of drilling structures on offshore platforms can be found in Reference[10].

4.1.6.4 Extreme Temperature

Because of the effect of low temperatures on structural steel, it will be no use to change (decrease) the allowable unit stresses mentioned in the preceding paragraphs titled “Allowable Stresses.” Low temperature phenomena in steel are well established in principle. Structures to be used under extreme conditions should use special materials that have been, and are being, developed for this application.

4.1.7 Manufacturing, Inspection, and Delivery

In addition to meeting the design requirements of the specification, the materials and manufacture of drilling structures must meet design specifications, special process requirements for welding and heat treatment, and quality control and quality assurance requirements of API 4F and other applicable AWS, API, and AISC specifications.

The purchaser’s inspector shall, with proper notice, have free entry at all times to all parts of the manufacturer’s works concerned with the manufacture of the products ordered, so long as such inspections are conducted as to not interfere unnecessarily with the operations of the works. When requested by a prospective purchaser of the equipment for his use or by a user of the equipment, the manufacturer shall make available for examination details of computations, drawings, tests, or other supporting data as may be necessary to demonstrate compliance with the API 4F specification.

The manufacturer shall furnish to purchaser one set of instructions that covers operational features, block reeving diagram, and lubrication points for each drilling or well servicing structure. Instructions shall be included to cover erection and lowering of the mast and/or substructure. A facsimile of the nameplate shall be included in the instructions.

4.1.8 Standard Derricks

A standard derrick is a structure of square cross-section and set dimensions. At one time such standardization was desirable, but it is largely irrelevant today and standard

derricks are seldom, if ever, specified. Appendix B in the API 4F specification lists standard derrick information.

4.1.9 Maintenance and Use of Drilling and Well Servicing Structures

Maintenance and use of drilling and well servicing structures should always be performed in accordance with the manufacturer’s instructions and the most current edition of API RP 54, *Recommended Practices for Occupational Safety and Health for Oil and Gas Well Drilling and Servicing Operations*. In cases where this material is insufficient and the manufacturer is not available or is unable to provide sufficient guidance, API RP 4G [2] is an excellent source of information for users regarding the maintenance and use of drilling and well servicing structures. Covered topics include

- Structural repair and modification
- Raising line inspection and replacement
- Periodic structural inspections
- Guying, guyline anchors, and foundations for portable masts with guylines
- Precautions and procedures for low-temperature operations

A particularly useful presentation is made for reduced-footprint guying patterns for portable masts. While the use of such patterns requires higher guyline anchor capacities and derating of the masts maximum rated static hook load, they provide the user with solutions for avoidance of obstructions at the well-site such as rocks, pits, and electric lines.

Evaluation, repairs, and modifications of drilling and well servicing structures should be carried out by qualified personnel and should take into account the impact of such work on operating capacities, environmental loads, erection loads, transportation loads, lifting loads, structural overturning and foundation requirements, and other conditions as may be applicable. All work associated with such modifications should be done under the governance of a qualified quality assurance program in accordance with the instructions of the qualified individuals.

Both users and well-site owners and operators should exercise diligence in defining responsibilities of involved parties regarding the selection, installation, and maintenance of structures, foundations, cellars, and anchors for the intended job, as well as the selection and training of personnel for all work.

4.1.10 Wellheads

Early in the twentieth century, the oil industry entered a new phase of importance to the expanding industrial base of the

United States. Oil became a major commodity and deeper wells were more prolific. The invention of the roller cone drill bit and later the PDC bit allowed drillers to drill deeper and through greater varieties of rock formations. In these new subsurface environments, new methods of containing and controlling wellbore high-pressure formation fluids during drilling and production had to be developed. Ever longer “inverse telescope” cemented casing and liner strings were early technological developments. However, the top of these casing strings still had to be supported with structural elements (wellheads) that complement the rig structures on which the BOP stack can be attached which in turn allows the safe passage of drilling tools and other subsurface tools during the drilling, completions, and production operations. Patents for new wellheads have flourished through the years as suppliers searched for more economical procedures and components. These new wellhead designs accommodated increasingly complicated concentric casing string sizes. All these casing string sizes had to be supported with an individual casing hanger. Each casing string had to be cemented and their respective annular seals maintained during operations to insure zonal isolation between separate casing strings.

4.1.10.1 Wellhead Configurations

The newest wellhead designs follow much of the same design principles as those early wellhead developments. However, the temperatures, pressures, and corrosiveness of these deeper subsurface fluids are much greater. The wellbore temperatures and pressures can reach 350 °F (176.6 °C) and 30,000 psi (206.8 MPa) and contain H₂S and CO₂. Each of these conditions can have significant detrimental effects on wellhead, casing hanger, tubing hanger, and seal assembly service life.

4.1.10.2 Wellhead Specifications and Ratings

The industry standard specifications for the manufacture and service of wellheads and wellhead elements are given in the publication *API 6A, “Specification for Wellhead and Christmas Tree Equipment”*, January 2011 [11]. API Specification 6A first appeared in 1961, when the existing flanged end specifications were consolidated into one specification for flanged end wellheads and loose flanges. It is published as an aid to the procurement of wellheads and valves, as well as a guide to the manufacturers. Since 1961, API 6A has gone through various changes that reflect the innovation and advances of the petroleum industry over that period and the adjustments by the API Specification 6A committee to stay current with international industry practices as they became widely accepted. The scope of API 6A includes

TABLE 4.1.3 Wellhead Temperature Ratings [11]

Temperature Classification	Operating Range	
	°F	°C
K	−75 to 180	−60 to 82
L	−50 to 180	−46 to 82
N	−50 to 140	−46 to 60
P	−20 to 180	−29 to 82
S	0 to 140	−18 to 60
T	0 to 180	−18 to 82
U	0 to 250	−18 to 121
V	35 to 250	2 to 121

all wellhead equipment including casing heads and spools; crossover adapters, Tees, and crosses; casing hangers and tubing hangers; and valves and chokes. Three critical issues addressed by API 6A are temperature and pressure ratings of equipment and material. Table 4.1.3 gives the wellhead operating temperature ratings.

Table 4.1.4 gives the wellhead operating pressure ratings.

Table 4.1.5 gives the wellhead material classes.

Additional specifications identified in API 6A include:

- Design methods
- Product specifications levels/material tractability (PSL 1–4)
- Performance requirements (PR1 and PR2)
- Welding specifications
- Quality control
- Repair and remanufacture of equipment

TABLE 4.1.4 Wellhead Pressure Ratings [11]

Maximum Rated Working Pressure	
PSI	MPa
2000	13.8
3000	20.7
5000	34.5
10,000	69.0
15,000	103.5
20,000	138.0

4.1.10.3 Wellhead Types and Selections

There are two general types of wellheads in use today:

- Stacked—each wellhead is independent and designed to support one string of casing. Wells using multiple strings of casing will stack/bolt together multiple casing heads as each string of casing is run. This wellhead system type is used for land operations and on shallow water stationary platforms.
- Multi-bowl/unitized—a casing head system with the capability to hold multiple strings of casing in one casing head. This type is often used on offshore platforms where stack-up height is a problem.

Wellheads, regardless of the manufacturer, type, or model, have three basic purposes:

1. Suspend casing and tubing strings
2. Isolate the annulus between the casing, or tubing strings
3. Provide a secure conduit between the reservoir and the surface facilities (i.e., flowline).

API 6A furnishes data sheets that identify all of the variables needed for the proper selection of a wellhead however; they can generally be broken down into the following series of questions:

1. Stacked versus multi-bowl
2. Flanged versus clamp
3. Slip-type hanger versus mandrel
4. Welded versus non-welded connections
5. Stacked valve tree versus composite block
6. Casing program (sizes/nominal weights, material grades, lengths, load shoulder ratings)

7. Drill bit program (ID bore)

8. Anticipated produced fluids (materials selections).

4.1.10.4 Starting Heads

The first wellhead installed goes by many names (see Figure 4.1.4). Starting head, in the early years of the industry was called the “Braden Head.” More currently the starting head is called an “A Section”. This head is typically “connected” to the top of the Surface casing string. The “connection” between the top of the surface casing string and the A Section can be a welded connection, or a threaded connection, or have a specialty connector. While welding is the most generally used method (particularly for land operations), threaded heads are often used on very low cost, low technology land wells. The specialty connector is used on offshore platform wells that have a producing well nearby on the platform (i.e., welding would require that those producing wells to be shut in during the welding process). These specialty connections utilize mechanical gripping dogs that bite into the casing outer surfaces (dogs are activated by screws) to secure it to the pipe. Elastomer seals provide the pressure integrity needed with these specialty connections. The top of the wellhead is generally a flange connection with a metal to metal seal ring groove and the sides of the wellhead will have studded outlets to accept valves. A typical drilling operation will cap one outlet and place a valve(s) on the side that appropriate for the operation. The valve outlets will also contain threads for a “VR” plug. The “VR” plug is a safety device, used to temporarily seal the outlet, allowing a leaking valve to be removed, replaced or repaired. The internal bore (top bowl) of the wellhead has an internal load shoulder to support the casing hanger for the next string of casing. Above the load shoulder will be an area for an annular seal.

FIGURE 4.1.4 Starting head (Courtesy GE Oil and Gas).

4.1.10.5 Casing Spools

Figure 4.1.5 shows a cutaway of a typical casing spool. The casing spool will often be the second casing head installed on a well. A shallow well with a limited number of casing strings may not use an intermediate string before the production string. In these cases a tubing spool will be installed instead. Casing spools and tubing spools have few differences, which will be discussed in next subsection. Like the starting head, the casing spool has multiple names and may be called a casing spool or “B Section”. The casing spool will have matching bottom flange to the starting head top flange. Typically, the casing spool will have a pressure rating one rating higher than the starting head below it. The internal part of the casing spool will have a top bowl and a bottom bowl. The top bowl will be similar to the starting head and have a casing hanger load shoulder and annulus seal area. The bottom bowl is prepared to receive the top of the last casing string installed. The casing string hung off in the starting head will have been cut off at a predetermined length that allows it to seal in the bottom bowl of the casing spool. The type of seal used in the bottom bowl will depend on the wellbore fluids (e.g., composition, temperature, and

pressure). Elastomer seals will be the most common but metal to metal seals are used in high-temperature and high-pressure operations.

4.1.10.6 Tubing Spools

Figure 4.1.6 shows a cutaway of a tubing spool. As noted above the tubing spool works and acts very similar to the casing spool. The first difference between the casing spool and the tubing spool is in the top bowl and the top flange. The top flange of a tubing spool will contain hold-down pins/lock-down pins designed to engage the tubing hanger and hold it place. Production fluids from the reservoir flow through the inside of the production tubing to the surface production facilities (e.g., separators, tank batteries, pipelines). These hot production fluids and gases expand as the fluids moves up the inside the tubing string. The steel tubing is in turn heated by heat transfer from the flowing fluids. The metal tubing exhibits thermal expansion and attempts to lengthen and push the upper part of the tubing upward to the surface. The hold-down pins in the tubing spool are designed to prevent this tubing movement. While hold-down pins accomplish one task they

FIGURE 4.1.5 Casing spools (Courtesy GE Oil and Gas).

FIGURE 4.1.6 Tubing spool (Courtesy GE Oil and Gas).

create another possible problem. Penetrating the top flange into a pressurized bore means the pins must have pressure integrity. A series of seals are required to accomplish this. Some manufactures use seals the require compression from a gland nut so they can hold pressure. Generally that means any time movement of the hold-down is required, the gland nut must be backed off, releasing any compressing force on the pins. After the pin is moved (in or out) the gland nut must be re-tightened. This potential for tubing movement together with the hold down pins, seals, and gland nut assemblies create opportunities for leaks.

The second difference between the casing spool and the tubing spool is in the upper bowl of the tubing spool. If a tubing hanger being installed requires a specific radial alignment with the Christmas tree, the tubing hanger must be locked from rotation. Examples would include dual completion strings and tubing hangers with downhole SCSSV valves. An MC guide screw penetrates the tubing spool in the top bowl (similar to the hold down pins in the flange) engaging a slot on the tubing hanger, aligning it as required. The MC guide screw will pass thru a gland nut (which can also create a possible leak path). Not all tubing spools will have a MC guide screw.

4.1.10.7 Casing Hangers

Casing hangers as the name implies is used to hang the casing in the wellhead. Some locations may elect to set casing on the bottom of the hole but the most common method is to suspend the casing. Three common terms used for casing hangers are manual hangers, automatic hangers and mandrel hangers. Manual hangers are typically landed in the wellhead after the casing has been cemented and the casing is stretched. The slips on the ID of the hanger will bite into the pipe and the remaining load is transmitted to the

casing head load shoulder. The load path is from the pipe to the slips, to the casing hanger body to the casing head load shoulder. The annulus seal is then energized manually by applying torque to a series of bolts in the top of the casing hanger. Automatic casing hangers employ the load from the stretched drill pipe to energize the annulus seal. The load path is from the pipe to the slips, to the casing hanger body, through the seal, to the casing head load shoulder. For obvious reasons it is extremely important for the vendor to provide the requirements to properly energize the seal. The third type of casing hanger is the mandrel hanger. The mandrel is actually screwed onto the casing joint and does not use slips to grip the pipe. The hanger will often have a seal integrated into the OD and it requires minimum amount of loading to seal. Mandrel hangers are most often used in multi-bowl wellheads and the annulus seal can be a separate component that is installed after the hanger is landed. Generally the seal is a low-compression elastomer.

API 6A identifies five groups of casing hangers and tubing hangers. The Groups 1 to 5 are defined by their external configurations, with or without seals, retention methods, and internal configurations [11]. These are

Group 1: Hangs casing with no annular seas.

Group 2: Hangs casing and seals pressure from one direction.

Group 3: Hangs casing and seals pressure from top and bottom with or without ring-joint isolation seal and downhole lines.

Group 4: Same as Group 3, with that hanger held in place by mechanical means applied to a retention feature.

Group 5: Same as Group 4, with the hanger receiving back-pressure valve.

4.2 HOISTING SYSTEM

Section reviewed by Bill Lyons

A hoisting system, as shown in Figure 4.2.1, is composed of the drawworks, traveling block, crown block, extra line storage spool, various clamps, hooks, and wire rope.

Normally, a hoisting system has an even number of working lines between the traveling block and the crown block. The fast line is spooled onto the drawworks' hoisting drum. The dead line is anchored to the rig floor across from the drawworks. The weight indicator is a load cell incorporated in the dead line anchor.

The mechanical advantage of the hoisting system is determined by the block and tackle and the number of working lines between the crown block and the traveling block [1].

Thus, for the static condition (i.e., no friction losses in the sheaves at the blocks), $F_f(lb)$, the force in the fast line to hold the hook load, is

$$F_f = \frac{W_h}{j} \quad (4.2.1)$$

where W_h is the weight of the traveling block plus the weight of the drill string suspended in the hole, corrected for buoyancy effects in pounds; and j is the number of working lines between the crown block and traveling block. Under these static conditions, $F_d(lb)$, the force in the dead line, is

$$F_d = \frac{W_h}{j} \quad (4.2.2)$$

FIGURE 4.2.1 Schematic of simplified hoisting system on rotary drilling rig [1].

The mechanical advantage (ma) under these static conditions is

$$ma(\text{static}) = \frac{W_h}{F_f} = j \quad (4.2.3)$$

When the hook load is lifted, friction losses in crown block and traveling block sheaves occur. It is normally assumed that these losses are approximately 2% deduction per working line. Under dynamic conditions, there will be an efficiency factor for the block and tackle system to reflect these losses. The efficiency will be denoted as the hook-to-drawwork efficiency (e_h). The force in the fast line under dynamic conditions (i.e., hook is moving) will be

$$F_f = \frac{W_h}{e_h j} \quad (4.2.4)$$

Equation 4.2.2 remains unchanged by the initiation of hook motion (i.e., the force in the dead line is the same under static or dynamic conditions). The mechanical advantage (ma) under dynamic conditions is

$$ma(\text{dynamic}) = e_h j \quad (4.2.5)$$

The total load on the derrick under dynamic conditions, $F_t(lb)$, will be

$$F_t = W_h + \frac{W_h}{e_h j} + \frac{W_h}{j} + W_c + W_t \quad (4.2.6)$$

where W_c is the weight of the crown block, and W_t is the weight of tools suspended in the derrick, both in pounds.

Example 4.2.1

For dynamic conditions, find the total load on a derrick that is capable of lifting a 600,000-lb drill string with an 8-working line block and tackle. The crown block weighs 9,000 lb and the traveling block weighs 4,500 lb. Assume that there are no other tools hanging in the derrick and that the dead line is attached to the rig floor across from the drawworks in its normal position (see Figure 4.2.1). Assume the standard deduction of 2% per working line to calculate e_h .

$$e_h = 1.00 - 0.02(8) = 0.84$$

From Equation 4.2.6

$$\begin{aligned} F_t &= 604,500 + \frac{600,000}{0.84(8)} + \frac{600,000}{8} + 9,000 \\ &= 604,500 + 89,286 + 75,000 + 9,000 \\ &= 786,786 \text{ lb} \end{aligned}$$

4.2.1 Drawworks

The drawworks is the key operating component of the hoisting system. On most modern rotary drilling rigs, the prime movers either operate the hoisting drum within the drawworks or operate the rotary table through the transmission within the drawworks. Thus the drawworks is a complicated mechanical system with many functions [1,2].

4.2.1.1 Functions

The drawworks does not carry out only hoisting functions on the rotary drilling rig. In general, the functions of the drawworks are as follows:

1. Transmit power from the prime movers (through the transmission) to its hoisting drum to lift drill string, casing string, or tubing string, or to pull in excess of these string loads to free stuck pipe.
2. Provide the braking systems on the hoist drum for lowering drill string, casing string, or tubing string into the borehole.
3. Transmit power from the prime movers (through the transmission) to the rotary drive sprocket to drive the rotary table.
4. Transmit power to the catheads for breaking out and making up drill string, casing string, and tubing string.

Figure 4.2.2 is a schematic of drawworks together with the prime mover power source.

4.2.1.2 Design

The drawworks basically contains the hoist drum, the transmissions, the brake systems, the clutch systems, rotary drive sprocket, and cathead. Figure 4.2.3 shows a schematic of the drawworks.

The power is provided to the drawworks by the prime movers at the master clutch (see Figure 4.2.2) and is transmitted to the master clutch shaft via sprockets and roller chain drives. The speed and the torque from the prime movers are controlled through the compound. The compound is a series of sprockets, roller chain drives, and clutches that allow the driller to control the power to the drawworks. The driller operates the compound and the drawworks (and other rig functions) from a driller's console (Figure 4.2.4).

With the compound, the driller can obtain as many as 12 gears working through the drawworks transmission.

In Figure 4.2.4, the driller's console is at the left of the drawworks. Also, the hoisting drum and sand reel can be seen. The driller's brake control is between the driller's console and the drawworks to control the brake systems of the hoisting drum.

Hoisting Drum

The hoisting drum (usually grooved) is probably the most important component on the drawworks. It is through the drum that power is transmitted to lift the drill string with the drilling line (wire rope) wound on the drum. From the standpoint of power requirements for hoisting, the ideal drum would have a diameter as small as possible and a width as great as possible. From the standpoint of drilling line wear and damage, the hoisting drum would have the largest drum diameter. Therefore, the design of the hoisting drum must be compromised to obtain an optimum design. Thus, the hoist drum is usually designed to be as small as practical, but the drum is designed to be large enough to permit fast line speeds in consideration of operation and economy.

Often it is necessary to calculate the line-carrying capacity of the hoist drum. The capacity or length of drilling line in the first layer on the hoist drum L_1 (ft) is

$$L_1 = \frac{\pi}{12}(D + d)\frac{\ell}{d} \quad (4.2.7)$$

where D is the drum diameter, d is the line diameter, and ℓ is the hoisting drum length, all in inches.

The length of the second layer, L_2 (ft) is

$$L_2 = \frac{\pi}{12}(D + 3d)\frac{\ell}{d} \quad (4.2.8)$$

The length of the n^{th} layer L_n (ft) is

$$L_n = \frac{\pi}{12}[D + (2n - 1)d]\frac{\ell}{d} \quad (4.2.9)$$

where n is the total number of layers on the hoisting drum.

The total length of drilling line on the hoisting drum, L_t (ft), will be the sum of all the layers;

$$L_t = \frac{\pi}{12}(D + h)\frac{\ell h}{d^2} \quad (4.2.10)$$

where h is the hoist drum flange height in inches.

Example 4.2.2

A hoist drum has an inside length of 48 in. and an outside diameter of 30 in. The outside diameter of the flange is 40 in. The drilling line diameter is 1 in. Find the total line capacity of the drum. The flange length is

$$h = \frac{40 - 30}{2} = 5 \text{ in.}$$

The total length (capacity) is

$$\begin{aligned} L_t &= \frac{\pi}{12}(30 + 5)\frac{(48)(5)}{(1)^2} \\ &= 2199 \text{ ft} \end{aligned}$$

FIGURE 4.2.4 The hoist on the rig floor. (Courtesy of Varco, Inc.).

Transmission and Clutch

The transmission in the drawworks generally has six to eight spreads. Large rigs can have more gears in the drawworks transmissions. More gearing capacity is available when the compound is used. This transmission uses a combination of sprockets and roller chain drives and gears to accomplish the change of speeds and torque from the prime movers (via the compound). The clutches used in the transmitting of prime mover power to the drawworks are jaw-type positive clutches and friction-type clutches. In modern drawworks, nearly all clutches are pneumatically operated from the driller's console. The driller's console also controls the shifting of gears within the drawworks.

Torque converters used in most drawworks are designed to absorb shocks from the prime movers or the driven equipment and to multiply the input torque. Torque converters are used in conjunction with internal combustion prime movers when these engines are used directly to drive the drawworks. More modern drawworks are driven by electric drives since such prime movers usually simplify the drawworks.

Brakes

The brake systems of the drawworks are used to slow and stop the movement of the large weights that are being lowered into the borehole. The brake system will be in continuous use when a round trip is made. The principal brake of the drawworks is the friction-type mechanical brake system. But when this brake system is in continuous use, it would generate a great deal of heat. Therefore, an auxiliary brake system is used to slow the lowering speeds before the friction-type mechanical brake system is employed to stop the lowering motion. Hydraulic brake

system and electromagnetic brake system are the basic types of auxiliary brake system in use. The hydraulic brake system uses fluid friction (much like a torque converter) to absorb power as equipment is lowered. The electromagnetic brake system uses two opposed magnetic fields supplied by external electrical current to control the speed of the hoisting drum. The auxiliary brake system can only control the speed of lowering and cannot be used to stop the lowering as does the mechanical friction-type brake system.

Catheads

The catheads are small rotating spools located on the sides of the drawworks. The cathead is used as a power source to carry out routine operations on the rig floor and in the vicinity of the rig. These operations include making up and breaking out drill pipe and casing, pulling single joints of pipe and casing from the pipe rack to the rig floor. The sand reel is part of this mechanism. This small hoisting drum carries a light wire rope line (sand line) through the crown to carry out pulling operations on the rig floor or in the vicinity of the rig.

Power Rating

In general, the drawworks is rated by its input horsepower. But it used to be rated by depth capability along with a specific size of drill pipe to which the depth rating pertains. The drawworks horsepower input required HP_{in} for hoisting operations is

$$HP_{in} = \frac{W_{vh}}{33,000e_h e_m} \quad (4.2.11)$$

where W is the hook load in lb, v_h is the hoisting velocity of the traveling block in ft/min, e_h is the hook-to-drawworks efficiency, and e_m is the mechanical efficiency within the drawworks and coupling between the prime movers and the drawworks (usually taken as about 0.85).

Example 4.2.3

It is required that the drawworks input power be able to lift 600,000 lb at a rate of 50 ft/min. There are eight working lines between the traveling block and the crown block. Three input power systems are available: 1,100, 1,400 and 1,800 hp. Which of the three will be the most appropriate? The value of e_h is

$$e_h = 1.00 - 0.02(8) = 0.84$$

The input horsepower is

$$\begin{aligned} \text{HP} &= \frac{600,000(50)}{33,000(0.84)(0.85)} \\ &= 1273.2 \end{aligned}$$

The input power system requires 1400 hp.

4.2.1.3 AC Drawworks

Variable-speed AC technology has enabled the development of a new class of drawworks (Figure 4.2.5). In the traditional DC traction motor and torque converter–driven drawworks, the speed of the prime mover was limited to approximately 1200 rpm. These low speeds required the drawworks to have shifting transmissions to get the correct speed and line pull combinations required for different drilling conditions. With AC technology, the motors operate at speeds up to 3000 rpm at continuous rated horsepower. This wider operating speed of the prime mover allow for drawworks designs without a multispeed transmission. Most of the new AC drawworks are gear driven, eliminating the roller chains used in DC drawworks.

The main advantage of an AC-powered, gear-driven drawworks is the ability to operate in hoist, lower, and stop modes without setting a parking brake or engaging and disengaging a drum clutch each time a change is made from one mode to another. The operating characteristics of the AC motors allow holding full torque at zero speed, and in the lowering mode, the motor absorbs energy in back EMF, which is then dissipated across a resistor bank or regenerated back into the total rig power grid. This four-quadrant motor control allows full operator control with a single joystick.

The AC drawworks, contains the hoist drum directly coupled to the hoist drum shaft, the spring applied, pneumatically released parking brakes, also directly coupled to the hoist drum shaft, and the gearboxes with the AC motors directly coupled. Some versions of AC drawworks use

FIGURE 4.2.5 Design safety factor and rating relationships. (Courtesy of Varco, Inc.).

hydraulically released spring applied brakes acting directly on the flanges of the hoist drum. These machines generally do not have self-contained catheads or provisions for them.

Figure 4.2.6 shows the velocity profile for the operation of the AC drawworks in the hoist and lowering modes. The maximum allowable speed is a function of the load being lifted and the operator-commanded speed. The AC drawworks control system allows the maximum acceleration, maximum velocity, and maximum deceleration of the traveling assembly in both the hoisting and lowering directions while maintaining safe and reliable operation. By following the velocity profile, the drawworks control system optimizes the operator's ability to maximize the speed of trips between positions in the derrick (between the travel limits) while maintaining safe operation. Travel of the block assembly following the full-velocity profile (from upper travel limit to the lower travel limit and back again) is described below for operation under normal conditions.

Most of the new land and offshore deep drilling rigs are equipped with AC variable frequency electric motors to operate their hoisting systems. Deep drilling rig hoisting systems during these operations are required to move massive drill strings and casing strings in and out of their respective wells. Such operations can produce high-inertia loads as motion of these strings is initiated which can be nearly twice as high as the operational static design

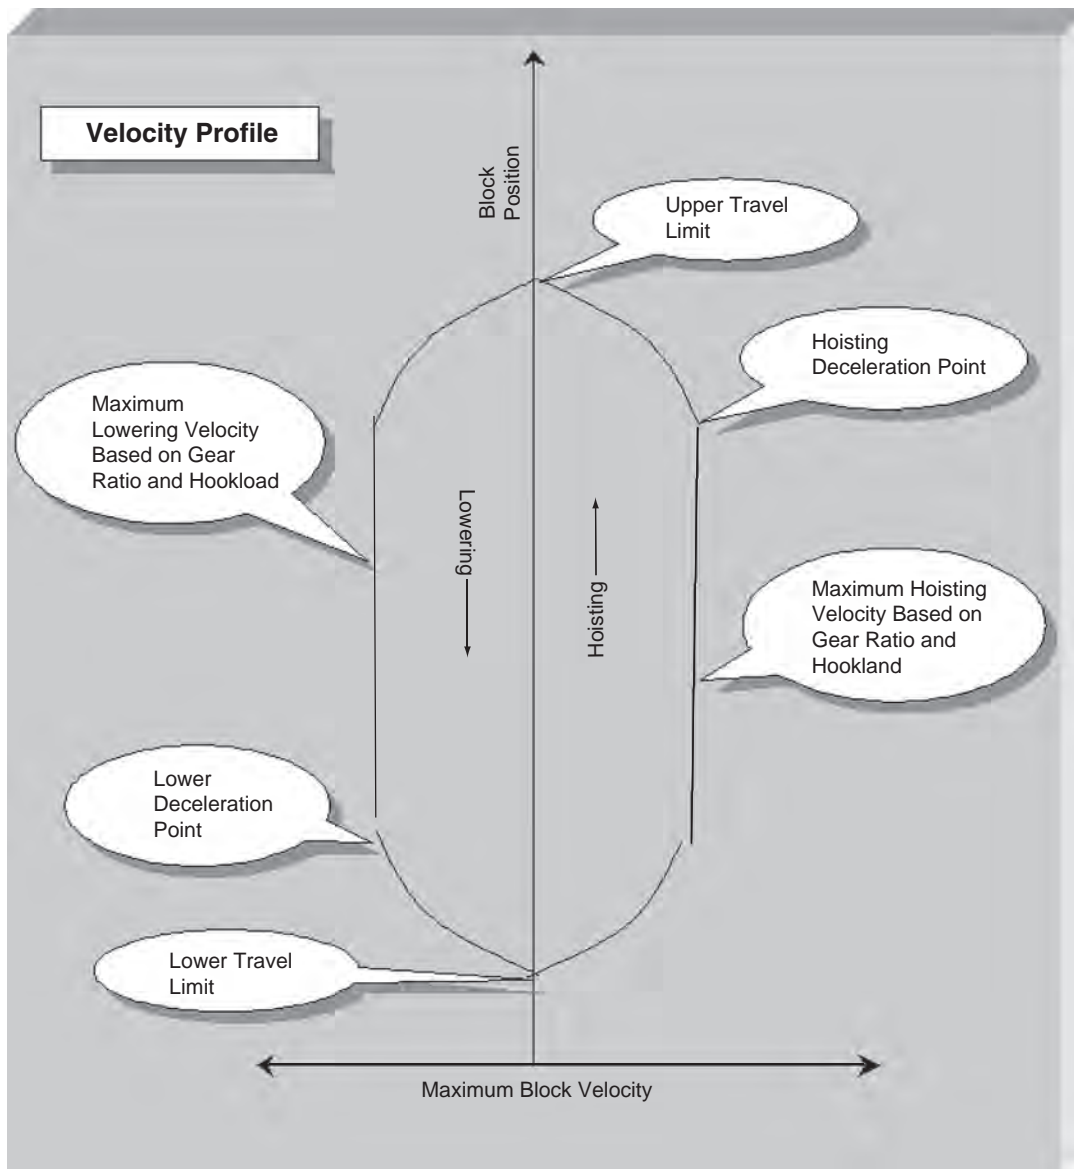

FIGURE 4.2.6 Block velocity profile. (Courtesy of Varco, Inc.).

loads. To counter these potentially hazardous impact loads, soft starter motor technologies have been developed. Soft starter technologies are systems for AC electric motors that can temporarily reduce the short time mechanical loads on the motor (and thus the rig and platform structures) by controlling the electric current surge to the AC motor during motor initiation of motor rotor rotation. These soft start systems can be either mechanical, or electrical, or a combination of both.

Lower Deceleration Point

When lowering, the lower deceleration point is the lowest position at which mechanical braking can be utilized to

safely stop the block without passing the lower travel limit. The lower deceleration point is calculated by adding the calculated stopping distance for downward travel to the lower travel limit position. Stopping distance is calculated based on available braking torque and system inertia, which, in addition to constant system parameters, includes variables such as lines strung, hookload, and block position.

Lower Travel Limit

The lower travel limit is the driller-defined position of lower-most travel.

Hoisting Deceleration Point

When hoisting, the hoisting deceleration point is the uppermost position at which the block will begin deceleration to safely stop the blocks without passing the upper travel limit and keep tension in the drill line. The hoisting deceleration point is calculated by subtracting the stopping distance from the upper travel limit. Stopping distance is calculated based on available braking torque and system inertia, which in addition to constant system parameters, includes variables such as lines strung, hookload, and block position.

Upper Travel Limit

The upper travel limit is the operator-defined position of uppermost travel.

Velocity Control

The VFD system works as a velocity-control system. The position of the drawworks control joystick is a velocity command sent to the controller that commands the VFD to go to the desired block speed (as limited by the velocity profile). The central position of the joystick represents zero velocity (i.e., stationary drum). The difference between the desired velocity and the actual velocity is an error signal. The magnitude of this error signal determines the force to be applied to the load.

4.2.2 Drilling and Production Hoisting Equipment

Drilling and production hoisting equipment include the following [1,2]:

1. *Crown block sheaves and bearings*: The stationary pulley system at the top of the derrick or mast.
2. *Traveling blocks*: A heavy duty pulley system that hangs in the derrick and travels up and down with the hoisted tools. It is connected to the crown block with a wire rope that ultimately runs to the hoisting drum.
3. *Block-to-hook adapters*: A metal piece that attaches to the bottom of the traveling block and serves as the mount for the hook.
4. *Connectors and link adapters*.
5. *Drilling hooks*: The hook that attaches to the traveling block to connect the bail of the swivel.
6. *Tubing and sucker rod hooks*: Hooks connected to the traveling block for tubing and sucker-rod hoisting operations.
7. *Elevator links*: The elevator is a hinged clamp attached to the hook and is used to hoist drill pipe, tubing, and casing. The actual clamp is in a pair of links that in turn attaches to a bail supported on the hook.
8. *Casing, tubing and drill pipe elevators*.
9. *Sucker rod elevator*.
10. *Rotary swivel bail adapters*: A bail adaptor that allows the bail of the swivel to be grasped and hoisted with elevators.

11. *Rotary swivels*. The swivel connecting the nonrotating hook and the rotating kelly while providing a nonrotating connection through which mud enters the kelly.
12. *Spiders*: The component of the elevator that latches onto the hoisted item.
13. *Deadline tiedowns*: The deadline is the nonmoving end of the wire rope from the hoisting down through the crown and traveling blocks. This end is anchored at ground level with a tiedown.
14. *Kelley spinners, when used as tension members*: An adapter between the swivel and the kelly that spins the Kelley for rapid attachment and disattachment to joints of drill pipe.
15. *Rotary tables, as structural members*: The rotary table rotates to turn the drill string. It is also used to support the drill string during some phases of operation.
16. *Tension members of subsea handling equipment*.
17. *Rotary slips*: Wedging devices used to clamp the tool string into the rotary table. The wedging action is provided by friction.

4.2.2.1 Material Requirements

Castings

Steel castings used in the manufacture of the main load carrying components of the drilling and production hoisting equipment shall conform to ASTM A781: "Common Requirements for Steel and Alloy Castings for General Industrial Use," and either an individual material specification listed therein or a proprietary material specification that as a minimum conforms to ASTM A781.

Forgings

Steel forgings used in the manufacture of the main load carrying components of the equipment shall conform to ASTM A668: "Steel Forgings, Carbon and Alloy, for General Industrial Use" and ASTM A778: "Steel Forgings, General Requirements." A material specification listed in ASTM A778 or a proprietary specification conforming to the minimum requirements of ASTM A788 may be used.

Plates, Shapes, and Bar Stock

Structural material used in the manufacture of main load carrying components of the equipment shall conform to applicable ASTM or API specifications covering steel shapes, plates, bars, or pipe, or a proprietary specification conforming to the minimum requirements of applicable ASTM or appropriate standard. Structural steel shapes having a specified minimum yield strength less than 33,000 psi, or steel pipe having a specified minimum yield strength less than 35,000 psi shall not be used.

4.2.2.2 Design Rating and Testing

All hoisting equipment shall be rated in accordance with the requirements specified herein. Such ratings shall consist of

a maximum load rating for all items, and a main-bearing rating for crown blocks, traveling blocks, and swivels. *The traveling block and crown block ratings are independent of wire rope size and strength.* Such ratings shall be calculated as specified herein and in accordance with good engineering practices. The ratings determined herein are intended to apply to new equipment only.

Maximum Load Rating

The maximum load ratings shall be given in tons (2,000-lb units). The size class designation shall represent the dimensional interchangeability and the maximum rated load of equipment specified herein. The recommended size classes are as follows (ton):

5	40	350
10	65	500
15	100	650
25	150	750
250	1,000	

For purpose of interchangeability contact radii shall comply with [Table 4.2.1](#).

Maximum Load Rating Bases

The maximum load rating will be based on the design safety factor and the yield strength of the material. Crown block beams are an exception and shall be rated and tested in

accordance with API Spec 4F, “Specification for Drilling and Well Servicing Structures.”

Crown Block

For crown block design, see API Specification 4F. Crown block sheaves and bearings shall be designed in accordance with API Specification 8A.

Spacer Plates

Spacer plates of traveling blocks, not specifically designed to lend support to the sheave pin, shall not be considered in calculating the rated capacity of the block.

Sheave Pins

In calculations transferring the individual sheave loads to the pins of traveling blocks, these loads shall be considered as uniformly distributed over a length of pin equal to the length of the inner bearing race or over an equivalent length if an inner race is not provided.

Design Factor

The design safety factors shall be calculated as follows (Figure 4.2.7) for the relationship between the design safety factor and rating:

Calculated Rating (ton)	Yield Strength Design Safety Factor, SF _D
150 or less	3.00
Over 150 to 500	$3.00 - \frac{0.75(R^* - 150)}{350}$
Over 500	2.25

*R=rating in tons (2,000-lb units).

FIGURE 4.2.7 Design safety factor and rating relationships [1].

Mechanical Properties

The mechanical properties used for design shall be the minimum values allowed by the applicable material specification or shall be the minimum values determined by the manufacturer in accordance with the test procedures specified in ASTM A370: “Methods and Definitions for Mechanical Testing of Steel Products,” or by mill certification for mill products. The yield point shall be used in lieu of yield strength for those materials exhibiting a yield point. Yield strength shall be determined at 0.2% offset.

Shear Strength

For the purpose of calculations involving shear, the ratio of yield strength in shear-to-yield strength in tension shall be 0.58.

Extreme Low Temperature

Maximum load ratings shall be established at room temperature and shall be valid down to 0°F (-18°C). *The equipment at rated loads when temperature is less than 0°F is not recommended unless provided for by the supplement requirements. When the equipment is operating at lower temperatures, the lower impact absorbing characteristics of many steels must be considered.*

Test Unit

To ensure the integrity of design calculations, a test shall be made on one full size unit that in all respects represents the typical product. For a family of units of the same design concept but of varying sizes, or ratings, one test will be sufficient to verify the accuracy of the calculation method used, if the item tested is approximately midway of the size and rating range of the family, and the test results are applicable equally to all units in that family. Significant changes in design concept or the load rating will require supportive load testing.

Parts Testing

Individual parts of a unit may be tested separately if the holding fixtures simulate the load conditions applicable to the part in the assembled unit.

Test Fixtures

Test fixtures shall support the unit (or part) in essentially the same manner as in actual service, and with essentially the same areas of contact on the load-bearing surfaces.

Test Procedure

1. The test unit shall be loaded to the maximum rated load. After this load has been released, the unit shall be checked for useful functions. The useful function of all equipment parts shall not be impaired by this loading.

2. Strain gages may be applied to the test unit at all points where high stresses are anticipated, provided that the configuration of the units permits such techniques. The use of finite element analysis, models, brittle lacquer, etc., is recommended to confirm the proper location of strain gages. Three-element strain gages are recommended in critical areas to permit determination of the shear stresses and to eliminate the need for exact orientation of the gages.
3. The maximum test load to be applied to the test unit shall be $0.80 \times R \times SF_D$, but not less than $2R$. Where R equals the calculated load rating in tons, SF_D is design safety factor.
4. The unit shall be loaded to the maximum test load carefully, reading strain gage values and observing for yielding. The test unit may be loaded as many times as necessary to obtain adequate test data.
5. Upon completion of the load test, the unit shall be disassembled and the dimensions of each part shall be checked carefully for evidence of yielding.

Determination of Load Rating

The maximum load rating may be determined from design and stress distribution calculations or from data acquired during a load test. Stress distribution calculations may be used to load rate the equipment only if the analysis has been shown to be within acceptable engineering allowances as verified by a load test on one member of the family of units of the same design. The stresses at that rating shall not exceed the allowed values. Localized yielding shall be permitted at areas of contact. In a unit that has been load tested, the critical permanent deformation determined by strain gages or other suitable means shall not exceed 0.002 in./in. If the stresses exceed the allowed values, the affected part or parts must be revised to obtain the desired rating. Stress distribution calculations may be used to load rate the equipment only if the analysis has been shown to be within acceptable engineering allowances as verified by a load test of one member of the family of units of the same design.

Alternate Test Procedure and Rating

Destructive testing may be used provided an accurate yield and tensile strength for the material used in the equipment has been determined. This may be accomplished by using tensile test specimens of the actual material and determining the yield strength to ultimate strength ratio. This ratio is then used to obtain the rating R (ton) of the equipment by the following equation:

$$R = \frac{\left(\frac{YS}{TS}\right) L_B}{SF_D} \quad (4.2.12)$$

where SF_D = yield strength design safety factor
 YS = yield strength in psi
 TS = ultimate tensile strength in psi
 L_B = breaking load in tons

Load Testing Apparatus

The load apparatus used to simulate the working load on the test unit shall be calibrated in accordance with ASTM E-4: "Standard Methods of Verification of Testing Machines," so as to assure that the prescribed test load is obtained.

Block Bearing Rating

The bearing rating of crown and traveling blocks shall be determined by

$$W_b = \frac{NW_r}{714} \quad (4.2.13)$$

where W_b = calculated block bearing rating in tons
 N = number of sheaves in the block
 W_r = individual sheave bearing rating at 100 rpm for 3,000-hr minimum life for 90% of bearings in pounds.

Swivel Bearing Rating

The bearing rating of swivels shall be determined by

$$W_s = \frac{W_r}{1600} \quad (4.2.14)$$

where W_s = calculated main thrust-bearing rating at 100 rpm in tons
 W_r = main bearing thrust rating at 100 rpm for 3000-hr minimum life for 90% of bearings in pounds.

Traveling Block Hood Eye Opening Rating

The traveling block top handling member shall, for 500-ton size class and larger, have a static load rating based on safety factors given in the preceding paragraph titled "Design Factor."

Design Changes

When any change made in material, dimension, or construction might decrease the calculated load or bearing ratings, the unit changed shall be rerated, and retested if necessary. Parts of the modified unit that remain unchanged from the original design need not be retested, provided such omission does not alter the test results of the other components.

Records

The manufacturer shall keep records of all calculations and tests. When requested by prospective purchaser or by a user of the equipment, the manufacturer shall examine the details of computations, drawings, tests, or other supporting data

necessary to demonstrate compliance with the specification. It shall be understood that such information is for the sole use of the user or prospective purchaser for checking the API rating, and the manufacturer shall not be required to release the information from his custody.

4.2.2.3 Elevators

Drill pipe elevators for taper shoulder and square shoulder weld-on tool joints shall have bore dimensions as specified in [Table 4.2.2](#).

The permissible tolerance on the outside diameter immediately behind the tubing upset may cause problems with slip-type elevators.

4.2.2.4 Rotary Swivels

Rotary Swivel Pressure Testing

The assembled pilot model of rotary swivels shall be statically pressure tested. All cast members in the rotary swivel hydraulic circuit shall be pressure tested in production. This test pressure shall be shown on the cast member.

The test pressure shall be twice the working pressure up to 5,000 psi (incl.). For working pressures above 5,000 psi, the test pressure shall be one and one-half times the working pressure.

Swivel Gooseneck Connection

The angle between the gooseneck centerline and vertical shall be 15°. The swivel gooseneck connections shall be 2, 2½, 3, 3½, 4, or 5-in. nominal line pipe size as specified on the purchase order (see [Figure 4.2.8](#)). Threads on the gooseneck connection shall be internal line pipe threads conforming to API Standard 5B: “Threading, Gaging, and Thread Inspection of Casing, Tubing, and Line Pipe Threads.” Rotary swivel gooseneck connections shall be marked with the size and type of thread, such as 3 API LP THD.

Rotary Hose Safety Chain Attachment

Swivels with gooseneck connections in 2 in. or larger shall have a suitable lug containing a 1⅛-in. hole to accommodate the clevis of a chain having a breaking strength of 16,000 lb. The location of the lug is the choice of the manufacturer.

4.2.2.5 Sheaves for Hoisting Blocks

The sheave diameter shall be the overall diameter D as shown in [Figure 4.2.9](#). Sheave diameters shall, wherever practicable, be determined in accordance with recommendations given in the section titled “Wire Rope.”

Grooves for drilling and casing line sheaves shall be made for the rope size specified by the purchaser. The bottom of the groove shall have a radius R, [Table 4.2.3](#),

subtending an arc of 150°. The sides of the groove shall be tangent to the ends of the bottom arc. Total groove depth shall be a minimum of 1.33d and a maximum of 1.75d (d is the nominal rope diameter shown in [Figure 4.2.9](#)).

In the same manner, grooves for sand-line sheaves shall be made for the rope size specified by the purchaser. The bottom of the groove shall have a radius R, [Table 4.2.2](#), subtending an arc of 150°. The sides of the groove shall be tangent to the ends of the bottom arc. Total groove depth shall be a minimum of 1.75d and a maximum of 3d, and d is nominal rope diameter (see [Figure 4.2.9](#)).

Sheaves should be replaced or reworked when the groove radius decreases below the values shown in [Table 4.2.4](#). Use sheave gages as shown in [Figure 4.2.10](#). [Figure 4.2.10A](#) shows a sheave with a minimum groove radius, and [Figure 4.2.10B](#) shows a sheave with a tight groove.

4.2.2.6 Contact Surface Radii

Figures 4.2.11, 4.2.12, 4.2.13 and [Table 4.2.1](#) show recommended radii of hoisting tool contact surfaces. These recommendations cover hoisting tools used in drilling, and tubing hooks, but all other workover tools. Contact radii are intended to cover *only points of contact* between two elements and are not intended to define other physical dimensions of the connecting parts.

4.2.2.7 Inspection, Nondestructive Examination, and Compliance

Inspection

While work on the contract of the purchaser is being performed, the purchaser’s inspector, shall have reasonable access to the appropriate parts of the manufacturer’s works concerning the manufacture of the equipment ordered hereunder. Inspection shall be made at the works prior to shipment, unless otherwise specified, and shall be conducted so as not to interfere unnecessarily with the works’ operation or production schedules.

Nondestructive Examination

The manufacturer shall have a reasonable written nondestructive examination program to assure that the equipment manufactured is suitable for its intended use. If the purchaser’s inspector desires to witness these operations, the manufacturer shall give reasonable notice of the time at which the examinations are to be performed.

Compliance

The manufacturer is responsible for complying with all of the provisions of the specification.

4.2.2.8 Supplementary Requirements

Magnetic Particle Examination

All accessible surfaces of the main load carrying components of the equipment shall be examined by a magnetic particle examination method or technique conforming to the requirements of ASTM E709: "Recommended Practice for Magnetic Particle Examination." Acceptance limits shall be as agreed upon by the manufacturer and the purchaser.

Liquid Penetrant Examination

All accessible surfaces of the main load carrying components of the equipment shall be examined by a liquid penetrant examination or technique conforming to the requirements of ASTM E165: "Recommended Practice for the Liquid Penetrant Examination Method." Acceptance limits shall be as agreed upon by the manufacturer and the purchaser.

FIGURE 4.2.11 Elevator link [2].

Ultrasonic Examination

Main load carrying components of the equipment shall be ultrasonically examined in accordance with applicable ASTM standards. The extent of examination, method of examination, and basis for acceptance shall be agreed upon by the manufacturer and purchaser.

Radiographic Examination

Main load carrying components of the equipment shall be examined by means of gamma rays or x-rays. The procedure used shall be in accordance with applicable ASTM

FIGURE 4.2.12 Elevator link and link ear contact surface radii [1].

FIGURE 4.2.13 Hook and swivel bail contact surface radii [1].

standards. Types and degrees of discontinuities considered shall be compared to the reference radiographs of ASTM as applicable. The extent of examination and the basis for acceptance shall be agreed upon by the manufacturer and purchaser.

Traceability

The manufacturer shall have reports of chemical analysis, heat treatment, and mechanical property tests for the main load carrying components of the equipment.

Welding

Where welding is involved in the critical load path of main load carrying components, recognized standards shall be used to qualify welders and procedures.

Extreme Low Temperature

Equipment intended for operation at temperatures below 0°F may require special design and/or materials.

4.2.3 Hoisting Tool Inspection and Maintenance Procedures

4.2.3.1 Inspection

Frequency of Inspection

Field inspection of drilling, production, and workover hoisting equipment in an operating condition should be made on a regular basis. A thorough on-the-job shutdown inspection should be made on a periodic basis, typically at 90 to 120-day intervals, or as special circumstances may require.

Critical loads may be experienced; for example, severe loads, impact loads such as jarring, pulling on stuck pipe, and/or operating at low temperatures. If in the judgement of the supervisor a critical load has occurred, or may occur, an on-the-job shutdown inspection equivalent to the periodic field inspection should be conducted before and after the occurrence of such loading. If critical loads are unexpectedly encountered, the inspection should be conducted immediately after such an occurrence.

When necessary, disassembly inspection of hoisting equipment should be made in a suitably equipped facility.

Methods of Inspection

Hoisting equipment should be inspected on a regular basis for cracks, loose fits or connections, elongation of parts, and other signs of wear, corrosion, or overloading. Any equipment showing cracks, excessive wear, etc., should be removed from service.

The periodic or critical load inspection in the field should be conducted by the crew with the inspector. For the periodic or critical load inspection, all foreign matter should be removed from surfaces inspected. Total field disassembly is generally not practical, and is not recommended, except as may be indicated in the detailed procedure for each tool.

Equipment, if necessary, should be disassembled in a suitably equipped facility and inspected for excessive wear, cracks, flaws, or deformation. Corrections should be made in accordance with the recommendations of the manufacturer. Before inspection, all foreign material, such as dirt, paint, grease, oil, scale, etc., should be removed from the inspected areas by a suitable method. The equipment should be disassembled as much as necessary to permit inspection of all load bearing parts, and the inspection should be made by trained, competent personnel.

4.2.3.2 Maintenance and Repairs

A regular preventive maintenance program should be established for all hoisting tools. Written maintenance procedures should be given to the crew or maintenance personnel. Maintenance procedures should be specified for each tool, as well as the specific lubricants to be used, and should be based on the tool manufacturer's recommendation. This recommended practice includes generalized procedures that are considered a minimum program. Care should be taken that instruction plates, rating plates, and warning labels are not missing, damaged, or illegible.

If repairs are not performed by the manufacturer, such repairs should be made in accordance with methods or procedures approved by the manufacturer. Minor cracks or defects, which may be removed without influence on safety or operation of the equipment, can be removed by grinding or filing. Following repair, the part should again be inspected by an appropriate method to ensure that the defect has been completely removed.

Antifriction bearings play an important part in the safe performance of the tool. The most likely requirements for bearing placement are very loose or bent cages (retainers), corrosion, abrasion, inadequate (or improper) lubrication, and spalling from fatigue. Excessive clearance may indicate improper adjustment or assembly and should be corrected.

Repair of antifriction bearings should not be attempted by field or shop personnel. Consultation with the equipment manufacturer is recommended in case of unexplained or repeated bearing failure.

If the tool or part is defective beyond repair, it should be destroyed immediately.

Welding should not be done on hoisting tools without consulting the manufacturer. Without full knowledge of the design criteria, the materials used and the proper procedures (stress relieving, normalizing, tempering, etc.), it is possible to reduce the capacity of a tool sufficiently to make its continued use dangerous.

Inspection and maintenance (lubrication) of wire rope used in hoisting should be carried out on a regular basis. Wire rope inspection and maintenance recommendations are included in API RP 9B, "Application, Care and Use of Wire Rope for Oil Field Service" (see "Wire Rope") [3-5].

4.2.3.3 Inspection and Maintenance Illustrations

Figures 4.2.14 through 4.2.31 are self-explanatory illustrations of generalized inspection and maintenance recommendations for each of the hoisting tools.

FIGURE 4.2.14 Crown block [2].

MAINTENANCE:

1. Keep clean.
2. Lubricate bearings.
3. Remove any rust and weather protect as required.
4. Check and secure all fasteners.

FIGURE 4.2.15 Traveling block [2].

MAINTENANCE:

1. Keep clean.
2. Grease coat wear surface of clevis.
3. Remove any rust and weather protect as required.
4. Check and secure all pins.

FIGURE 4.2.16 Block-to-hook adapter [2].

- MAINTENANCE:**
1. Keep clean.
 2. Grease coat wear surfaces.
 3. On units with hydraulic snubber check oil level and change oil at intervals recommended by manufacturer.
 4. Oil pins not accessible to grease lubrication.
 5. Remove any rust and weather protect as required.
 6. Check and secure pins and fasteners.

FIGURE 4.2.17 Link adapter [2].

4.2.4 Wire Rope

Wire rope includes (1) bright (uncoated), galvanized, and drawn-galvanized wire rope of various grades and construction, (2) mooring wire rope, (3) torpedo lines, (4) well-measuring wire, (5) well-measuring strand, (6) galvanized wire guy strand, and (7) galvanized structural rope and strand [3–5].

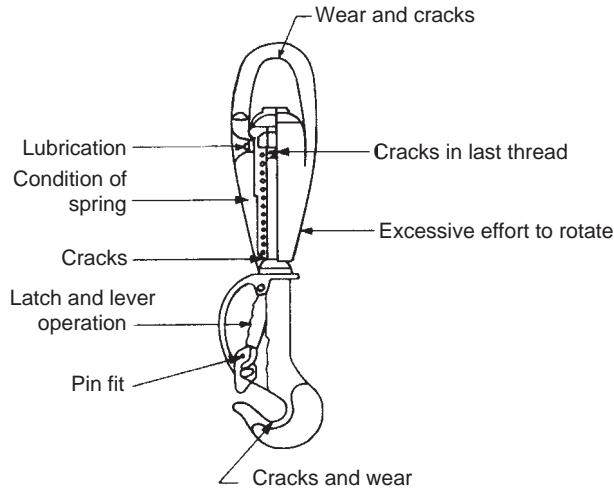

4.2.4.1 Material

Wire used in the manufacture of wire rope is made from (1) acid or basic open-hearth steel, (2) basic oxygen steel, or (3) electric furnace steel. Wire tested before and after fabrication shall meet different tensile and torsional requirements as specified in Tables 4.2.5 and 4.2.6 [4,5].

- MAINTENANCE:**
1. Keep clean.
 2. Grease coat latching mechanism, link arms, and saddle.
 3. Lube all grease fittings.
 4. On units with hydraulic snubber check oil level and change oil at intervals recommended by manufacturer.
 5. Oils pins not accessible to grease lubrication.
 6. Remove any rust and weather protect as required.
 7. Check and secure pins and fasteners.

FIGURE 4.2.18 Drilling hook [2].

MAINTENANCE:

1. Keep clean.
2. Grease coat latching mechanism, hook, and bail throat.
3. Grease main bearing.
4. Oil pins not accessible to grease lubrication.
5. Remove any rust and weather protect as required.
6. Check and secure pins and fasteners.

FIGURE 4.2.19 Tubing and sucker rod hook [2].

MAINTENANCE:

1. Keep clean.
2. Grease coat upper and lower eye wear surfaces.
3. Remove any rust and weather protect as required.

FIGURE 4.2.20 Elevator link [2].

MAINTENANCE:

1. Keep clean.
2. Grease coat link arm wear surfaces, latch lug and bore seat on bottleneck elevators.
3. Lubricate hinge pin.
4. Remove any rust and weather protect as required.
5. Check and secure pins and fasteners.

FIGURE 4.2.21a Casing, tubing, and drill pipe elevators and side door elevators [2].

MAINTENANCE:

1. Keep clean.
2. Grease coat link arm wear surfaces, latch lug and bore seat on bottleneck elevators.
3. Lubricate hinge pin.
4. Remove any rust and weather protect as required.
5. Check and secure pins and fasteners.

FIGURE 4.2.21b Casing, tubing, and drill pipe elevators and center latch elevators [2].

FIGURE 4.2.21c Casing, tubing, and drill pipe elevators and slip type elevators [2].

FIGURE 4.2.22 Sucker rod elevators [2].

MAINTENANCE:

1. Keep clean.
2. Lubricate pivot and pin.
3. Remove any rust and weather protect as required.
4. Check and secure pins and fasteners.

FIGURE 4.2.23 Swivel bail adapter [2].

MAINTENANCE:

1. Keep clean.
2. Grease coat bail throat wear surface.
3. Lubricate bail pins, oil seals, upper bearing, and packing.
4. Check oil level as recommended by manufacturer.
5. Change oil at intervals recommended by manufacturer.
6. Remove any rust and weather protect as required.
7. Check and secure fasteners.
8. Protect threads at the gooseneck inlet and on the coupling nipple when not assembled during handling. Thread protection should be used.

FIGURE 4.2.24 Rotary swivel [2].

MAINTENANCE:

1. Keep clean.
2. Lubricate taper before each trip.
3. Remove any rust and weather protect as required.

FIGURE 4.2.25 Spider [2].

MAINTENANCE:

1. Keep clean.
2. Grease coat surface of wire line spool.
3. On units equipped with load cell for weight indicator, lubricate pivot bearing.
4. Remove any rust and weather protect as required.

FIGURE 4.2.26 Deadline anchor [2].

MAINTENANCE:

1. Keep clean.
2. Use thread compound on pin and box, and apply proper makeup torque in accordance with API RP-7G recommendations.
3. Maintain power unit in accordance with manufacturer's recommendations.
4. Remove any rust and weather protect as required.
5. Check and secure fasteners.

FIGURE 4.2.27 Kelly spinner [2].

MAINTENANCE:

1. Keep clean.
2. Remove any rust and weather protect as required.

FIGURE 4.2.28 Rotary table [2].

INSPECTION:

Heave compensator designs vary considerably among manufacturers, therefore, manufacturer's recommendations should be closely followed. In general, load carrying members should be checked for wear, cracks, flaws, and deformation. For compensators with integral traveling block and hook adaptor, the procedures defined in Figures. 4.2.11 and 4.2.12 apply to those parts of the assembly.

MAINTENANCE:

1. Keep clean.
2. Follow manufacturer's recommendations for specific unit.
3. For compensators with integral traveling block and hook adaptor, the procedures in Figures. 4.2.11 and 4.2.12 apply to those parts of the assembly.
4. Remove any rust and weather protect as required.

FIGURE 4.2.29 Heave compensator [2].

INSPECTION:

Tension members for sub sea handling equipment should be inspected according to the manufacturer's recommendations. In general, tension members should be checked for wear, cracks, reduction of area and elongation.

MAINTENANCE:

1. Tension members in sub sea handling equipment should be maintained in accordance with manufacturer's recommendations.

FIGURE 4.2.30 Tension members of subsea handling equipment [2].

**MAINTENANCE:**

1. Keep clean.
2. Check the insert slots for wear and replace inserts as required.
3. Lubricate hinge pin.
4. Remove any rust and protect as required.
5. Use straight edge to detect uneven wear or damage.
6. *Caution:* Do not use wrong size slips—Match pipe and slip size.

FIGURE 4.2.31 Rotary slips [2].

Galvanized Wire Rope

Galvanized wire rope shall be made of wire having a tightly adherent, uniform and continuous coating of zinc applied after final cold drawing, by the electrodeposition process or by the hot-galvanizing process. The minimum weight of zinc coating shall be as specified in [Table 4.2.7](#).

Drawn-Galvanized Wire Rope

Drawn-galvanized wire rope shall be made of wire having a tightly adherent, uniform, and continuous coating of zinc applied at an intermediate stage of the wire drawing operation, by the electrodeposition process or by the hot-galvanizing process. The minimum weight of zinc coating shall be as specified in [Table 4.2.8](#).

4.2.4.2 Properties and Tests for Wire and Wire Rope

Selection of Test Specimens

For the test of individual wires and of rope, a 10-ft (3.05-m) section shall be cut from a finished piece of unused and undamaged wire rope; such sample must be new or in an unused condition. The total wire number to be tested shall be equal to the number of wires in any one strand, and the wires shall be selected from all strands of the rope. The specimens shall be selected from all locations or positions so that they would constitute a complete composite strand exactly similar to a regular strand in the rope. The specimen for all "like-positioned" (wires symmetrically placed in a strand) wires to be selected so as to use as nearly as possible an equal number from each strand. Any unsymmetrically placed wires, or marker wires, are to be disregarded entirely.

TABLE 4.2.8 Weight of Zinc Coating for Drawn-Galvanized Rope Wire [4,5]

(1)	(2)	(3)	(4)
Diameter of Wire		Minimum Weight of Zinc Coating	
in.	mm	oz./ft ²	kg/m ²
0.018 to 0.028	0.46 to 0.71	0.10	0.03
0.029 to 0.060	0.74 to 1.52	0.20	0.06
0.061 to 0.090	1.55 to 2.29	0.30	0.09
0.091 to 0.140	2.31 to 3.56	0.40	0.12

Center wires are subject to the same stipulations that apply to symmetrical wires.

Selection and testing of wire prior to rope fabrication will be adequate to ensure the after-fabrication wire rope breaking strength and wire requirements can be met. Prior to fabrication, wire tests should meet the requirements of Table 4.2.6 [4,5].

Conduct of Tests

The test results of each test on any one specimen should be associated and may be studied separately from other specimens.

If, when making any individual wire test on any wire, the first specimen fails, not more than two additional specimens from the same wire shall be tested. The average of any two tests showing failure or acceptance shall be used as the value to represent the wire. The test for the rope may be terminated at any time sufficient failures have occurred to be the cause for rejection.

The purchaser may at his or her expense test all of the wires if the results of the selected tests indicate that further checking is warranted.

Tensile Requirements of Individual Wire

Specimens shall not be less than 18 in. (457 mm) long, and the distance between the grips of the testing machine shall not be less than 12 in. (305 mm). The speed of the movable head of the testing machine, under no load, shall not exceed 1 in./min (0.4 mm/s). Any specimen breaking within $\frac{1}{4}$ in. (6.35 mm) from the jaws shall be disregarded and a retest made.

Note: The diameter of wire can more easily and accurately be determined by placing the wire specimen in the test machine and applying a load not over 25% of the breaking strength of the wire.

The breaking strength of either bright (uncoated) or drawn-galvanized wires of the various grades shall meet the values shown in Table 4.2.5 or Table 4.2.6 for the size wire being tested. Wire tested after rope fabrication allows one wire in 6×7 classification, or three wires in 6×19 and 8×19 classifications and 18×7 and 19×7 constructions, or six wires in 6×37 classification or nine wires in 6×61 classification, or twelve wires in 6×91 classification wire rope to fall below but not more than 10% below the tabular value for individual minimum. If, when making the specified test, any wires fall below, but not more than 10% below the individual minimum, additional wires from the same rope shall be tested until there is cause for rejection or until all of the wires in the rope have been tested. Tests of individual wires in galvanized wire rope and of individual wires in strand cores and in independent wire rope cores are not required [4,5].

Torsional Requirements of Individual Wire

The distance between the jaws of the testing machine shall be 8 in. $\pm \frac{1}{16}$ in. (203 mm \pm 1 mm). For small diameter

0.017 to 0.020	0.43 to 0.52	2	9
0.021 to 0.030	0.53 to 0.77	4	18
0.031 to 0.040	0.78 to 1.02	6	27
0.041 to 0.050	1.03 to 1.28	8	36
0.051 to 0.060	1.29 to 1.53	9	40
0.061 to 0.070	1.54 to 1.79	11	49
0.071 to 0.080	1.80 to 2.04	13	58
0.081 to 0.090	2.05 to 2.30	16	71
0.091 to 0.100	2.31 to 2.55	19	85
0.101 to 0.110	2.56 to 2.80	21	93
0.111 to 0.120	2.81 to 3.06	23	102
0.121 to 0.130	3.07 to 3.31	25	111

*Weights shall not exceed twice the minimums listed.

wires, where the number of turns to cause failure is large, and in order to save testing time, the distance between the jaws of the testing machine may be less than 8 in. (203 mm). One end of the wire is to be rotated with respect to the other end at a uniform speed not to exceed sixty 360° (6.28 rad) twists per minute, until breakage occurs. The machine must be equipped with an automatic counter to record the number of twists causing breakage. One jaw shall be fixed axially and the other jaw movable axially and arranged for applying tension weights to wire under test. Tests in which breakage occurs within $\frac{1}{8}$ in. (3.18 mm) of the jaw shall be discarded.

In the torsion test, the wires tested must meet the values for the respective grades and sizes as covered by [Table 4.2.8](#) or [Table 4.2.9](#). In wire tested after rope fabrication, it will be permissible for two wires in 6×7 classification or five wires in 6×19 and 8×19 classifications and 18×7 and 19×7 constructions or ten wires in 6×37 classification or fifteen wires in 6×61 classification, or twenty wires in 6×91

classification rope to fall below, but not more than 30% below, the specified minimum number of twists for the individual wire being tested.

During the torsion test, tension weights as shown in [Table 4.2.9](#) shall be applied to the wire tested.

The minimum torsions for individual bright (uncoated) or drawn-galvanized wire of the grades and sizes shown in Columns 7, 12, and 17 of [Tables 4.2.5](#) and [4.2.6](#) shall be the number of 360° (6.28 rad) twists in an 8-in. (203 mm) length that the wire must withstand before breakage occurs. Torsion tests of individual wires in galvanized wire rope and of individual wires in strand cores and independent wire rope cores are not required [4,5].

When the distance between the jaws of the testing machine is less than 8 in. (203 mm), the minimum torsions shall be reduced in direct proportion to the change in jaw spacing, or determined by

$$T_s = \frac{(T_L)(L_s)}{(L_L)} \quad (4.2.15)$$

where T_s = minimum torsions for short wire

T_L = minimum torsions for 8-in. (203-mm) length as given in [Table 4.2.5](#) for size and grade of wire

L_s = distance between testing-machine jaws for short wire in in. (mm)

L_L = 8 in. (203 mm)

Breaking Strength Requirements for Wire Rope

The nominal strength of the various grades of finished wire rope with fiber core shall be as specified in [Tables 4.2.10](#), [4.2.11](#), and [4.2.12](#). The nominal strength of the various grades of wire rope having a strand core or an independent wire-rope core shall be as specified in [Tables 4.2.13](#) through [4.2.18](#). The nominal strength of the various types of flattened strand wire rope shall be specified in [Table 4.2.19](#). The nominal strength of the various grades of drawn-galvanized wire rope shall be specified in [Tables 4.2.10](#) through [4.2.19](#) [4,5].

When testing finished wire-rope tensile test specimens to their breaking strength, suitable sockets shall be attached by the correct method. The length of test specimen shall not be less than 3 ft (0.91 m) between sockets for wire ropes up to 1-in. (25.4 mm) diameter and not less than 5 ft (1.52 m) between sockets for wire ropes $1\frac{1}{8}$ -in. (28.6 mm) to 3-in. (77 mm) diameter. On wire ropes larger than 3 in. (77 mm), the clear length of the test specimen shall be at least 20 times the rope diameter. The test shall be valid if failure occurs 2 in. (50.8 mm) from the sockets or holding mechanism.

Due to the variables in sample preparation and testing procedures, it is difficult to determine the true strength. Thus, the actual breaking strength during test shall be at least 97.5% of the nominal strength as shown in the applicable table. If the first specimen fails at a value below the 97.5% nominal strength value, a second test shall be made, and if the second test meets the strength requirements, the wire rope shall be accepted [4,5].

4.2.4.3 Manufacture and Tolerances

Strand Construction

The 6×7 classification ropes shall contain six strands that are made up of 3 through 14 wires, of which no more than 9 are outside wires fabricated in one operation.* See Table 4.2.10 and Figure 4.2.32.

The 6×19 classification ropes shall contain 6 strands that are made up of 15 through 26 wires, of which no more than 12 are outside wires fabricated in one operation. See Tables 4.2.11 and 4.2.13 and Figures 4.2.33 to 4.2.38. The 6×37 classification ropes shall contain six strands that are made up of 27 through 49 wires, of which no more than 18 are outside wires fabricated in one operation. See Tables 4.2.11 and 4.2.14 and Figures 4.2.39 to 4.2.46.

The 6×61 classification ropes shall contain six strands that are made up of 50 through 74 wires, of which no more than 24 are outside wires fabricated in one operation. See Table 4.2.15 and Figures 4.2.47. and 4.2.48.

The 6×91 classification wire rope shall have six strands that are made up of 75 through 109 wires, of which no more than 30 are outside wires fabricated in one operation. See Table 4.2.16 and Figures 4.2.49. and 4.2.50.

The 8×19 classification wire rope shall have eight strands that are made up of 15 through 26 wires, of which no more than 12 are outside wires fabricated in one operation. See Table 4.2.17 and Figures 4.2.51. and 4.2.52.

The 18×7 and 19×7 wire rope shall contain 18 or 19 strands, respectively. Each strand is made up of seven wires. It is manufactured counterhelicallly laying an outer 12-strand layer over an inner 6×7 or 7×7 wire rope. This produces a rotation-resistant characteristic. See Tables 4.2.12 and 4.2.18 and Figures 4.2.53 and 4.2.54.

The 6×25 “B,” 6×27 “H,” 6×30 “G,” and 6×31 “V” flattened strand wire rope shall have six strands with 24 wires fabricated in two operations around a semitriangular shaped core. See Table 4.2.19 and Figures 4.2.55 to 4.2.58.

In the manufacture of uniform-diameter wire rope, wires shall be continuous. If joints are necessary in individual wires, they shall be made, prior to fabrication of the strand, by brazing or electric welding. Joints shall be spaced in accordance with the equation.

$$J = 24D \quad (4.2.16)$$

where J = minimum distance between joints in main wires in any one strand in in. mm

D = nominal diameter of wire rope in in. mm

Wire rope is most often furnished preformed, but can be furnished non-preformed, upon special request by the purchaser. A preformed rope has the strands shaped to the helical form they assume in the finished rope before the strands have been fabricated into the rope. The strands of such preformed rope shall not spring from their normal position when the seizing bands are removed. Cable tool is one of the few application for which nonpreformed is still used.

The Lay of Finished Rope

Wire rope shall be furnished right lay or left lay and regular lay or Lang lay as specified by the purchaser (Figure 4.2.59). If not otherwise specified on the purchase order, right-lay, regular-lay rope shall be furnished. For 6×7 wire ropes, the lay of the finished rope shall not exceed eight times the nominal diameter. For 6×19, 6×37, 6×61, 6×91 and 8×19 wire rope, the lay of the finished rope shall not exceed $7\frac{1}{4}$ times the nominal diameter. For flattened strand rope designations 6×25 “B,” 6×27 “H,” 6×30 “G,” and 6×31 “V,” the lay of the finished rope shall not exceed eight times the nominal diameter.

Diameter of Ropes and Tolerance Limits

The diameter of a wire rope shall be the diameter of a circumscribing circle and shall be measured at least 5 ft (1.52 m) from properly seized end with a suitable caliper (Figure 4.2.60). The diameter tolerance* of wire rope shall be

Nominal inch diameter: −0% to +5%

Nominal mm diameter: −1% to +4%

Diameter of Wire and Tolerance Limits

In separating the wire rope for gaging of wire, care must be taken to separate the various sizes of wire composing the

*One operation strand—When the king wire of the strand becomes so large (manufacturer’s discretion) that it is considered undesirable, it is allowed to be replaced with a seven-wire strand manufactured in a separate stranding operation. This does not constitute a two-operation strand.

*A question may develop as to whether or not the wire rope complies with the oversize tolerance. In such cases, a tension of not less than 10% nor more than 20% of nominal required breaking strength is applied to the rope, and the rope is measured while under this tension.

different layers of bright (uncoated), drawn-galvanized, or galvanized wires in the strand. In like-positioned wires total variations of wire diameters shall not exceed the values of Table 4.2.20 [4,5].

Fiber Cores

For all wire ropes, all fiber cores shall be hard-twisted, best-quality, manila, sisal, polypropylene, or equivalent. For wire ropes of uniform diameter, the cores shall be of uniform

diameter and hardness, effectively supporting the strands. Manila and sisal cores shall be thoroughly impregnated with a suitable lubricating compound free from acid. Jute cores shall not be used.

Lengths

Length of wire rope shall be specified by the purchaser. If minimum length is critical to the application, it shall be specified and conform to the following tolerances.

Correct way to measure the diameter of wire rope. Incorrect way to measure the diameter of wire rope.

FIGURE 4.2.60 Measurement of diameter [4,5].

Lubrication

All wire rope, unless otherwise specified, shall be lubricated and impregnated in the manufacturing process with a suitable compound for the application in amounts best adapted to individual territories. This lubricant should thoroughly protect the ropes internally and externally to minimize rust or corrosion until the rope is put in service.

4.2.4.4 Mooring Wire Rope

Mooring wire rope is used as anchor lines in spread mooring systems, and shall comply with all the provisions of wire rope.

Wire rope for this use should be one operations, right lay, regular lay, independent wire rope core, preformed, galvanized or bright. The nominal strength of galvanized and bright mooring wire rope shall be as specified in Table 4.2.21. For bright mooring wire ropes, the wire grade

NOTE: For tests see Paragraph titled "Acceptance."

shall comply with the requirements for Extra Improved Plow Steel.

4.2.4.5 Torpedo Lines

Torpedo lines shall be bright (uncoated) or drawn-galvanized, and shall be right, regular lay. The lay of the finished rope shall not exceed eight times the nominal diameter.

Torpedo lines shall be made of five strands of five wires each, or five strands of seven wires each. The strands of the 5×5 construction shall have one center wire and four outer wires of one diameter, fabricated in one operation. The five strands shall be laid around one fiber or cotton core (Figure 4.2.61). The strands of the 5×7 construction shall have one center wire and six outer wires of one diameter, fabricated in one operation. The strands shall be laid around one fiber or cotton core (Figure 4.2.62).

The four outer wires in each strand of the 5×5 construction [both bright (uncoated) and drawn-galvanized] and all

FIGURE 4.2.61 5×5 construction torpedo line [4,5].

the wires in each strand of the 5×7 construction [both bright (uncoated) and drawn-galvanized] shall have the breaking strengths as in Tables 4.2.11 and 4.2.12 for the specified grade and applicable wire size. The center wire of the 5×5 construction shall be hard drawn or annealed and shall not be required to meet the minimum breaking strength specified for the outer wires (the center wire represents about 5% of the total metallic area of the rope and is substantially a filler wire).

FIGURE 4.2.62 5x7 construct torpedo line [4,5].

The nominal strength of torpedo lines shall be as specified in Tables 4.2.22 and 4.2.23. When testing finished ropes to their breaking strength, suitable sockets or other acceptable means of holding small cords shall be used. The length of tension test specimen shall be not less than 1 ft (0.305 m) between attachments. If the first specimen fails at a value below the specified nominal strength, two additional

specimens from the same rope shall be tested, one of which must comply with the nominal strength requirement.

The diameter of the ropes shall be not less than the specified diameter. Torpedo-line lengths shall vary in 500-ft (152.4 m) multiplies.

4.2.4.6 Well-Measuring Wire

Well-measuring wire shall be in accordance with Table 4.2.24 and shall consist of one continuous piece of wire without brazing or welding of the finished wire. The wire shall be made from the best quality of specified grade of material with good workmanship and shall be free from defects that might affect its appearance or serviceability. Coating on well-measuring wire shall be optional with the purchaser.

* For well-measuring wire of other materials or coatings, refer to supplier for physical properties.

A specimen of 3-ft (0.91 m) wire shall be cut from each coil of well-measuring wire. One section of this specimen shall be tested for elongation simultaneously with the test for tensile strength. The ultimate elongation shall be measured on a 10-in. (254 mm) specimen at instant of rupture, which must occur within the 10-in. (254 mm) gage length. To determine elongation, a 100,000-psi (690-mPa) stress shall be imposed upon the wire at which the extensometer is applied. Directly to the extensometer reading shall be added 0.4% to allow for the initial elongation occurring before application of extensometer.

The remaining section of the 3-ft (0.91-m) test specimen shall be gaged for size and tested for torsional requirements.

If, in any individual test, the first specimen fails, not more than two additional specimens from the same wire shall be tested. The average of any two tests showing failure or acceptance shall be used as the value to represent the wire.

4.2.4.7 Well-Measuring Strand

Well-measuring strand shall be bright (uncoated) or drawn-galvanized.

Well-measuring strand shall be left lay. The lay of the finished strand shall not exceed 10 times the nominal diameter.

Well-measuring strands may be of various combinations of wires but are commonly furnished in 1×16 (1-6-9) and 1×19 (1-6-12) constructions.

TABLE 4.2.25 Requirements for Well-Servicing Strand Bright or Drawn-Galvanized Carbon Steel [4,5]

1		2	3

	KN	20.9	36.5
Approximate mass	Lbs./100'	7.3	12.7
	kg/100'	3.3	5.8

Well-measuring strands shall conform to the properties listed in Table 4.2.25.

To test finished strands to their breaking strength, suitable sockets or other acceptable means of holding small cords shall be used.

4.2.4.8 Wire Guy Strand and Structural Rope and Strand

Galvanized wire guy strand shall conform to ASTM A-475: "Zinc-Coated Steel Wire Strand." Aluminized wire guy strand can conform to ASTM A-474: "Aluminum Coated Steel Wire Strand." Galvanized structural strand shall conform to ASTM A-586: "Zinc-Coated Steel Structural Strand." Galvanized structural rope shall conform to ASTM A-603: "Zinc-Coated Steel Structural Wire Rope:"

4.2.4.9 Packing and Marking

Finished wire rope, unless otherwise specified, shall be shipped on substantial round-head reels. Reels on which sand lines, drilling lines, or casing lines are shipped shall have round arbor holes of 5 in. (127 mm) to $5\frac{3}{4}$ in. (146 mm) diameter. When reel is full of rope, there shall be a clearance of not less than 2 in. (51 mm) between the full reel and the outside diameter of the flange.

The manufacturer shall protect the wire rope on reels from damage by moisture, dust, or dirt with a water-resistant covering of builtup material, such as tar paper and burlap, or similar material.

The following data shall be plainly marked on the face of the wire-rope reel:

1. Name of manufacturer.
2. Reel Number.
3. API monogram only by authorized manufacturers.
4. Grade (plow steel, improved plow steel, or extra improved plow steel).
5. Diameter of rope, in. (mm).
6. Length of rope, ft (m).
7. Type of construction (Warrington, Seale, or filler wire).
8. Type of core (fiber, wire, plastic, or fiber and plastic).

4.2.4.10 Inspection and Rejection

The manufacturer will, on request of the purchaser, conduct tests as called for in specifications on reasonable notice from the purchaser. During the tests, the manufacturer will afford opportunity to the purchaser's representative to present.

The manufacturer, when delivering wire rope with the API monogram and grade designation, should warrant that such material complies with the specification. The wire rope rejected under specifications should not be wound on reels bearing the API monogram, or sold as API wire rope. When the wire rope wound on reels bearing the API monogram is rejected, the monogram shall be removed.

It is recommended that whenever possible, the purchaser, upon receipt, shall test all new wire rope purchased in accordance with specifications. If a rope fails to render satisfactory service, it is impractical to retest such used rope. It is therefore required that the purchaser shall preserve at

least one test specimen of all new rope purchased, length of specimen to be at least 10 ft (3.05 m), properly identified by reel number, etc. Care must be taken that no damage will result by storage of specimen.

If the purchaser is not satisfied with the wire rope service, he or she shall send the properly preserved sample or a sample of the rope from an unused section to any testing laboratory mutually agreed upon by the purchaser and the manufacturer, with instructions to make a complete API test, and notify the manufacturer to have a representative present. If the report indicates compliance with specifications, the purchaser shall assume cost of testing; otherwise, the manufacturer shall assume the expense and make satisfactory adjustments not exceeding full purchase price of the rope. If the report indicates noncompliance with specifications, the testing laboratory shall forward a copy of the test report to the manufacturer.

4.2.4.11 Wire-Rope Sizes and Constructions

Typical sizes and constructions of wire rope for oilfield service are shown in Table 4.2.26. Because of the variety of equipment designs, the selection of other constructions than those shown is justifiable.

In oil field service, wire rope is often referred to as wire line or cable. For clarity, these various expressions are incorporated in this recommended practice.

4.2.4.12 Field Care and Use of Wire Rope

Handling on Reel

When handling wire rope on a reel with a binding or lifting chain, wooden blocks should always be used between the rope and the chain to prevent damage to the wire or distortion of the strands in the rope. Bars for moving the reel should be used against the reel flange, and not against the rope. The reel should not be rolled over or dropped on any hard, sharp object to protect the rope, and should not be dropped from a truck or platform to avoid damage to the rope and the reel.

Rolling the reel in or allowing it to stand in any harmful medium such as mud, dirt or cinders should be avoided. Planking or cribbing will be of assistance in handling the reel as well as in protecting the rope against damage.

Handling during Installation

Blocks should be strung to give a minimum of wear against the sides of sheave grooves. It is also good practice in changing lines to suspend the traveling block from the crown on a single line. This tends to limit the amount of rubbing on guards or spacers, as well as chances for kinks. This is also very effective in pull-through and cutoff procedures.

TABLE 4.2.26 Typical Sizes and Constructions of Wire Rope for Oilfield Service [4,5]

FS — Flattened strand	EIPS — Extra improved plow steel		LL — Left lay
FW — Filler-Wire	PF — Preformed		FC — Fiber core
PS — Plow steel	NPF — Non-preformed		IWRC — Independent wire rope core

¹Single linc pulling of rods and tubing requires left lay construction or 18 x 7 or 19 x 7 construction. Either left lay or right lay may be used for multiple line pulling.

²Bright wire sand lines are regularly furnished; galvanized finish is sometimes required.

³Applies to pumping units having one piece of wire rope looped over an ear on the horsehead and both ends fastened to a polished-rod equalizer yoke.

⁴Applies to pumping units having two vertical lines (parallel) with sockets at both ends of each line.

⁵See API Spec 4E: *Specification for Drilling and Well Servicing Structures*.

The reel should be set up on a substantial horizontal axis, so that it is free to rotate as the rope is pulled off, and the rope will not rub against derrick members or other obstructions while being pulled over the crown. A snatch block with a suitable size sheave should be used to hold the rope away from such obstructions.

A suitable apparatus for jacking the reel off the floor and holding it so that it can turn on its axis is desirable. Tensions should be maintained on the wire rope as it leaves the reel by restricting the reel movement. A timber or plank provides satisfactory brake action. When winding the wire rope onto the drum, sufficient tension should be kept on the rope to assure tight winding.

To replace a worn rope with a new one, a swivel-type stringing grip for attaching the new rope to the old rope is recommended. This will prevent transferring the twist from one piece of rope to the other. Ensure that the grip is properly applied. The new rope should not be welded to the old rope to pull it through the system.

Care should be taken to avoid kinking a wire rope since a kink can be cause for removal of the wire rope or damaged section. Wire ropes should not be struck with any object, such as steel hammer, derrick hatchet, or crowbar, that may cause unnecessary nicks or bruises. Even a soft metal hammer can damage a rope. Therefore, when it is necessary to crowd wraps together, any such operation should be performed with the greatest care; and a block of wood should be interposed between the hammer and rope.

Solvent may be detrimental to a wire rope. If a rope becomes covered with dirt or grit, it should be cleaned with a brush.

After properly securing the wire rope in the drum socket, the number of excess or dead wraps or turns specified by the equipment manufacturer should be maintained. Whenever possible, a new wire rope should be run under controlled loads and speeds for a short period after installation. This will help to adjust the rope to working conditions. If a new coring or swabbing line is excessively wavy when first installed, two or four sinker bars may be added on the first few trips to straighten the line.

Care of Wire Rope in Service

The recommendations for handling a reel should be observed at all times during the life of the rope. The design factor should be determined by the following:

$$\text{Design factor} = \frac{B}{W} \quad (4.2.17)$$

where B = nominal strength of the wire rope in pounds

W = fast line tension

When a wire rope is operated close to the minimum design factor, the rope and related equipment should be in a good operating condition. At all times, the operating

personnel should minimize shock, impact, and acceleration or deceleration of loads. Successful field operations indicate that the following design factors should be regarded as minimum:

	Minimum Design Factor
Cable-tool line	3
Sand line	3
Rotary drilling line	3
Hoisting service other than drilling	3
Mast raising and lowering line	2.5
Rotary drilling line when setting casing	2
Pulling on stuck pipe and similar infrequent operations	2

Wire-rope life varies with the design factor; therefore, longer rope life can generally be expected when relatively high design factors are maintained.

To calculate the design factor for multipart string-ups, Figures 4.2.63 and 4.2.64 can be used to determine the value of W. W is the fast line tension and equals the fast line factor* times the hook load weight indicator reading. As an example,

drilling line 1 ³/₈ in. (35 mm) EIPS
 number of lines 10
 hook load 400,000 lb (181.4 tons)

Sheaves are roller bearing type.

From Figure 4.2.63, Case A, the fast line factor is 0.123. The fast line tension is then 400,000 lb (181.41 t) × 0.123 = 49,200 lb (22.3 t) = W. Following the formula above, the design factor is then the nominal strength of 1 ³/₈ in. (35 mm) EIPS drilling line divided by the fast line tension, or 192,000 lb (87.1 tons) ÷ 49,200 lb (22.3 t) = 3.9.

When working near the minimum design factor, consideration should be given to the efficiencies of wire rope bent around sheaves, fittings, or drums. Figure 4.2.65 shows how rope can be affected by bending.

Rope should be kept tightly and evenly wound on the drum. Sudden, severe stresses are injurious to a wire rope, and should be reduced to a minimum. Experience has indicated that wear increases with speed; economy results from moderately increasing the load and diminishing the speed. Excessive speeds may injure wire rope. Care should

*The fast line factor is calculated considering the tensions needed to overcome sheave bearing friction.

FAST LINE TENSION = FAST LINE FACTOR X LOAD

$$\text{EFFICIENCY} = \frac{(K^N - 1)}{K^N N (K-1)}$$

$$\text{Fast Line Factor} = \frac{1}{N \times \text{EFFICIENCY}}$$

NOTE: The above cases apply also where the rope is dead ended at the lower or traveling block or derrick floor after passing over a dead sheave in the crown.

*In these tables the K factor for sheave friction is 1.09 for plain bearings and 1.04 for roller bearings. Other K factors can be used if recommended by the equipment manufacturer.

FIGURE 4.2.63 Efficiency of wire-rope reeving for multiple sheave blocks, Cases A, B, and C [3].

be taken to see that the clamps used to fasten the rope for dead ending do not kink, flatten, or crush the rope.

Wire ropes are well lubricated when manufactured; however, this lubrication will not last throughout the entire service life of the rope. Periodically, therefore, the rope will need to be field lubricated. When necessary, lubricate the rope with a good grade of lubricant that will penetrate and adhere to the rope, and that is free from acid or alkali.

The clamps used to fasten lines for dead ending shall not kink, flatten, or crush the rope. The rotary line dead-end tie down is equal in importance to any other part of the system. The dead-line anchorage system shall be equipped with a drum and clamping device strong enough to withstand the loading, and designed to prevent wire line damage that would affect service over the sheaves in the system.

The following precautions should be observed to prevent premature wire breakage in drilling lines.

1. *Cable-tool drilling lines.* Movement of wire rope against metallic parts can accelerate wear. This can also create sufficient heat to form martensite, causing embrittlement of wire and early wire rope removal. Such also can be formed by friction against the casing or hard rock formation.
2. *Rotary drilling lines.* Care should be taken to maintain proper winding of rotary drilling lines on the drawworks drum to avoid excessive friction that may result in the formation of martensite. Martensite may also be formed by excessive friction in worn grooves of sheaves, slippage in sheaves, or excessive friction resulting from rubbing against a derrick member. A line guide should be employed between the drum and the fast line sheave to reduce vibration and to keep the drilling line from rubbing against the derrick.

FIGURE 4.2.64 Efficiency of wire-rope reeving for multiple sheave blocks, Cases D and E [3].

Martensite is a hard, nonductile microconstituent formed when steel is heated above its critical temperature and cooled rapidly. In the case of steel of the composition conventionally used for rope wire, martensite can be formed if the wire surface is heated to a temperature near or somewhat in excess of 1400°F (760°C), and then cooled at a comparatively rapid rate. The presence of a martensite film at the surface of the outer wires of a rope that has been in service is evidence that sufficient frictional heat has been generated on the crown of the rope wires to momentarily raise the wire surface temperature to a point above the critical temperature range of the steel. The heated surface is then rapidly cooled by the adjacent cold metal within the wire and the rope structure, and an effective quenching results.

Figure 4.2.66A shows a rope that has developed fatigue fractures at the crown in the outer wires, and Figure 4.2.66B shows a photomicrograph (100× magnification) of a specimen cut from the crown of one of these outer wires. This photomicrograph clearly shows the depth of the martensite layer and the cracks produced by the inability of the martensite to withstand the normal flexing of the rope. The result is a disappointing service life for the rope. Most outer wire failures may be attributed to the presence of martensite.

Worn sheave and drum grooves cause excessive wear on the rope. All sheaves should be in proper alignment. The fast sheave should line up with the center of the hoisting drum. From the standpoint of wire-rope life, the condition and contour of sheave grooves are important and should be checked periodically. The sheave groove

FIGURE 4.2.65 Efficiencies of wire ropes bent around stationary sheaves (static stresses only) [3].

FIGURE 4.2.66 Fatigue fractures in outer wires caused by the formation of martensite [3].

should have a radius not less than that in Table 4.2.27; otherwise, rope life can be reduced. Reconditioned sheave grooves should conform to the recommended radii for new and reconditioned sheaves as given in Table 4.2.28. Each operator should establish the most economical point at which sheaves should be regrooved by considering the loss in rope life that will result from worn sheaves as compared to the cost involved in regrooving. When a new rope is to be installed on used sheaves, it is particularly important that the sheave grooves be checked as recommended. To ensure a minimum turning effort, all sheaves should be kept properly lubricated.

Seizing

Before cutting, a wire rope should be securely seized on each side of the cut by serving with soft wire ties. For

socketing, at least two additional seizings should be placed at a distance from the end equal to the basket length of the socket. The total length of the seizing should be at least two rope diameters and securely wrapped with a seizing iron. This is very important, as it prevents the rope untwisting and ensures equal tension in the strands when the load is applied.

The recommended procedure for seizing a wire rope is as follows:

- A. The seizing wire should be wound on the rope by hand as shown in Figure 4.2.67 (1). The coils should be kept together and considerable tension maintained on the wire.
- B. After the seizing wire has been wound on the rope, the ends of the wire should be twisted together by hand in a counterclockwise direction so that the twisted portion

Standard Machine Tolerance

FIGURE 4.2.67 Putting a seizing on a wire rope [3].

of the wires is near the middle of the seizing (see Figure 4.2.67 (2)).

- C. Using "Carew" cutters, the twist should be tightened just enough to take up the slack (Figure 4.2.67 (3)). Tightening the seizing by twisting should not be attempted.
- D. The seizing should be tightened by prying the twist away from the axis of the rope with the cutters as shown in Figure 4.2.67 (4).
- E. The tightening of the seizing should be repeated as often as necessary to make the seizing tight.
- F. To complete the seizing operation, the ends of the wire should be cut off as shown in Figure 4.2.67 (5), and the twisted portion of the wire tapped flat against the rope. The appearance of the finished seizing is illustrated in Figure 4.2.67 (6).

4.2.4.13 Socketing (Zinc Poured or Spelter)

Wire Rope Preparation

The wire rope should be securely seized or clamped at the end before cutting. Measure from the end of the rope a length equal to approximately 90% of the length of the socket basket. Seize or clamp at this point. Use as many seizings as necessary to prevent the rope from unlaying.

After the rope is cut, the end seizing should be removed. Partial straightening of the strands and/or wire may be necessary. The wires should then be separated and broomed out and the cores treated as follows:

1. *Fiber core*—Cut back length of socket basket.
2. *Steel core*—Separate and broom out.
3. *Other*—Follow manufacturer's recommendations.

Cleaning

The wires should be carefully cleaned for the distance inserted in the socket by one of the following methods:

Acid cleaning

1. *Improved plow steel and extra improved plow steel, bright and galvanized.* Use a suitable solvent to remove lubricant. The wires then should be dipped in commercial muriatic acid until thoroughly cleaned. The depth of immersion in acid must not be more than the broomed length. The acid should be neutralized by rinsing in a bicarbonate of soda solution. Fresh acid should be prepared when satisfactory cleaning of the wires requires more than one minute. (Prepare new solution—do not merely add new acid to old.) Be sure acid surface is free of oil or scum. The wires should be dried and then dipped in a hot solution of zinc-ammonium chloride flux. Use a concentration of 1 lb (454 g) of zinc-ammonium chloride in 1 gal (3.8 L) of water and maintain the solution at a temperature of 180°F (82°C) to 200°F (93°C).
2. *Stainless steel.* Use a suitable solvent to remove lubricant. The wires then should be dipped in a hot caustic solution, such as oakite, then in a hot water rinse, and finally dipped in one of the following solutions until thoroughly cleaned:
 - a. commercial muriatic acid.
 - b. 1 part by weight of cupric chloride, 20 parts by weight of concentrated hydrochloric acid.
 - c. 1 part by weight of ferric chloride, 10 parts by weight of concentrated nitric or hydrochloric acid, 20 parts by weight of water.

Use the above solutions at room temperature. The wires should then be dipped in clean hot water. A suitable flux may be used.

Fresh solution should be prepared when satisfactory cleaning of the wires requires more than a reasonable time. (Prepare new solutions—do not merely add new solution to old solution.) Be sure solution surface is free of oil and scum.

3. *Phosphor bronze.* Use a suitable solvent to remove lubricant. The wires should then be dipped in commercial muriatic acid until thoroughly cleaned.
4. *Monel Metal.* Use a suitable solvent to remove lubricant. The wires then should be dipped in the following solution until thoroughly cleaned: 1 part glacial acetic acid + 1 part concentrated nitric acid.

This solution is used at room temperature. The broom should be immersed from 30 to 90 s. The depth of immer-

sion in the solution must not be more than broomed length. The wires should then be dipped in clean hot water.

4.2.4.13.1 Ultrasonic cleaning (all grades)

An ultrasonic cleaner suitable for cleaning wire rope is permitted in lieu of the acid cleaning methods described previously.

4.2.4.13.2 Other cleaning methods

Other cleaning methods of proven reliability are permitted.

Attaching Socket

Preheat the socket to approximately 200°F (93°C). Slip socket over ends of wire. Distribute all wires evenly in the basket and flush with top of basket. Be sure socket is in line with axis of rope.

Use only zinc not lower in quality than high grade per ASTM Specification B-6. Heat zinc to a range allowing pouring at 950°F (510°C) to 975°F (524°C). Skim off any dross accumulated on the surface of the zinc bath. Pour molten zinc into the socket basket in one continuous pour if possible. Tap socket basket while pouring.

Final Preparation

Remove all seizings. Apply lubricant to rope adjacent to socket to replace lubricant removed by socketing procedure. Socket is then ready for service.

Splicing

Splicing wire rope requires considerable skill, and the instructions for splicing wire rope will be found in the catalogues of most of the wire-rope manufacturers, where the operation sequence is carefully described, and many clear illustrations are presented. These illustrations give, in fact, most of the information needed.

Socketing (Thermo-Set Resin)

Before proceeding with thermo-set resin socketing, the manufacturer's instructions for using this product should be carefully read. Particular attention should be given to sockets designed specifically for resin socketing. Other thermo-set resins used may have specifications that differ from those shown in this section.

Seizing and Cutting the Rope

The rope manufacturer's directions for a particular size or construction of rope are to be followed with regard to the number, position, and length of seizings, and the seizing wire size to be used. The seizing, which will be located at the base of the installed fitting, must be positioned so that the ends of the wires to be embedded will be slightly below the level of the top of the fitting's basket. Cutting the rope can best be accomplished by using an abrasive wheel.

Opening and Brooming the Rope End

Prior to opening the rope end, place a short temporary seizing directly above the seizing that represents the base of the broom. The temporary seizing is used to prevent brooming the wires to full length of the basket, and also to prevent the loss of lay in the strands and rope outside the socket. Remove all seizings between the end of the rope and the temporary seizing. Unlay the strands of the rope. Starting with the IWRC, or strand core, open each strand and each strand of the rope, and broom or unlay the individual wires. (A fiber core may be cut in the rope at the base of the seizing. Some prefer to leave the core in. Consult the manufacturer's instructions.) When the brooming is completed, the wires should be distributed evenly within a cone so that they form an included angle of approximately 60°. Some types of sockets require a different brooming procedure and the manufacturer's instructions should be followed.

Cleaning the Wires and Fittings

Different types of resin with different characteristics require varying degrees of cleanliness. The following cleaning procedure was used for one type of polyester resin with which over 800 tensile tests were made on ropes in sizes $\frac{1}{4}$ -in. (6.5 mm) to $3\frac{1}{2}$ -in. (90 mm) diameter without experiencing any failure in the resin socket attachment.

Thorough cleaning of the wires is required to obtain resin adhesion. Ultra-sonic cleaning in recommended solvents (such as trichloroethylene or 1,1,1-trichloroethane or other nonflammable grease-cutting solvents) is the preferred method in accordance with OSHA standards. If ultrasonic cleaning is not available, trichloroethane may be used in brush or dip-cleaning; but fresh solvent should be used for each rope end fitting and should be discarded after use. After cleaning, the broom should be dried with clean compressed air or in another suitable fashion before proceeding to the next step. Using acid to etch the wires before resin socketing is *unnecessary and not recommended*. Also, the use of flux on the wires before pouring the resin should be avoided since *this adversely affects bonding of the resin to the steel wires*. Since there is a variation in the properties of different resins, the manufacturer's instructions should be carefully followed.

Placement of the Fitting

The rope should be placed vertically with the broom up, and the broom should be closed and compacted to insert the broomed rope end into the fitting base. Slip on the fitting, removing any temporary bending or seizing as required. Make sure the broomed wires are uniformly spaced in the basket with the wire ends slightly below the top edge of the basket, and make sure the axis of the rope and the fitting are aligned. Seal the annular space between the base of the

fitting and the exiting rope to prevent leakage of the resin from the basket. A nonhardening butyl rubber base sealant gives satisfactory performance. Make sure the sealant does not enter the socket base, so that the resin may fill the complete depth of the socket basket.

Pouring the Resin

Controlled heat-curing (no open flame) at a temperature range of 250 to 300°F (121 to 149°C) is recommended; and is required if ambient temperatures are less than 60°F (16°C) (which may vary with different resins). When controlled heat curing is not available and ambient temperatures are not less than 60°F (16°C), the attachment should not be disturbed and tension should not be applied to the socketed assembly for at least 24 hr.

Lubrication of Wire Rope after Socket Attachment

After the resin has cured, relubricate the wire rope at the base of the socket to replace the lubricant that was removed during the cleaning operation.

Resin Socketing Compositions

Manufacturer's directions should be followed in handling, mixing, and pouring the resin composition.

Performance of Cured Resin Sockets

Poured resin sockets may be moved when the resin has hardened. After ambient or elevated temperature cure recommended by the manufacturer, resin sockets should develop the nominal strength of the rope; and should also withstand, without cracking or breakage, shock loading sufficient to break the rope. Manufacturers of resin socketing material should be required to test to these criteria before resin materials are approved for this end use.

Attachment of Clips

The clip method of making wire-rope attachments is widely used. Drop-forged clips of either the U-bolt or the double-saddle type are recommended. When properly applied as described herein, the method develops about 80% of the rope strength in the case of six strand ropes.

When attaching clips, the rope length to be turned back when making a loop is dependent upon the rope size and the load to be handled. The recommended lengths, as measured from the thimble base, are given in Table 4.2.29. The thimble should first be wired to the rope at the desired point and the rope then bent around the thimble and temporarily secured by wiring the two rope members together.

The first clip should be attached at a point about one base width from the last seizing on the dead end of the rope and tightened securely. The saddle of the clip should rest upon the long or main rope and the U-bolt upon the dead end.

All clips should be attached in this manner (Figure 4.2.68). The short end of the rope should rest squarely upon the main portion.

The second clip should be attached as near the loop as possible. The nuts for this clip should not be completely tightened when it is first installed. The recommended number of clips and the space between clips are given in Table 4.2.29. Additional clips should be attached with an equal spacing between clips. Before completely tightening the second and any of the additional clips, some stress

NOTE 1: If a pulley is used in place of a thimble for turning back the rope, add one additional clip.

should be placed upon the rope in order to take up the slack and equalize the tension on both sides of the rope.

When the clips are attached correctly, the saddle should be in contact with the long end of the wire rope and the U-bolt in contact with the short end of the loop in the rope as shown in Figure 4.2.68. The incorrect application of clips is illustrated in Figure 4.2.69.

The nuts on the second and additional clips should be tightened uniformly, by giving alternately a few turns to one side and then the other. It will be found that the application of a little oil to the threads will allow the nuts to be drawn tighter. After the rope has been in use a short time, the nuts on all clips should be retightened, as stress tends to stretch the rope, thereby reducing its diameter. The nuts should be tightened at all subsequent regular inspection periods. A half hitch, either with or without clips, is not desirable as it malforms and weakens wire rope.

4.2.4.14 Reeving of Wire Rope

Figure 4.2.70 illustrates, in a simplified form, the generally accepted methods of reeving (stringing up) in-line crown and traveling blocks, along with the location of the drawworks drum, monkey board, drill pipe fingers, and deadline anchor in relation to the various sides of the derrick. Ordinarily, the only two variables in reeving systems, as illustrated, are the number of sheaves in the crown and traveling blocks or the number required for handling the load, and the location of the deadline anchor. Table 4.2.30 gives the right-hand string-ups. The reeving sequence for

the left-hand reeving with 12 lines on a seven-sheave crown-block and six-sheave traveling block illustrated in Figure 4.2.70 is given in Arrangement No. 1 of Table 4.2.30. The predominant practice is to use left-hand reeving and locate the deadline anchor to the left of the derrick vee. In selecting the best of the various possible methods for reeving casing or drilling lines, the following basic factors should be considered:

1. Minimum fleet angle from the drawworks drum to the first sheave of the crown block, and from the crown block sheaves to the traveling block sheaves.
2. Proper balancing of crown and traveling blocks.
3. Convenience in changing from smaller to larger number of lines, or from larger to smaller number of lines.
4. Location of deadline on monkey board side for convenience and safety of derrickman.
5. Location of deadline anchor, and its influence upon the maximum rated static hook load of derrick.

4.2.4.15 Recommended Design Features

The proper design of sheaves, drums, and other equipment on which wire rope is used is very important to the service life of wire rope. It is strongly urged that the purchaser specify on his order that such material shall conform with recommendations set forth in this section.

The inside diameter of socket and swivel-socket baskets should be $\frac{5}{32}$ in. larger than the nominal diameter of the wire rope inserted. Alloy or carbon steel, heat treated, will

FIGURE 4.2.68 Correct method of attaching clips to wire rope [3].

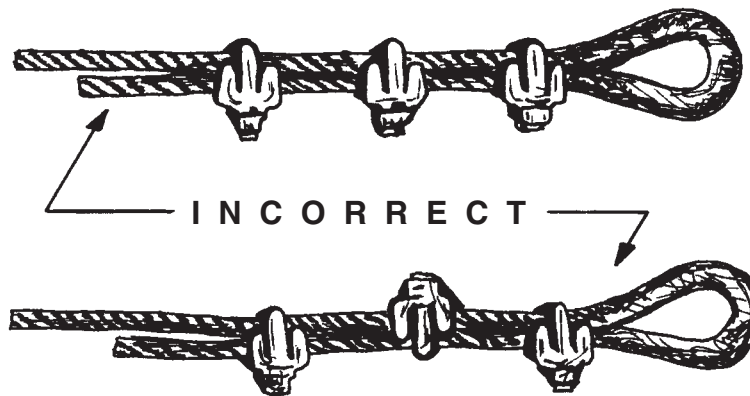

FIGURE 4.2.69 Incorrect methods of attaching clips to wire rope [3].

FIGURE 4.2.70 Typical reeving diagram for 14-line string-up with eight-sheave crown block and seven-sheave traveling block: left-hand reeving [3].

best serve for sheave grooves. Antifriction bearings are recommended for all rotating sheaves.

Drums should be large enough to handle the rope with the smallest possible number of layers. Drums having a diameter of 20 times the nominal wire-rope diameter should be considered minimum for economical practice. Larger diameters than this are preferable. For well-measuring wire, the drum diameter should be as large as the design of the equipment will permit, but should not be less than 100 times the wire diameter. The recommended grooving for wire-rope drums is as follows:

- A. On drums designed for multiple-layer winding, the distance between groove centerlines should be approximately equal to the nominal diameter of the wire rope plus one-half the specified oversize tolerance. For the best spooling condition, this dimension can vary according to the type of operation.
- B. The curvature radius of the groove profile should be equal to the radii listed in Table 4.2.28.
- C. The groove depth should be approximately 30% of the nominal diameter of the wire rope. The crests between

grooves should be rounded off to provide the recommended groove depth.

Diameter of Sheaves

When bending conditions over sheaves predominate in controlling rope life, sheaves should be as large as possible after consideration has been given to economy of design, portability, etc. When conditions other than bending over sheaves predominate as in the case of hoisting service for rotary drilling, the size of the sheaves may be reduced without seriously affecting rope life. The following recommendations are offered as a *guide* to designers and users in selecting the proper sheave size.

$$D_T = d \times F \tag{4.2.18}$$

where D_T = tread diameter of sheave in in. (mm) (see Figure 4.2.71)

d = nominal rope diameter in in.(mm), and

F = sheave-diameter factor, selected from Table 4.2.31.

TABLE 4.2.30 Recommended Reeving Arrangements for 12-, 10-, 8-, and 6-Line String-ups Using 7-Sheave Crown Blocks with 6-Sheave Traveling Blocks and 6-Sheave Crown Blocks with 5-Sheave Traveling Blocks [3]

* Follow manufacturer's recommendations.
Condition A—Where bending over sheaves is of major importance, sheaves at large as those determined by factors under condition A are recommended.
Condition B—Where bending over sheaves is important, but some sacrifice in rope life is acceptable to achieve portability, reduction in weight, economy of design, etc., sheaves at least as large as those determined by factors under condition B are recommended.
Condition C—Some equipment is used under operating conditions which do not reflect the advantage of the selection of sheaves by factors under condition A or B. In such cases, sheave-diameter factors may be selected from Figure 4.2.71 and Table 4.2.30. As smaller factors are selected, the bending life of the wire rope is reduced and it becomes an increasingly important condition of rope service. Some conception of relative rope service with different rope constructions and/or different sheave sizes may be obtained by multiplying the ordinate found in Figure 4.2.71 by the proper construction factor indicated in Table 4.2.30.

It should be stressed that if sheave design is based on condition C, fatigue due to serve bending can occur rapidly. If other operation conditions are not present to cause the rope to be removed from service, this type of fatigue is apt to result in wires breaking where they are not readily visible to external examination. Any condition resulting in rope deterioration of a type that is difficult to judge by examination during service should certainly be avoided.

The diameter of sheaves for well-measuring wire should be as large as the design of the equipment will permit but not less than 100 times the diameter of the wire.

Sheave Grooves

On all sheaves, the arc of the groove bottom should be smooth and concentric with the bore or shaft of the sheave.

The centerline of the groove should be in a plane perpendicular to the axis of the bore or shaft of the sheave.

Grooves for drilling and casing line sheaves shall be made for the rope size specified by the purchaser. The groove bottom shall have a radius R (Table 4.2.28) subtending an arc of 150°. The sides of the groove shall be tangent to the ends of the bottom arc. Total groove depth shall be a minimum of 1.33d and a maximum of 1.75d (d is the nominal rope diameter shown in Figure 4.2.71).

Grooves for sand-line sheaves shall be made for the rope size specified by the purchaser. The groove bottom shall have a radius R (Table 4.2.28) subtending an arc of 150°. The sides of the groove shall be tangent to the ends of the bottom arc. Total groove depth shall be a minimum of 1.75d and a maximum of 3d (d is nominal rope diameter shown in Figure 4.2.72B).

Grooves on rollers of oil savers should be made to the same tolerances as the grooves on the sheaves.

Sheaves conforming to the specifications (Specification 8A) shall be marked with the manufacturer's name or mark, the sheave groove size and the sheave OD. These markings shall be cast or stamped on the outer rim of the sheave groove and stamped on the nameplate of crown and traveling blocks. For example, a 36-in. sheave with 1 1/8 in. groove shall be marked

AB CO 1 1/8 SPEC 8A

Sheaves should be replaced or reworked when the groove radius decreases below the values shown in Table 4.2.27. Use sheave gages as shown in Figure 4.2.72A shows a sheave with a minimum groove radius, and 4.2.72B shows a sheave with a tight groove.

4.2.4.16 Evaluation of Rotary Drilling Line.

The total service performed by a rotary drilling line can be evaluated by considering the amount of work done by the line in various drilling operations (drilling, coring, fishing,

FIGURE 4.2.72 Use Of Sheave Gage [3].

setting casing, etc.), and by evaluating such factors as the stresses imposed by acceleration and deceleration loadings, vibration stresses, stresses imposed by friction forces of the line in contact with drum and sheave surfaces, and other even more indeterminate loads. However, for comparative purposes, an approximate evaluation can be obtained by computing only the work done by the line in raising and lowering the applied loads in making round trips, and in the operations of drilling, coring, setting casing, and short trips.

Round-Trip Operations

Most of the work done by a drilling line is that performed in making round trips (or half-trips) involving running the string of drill pipe into the hole and pulling the string out of the hole. The amount of work performed per round trip should be determined by

$$T_r = \frac{D(L_s + D)W_m}{10,560,000} + \frac{D\left(M + \frac{1}{2}C\right)}{2,640,000} \quad (4.2.19)$$

where T_r = ton-miles (weight in tons times distance moved in miles)

D = depth of hole in feet

L_s = length of drill-pipe stand in feet

N = number of drill-pipe stands

W_m = effective weight per foot of drill-pipe from Figure 4.2.73.

M = total weight of traveling block-elevator assembly in pounds.

C = effective weight of drill-collar assembly from Figure 4.2.73 minus the effective weight of the same length of drill-pipe from Figure 4.2.73 in pounds

Drilling Operations

The ton-miles of work performed in drilling operations is expressed in terms of work performed in making round trips, since there is a direct relationship as illustrated in the following cycle of drilling operations.

1. Drill ahead length of the kelly.
2. Pull up length of the kelly.
3. Ream ahead length of the kelly.
4. Pull up length of the kelly to add single or double.
5. Put kelly in rat hole.
6. Pick up single or double.
7. Lower drill stem in hole.
8. Pick up kelly.

Analysis of the cycle of operations shows that for any hole, the sum of operations 1 and 2 is equal to one round trip; the sum of operations 3 and 4 is equal to another round trip; the sum of operation 7 is equal to one-half a round trip; and the

sum of operations 5, 6, and 8 may, and in this case does, equal another one-half round trip, thereby making the work of drilling the hole equivalent to three round trips to bottom, and the relationship can be expressed as

$$T_d = 3(T_2 - T_1) \quad (4.2.20)$$

where T_d = ton-mile drilling

T_1 = ton-miles for one round trip at depth D_1 (depth where drilling started after going in hole, in ft)

T_2 = ton-miles for one round trip at depth D_2 (depth where drilling stopped before coming out of hole in ft)

If operations 3 and 4 are omitted, then formula 4.2.20 becomes

$$T_d = 2(T_2 - T_1) \quad (4.2.21)$$

Coring Operations

The ton-miles of work performed in coring operations, as for drilling operations, is expressed in terms of work performed in making round trips, since there is a direct relationship illustrated in the following cycle of coring operations.

1. Core ahead length of core barrel.
2. Pull up length of kelly.
3. Put kelly in rat hole.
4. Pick up single.
5. Lower drill stem in hole.
6. Pick up kelly.

Analysis of the cycle of operation shows that for any one hole, the sum of operations 1 and 2 is equal to one round trip; the sum of operations 5 is equal to one-half a round trip; and the sum of operations 3, 4, and 6 may, and in this case does, equal another one-half round trip, thereby making the work of drilling the hole equivalent to two round trips to bottom, and the relationship can be expressed as

$$T_c = 2(T_4 - T_3) \quad (4.2.22)$$

where T_c = ton-mile coring

T_3 = ton-miles for one round trip at depth D_3 (depth where coring started after going in hole, in feet)

T_4 = ton-miles for one round trip at depth D_4 (depth where coring stopped before coming out of hole, in feet)

Setting Casing Operations

The calculation of the ton-miles for the operation for setting casing should be determined as in round-trip operations as for drill pipe, but with the effective weight of the casing

FIGURE 4.2.73 Effective weight of pipe-in-drilling fluid [3].

being used, and with the result being multiplied by one-half, since setting casing is a one-way (one-half round-trip) operation. Ton-miles for setting casing can be determined from

$$T_s = \frac{D(L_{cs} + D)(W_{cm})}{10,560,000} + \frac{D\left(M + \frac{1}{2}C\right)}{2,640,000} \left(\frac{1}{2}\right) \quad (4.2.23)$$

Since no excess weight for drill collars need be considered, Equation 4.2.23 becomes

$$T_s = \frac{D(L_{cs} + D)(W_{cm})}{10,560,000} + \frac{DM}{2,640,000} \left(\frac{1}{2}\right) \quad (4.2.24)$$

where T_s = ton-miles setting casing
 L_{cs} = length of joint of casing in ft.
 W_{cm} = effective weight per foot of casing in lb/ft

The effective weight per foot of casing W_{cm} may be estimated from data given on [Figure 4.2.73](#) for drill pipe (using the approximate lb/ft), or calculated as

$$W_{cm} = W_{ca} (1 - 0.015B) \quad (4.2.25)$$

where W_{ca} is weight per foot of casing in air in lb/ft
 B is weight of drilling fluid from [Figure 4.2.74](#)
 or [Figure 4.2.75](#) in lb/gal

Short Trip Operations

The ton-miles of work performed in short trip operations, as for drilling and coring operations, is also expressed in terms of round trips. Analysis shows that the ton-miles of work done in making a short trip is equal to the difference in round trip ton-miles for the two depths in question.

$$T_{ST} = T_6 - T_5 \quad (4.2.26)$$

where T_{ST} = ton-miles for short trip
 T_5 = ton-miles for one round trip at depth D_5 (shallower depth)
 T_6 = ton-miles for one round trip at depth D_6 (deeper depth)

For the comparative evaluation of service from rotary drilling lines, the grand total of ton-miles of work performed will be the sum of the ton-miles for all round-trip operations (Equation 4.2.19), the ton-miles for all drilling operations (Equation 4.2.20), the ton-miles for all coring operations (Equation 4.2.22), the ton-miles for all casing setting operations (Equation 4.2.23), and the ton-miles for all short trip operations (Equation 4.2.26). By dividing the grand total ton-miles for all wells by the original length of line in feet, the evaluation of rotary drilling lines in ton-miles per foot on initial length may be determined.

4.2.4.17 Rotary Drilling Line Service-Record Form

[Figure 4.2.76](#) is a rotary drilling line service-record form. It can be filled out on the bases of [Figure 4.2.77](#) and previous discussion.

4.2.4.18 Slipping and Cutoff Practice for Rotary Drilling Lines

Using a planned program of slipping and cutoff based upon increments of service can greatly increase the service life of drilling lines. Determining when to slip and cut depending only on visual inspection, will result in uneven wear, trouble with spooling (line “cutting in” on the drum), and

long cutoffs, thus decreasing the service life. The general procedure in any program should be to supply an excess of drilling line over that required to string up, and to slip this excess through the system at such a rate that it is evenly worn and that the line removed by cutoff at the drum end has just reached the end of its useful life.

Initial Length of Line

The relationship between initial lengths of rotary lines and their normal service life expectancies is shown in [Figure 4.2.78](#). Possible savings by the use of a longer line may be offset by an increased cost of handling for a longer line.

Service Goal

A goal for line service in terms of ton-miles between cutoffs should be selected. This value can initially be determined from [Figures 4.2.79](#) and [4.2.80](#) and later adjusted in accordance with experience. [Figure 4.2.81](#) shows a graphical method of determining optimum cutoff frequency.

Variations in Line Service

Ton-miles of service will vary with the type and condition of equipment used, drilling conditions encountered, and the skill used in the operation. A program should be “tailored” to the individual rig. The condition of the line as moved through the reeving system and the condition of the cutoff portions will indicate whether the proper goal was selected. In all cases, visual inspection of the wire rope by the operator should take precedence over any predetermined procedures. (See [Figure 4.2.81](#) for a graphical comparison of rope services.)

Cutoff Length

The following factors should be considered in determining a cutoff length:

1. The excess length of line that can conveniently be carried on the drum.
2. Load-pickup points from reeving diagram.
3. Drum diameter and crossover points on the drum.

The crossover and pickup points should not repeat. This is done by avoiding cutoff lengths that are multiples of either drum circumference, or lengths between pickup points. Successful programs have been based on cutoff lengths ranging from 30 to 150 ft. [Table 4.2.32](#) shows a recommended length of cutoff (number of drum laps) for each height derrick and drum diameter.

FIGURE 4.2.74 Relative service for various D_T/d ratios for sheaves [3]. See "Diameter of Sheaves," subparagraph title "Variation of Different Service Applications." Based on laboratory tests involving systems consisting of sheaves only.

FIGURE 4.2.75 Effective weight of drill collars in drilling fluid [3].

FIGURE 4.2.77 Rotary-drilling ton-mile charts [3].

FIGURE 4.2.78 Relationship between rotary-line initial length and service life [3]. Empirical curves were developed from general field experience.

Explanation:

To determine (approximately) the desirable ton-miles before the first cutoff on a new line, draw a vertical line from the derrick height to the wireline size used. Project this line horizontally to the ton-mile figure given for the type of drilling encountered in the area. Subsequent cutoffs should be made at 100 ton-miles less than those indicated for 1 1/8-in. and smaller lines, and at 200 ton-miles less than 1 1/4-in. and 1 3/8-in. lines.

FIGURE 4.2.79 Ton-mile derrick height and line-size relationships [3]. The values for ton-miles before cutoff, as given in Figure 4.2.79 were calculated for improved plow steel with an independent wire-rope core and operating at a design factor of 5. When a design factor other than 5 is used, these values should be modified in accordance with Figure 4.2.80. The values given in Figure 4.2.79 are intended to serve as a guide for the selection of initial ton-mile values are explained in Par. "Service Goal." These values are conservative, and are applicable to all typical constructions of wire rope as recommended for the rotary drilling lines shown in Table 4.2.5.

FIGURE 4.2.80 Relationship between design factors and ton-mile service factors [3]. *NOTE: Light loads can cause rope to wear out from fatigue prior to accumulation of anticipated ton-miles. Based on laboratory tests on bending over sheaves.*

FIGURE 4.2.81 Graphic method of determining optimum frequency of cutoff to give maximum total ton-miles for a particular rig operating under certain drilling conditions [3].

133 to 140						15½	14½	12½	11½	11½	10½	9½		
120 to 132				17½	15½	14½	12½	12½	11½	10½	9½	9½		
91 to 119		19½	17½	14½	12½	11½	10½	9½	9½	8½				
73 to 90		17½	14½	12½	11½									
Up through 72	12½	11½												

*In order to insure a change of the point of crossover on the drum, where wear and crushing are most severe, the laps to be cut off are given in multiples of one-half lap or one quarter lap dependent upon the type of drum grooving.

Example:

Assumed conditions:

- A. Derrick height: 138 ft
- B. Wire-line size: 1¼ in.
- C. Type drilling: #3
- D. Drum diameter: 28 in.
- E. Design factor: 3.

Solution:

1. From Fig. 4.2.79 determine that (for a line with a design factor of 5) the first cutoff would be made after 120 ton-miles and additional cut-offs after each successive 1000 ton-miles.
2. Since a design factor of 3 applies, Fig. 4.2.80 indicates that these values should be multiplied by a factor of 0.58. Hence the first cutoff should be made after 696 ton-miles and additional cutoffs after each successive 580 ton-miles.
3. From Table 4.2.32 determine that 11½ drum laps (84 ft) should be removed at each cutoff.
4. Slip 21 ft every 174 ton-miles for four times and cut off after the fourth slip. Thereafter, slip 21 ft every 145 ton-miles and cut off on the fourth slip.

Slipping Program

The number of slips between cutoffs can vary considerably depending upon drilling conditions and the length and frequency of cutoffs. Slips should be increased if the digging is rough, if jarring jobs occur, etc. Slipping that causes too much line piles up on the drum, particularly an extra layer on the drum, before cutoff should be avoided. In slipping the line, the rope should be slipped an amount such that no part of the rope will be located for a second time in a position of severe wear. The positions of severe wear are the point of crossover on the drum and the sections in contact with the traveling-block and crown-block sheaves at the pickup position. The cumulative number of feet slipped between cutoffs should be equal to the recommended feet for ton-mile cutoff. For example, if cutting off 80 ft every 800 ton-

miles, 20 ft should be slipped every 200 ton-miles, and the line cut off on the fourth slip.

4.2.4.19 Field Troubles and Their Causes

All wire rope will eventually deteriorate in operation or have to be removed simply by virtue of the loads and reversals of load applied in normal service. However, many conditions of service or inadvertent abuse will materially shorten the normal life of a wire rope of proper construction although it is properly applied. The following field troubles and their causes give some of the field conditions and practices that result in the premature replacement of wire rope. It should be borne in mind that in all cases the contributory cause of removal may be one or more of these practices or conditions.

Wire-Rope Trouble	Possible Cause
Rope broken (all strands)	Overload resulting from severe impact, kinking, damage, localized water, weakening of one or more strands, or rust-bound condition and loss of elasticity. Loss of metallic area due to broken wires caused by severe bending.
One or more whole strands parted.	Overloading, kinking, divider interference, localized wear, or rust-bound condition. Fatigue, excessive speed, slipping, or running too loosely. Concentration of vibration at dead sheave or dead-end anchor.
Excessive corrosion.	Lack of lubrication. Exposure to salt spray, corrosion gases, alkaline water, acid water, mud, or dirt. Period of inactivity without adequate protection.
Rope damage by careless handling in hauling to the well or location	Rolling reel over obstructions or dropping from car, truck, or platform. The use of chains for lashing, or the use of lever against rope instead of flange. Nailing through rope to flange.
Damage by improper socketing.	Improper seizing that allows slack from one or more strands to work back into rope; improper method of socketing or poor workmanship in socketing, frequently shown by rope being untwisted at socket, loose or drawn.
Kinks, dog legs, and other distorted places.	Kinking the rope and pulling out the loops such as improper coiling or unreeling. Improper winding on the drum. Improper tie-down. Open-drum reels having longitudinal spokes too widely spaced. Divider interference. The addition of improperly spaced cleats increase the drum diameter. Stressing while rope is over small sheave or obstacle.
Damage by hooking back slack too tightly to girt.	Operation of walking beam causing a bending action on wires at clamp and resulting in fatigue and cracking of wires, frequently before rope goes down into hole.
Damage or failure on a fishing job.	Rope improperly used on a fishing job, resulting in damage or failure as a result of the nature of the work.
Lengthening of lay and reduction of diameter.	Frequently produced by some type of overloading, such as an overload resulting in a collapse of the fiber core in swabbing lines. This may also occur in cable-tool lines as a result of concentrated pulsating or surging forces that may contribute to fiber-core collapse.
Premature breakage of wires.	Caused by frictional heat developed by pressure and slippage, regardless of drilling depth.
Excessive wear in spots.	Kinks or bends in rope due to improper handling during installation or service. Divider interference; also, wear against casing or hard shells or abrasive formations in a crooked hole. Too infrequent cutoffs on working end.
Spliced rope.	A splice is never as good as a continuous piece of rope, and slack is liable to work back and cause irregular wear.
Abrasion and broken wires in a straight line. Drawn or loosened strands. Rapid fatigue breaks.	Injury due to slipping rope through clamps.
Reduction in tensile strength or damage to rope.	Excessive heat due to careless exposure to fire or torch.

Continued

Wire-Rope Trouble	Possible Cause
Distortion of wire rope.	Damage due to improperly attached clamps or wire-rope clips.
High strands.	Slipping through clamps, improper seizing, improper socketing or splicing, kinks, dog legs, and core popping.
Wear by abrasion.	Lack of lubrication. Slipping clamp unduly. Sandy or gritty working conditions. Rubbing against stationary object or abrasive surface. Faulty alignment. Undersized grooves and sheaves.
Fatigue breaks in wires.	Excessive vibration due to poor drilling conditions, i.e., high speed, rope, slipping, concentration of vibration of at dead sheave or dead-end anchor, undersized grooves and sheaves, and improper selection of rope construction. Prolonged bending action over spudder sheaves, such as that due to hard drilling.
Spiraling or curling.	Allowing rope to drag or rub over pipe, sill, or any object during installation or operation. It is recommended that a block with sheave diameter 16 times the nominal wire-rope diameter, or larger, be used during installation of the line.
Excessive flattening or crushing.	Heavy overload, loose winding on drum, or cross winding. Too infrequent cutoffs on working end of cable-tool lines. Improper cutoff and moving program for cable-tool lines.
Bird-caging or core-popping.	Sudden unloading of line such as hitting fluid with excessive speed. Improper drilling motion or jar action. Use of sheave or too small diameter or passing line around sharp bend.
Whipping off of rope	Running too loose.
Cutting in on drum.	Loose winding on drum. Improper cutoff and moving program for rotary drilling lines. Improper or worn drum grooving or line turnback plate.

4.3 ROTARY EQUIPMENT

Section reviewed by Bill Lyons, Dwayne Tyus, Randy Pynch, and Adam Pitts

Rotary equipment refers to all pieces of surface equipment in drilling operations that actually rotate or introduce rota-

tional force to the drill string. This equipment includes the swivel and the rotary hose, the upper and lower Kelly valves, the Kelly, the Kelly bushings, the master bushing, and the rotary table.

4.3.1 Swivel and Rotary Hose

4.3.1.1 Swivel

The swivel (Figure 4.3.1) is suspended from the hook and traveling block and forms the top part of the drill stem. It allows for the rotation of the Kelly and provides a pressure tight connection from the rotary hose to the drill string to allow the circulation of drilling fluids.

The swivel is made up of a stationary and a rotating part and has to support the entire string weight during drilling operations. The rotating part turns over the main axial bearing, which is mounted in an oil filled housing. The fluid-tight connection between the two parts consists of a wash pipe assembly. The seal unit is the most vulnerable part of the swivel (Figure 4.3.2). Daily greasing of the seals

and ensuring sufficient hydraulic fluid level will prevent leakage and decrease wear on the wash pipe assembly [1,2].

4.3.1.2 Rotary Hose

Although the rotary hose is not a rotating element, it is included here because of its connection to the swivel. It serves as a flexible high-pressure conduit between the stand pipe and the swivel and allows vertical travel of the swivel and block (Figure 4.3.3).

Usual length of the rotary hose is 45 ft. The minimum burst pressure rating should be $2\frac{1}{2}$ times the allowable working pressure. A pressure test should be conducted before drilling a new hole section. Further rotary hose specifications are provided in API RP7G.

4.3.2 Drill-Stem Subs

Different types of drill-stem subs are depicted in Figures 4.3.4 and 4.3.5. The classification of drill-stem subs is presented in Table 4.3.1. Their location within the string can be seen at Figure 4.3.6.

4.3.2.1 Swivel Sub

The outside diameter of the swivel sub is at least equal to the diameter of the outside of the upper Kelly box. The swivel sub should have a minimum of 8 in. of tong space length. The minimum diameter is equal to the Kelly diameter. The swivel sub is machined with a pin-up and pin-down left-handed rotary-shouldered connection.

4.3.2.2 Upper Kelly Valve

The upper Kelly valve or Kelly cock (Figure 4.3.7) is located between the swivel sub and the Kelly. The Kelly cock is a flapper-type valve. This valve must be manually closed to isolate the Kelly and drill string from the swivel and rotary hose. The valve can be partially opened by starting up the mud pumps, but it must be fully opened manually to prevent mud cutting.

4.3.2.3 Lower Kelly Valve

The lower Kelly valve or Kelly cock is located between the Kelly and the lower Kelly saver sub. This valve is a full-opening, ball-type valve typically operated with a hex-type wrench (Figure 4.3.8). By closing this valve before breaking a joint, this valve will prevent mud spilling on to the drill floor.

If working space is restricted and length is an issue, a shorter, more compact single-piece Kelly valve can be used instead (Figure 4.3.9).

The spring-loaded mud check valve (Figure 4.3.10) can be used as an alternative to the manually operated valves. When the mud pumps are shut off, this valve closes automatically to prevent mud spilling onto the rig floor. This tool is designed as full opening or full closing to avoid a pressure loss across the valve during circulation.

4.3.3 Kelly

The Kelly is a square or hexagonally shaped pipe (Figure 4.3.11). It transmits the power from the rotary table to the drill string. At the same time it serves as a conduit for the drilling fluid, it absorbs torque from the drill string and carries the entire axial load. It is the most heavily loaded component of the drill string. Refer to API RP7G for dimensions and further specifications [3].

Square Kellies are normally forged over the drive section, whereas hexagonal Kellies have been machined from bar stock. Typically, the machined flats have a greater resistance to wear than the forged surfaces.

Kellies are manufactured from AISI 4145-modified, fully heat-treated alloy steel with a Brinell hardness range of 285-341 and a minimum average Charpy impact value of 40 ft-lb [4,5].

Upper and lower upsets are kept long so that the Kelly can be rethreaded in case of thread damage.

For Kellies with the same outside diameter, a hexagonal Kelly will have a stronger drive section than a square Kelly (Figure 4.3.12). Under a given load the stress levels in the hexagonal Kelly will be lower, leading to a longer service life.

Service life as mentioned previously is greatly influenced by the maintenance of the drive bushing. Frequent adjustments of the rollers should be conducted to minimize play between the Kelly and the drive bushing.

Frequent inspections of the following items will increase the service life of all components:

- The corners of the drive section (surface wear)
- Transition between the upset and the drive section (cracking)
- Straightness of the Kelly

Operating with a bent Kelly will cause

- Severe vibrations at surface
- Additional wear on the drill pipe tools joints and the BOP and well head

FIGURE 4.3.1 Swivel nomenclature.

- Additional bending stresses in the drill string
- Rapid wear on the Kelly and master bushings.

4.3.4 Rotary Table and Bushings

4.3.4.1 Rotary Table

The rotary table (Figure 4.3.13) serves a dual function: It provides the rotary movement to the Kelly and applies torque to the drill string. As the rotary table runs, the master bushing, the Kelly, the drill pipe, and the bit also turn. The rotary table is driven by an independent electric motor or

on diesel mechanical drives by a compound drive by the drawworks engine.

When tripping pipe in and out of the well, the rotary table supports the drill string when the load is not suspended from the hook. At those times, it carries the entire weight of the drill string.

The rotary table (Figure 4.3.14) rests on reinforced beams in the rig floor that transfer the loads to the sub structure of the rig. The rotary has a cast or reinforced steel base that acts as a foundation to provide the strength and stability for this piece of equipment. The turntable rotates in

FIGURE 4.3.2 National (ideal) swivel.

the base using a heavy ball bearing and a ring gear shrunk over the turntable.

The ring gear is driven by a pinion shaft with roller bearings and seals. A detachable sprocket is connected to the pinion shaft on diesel mechanical drives or a coupling connector when driven by an electric motor. The rotary table is equipped with a locking device that is used when making up or breaking out the drill bit. It is also used to lock the drill string in place when directionally drilling with a motor. This lock should not be used when making up or breaking

out pipe during a round trip. The combination of torque and bending moment can lead to premature pipe failure. The turntable has an opening in the center that houses the master bushing.

4.3.4.2 Master Bushing

The master bushing fits into the turntable and makes it possible to transfer the rotational movement of the rotary table to the Kelly. It also accommodates the slips when pipe is to be suspended in the rotary table. Because the bushings

FIGURE 4.3.13 Rotary table with pin drive master bushings.

FIGURE 4.3.14 Rotary table with split master bushing.

are a removable insert, they also function as a wear sleeve for the rotary table.

There are two types of master bushings:

- Square drive master bushings (Figure 4.3.15)
- Pin drive master bushings (Figure 4.3.16)

Master bushings are constructed as a solid single piece (Figure 4.3.17), as a split bushing in two halves (Figure 4.3.18), or as a hinged type (Figure 4.3.19). All are machined with a taper to accommodate a range of pipe and slip sizes.

The API requirements for rotary table openings for square drive master bushings, and the sizes of the square drive and pin drive master bushings are specified in API RP7G.

4.3.4.3 Kelly Bushing

The Kelly bushing engages with the master bushing. It locks into the master bushing and transfers the rotary torque to the Kelly. There are two types of Kelly bushings:

- Square drive Kelly bushing that engages in a square master bushing (Figure 4.3.20).
- Pin drive Kelly bushing that engages in the pin drive holes of the master bushing (Figure 4.3.21).

The Kelly bushing is equipped with rollers that allow axial movement of the Kelly while the rotary is stationary or rotating.

For a square Kelly, the Kelly bushing is fitted with four plane rollers. For a hexagonal Kelly, the Kelly bushing is fitted with two plane rollers and two 120° V-rollers (Figure 4.3.22) or with six flat rollers.

Another version of the Kelly bushing is the double roller-type Kelly bushing (Figure 4.3.23). This Kelly drive has two rollers per Kelly flat stacked above each other in a roller assembly block. This Kelly bushing is used in high-torque applications. It reduces wear to the Kelly and itself through a wider force distribution.

For installation and maintenance every Kelly bushing is equipped with a cover that can be removed to allow access and removal of the rollers.

All rollers are adjustable to minimize the available play of the Kelly in the bushing. This will reduce vibration on the rotary and the drill string and reduce wear on the Kelly.

4.3.5 Top Drive Systems

The top drive systems are replacements for the conventional Kelly and rotary table in providing the rotary power to apply torque and rotation to the top of the drill string (or casing string) while still allowing drilling fluid circulation. The majority of the top drive systems are characterized by a

guide track with two rails (or a single wide track) affixed to the mast (or derrick) which allows a “dolly” containing either a hydraulic motor or an electric motor (DC or AC) to move up and down along the guide track. The motor on the dolly is used to rotate the top of the drill string (or casing string). The guide track resists the motor reaction torque by transferring those forces to the stationary track on the mast. The protective enclosure structure or dolly that travels on the rails (or beam) contains several other important components to facilitate the rotation of the top of the drill string (or casing string). In the dolly the motor (either hydraulic or electric) is mounted vertically with a drive gear affixed to the bottom of the output motor shaft (see Figures 4.3.24 and 4.3.25). Mounted vertically adjacent to the motor is a hollow drive shaft called a quill that has its top end suspended from a swivel and bottom end with a gear section that is driven via a transmission gear box by the drive gear on the output shaft on the bottom of the motor. When the motor is actuated, its output shaft gear drives the gear that is integrated into the spline gear at the bottom of the quill. When the bottom of the quill is made up the top of a drill string, the quill provides rotation motion and torque to the entire drill string and thereby to the drill bit.

Figure 4.3.24 shows a simple schematic of a top drive system with two hydraulic gear motors mounted vertically, the one on top of the other. The output shaft of these series mounted hydraulic motors is at the bottom of the bottom motor. Figure 4.3.25 shows a simple schematic of a top drive with either a DC or AC electric motor. In these top drive designs the electric motor is mounted vertically with the output shaft at the bottom of the motor. These top drive systems are rated by both their rotary horsepower capability of the top drive motor and their vertical lifting load capability of the swivel main drive shaft structure. For example, a popular hydraulic top drive system is rated as “1205 horsepower and 500 tons”. The top drive system’s dolly is basically a structural link in the chain of load support from the traveling block to the drill string or casing loads. Therefore, the load capability of the top drive system dolly should be selected to be the same or slightly greater than that of the traveling block. Table 4.3.2 gives the approximate matching of hydraulic and electric top drive motor system horsepower with corresponding top drive system structural load capabilities that are offered by most top drive system manufacturers.

Table 4.3.2 refers mainly to top drive systems that are utilized in land-based drilling rigs. Offshore drilling rigs on semi-submersible or drill ship typically require horsepower and load capabilities greater than those of land-based drilling rigs. Top drive systems for these offshore operations that require structural load capacities beyond 1000 tons typically use two or three electric motors (of those shown in the table) together on a single large dolly.

TABLE 4.3.2 Top Drive System: Approximate Power vs. Load Capabilities.

Power (hp)	Load (tons)
up 400	150
475	250
600	350
750	500
900	500–650
1100	500–650
1200	500–750
1350	750–1000

The main advantages of top drive systems are

1. The top drive systems allow the drill string or casing string to be rotated while the mud pumps are circulating the drilling fluids when running into or out of the borehole.
2. Well control operations are enhanced due to the ability to screw into a drill string or at any position in the derrick or mast to circulate drilling fluids.
3. Rig crew safety and efficiency are greatly improved since it is much easier and safer for the rig crew to makeup and break connections of stands as well as singles, thereby reducing the hazards of rotary tongs and chain spinning.
4. Most top drive systems will be accompanied by automated operations as well as sophisticated rig floor and pipe rack pipe handling equipment that further enhances rig crew safety.

4.3.5.1 Development History

The development of this new top drive drilling technology was first carried out in the mining industry in the late 1960s [6]. In this industry, small mobile drilling rigs are required to drill ahead at surface locations and in underground shafts at the mining face to obtain rock cores sample to show where the ore veins are located relative to the current mining faces. It was not practical to use conventional kelly with rotary table systems on these small rigs. Therefore, a hydraulic pump/top drive motor concept was created to operate on small rig masts that allowed the hydraulic motor to move along a track on the mast to provide torque and rotation to the top of a drill string. These early small drilling rigs utilized API 2 3/8" Range 1 drill pipe or drill rods with small diameters (BQ, NQ, HQ, and PQ at 1.43", 1.87",

2.50", and 3.35", respectively). API drill pipe and drill tubing are available in lengths of 15' to 18' and drill rod lengths are available in a variety of lengths up to 10'. These early top drive rig designs allowed a one or two man crew to operate the new style of rotary drilling rig. These small rigs were fitted with a retractable rig platform to allow slips to be used to suspend the drill string (or other downhole drilling tools) and to aid in breaking connections during run-in and run-out of borehole operations.

Today these small top drive drilling rigs are used in a variety of industries that require highly mobile units to drill to depths of up to a thousand feet or so (e.g., mining and petroleum industries, water well industries, construction operations and geological/environment regulatory organizations). In the past three decades the petroleum industry has adopted the top drive systems for nearly all newer large land and offshore drilling and completion rigs being manufactured. The reason for requiring top drive systems on the new rigs and for retrofitting some older rigs with top drives systems is because of the industry's ever increasing requirements to drill highly directional boreholes. It became evident in the late 1970s with the increase in directional drilling, especially on offshore development platforms with template platform locations, that the drill string would have to be rotated when pulling the drill string out of the borehole (i.e., conventional rig prime mover operate either the hoisting system or the rotary table). The coefficient of dynamic friction is less than the coefficient of static friction between rock and the steel drill string. So if the petroleum industry wants to take full advantage of the continuous improvements in wellbore positioning and directional drilling technologies that were being developed in the service companies to drill long reach horizontal and other high-angle boreholes, it would have to have modern drill rigs that would allow these technologies to be used to maximum effect (e.g., to rotate the drill string as it is pull out of the borehole) [7,8].

4.3.5.2 Hydraulic Power Top Drive Systems

When the petroleum industry embraced the top drive system concept in the early 1970s, all early power swivels (used to retrofit older rotary table rigs) and early manufactured rigs with top drives utilized hydraulic power for their top drive systems. Hydraulic power top drives require a separate prime mover to power a hydraulic pump (usually a single action triplex, quad-plex, or larger positive displacement pump) located on a skid adjacent to the rig. The skid mounted hydraulic pump has two hydraulic lines running from the pump to the hydraulic motor(s) on the track mounted top drive (or on the power swivel). Figure 4.3.24 shows these two hydraulic lines at the top drive. One line supplies high pressure, high flow rate hydraulic fluid to the top drive hydraulic motor. The other line returns the

FIGURE 4.3.26 Typical torque vs. rotary speed for hydraulic top drive system ~1000 hp (Courtesy of Tesco Corporation).

hydraulic fluid from the top drive motor(s) to the pump reservoir to be picked up by the pump to the motors again. These are closed loop hydraulic systems. Most modern hydraulic top drive system designs have two hydraulic motors stacked on top of each other with a valve control system between the two hydraulic motors. When high torque is required by the top drive system at low rpms (i.e., low-range operation), all the hydraulic fluid is channeled through both hydraulic motors in series, the top motor first and then to the bottom motor. Figure 4.3.26 shows a typical low-range plot of torque versus rpm for a top drive system rated at approximately ~1100 horsepower. When higher rpm is required for the drilling operations (greater than approximately 100 rpm), the valve control system is shifted to allow all the hydraulic fluid from the skid mounted pump to be channeled through the lower hydraulic motor only. Figure 4.3.26 shows a typical high-range plot of torque versus rpm for the same 1000 horsepower rated top drive discussed above. An important issue with hydraulic top drive systems has been the heat generated in the hydraulic fluid while it is providing power to the hydraulic motors. This heat must be dissipated via cooling loops or air vanes or it may cause elastomer seal failures and resulting leaks in the hydraulic power system.

4.3.5.3 DC Motor Top Drive Systems

Since the initial application of the top drive technologies to large deep drilling petroleum drilling rigs, improvements in the top drive system technologies have continued. Most new deep drilling land rigs are now designed to operate with electric power and have auxiliary skid mounted electric power plants that are part of their rig up operation. Large offshore facilities are operating in remote parts of the world

have significant integral natural gas or diesel prime mover powered electric generation power plants. This has allowed the development of electric motors to be used as top drive systems for both deep drilling land rigs and especially for offshore drilling systems. The first electric motors to be used for top drives were DC motors. DC motors for top drives systems are generally either of the shunt or series design. The shunt DC motors have excellent speed control characteristics and tend to have poor torque control. The series DC motors have excellent torque control and tend to have poor to speed control (e.g., series DC motors have their maximum torque at zero or stall speed). Figure 4.3.27 shows a typical DC shunt motor ~1100 hp top drive motor plot of torque versus rotary rpm. Figure 4.3.28 shows a typical DC series motor ~1100 hp top drive motor plot of torque versus rotary rpm. However, DC motors are heavy and usually require high maintenance in most land oil field location environments. Also, DC motors are not well suited for rig locations that might have hazardous flammable gas environments since motor brush contacts with the commutator that could create a dangerous spark during motor operations.

4.3.5.4 AC Motor Top Drive Systems

In recent years, top drive engineering designers have developed variable frequency AC motors for use on top drive systems. These new AC motors can be designed to mimic most desirable DC torque and rotation speed characteristics. The AC motors also have the added benefit of allowing less complicated prime mover electric power plants facilities for support of this type top drive system in both land and offshore operations. Figure 4.3.29 shows the plot of a typical AC motor of torque vs. rotary rpm of a typical ~1100 hp top

FIGURE 4.3.27 Typical torque vs. rotary speed for DC (shunt) motor top drive system ~1000 hp (Courtesy CanRig Drilling Technology Ltd).

FIGURE 4.3.28 Typical torque vs. rotary speed for DC (series) motor top drive system ~1000 hp (Courtesy CanRig Drilling Technology Ltd).

FIGURE 4.3.29 Typical torque vs. rotary speed for AC motor top drive system ~1000 hp (Courtesy CanRig Drilling Technology Ltd).

drive system. In general, the variable frequency AC motors allow good control of both torque and speed in a lighter and more maintenance friendly system. Most of the new offshore deep drilling rigs are equipped with AC variable frequency electric motors. Deep drilling top drive systems during these operations are required to move massive drill strings and casing strings in and out of these offshore wells. These operations can produce high-inertia loads which can be nearly twice as high as the operational static design loads when these strings are moved. To counter these potentially hazardous impact loads, soft starter motor technologies have

been developed. Soft starter technologies are systems for AC electric motors that can temporarily reduce the short time mechanical loads on the motor (and the rig structures) by controlling the electric current surge to the AC motor during motor initiation of motor rotor rotation.

Today there are a variety of top drive systems in use on both land rigs and offshore rigs. Some of these rigs maybe equipped with hydraulic top drive systems and DC electric top drive systems, but the majority of the newer installations using new drilling rigs will likely all be equipped with AC electric top drive systems with soft start technologies.

4.4 MUD PUMPS

Section reviewed by Bill Lyons and James Falconer

Mud pumps consume more than 60% of all the horsepower used in rotary drilling. Mud pumps are used to circulate drilling fluid through the mud circulation system while drilling. A pump with two fluid cylinders, as shown in [Figure 4.4.1](#), is called a duplex pump. A three-fluid-cylinder pump, as shown in [Figure 4.4.2](#), is called a triplex pump. Duplex pumps are usually double action, and triplex pumps are usually single action. Pumps with six chambers are commercially available as well ([Figure 4.4.3](#)).

Mud pumps consists of a power input end and a fluid output end. The power input end, shown in [Figure 4.4.4](#) transfers power from the driving engine (usually diesel or electric) to the pump crankshaft. The fluid end does the actual work of pumping the fluid. A cross-section of the fluid end is shown in [Figure 4.4.5](#).

FIGURE 4.4.1 Duplex slush (mud) pump. (Courtesy of National Oilwell.).

FIGURE 4.4.2 Triplex mud pumps. (Courtesy of Weatherford International, Inc.).

4.4.1 Pump Installation

4.4.1.1 Suction Manifold

The hydraulic horsepower produced by mud pumps depends mainly on the geometric and mechanical arrangement of the suction piping. If suction-charging centrifugal pumps (e.g., auxiliary pumps that help move the mud to the mud pump) are not used, the pump cylinders have to be filled by the hydrostatic head.

Incomplete filling of the cylinders can result in hammering, which produces destructive pressure peaks and shortens the pump life. Filling problems become more important with higher piston velocities. The suction pressure loss through the suction valve and seat is from 5 to 10 psi. Approximately 1.5 psi of pressure is required for each foot of suction lift. Since the maximum available atmospheric pressure is 14.7 psi (sea level), suction pits placed below the pump should be eliminated. Instead, suction tanks placed

FIGURE 4.4.3 Six chamber mud pump. (Courtesy of National Oilwell, Inc.).

FIGURE 4.4.4 Power end of mud pump. (Courtesy of LTV Energy Products Company.).

level with or higher than the pump should be used to ensure a positive suction head. Figure 4.4.6 shows an ideal suction arrangement with the least amount of friction and low inertia.

A poorly designed suction entrance to the pump can produce friction equivalent to 30 ft of pipe. Factors contributing to excessive suction pipe friction are an intake connection with sharp ends, a suction strainer, suction pipe with a small diameter, long runs of suction pipe, and numerous fittings along the suction pipe. Minimizing the effect of inertia

requires a reduction of the suction velocity and mud weight. It is generally practical to use a short suction pipe with a large diameter.

When a desirable suction condition cannot be attained, a charging pump becomes necessary. This is a common solution used on many modern rigs.

4.4.1.2 Cooling Mud

Mud temperatures of 150° can present critical suction problems. Under low pressure or vacuum existing in the cylinder on the suction stroke, the mud can boil, hence decreasing the suction effectiveness. Furthermore, hot mud accelerates the deterioration of rubber parts, particularly when oil is present. Large mud tanks with cooling surfaces usually solve the problem.

4.4.1.3 Gas and Air Separation

Entrained gas and air expands under the reduced pressure of the suction stroke, lowering the suction efficiency. Gas in water-base mud may also deteriorate the natural rubber parts used. Gases are usually separated with baffles or by changing mud composition.

4.4.1.4 Settling Pits

The normally good lubricating qualities of mud can be lost if cuttings, particularly fine sand, are not effectively separated from the mud. Adequate settling pits and shale shakers usually eliminate this trouble. Desanders are used occasionally.

FIGURE 4.4.6 Installation of mud pump suction piping. (Courtesy of International Association of Drilling Contractors.).

4.4.1.5 Discharge Manifold

A poorly designed discharge manifold can cause shock waves and excessive pressure peaks. This manifold should be as short and direct as possible, avoiding any sharp turns. The conventional small atmospheric air chamber, often furnished with pumps, supplies only a moderate cushioning effect. For best results, this air chamber should be supplemented by a large atmospheric air chamber or by a precharged pulsation dampener.

4.4.2 Pump Operation

4.4.2.1 Priming

A few strokes of the piston in a dry liner may ruin the liner. When the pump does not fill by gravity or when the cylinders have been emptied by standing too long or by replacement of the piston and liner, it is essential to prime the pump through the suction valve cap openings.

4.4.2.2 Cleaning the Suction Manifold

Suction lines are often partly filled by settled sand and by debris from the pits, causing the pump to hammer at abnormally low speeds. Frequent inspection and cleaning of the suction manifold is required. The suction strainer can also be a liability if it is not cleaned frequently.

4.4.2.3 Cleaning the Discharge Strainer

The discharge strainer often becomes clogged with pieces of piston and valve rubber. This may increase the pump pressure that is not shown by the pressure gauge beyond the strainer. The strainer should be inspected and cleaned frequently to prevent a pressure buildup.

4.4.2.4 Lost Circulation Materials

Usually special solids, such as nut shells, limestone, expanded perlite, etc., are added to the drilling muds to fill or clog rock fractures in the open hold of a well. Most of these lost circulation materials can shorten the life of pump

parts. They are especially hard on valves and seats when they accumulate on the seats or between the valve body and the valve disc.

4.4.2.5 Parts Storage

Pump parts for high-pressure service are made of precisely manufactured materials and should be treated accordingly. In storage at the rig, metal parts should be protected from rusting and physical damage, and rubber parts should be protected from distortion and from exposure to heat, light, and oil. In general, parts should remain in their original packages where they are usually protected with rust-inhibiting coatings and wrappings and are properly supported to avoid damage. Careless stacking of pistons may distort or cut the sealing lips and result in early failures. Hanging lip-type or O-ring packings on a hook or throwing them carelessly into a bin may ruin them. Metal parts temporarily removed from pumps should be thoroughly cleaned, greased, and stored like new parts.

4.4.3 Pump Performance Charts

The charts indicating the pump output per stroke are shown in Table 4.4.1 and 4.4.2 for duplex and triplex pumps, respectively [2,3].

4.4.4 Mud Pump Hydraulics

The required pump output can be approximated as follows [4–6]: Minimum Q (gal/min):

$$Q_{\min} = (30 \text{ to } 50) D_h \quad (4.4.1)$$

or

$$Q_{\min} = 481 \frac{D_h^2 - D_p^2}{\gamma D_h} \quad (4.4.2)$$

where D_h = hole diameter in in.

D_p = pipe diameter in in.

γ = mud specific weight in lb/gal

The required pump working pressure PWP (psi) can be calculated as

$$\text{PWP} = \Delta P_s + \Delta P_d + \Delta P_a + \Delta P_b \quad (4.4.3)$$

where ΔP_s = pressure loss through surface equipment in psi

ΔP_d = pressure loss through the inside of the drill string in psi

ΔP_a = pressure loss in annulus in psi

ΔP_b = pressure drop through bit nozzles in psi

Table 4.4.3 shows the diameters and areas of various nozzle sizes.

The required pump hydraulic horsepower (PHHP) can be calculated as

$$\text{PHHP} = \text{HHP}_{\text{circ}} + \text{HHP}_{\text{bit}} \quad (4.4.4)$$

where HHP_{circ} = total HHP loss due to pressure losses in the circulating system

HHP_{bit} = hydraulic horsepower required at the bit

The general hydraulic horsepower is

$$\text{HHP} = \frac{Q \Delta P}{1714} \quad (4.4.5)$$

where Q = flow rate in gal/min

ΔP = pressure difference in psi

The minimum bit HHP is shown in Figure 4.4.7. The maximum useful bit HHP is shown in Figure 4.4.8 and Figure 4.4.9 [2].

4.4.5 Useful Formulas and Mud Pump Characteristics

There are a variety of mud pumps that are used in drilling operations. The most used types of mud pumps today in land operations are the duplex double-action pump and the triplex single-action pump. In the past two decades, several new mud pump designs have been successful in drilling operations, particularly offshore operations. These newer pumps are the quadruplex pump with four plungers (or liners), the quintuplex pump with five plungers (or liners), and the hex-pump with six plungers (or liners).

The quadruplex and quintuplex pumps are similar in design to the triplex pump in that they are single-action horizontal in-line machines (similar to the triplex pumps shown in Figure 4.4.2). The hex-pump design is quite different. Its six single-action plungers operate vertically and move with a downward power stroke (shown in Figure 4.4.3). These plungers are placed in a circle and are actuated by a large cam that is rotated by a variable frequency AC prime mover. The hex-pump is being developed mostly for offshore operations where its platform footprint will be less than two triplex pumps.

The duplex double-action pump flow rate q (gpm) as a function of liner diameter d_1 (in.) and rod diameter d_2 (in.), stroke length l (in.), N (rpm), p (psig), e_v and e_m is

$$q = 0.0068 (2d_1^2 - d_2^2) l N e_v \quad (4.4.6)$$

The power, Power (hp), is

$$\text{Power} = \frac{p (2d_1^2 - d_2^2) l N}{252100.84 e_m} \quad (4.4.7)$$

The triplex single-action pump flow rate is

$$q = 0.0102 d_1^2 l N e_v \quad (4.4.8)$$

TABLE 4.4.4 NOV Triplex Model 12-P-160 Performance Data (stroke length 12 in., max. input horsepower 1600, max. SPM 120) (Courtesy National Oil Well, Inc.)

Liner Size (in.)	5.50	5.75	6.00	6.25	6.50	6.75	7.00	7.25
Vol./Stroke (gps)	3.70	4.05	4.41	4.78	5.17	5.57	6.00	6.43
Max. Press (psi)	5555	5085	4670	4305	3980	3690	3430	3200

The Power is

$$\text{Power} = \frac{pd_1^2 l N}{168067.2 e_m} \quad (4.4.9)$$

The quadruplex single-action pump flow rate is

$$q = 0.0136 d_1^2 l N e_v \quad (4.4.10)$$

The Power is

$$\text{Power} = \frac{pd_1^2 l N}{126050.4 e_m} \quad (4.4.11)$$

The quintuplex single-action pump flow rate is

$$q = 0.0170 d_1^2 l N e_v \quad (4.4.12)$$

The Power is

$$\text{Power} = \frac{pd_1^2 l N}{100840.3 e_m} \quad (4.4.13)$$

The hex-pump single-action pump flow rate is

$$q = 0.0204 d_1^2 l N e_v \quad (4.4.14)$$

The Power is

$$\text{Power} = \frac{pd_1^2 l N}{84033.6 e_m} \quad (4.4.15)$$

These equations can be used to determine the e_m and the e_v for a given situation. For example, Table 4.4.4 gives the data for a very widely used National Oil Well Model 12-P-160 triplex mud pump. Using Equation 4.4.8, the values in Table 4.4.4 can be used to solve for the value of e_v .

Using the data in Table 4.4.4 for the 7.25 in. liner, Equation 4.4.8 can be used to determine the value of e_v . Equation 4.4.8 is

$$6.43(120) = 0.0102(7.25)^2 (12.0) (120) e_v \quad (4.4.16)$$

Solving the above equation for e_v yields

$$e_v = 1.00 \quad (4.4.17)$$

In general, nearly all manufactures published data on mud pumps will present their data with an assumed value of $e_v = 1.0$. For most field calculations an assumed value of $e_v = 0.95$ is generally used.

Using the same data in Table 4.4.4 for the 7.25 in. liner, Equation 4.4.9 can be used to determine the value of e_m . Equation 4.4.9 is

$$1600 = \frac{(7.25)^2 (12.0) (120) (3200)}{168067.2 e_m} \quad (4.4.18)$$

Solving the above equation for e_m yields

$$e_m = 0.90 \quad (4.4.19)$$

In general, nearly all manufactures published data will present their data with the e_m values embedded. The analysis of Equations 4.4.18 and 4.4.19 demonstrate how the e_m values can be obtained.

4.5 DRILLING AND COMPLETION FLUIDS

Section reviewed by Thomas Carter and David Burt

4.5.1 Functions of Drilling Muds

4.5.1.1 Density, Specific Weight, and Specific Gravity

Density: The term “density” is the mass per unit volume. In the System International (SI) this is kg/m^3 , or kg/l , g/cm^3 . In the British Imperial System (BIS) and United States Customary System (USCS) the mechanical properties of a fluid are not published in mass per unit volume units (the BIS and USCS are basically the same). In the USCS, the mass per unit volume must be calculated from the published weight per unit volume (this latter term is denoted as specific weight). For decades the oil and the gas industry in the West has used the “density” name as a form of an oil field slang term for the USCS weight per unit volume published fluid mechanical properties usually published as lb/ft^3 , or lb/gal (the latter also written as ppg). The weight per unit volume of fresh water is 62.4 lb/ft^3 or 8.34 lb/gal . To obtain the USCS density terms (equivalent to the SI density terms) from the published specific weight values, both terms must be divided by the USCS acceleration of gravity constant, namely 32.2 ft/s^2 . This would give density values of

$$\rho_{\text{fw}} = \frac{\gamma_{\text{fw}}}{g} = \frac{62.4}{32.2} = 1.94 \frac{\text{lb} - \text{sec}^2}{\text{ft}^4} = 1.94 \frac{\text{slug}}{\text{ft}^3}$$

or

$$\rho_{\text{fw}} = \frac{\gamma_{\text{fw}}}{g} = \frac{8.34}{32.2} = 0.258 \frac{\text{lb} - \text{sec}^2}{\text{ft} - \text{gal}} = 0.258 \frac{\text{slug}}{\text{gal}}$$

Who knows what the slug is? Well of course most people don't know what the slug is because it is not used often in engineering practice. Basically, the slug is the USCS equivalent to the SI kilogram. The USCS slug is

$$1 \text{ slug} = 1 \frac{\text{lb} - \text{sec}^2}{\text{ft}}$$

Likewise, the SI kilogram is

$$1 \text{ kilogram} = 1 \frac{\text{N} - \text{sec}^2}{\text{m}}$$

where the N is the Newton which is force unit which is equivalent to the lb force unit in the USCS (the conversion is $4.445\text{N} = 1\text{lb}$). As the slug is not often written in the technical literature, the kilogram is very rarely written in the terms its basic terms of

$$\frac{\text{N} - \text{sec}^2}{\text{m}}$$

Specific Weight: Since the SI mechanical properties of a fluid are listed in density units then these density terms must be used to calculate the specific weight so that practical engineering calculations can be made. Therefore, the density of fresh water can be written in SI units as 1000 kg/m^3 , or 1 kg/l . To carry these calculations out, we must *multiply* these density terms by the SI acceleration of gravity constant, namely 9.81 m/s^2 . This would give the specific weight values of

$$\gamma_{\text{fw}} = \rho_{\text{fw}}g = 1000(9.81) = 9810 \frac{\text{N}}{\text{m}^3}$$

or

$$\gamma_{\text{fw}} = \rho_{\text{fw}}g = 1(9.81) = 9.810 \frac{\text{N}}{\text{liter}}$$

Note that currently there is a new oil field slang term being used. This is MW for “mud weight” (or CW for “cement weight”). These new slang terms are replacing the use of the old slang term of “density” particularly in the areas where the USCS is used. These terms are more scientifically correct since they refer to specific weight values.

Specific Gravity: The above is a complicate units situation especially for engineers who may have worked in one part of the world where either the SI or the USCS was being used and later are assigned to work in another part of the world where the other unit system dominates. Fortunately, instead of dealing with such complicated units situations, the specific gravity of a fluid can be determined from either the published SI density data or from the published USCS specific weight data. The specific gravity term can be defined as

$$\begin{aligned} \text{Specific gravity} &= \frac{\text{Density of a fluid}}{\text{Density of fresh water}} \\ &= \frac{\text{Specific weight of a fluid}}{\text{Specific weight of fresh water}} \end{aligned}$$

For example, consider an engineer from Germany is working temporarily for his operating company at a drilling location in the Gulf Coast region of the USA and wants to convert his SI density calculation result for a drilling mud to a USCS specific weight value for service company staff working at the location. His calculation result for the new drilling mud is 1.32 kg/l . Therefore, the specific gravity of this new drilling mud is

$$\text{Specific gravity} = \frac{1.32}{1.00} = 1.32$$

Therefore, the new drilling mud specific weight is

$$\text{Specific weight} = 1.32(8.34) = 11.0 \frac{\text{lb}}{\text{gal}}$$

or

$$\text{Specific weight} = 1.32(62.4) = 82.4 \frac{\text{lb}}{\text{ft}^3}$$

4.5.1.2 Drilling Fluid Definitions and General Functions

Results of research has shown that penetration rate and its response to weight on bit and rotary speed is highly dependent on the hydraulic horsepower reaching the formation at the bit. Because the drilling fluid flow rate and geometry sets the system pressure losses and these pressure losses set the hydraulic horsepower across the bit, it can be concluded that the drilling fluid is as important in determining drilling costs as all other “controllable” variables combined. Considering these factors, an optimum drilling fluid is properly formulated so that the flow rate necessary to clean the hole results in the proper hydraulic horsepower to clean the bit for the weight and rotary speed imposed to give the lowest cost, provided that this combination of variables results in a stable borehole which penetrates the desired target. This definition incorporates and places in perspective the five major functions of a drilling fluid [1,2].

4.5.1.3 Cool and Lubricate the Bit and Drill String

Considerable heat and friction is generated at the bit and between the drill string and wellbore during drilling operations. Contact between the drill string and wellbore can also create considerable torque during rotation and drag during trips. Circulating drilling fluid transports heat away from these frictional sites, reducing the chance of premature bit failure and pipe damage. The drilling fluid also lubricates the bit tooth penetration through the bottom hole debris into the rock and serves as a lubricant between the wellbore and drill string, reducing torque and drag.

4.5.1.4 Clean the Bit and the Bottom of the Hole

If the cuttings generated at the bit face are not immediately removed and started toward the surface, they will be ground very fine, stick to the bit, and in general retard effective penetration into uncut rock.

4.5.1.5 Suspend Solids and Transport Cuttings and Sloughings to the Surface

Drilling fluids must have the capacity to suspend weight materials and drilled solids during connections, bit trips, and logging runs, or they will settle to the low side or bottom of the hole. Failure to suspend weight materials can result in

a reduction in the drilling fluids density, which can lead to kicks and potential of a blowout.

The drilling fluid must be capable of transporting cuttings out of the hole at a reasonable velocity that minimizes their disintegration and incorporation as drilled solids into the drilling fluid system and able to release the cuttings at the surface for efficient removal. Failure to adequately clean the hole or to suspend drilled solids can contribute to hole problems such as fill on bottom after a trip, hole pack-off, lost returns, differentially stuck pipe, and inability to reach bottom with logging tools.

Factors influencing removal of cuttings and formation sloughings and solids suspension include

- Density of the solids
- Density of the drilling fluid
- Rheological properties of the drilling fluid
- Annular velocity
- Hole angle and geometry
- Slip velocity of the cuttings or sloughings

4.5.1.6 Stabilize the Wellbore and Control Subsurface Pressures

Borehole instability is a natural function of the unequal mechanical stresses and physical-chemical interactions and pressures created when supporting material and surfaces are exposed in the process of drilling a well. The drilling fluid must overcome the tendency for the hole to collapse from mechanical failure or from chemical interaction of the formation with the drilling fluid. The Earth’s pressure gradient at sea level is 0.465 psi/ft, which is equivalent to the height of a column of salt water with a density (1.07 SG) of 8.94 ppg. This relationship can change where geologic features vary, i.e., onshore areas where the lithology column is filled with fresh water equivalent to a 0.433 psi/ft gradient.

In most drilling areas, the fresh water plus the solids incorporated into the water from drilling subsurface formations is sufficient to balance the formation pressures. However, it is common to experience abnormally pressured formations that require high-density drilling fluids to control the formation pressures. Failure to control down-hole pressures can result in an influx of formation fluids, resulting in a kick or blowout. Borehole stability is also maintained or enhanced by controlling the loss of filtrate to permeable formations and by careful control of the chemical composition of the drilling fluid.

Most permeable formations have pore space openings too small to allow the passage of whole mud into the formation, but filtrate from the drilling fluid can enter the pore spaces. The rate at which the filtrate enters the formation depends on the pressure differential between the

formation and the column of drilling fluid and the quality of the filter cake deposited on the formation face.

Large volumes of drilling fluid filtrate and filtrates that are incompatible with the formation or formation fluids may destabilize the formation through hydration of shale and/or chemical interactions between components of the drilling fluid and the wellbore.

Drilling fluids that produce low-quality or thick filter cakes may also cause tight hole conditions, including stuck pipe, difficulty in running casing, and poor cement jobs.

4.5.1.7 Assist in the Gathering of Subsurface Geological Data and Formation Evaluation

Interpretation of surface geological data gathered through drilled cuttings, cores, and electrical logs is used to determine the commercial value of the zones penetrated. Invasion of these zones by the drilling fluid, its filtrate (oil or water) may mask or interfere with interpretation of data retrieved or prevent full commercial recovery of hydrocarbon.

4.5.1.8 Other Functions

In addition to the functions previously listed, the drilling fluid should be environmentally acceptable to the area in which it is used. It should be noncorrosive to tubulars being used in the drilling and completion operations. Most importantly, the drilling fluid should not damage the productive formations (such as clay hydration or wettability changes) within that are penetrated.

The functions described here are a few of the most obvious functions of a drilling fluid. Proper application of drilling fluids is the key to successfully drilling in various environments.

4.5.2 Classifications

A generalized classification of drilling fluids can be based on their fluid phase, alkalinity, dispersion, and type of chemicals used in the formulation and degrees of inhibition. In a broad sense, drilling fluids can be broken into five major categories.

4.5.2.1 Freshwater Muds—Dispersed Systems

The pH value of low-pH muds may range from 7.0 to 9.5. Low-pH muds include spud muds, bentonite-treated muds, natural muds, phosphate-treated muds, organic thinned muds (e.g., red muds, lignite muds, lignosulfonate muds), and organic colloid-treated muds. In this case, the lack of salinity of the water phase and the addition of chemical dispersants dictate the inclusion of these fluids in this broad category [3,4].

4.5.2.2 Inhibited Muds—Dispersed Systems

These are water-base drilling muds that repress the hydration and dispersion of clays through the inclusion of inhibiting ions such as calcium and salt. There are essentially four types of inhibited muds: lime muds (high pH), gypsum muds (low pH), seawater muds (unsaturated saltwater muds, low pH), and saturated saltwater muds (low pH). Newer-generation inhibited-dispersed fluids offer enhanced inhibitive performance and formation stabilization; these fluids include sodium silicate muds, formate brine-based fluids, and cationic polymer fluids.

4.5.2.3 Low Solids Muds—Nondispersed Systems

These muds contain less than 3–6% solids by volume, weight less than 9.5 lb/gal, and may be fresh or saltwater based. The typical low-solid systems are selective flocculent, minimum-solids muds, beneficiated clay muds, and low-solids polymer muds. Most low-solids drilling fluids are composed of water with varying quantities of bentonite and a polymer. The difference among low-solid systems lies in the various actions of different polymers.

4.5.2.4 Nonaqueous Fluids

Invert Emulsions

Invert emulsions are formed when one liquid is dispersed as small droplets in another liquid with which the dispersed liquid is immiscible. Mutually immiscible fluids, such as water and oil, can be emulsified by shear and the addition of surfactants. The suspending liquid is called the *continuous phase*, and the droplets are called the *dispersed* or *discontinuous phase*. There are two types of emulsions used in drilling fluids: oil-in-water emulsions that have water as the continuous phase and oil as the dispersed phase and water-in-oil emulsions that have oil as the continuous phase and water as the dispersed phase (i.e., invert emulsions) [5].

Oil-Base Muds (nonaqueous fluid [NAF])

Oil-base muds contain oil (refined from crude such as diesel or synthetic-base oil from natural gas) as the continuous phase and trace amounts of water as the dispersed phase. Oil-base muds generally contain less than 5% (by volume) water (which acts as a polar activator for organophilic clay), whereas invert emulsion fluids generally have more than 5% water in mud. Oil-base muds are usually a mixture of base oil, organophilic clay, and lignite or asphalt, and the filtrate is all oil.

4.5.3 Testing of Drilling Fluids

To properly control the hole cleaning, suspension, and filtration properties of a drilling fluid, testing of the fluid

properties is done on a daily basis. Most tests are conducted at the rig site, and procedures are set forth in the API RP13B-1 and -2. Testing of water-based fluids and nonaqueous fluids can be similar, but variations of procedures occur due to the nature of the fluid being tested [4,5].

4.5.3.1 Water-Base Muds Testing

To accurately determine the physical properties of water-based drilling fluids, examination of the fluid is required in a field laboratory setting. In many cases, this consists of a few simple tests conducted by the derrickman or mud Engineer at the rigsite. The procedures for conducting all routine drilling fluid testing can be found in the American Petroleum Institute's API RP13B-1 and -2 [4,5].

Specific Weight

Often referred to as the MW is expressed as pounds per gallon (lb/gal), pounds per cubic foot (lb/ft³), specific gravity (SG) or pressure gradient (psi/ft). Any instrument of sufficient accuracy within ± 0.1 lb/gal or ± 0.5 lb/ft³ may be used. The mud balance is the instrument most commonly used. The weight of a mud cup attached to one end of the beam is balanced on the other end by a fixed counterweight and a rider free to move along a graduated scale. The density of the fluid is a direct reading from the scales located on both sides of the mud balance (Figure 4.5.1).

Marsh Funnel Viscosity

Mud viscosity is a measure of the mud's resistance to flow. The primary function of drilling fluid viscosity is a to transport cuttings to the surface and suspend weighing materials. Viscosity must be high enough that the weighting material will remain suspended but low enough to permit sand and cuttings to settle out and entrained gas to escape at the surface. Excessive viscosity can create high pump pressure, which magnifies the swab or surge effect during tripping operations. The control of equivalent circulating density (ECD) is always a prime concern when managing the viscosity of a drilling fluid. The Marsh funnel is a rig site instrument used to measure funnel viscosity. The funnel viscosity is not used to calculate system pressure drop. The funnel is dimensioned so that by following standard procedures, the outflow time of 1 qt (946 ml) of freshwater at a

FIGURE 4.5.1 API mud balance.

FIGURE 4.5.2 Marsh funnel.

temperature of $70 \pm 5^\circ\text{F}$ is 26 ± 0.5 seconds (Figure 4.5.2). A graduated cup is used as a receiver.

Direct Indicating Viscometer

This is a rotational type instrument powered by an electric motor or by a hand crank (Figure 4.5.3). Mud is contained in the annular space between two cylinders. The outer cylinder or rotor sleeve is driven at a constant rotational velocity; its rotation in the mud produces a torque on the inner cylinder or bob (RPM). A torsion spring restrains the movement of the bob. A dial attached to the bob indicates its displacement on a direct reading scale. Instrument constraints have been adjusted so that plastic viscosity, apparent viscosity, and yield point are obtained by using readings from rotor sleeve speeds of 300 and 600 rpm.

Plastic viscosity (PV) in centipoise is equal to the 600 rpm dial reading minus the 300 rpm dial reading. Yield point (YP), in pounds per 100 ft², is equal to the 300-rpm dial reading minus the plastic viscosity. Apparent viscosity in centipoise is equal to the 600-rpm reading, divided by two.

Gel Strength

Gel strength is a measure of the inter-particle forces and indicates the gelling that will occur when circulation is stopped. This property prevents the cuttings from setting in the hole. High pump pressure is generally required to "break" circulation in a high-gel mud. Gel strength is measured in units of lbf/100 ft². This reading is obtained by

FIGURE 4.5.3 Six speed viscometer.

noting the maximum dial deflection when the rotational viscometer is turned at a low rotor speed (3 rpm) after the mud has remained static for some period of time (10 seconds, 10 minutes, or 30 minutes). If the mud is allowed to remain static in the viscometer for a period of 10 seconds, the maximum dial deflection obtained when the viscometer is turned on is reported as the *initial gel* on the API mud report form. If the mud is allowed to remain static for 10 minutes, the maximum dial deflection is reported as the *10-min gel*. The same device is used to determine gel strength that is used to determine the plastic viscosity and yield point, the Variable Speed Rheometer/Viscometer.

API Filtration

A standard API filter press is used to determine the filter cake building characteristics and filtration of a drilling fluid (Figure 4.5.4). The API filter press consists of a cylindrical mud chamber made of materials resistant to strongly alkaline solutions. A filter paper with a permeability of 50 md (millidarcy) is placed on the bottom of the chamber just above a suitable support. The total filtration area is $7.1 (\pm 0.1) \text{ in.}^2$. Below the support is a drain tube for discharging the filtrate into a graduated cylinder. The entire assembly is supported by a stand so 100-psi pressure can be applied to the mud sample in the chamber. At the end of the 30-minute filtration time, the volume of filtrate is reported as API filtration in milliliters. To obtain correlative results, one thickness of the proper 9-cm filter paper—Whatman No. 50, S&S No. 5765, or the equivalent—must be used. Thickness of the filter cake is measured and reported in 32nd of an inch. The cake is visually examined, and its consistency is reported using such notations as “hard,” “soft,” “tough,” “rubbery,” or “firm.”

Sand Content

The sand content in drilling fluids is determined using a 200-mesh sand sieve screen 2 inches in diameter, a funnel to fit the screen, and a glass-sand graduated measuring tube (Figure 4.5.5). The measuring tube is marked to indicate

FIGURE 4.5.4 API style filter press.

FIGURE 4.5.5 Sand content kit.

the volume of “mud to be added,” water to be added and to directly read the volume of solids on the bottom of the tube.

Sand content of the mud is reported in percent by volume. Also reported is the point of sampling (e.g., flowline, shale shaker, suction pit). Solids other than sand may be retained on the screen (e.g., lost circulation material and API barite), and the presence of such solids should be noted.

Liquids and Solids Content

A mud retort is used to determine the liquids and solids content of a drilling fluid. Mud is placed in a steel container and heated at high temperature until the liquid components have been distilled off and vaporized (Figure 4.5.6). The vapors are passed through a condenser and collected in a graduated cylinder. The volume of liquids (water and oil) is then measured. Solids, both suspended and dissolved, are determined by volume as a difference between the mud in container and the distillate in graduated cylinder. Drilling fluid retorts are generally designed to distill 10-, 20-, or 50-ml sample volumes.

For freshwater muds, a rough measure of the relative amounts of barite and clay in the solids can be made (Table 4.5.1). Because both suspended and dissolved solids are retained in the retort for muds containing substantial quantities of salt, corrections must be made for the salt. Relative amounts of high- and low-gravity solids contained in drilling fluids can be found in Table 4.5.1 For higher specific gravity muds, the HGS and LGS content can be

FIGURE 4.5.6 Retort kit (10 ml).

calculated and reported as volume percent (%v/v) and pounds per barrel (lb/bbl).

pH

Two methods for measuring the pH of drilling fluid are commonly used: (1) a modified colorimetric method using pH paper or strips and (2) the electrometric method using a glass electrode (Figure 4.5.7). The paper strip test may not be reliable if the salt concentration of the sample is high. The electrometric method is subject to error in solutions containing high concentrations of sodium ions unless a special glass electrode is used or unless suitable correction factors are applied if an ordinary electrode is used. In addition, a temperature correction is required for the electrometric method of measuring pH.

The paper strips used in the colorimetric method are impregnated with dyes so that the color of the test paper depends on the pH of the medium in which the paper is placed. A standard color chart is supplied for comparison with the test strip. Test papers are available in a wide range, which permits estimating pH to 0.5 units, and in narrow range papers, with which the pH can be estimated to 0.2 units.

The glass electrode pH meter consists of a glass electrode, an electronic amplifier, and a meter calibrated in pH units. The electrode is composed of (1) the glass electrode, a thin-walled bulb made of special glass within which is sealed a suitable electrolyte and an electrode, and (2) the reference electrode, which is a saturated calomel cell. Electrical connection with the mud is established through a saturated solution of potassium chloride contained in a tube surrounding the calomel cell. The electrical potential generated in the glass electrode system by the hydrogen ions in the drilling mud is amplified and operates the calibrated pH meter.

Resistivity

Control of the resistivity of the mud and mud filtrate while drilling may be desirable to permit enhanced evaluation of the formation characteristics from electric logs. The determination of resistivity is essentially the measurement of the resistance to electrical current flow through a known sample configuration at sample temperature. Measured resistance is converted to resistivity by use of a cell constant. The cell constant is fixed by the configuration of the sample in the cell and is determined by calibration with standard solutions of known resistivity. The resistivity is expressed in ohm-meters. This value is reduced at bottom hole temperature levels.

Filtrate Chemical Analysis

Standard chemical analyses have been developed for determining the concentration of various ions present in the mud. Tests for the concentration of chloride, hydroxyl, and calcium ions are required to fill out the API drilling mud report. The tests are conducted on a 1 ml sample of filtrate (i.e., reaction of a known volume of mud filtrate sample with a standard solution of known volume and concentration). The end of the chemical reaction is usually indicated by the change of color. The concentration of the ion being tested can be determined from a knowledge of the chemical reaction taking place.

Chloride

The chloride concentration is determined by titration with silver nitrate solution. This causes the chloride to be removed from the solution as AgCl^- , a white precipitate. The endpoint of the titration is detected using a potassium chromate indicator. The excess Ag present after all Cl^- has been removed from solution reacts with the chromate to form Ag_2CrO_4 , an orange-red precipitate. Contamination with chlorides generally results from drilling salt or from a saltwater flow. Salt can enter and contaminate the mud system when salt formations are drilled and when saline formation water enters the wellbore.

Alkalinity and Lime Content

Alkalinity is the ability of a solution or mixture to react with an acid. The *phenolphthalein alkalinity* refers to the amount of acid required to reduce the pH of the filtrate to 8.3, the phenolphthalein end point. The phenolphthalein alkalinity of the mud and mud filtrate is called the P_m and P_f , respectively. The P_f test includes the effect of only dissolved bases and salts, whereas the P_m test includes the effect of both dissolved and suspended bases and salts. The m and f indicate if the test was conducted on the whole mud or mud filtrate. The M_f alkalinity refers to the amount of acid required to reduce the pH to 4.3, the methyl orange end point. The methyl orange alkalinity of the mud and mud filtrate is called the M_m and M_f , respectively. The API diagnostic tests include the determination of P_m , P_f , and M_f . All values are reported in cubic centimeters of 0.02 N (normality = 0.02) sulfuric acid per cubic centimeter of sample. The lime content of the mud is calculated by subtracting the P_f from the P_m and dividing the result by 4.

The P_f and M_f tests are designed to establish the concentration of hydroxyl, bicarbonate, and carbonate ions in the aqueous phase of the mud. At a pH of 8.3, the conversion of hydroxides to water and carbonates to bicarbonates is essentially complete. The bicarbonates originally present in solution do not enter the reactions. As the pH is further reduced to 4.3, the acid reacts with the bicarbonate ions to form carbon dioxide and water.

The P_f and P_m test results indicate the reserve alkalinity of the suspended solids. As the $[\text{OH}^-]$ in solution is reduced, the lime and limestone suspended in the mud will go into solution and tend to stabilize the pH (Table 4.5.2). This reserve alkalinity generally is expressed as an excess lime

concentration, in lb/bbl of mud. The accurate testing of P_f , M_f , and P_m are needed to determine the quality and quantity of alkaline material present in the drilling fluid. The table below shows how the hydroxyl, carbonate, and bicarbonate ion concentrations based on these titrations.

Total Hardness

The total combined concentration of calcium and magnesium in the mud-water phase is defined as total hardness. These contaminants are often present in the water available for use in the drilling fluid makeup. In addition, calcium can enter the mud when anhydrite (CaSO_4) or gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) formations are drilled. Cement also contains calcium and can contaminate the mud. The total hardness is determined by titration with a standard (0.02 N) versenate hardness titrating solution (EDTA). The standard versenate solution contains sodium versenate, an organic compound capable of forming a chelate when combined with Ca^{2+} and Mg^{2+} .

The hardness test sometimes is performed on the whole mud as well as the mud filtrate. The mud hardness indicates the amount of calcium sulphate solids suspended in the mud and the amount of calcium in solution. This test usually is made on gypsum-treated muds to indicate the amount of excess CaSO_4 present in suspension. To perform the hardness test on mud, a small sample of mud is first diluted to 50 times its original volume with distilled water so that any undissolved calcium or magnesium compounds can go into solution. The mixture then is filtered through filter paper to obtain a clear filtrate. The total hardness of this filtrate then is obtained using the same procedure used for the filtrate from the low-temperature, low-pressure API filter press apparatus.

Methylene Blue Capacity (CEC or MBT)

It is desirable to know the cation exchange capacity (CEC) of the drilling fluid. To some extent, this value can be correlated to the reactive solids content of the mud. The test is only qualitative because organic material and other clays present in the mud also absorb methylene blue dye. The mud sample is treated with hydrogen peroxide to oxidize most of the organic material. The cation exchange capacity is reported in milliequivalent weights (mEq) of methylene blue dye per 100 ml of mud. The methylene blue solution used for titration is usually 0.01 N, so that the cation exchange capacity is numerically equal to the cubic centimeters of methylene blue solution per cubic centimeter of sample required to reach an end point. If other adsorptive materials are not present in significant quantities, the montmorillonite content of the mud in pounds per barrel is calculated to be five times the cation exchange capacity. The methylene blue test can also be used to determine cation exchange capacity of clays and shales. In the test, a weighed

TABLE 4.5.2 Alkalinity

Criteria	OH^- (mg/L)	CO_3^{2-} (mg/L)	HCO_3^- (mg/L)
$P_f = 0$	0	0	$1,220 M_f$
$2P_f < M_f$	0	$1,200 P_f$	$1,220 (M_f - 2P_f)$
$2P_f = M_f$	0	$1,200 P_f$	0
$2P_f > M_f$	$340 (2P_f - M_f)$	$1,200 (M_f - P_f)$	0
$P_f = M_f$	$340 M_f$	0	0

amount of clay is dispersed into water by a high-speed stirrer or mixer. Tiration is carried out as for drilling muds, except that hydrogen peroxide is not added. The cation exchange capacity of clays is expressed as milliequivalents of methylene blue per 100 g of clay.

4.5.3.2 Oil-Base and Synthetic-Base Mud (Nonaqueous Fluids Testing)

The field tests for rheology, mud density, and gel strength are accomplished in the same manner as outlined for water-based muds. The main difference is that rheology is tested at a specific temperature, usually 120°F or 150°F. Because oils tend to thin with temperature, heating the fluid is required and should be reported on the API Mud Report.

Sand Content

Sand content measurement is the same as for water-base muds except that the mud's base oil instead of water should be used for dilution. The sand content of oil-base mud is not generally tested.

HPHT Filtration

The API filtration test result for oil-base muds is usually zero. In relaxed filtrate oil-based muds, the API filtrate should be all oil. The API test does not indicate downhole filtration rates. The alternative high-temperature-high pressure (HTHP) filtration test will generally give a better indication of the fluid loss characteristics of a fluid under downhole temperatures (Figure 4.5.8).

The instruments for the HTHP filtration test consists essentially of a controlled pressure source, a cell designed to withstand a working pressure of at least 1,000 psi, a system for heating the cell, and a suitable frame to hold the cell and the heating system. For filtration tests at temperatures above 200°F, the filtrate will be vapor, so a pressurized collection cell is attached to the delivery tube to allow the filtrate to condense back to a liquid as it cools down in

FIGURE 4.5.8 HPHT fluid loss testing device.

temperature. The filter cell is equipped with a thermometer well, oil-resistant gaskets, and a support for the filter paper (Whatman no. 50 or the equivalent). A valve on the filtrate delivery tube controls flow from the cell. A nonhazardous gas such as nitrogen or carbon dioxide should be used as the pressure source. The test is usually performed at a temperature of 220 – 350°F (generally recommended to be 25-50 °F above the expected bottom hole temperature [BHT]) and a pressure of 500 psi (differential) over a 30-minute period. When other temperatures, pressures, or times are used, their values should be reported together with test results. If the cake compressibility is desired, the test should be repeated with pressures of 200 psi on the filter cell and 100 psi back pressure on the collection cell. The volume of oil collected at the end of the test should be doubled to correct to a surface area of 7.1 inches.

Electrical Stability

The electrical stability test indicates the stability of emulsions of water in oil mixtures. The emulsion tester consists of a reliable circuit using a source of variable AC current (or DC current in portable units) connected to strip electrodes (Figure 4.5.9). The voltage imposed across the electrodes can be increased until a current flows through the mud emulsion-breakdown point. Relative stability is indicated as the voltage at the breakdown point and is reported as the electric stability of the fluid on the daily API test report.

Liquids and Solids Content

Oil, water, and solids volume percent is determined by retort analysis as in a water-base mud. More time is required to get a complete distillation of an oil mud than for a water mud. The corrected water phase volume, the volume percent of low-gravity solids, and the oil-to-water ratio can then be calculated.

The volume oil-to-water ratio can be found from the procedure below:

$$\text{Oil fraction } 100 \times \frac{\% \text{ by volume oil or synthetic oil}}{\% \text{ by volume oil or synthetic oil} - \% \text{ by volume water}}$$

FIGURE 4.5.9 Electrical stability meter.

Chemical analysis procedures for nonaqueous fluids can be found in the API RB13-2 [5].

Alkalinity and Lime Content (NAF)

The whole mud alkalinity test procedure is a titration method that measures the volume of standard acid required to react with the alkaline (basic) materials in an oil mud sample. The alkalinity value is used to calculate the pounds per barrel of unreacted, “excess” lime in an oil mud. Excess alkaline materials, such as lime, help to stabilize the emulsion and neutralize carbon dioxide or hydrogen sulfide acidic gases.

Total Salinity (Water-Phase Salinity [WAF] for NAF)

The salinity control of NAF fluids is very important for stabilizing water-sensitive shales and clays. Depending on the ionic concentration of the shale waters and of the mud water phase, an osmotic flow of pure water from the weaker salt concentration (in shale) to the stronger salt concentration (in mud) will occur. This may cause dehydration of the shale and, consequently, affect its stabilization (Figure 4.5.10).

4.5.3.3 Specialized Tests

Other, more advanced laboratory-based testing is commonly carried out on drilling fluids to determine treatments or to define contaminants. Some of the more advanced analytical tests routinely conducted on drilling fluids include:

Advanced Rheology and Suspension Analysis

CHANDLER 7600 — A laboratory unit designed to test rheology under 40,000 psi and 600 °F.

FANN 50 — A laboratory test for rheology under temperature and moderate pressure (up to 1,000 psi and 500°F).

FANN 70 — Laboratory test for rheology under high temperature and high pressure (up to 20,000 psi and 500°F).

FANN 75 — A more advanced computer-controlled version of the FANN 70 (up to 20,000 psi and 500°F).

FANN IX77 - A fully automated unit that can measure rheological properties up to 30,000 psi and 600°F.

Several of these units can be equipped with a chiller to reduce the temperature of the sample down to 40°F to simulate the lower flow line temperature observed on deepwater well locations.

High-Angle Sag Test (HAST)

A laboratory test device to determine the suspension properties of a fluid in high-angle wellbores. This test is designed to evaluate particle setting characteristics of a fluid in deviated wells.

Dynamic HAST

Laboratory test device to determine the suspension properties of a drilling fluid under high angle and dynamic conditions.

FIGURE 4.5.10 Salt saturation curves.

4.5.3.4 Specialized Filtration Testing

FANN 90

Dynamic filtration testing of a drilling fluid under pressure and temperature. This test determines if the fluid is properly conditioned to drill through highly permeable formations. The test results include two numbers: the dynamic filtration rate and the cake deposition index (CDI). The dynamic filtration rate is calculated from the slope of the curve of volume versus time. The CDI, which reflects the erodability of the wall cake, is calculated from the slope of the curve of volume/time versus time. CDI and dynamic filtration rates are calculated using data collected after twenty minutes. The filtration media for the FAN 90 is a synthetic core. The core size can be sized for each application to optimize the filtration rate.

Particle-Plugging Test (PPT)

The PPT test is accomplished with a modified HPHT cell to examine sealing characteristics of a drilling fluid. The PPT, sometimes known as the PPA (particle-plugging apparatus), is key when drilling in high-differential-pressure environments.

Aniline Point Test

Determine the aniline point of an oil-based fluid base oil. This test is critical to ensure elastomer compatibility when using nonaqueous fluids.

Particle-Size Distribution (PSD) Test

The PSD examines the volume and particle size distribution of solid in a fluid. This test is valuable in determining the type and size of solids control equipment that will be needed to properly clean a fluid of undesirable solids.

Luminescence Fingerprinting

This test is used to determine if contamination of a synthetic-based mud has occurred with crude oil during drilling operations.

Lubricity Testing

Various lubricity meters and devices are available to the industry to determine how lubricous a fluid is when exposed to steel or shale. In high-angle drilling applications, a highly lubricious fluid is desirable to allow proper transmission of weight to the bit and reduce side wall sticking tendencies. Typical water-based muds will have a lubricity coefficient of 0.25 and a typical NAF mud will have a coefficient of the 0.10.

4.5.3.5 Shale Characterization Testing

Capillary Suction Time (CST)

Inhibition testing looks at the inhibitive nature of a drilling fluid filtrate when exposed to formation shale samples. The CST is one of many tests that are run routinely on shale samples to optimize the mud chemistry of a water-base fluid.

Linear-Swell Meter (LSM)

Another diagnostic test to determine the inhibitive nature of a drilling fluid on field shale samples. The LSM looks at long-term exposure of a fluid filtrate to a formation shale sample. Test times for LSM can run up to 14 days.

Shale Erosion

Shale inhibition testing looks at the inhibitive nature of a drilling fluid and examines the erodability of a shale when exposed to a drilling fluid. Various tests procedures for this analytical tool.

Return Permeability

Formation damage characterization of a fluid through an actual or simulated core is accomplished with the return permeability test. This test may be required when designing specialized reservoir drilling fluids to minimize formation impairment.

Bacteria Testing

Tests for the presence of bacteria in water-base muds; this is especially important in low-pH fluids because bacterial growth is high in these types of fluids. Biocide treatments should be based on this test result.

Static Aging

The aging test is used to determine how bottom-hole conditions affect mud properties. Aging cells were developed to aid in predicting the performance of drilling mud under static, high-temperature conditions. If the bottom-hole temperature is greater than 212°F, the aging cells should be pressurized with nitrogen, carbon dioxide, or air to a desired pressure to prevent boiling and vaporization of the mud.

After the aging period, three properties of the aged mud are determined before the mud is agitated or stirred: shear strength, free oil (top oil separation in NAF), and solids setting. Shear strength indicates the gelling tendencies of fluid in the borehole. Second, the sample should be observed to determine if free oil is present. Separation of free oil is an indication of emulsion instability in the borehole and is expressed in 32nd of an inch. Setting of mud solids indicates the formation of a hard or soft layer or sediment in the borehole. After the unagitated sample has been examined, the sample is sheared, and the usual tests for determining rheological and filtration properties are performed.

4.5.3.6 Drilling Fluid Additives

Each drilling fluid vendor provides a wide array of basic and specialty chemicals to meet the needs of the drilling industry. The general classification of drilling fluid additives below is based on the definitions of the International Association of Drilling Contractors (IADC):

- A. Alkalinity or pH control additives are products designed to control the degree of acidity or alkalinity of a drilling fluid. These additives include lime, caustic soda, and bicarbonate of soda.
- B. Bactericides reduce the bacteria count of a drilling fluid. Para-formaldehyde, isothiazaline, carbanate, caustic soda, lime, and starch are commonly used as preservatives.
- C. Calcium removers are chemicals used to prevent and to overcome the contaminating effects of anhydride and gypsum, both forms of calcium sulfate, which can wreck the effectiveness of nearly any chemically treated sodium-based mud. The most common calcium removers are caustic soda, soda ash, bicarbonate of soda, and certain polyphosphates.
- D. Corrosion inhibitors such as hydrated lime and amine salts are often added to mud and to air-gas systems. Mud containing an adequate percentage of colloids, certain emulsion muds, and oil muds exhibit, in themselves, excellent corrosion-inhibiting properties.
- E. Defoamers are products designed to reduce foaming action, particularly that occurring in brackish water and saturated saltwater muds.
- F. Emulsifiers are used for creating a heterogeneous mixture of two liquids. These include modified lignosulfonates, certain surface-active agents, anionic and nonionic (negatively charged and noncharged) products.
- G. Filtrate, or fluid loss, reducers such as bentonite clays, sodium carboxymethyl cellulose (CMC), and pregelatinized starch serve to reduce the filter loss, a measure of the tendency of the liquid phase of a drilling fluid to penetrate into the formation.
- H. Flocculants are used sometimes to increase gel strength. Salt (or brine), hydrated lime, gypsum, and sodium tetraphosphates may be used to cause the colloidal particles of a suspension to group into bunches of "flocks," causing solids to settle out.
- I. Foaming agents are most often chemicals that also act as surfactants (surface-active agents) to foam in the presence of water. These foamers permit air or gas drilling through water-production formations.
- J. Lost circulation materials (LCM) include nearly every possible product used to stop or slow the loss of circulating fluids into the formation. This loss must be differentiated from the normal loss of filtration liquid and from the loss of drilling mud solids to the filter cake (which is a continuous process in an open hole).
- K. Extreme-pressure lubricants are designed to reduce torque by reducing the coefficient of friction and thereby increase horsepower at the bit. Certain oils, graphite powder, and soaps are used for this purpose.
- L. Shale control inhibitors such as gypsum, sodium silicate, chrome lignosulfonates, as well as lime and salt are used to control caving by swelling or hydrous disintegration of shales.
- M. Surface-active agents (surfactants) reduce the interfacial tension between contacting surfaces (e.g., water—oil, water—solid, water—air); these may be emulsifiers, de-emulsifiers, flocculants, or deflocculents, depending upon the surfaces involved.
- N. Thinners and dispersants modify the relationship between the viscosity and the percentage of solids in a drilling mud and may further be used to vary the gel strength and improve "pumpability." Tannins (quebracho), various polyphosphates, and lignitic materials are chosen as thinners or as dispersants, because most of these chemicals also remove solids by precipitation or sequestering, and by deflocculation reactions.
- O. Viscosifiers such as bentonite, CMC, Attapulgitic clays, sub-bentonites, and asbestos fibers are employed in drilling fluids to ensure a high viscosity—solids ratio.
- P. Weighting materials, including barite, iron oxides, and similar products possessing extraordinarily high specific gravities, are used to control formation pressures, check caving, facilitate pulling dry drill pipe on round trips, and aid in combating some types of circulation loss.

The most common commercially available drilling mud additives are published annually by *World Oil*. The listing includes names and descriptions of more than 2,000 mud additives.

4.5.3.7 Clay Chemistry

Water-base drilling fluids normally contain a number of different types of clays. Most of the clays are added to attain certain physical properties (e.g., fluid loss, viscosity, yield point) and eliminate hole problems.

The most common clays incorporated into the drilling fluid from the formation (in the form of drill solids) are calcium montmorillonite, illites, and kaolinites. The most used commercial clay is sodium montmorillonite.

Bentonite is added to water-base drilling fluids to increase the viscosity and gel strength of the fluid. This results in quality suspension properties for weight materials and increases the carrying capacity for removal of solids from the well. The most important function of bentonite is to improve the filtration and filter cake properties of the water-base drilling fluid.

Clay particles are usually referred to as clay platelets or sheets. The structure of the sodium montmorillonite platelet has sheets consisting of three layers. The platelet,

if looked at under an electron microscope, reveals that the sections are honeycombed inside the three layers. The three-layered (sandwich-type) sheet is composed of two silica tetrahedral layers with an octahedral aluminum center core layer between them. The section layers are bonded together in a very intricate lattice-type structure.

Cations are absorbed on the basal surface of the clay crystals to form a natural forming structure. This occurred in the earth over a period of 100 million years. The positive sodium or calcium cations compensate for the atomic substitution in the crystal structure (the isomorphic substitution that took place in forming of the clay). This is the primary way that sodium clays are differentiated from calcium clays.

Sodium montmorillonite absorbs water through expansion of the lattice structure. There are two mechanisms by which hydration can occur:

1. Between the layers (osmotic). The exposure of the clay to water vapor causes the water to condense between the layers, expanding them. The lower the concentration of sodium and chloride in the water, the greater the amount of water that can be absorbed into the clay lattice structure.
2. Around layers (crystalline). There is a layer of water that surrounds the clay particles (a cloud of Na^+ with water molecules held to the platelet by hydrogen bonding to the lattice network by the oxygen on the face of the platelet). The structure of water and clay is commonly called an envelope. (It must be remembered that the water envelope has viscosity.)

Aggregation

Clays are said to be in the aggregated state when the platelets are stacked loosely in bundles. When clay is collapsed and its layers are parallel, the formation is like a deck of cards stacked in a box. This is the state of sodium bentonite in the sack having a moisture content of 10%. When added to freshwater (does not contain a high concentration of chlorides), diffuses of water into the layers occurs, and swelling or dispersion results.

In solutions with high chloride concentrations, the double layer is compressed still further, and aggregation occurs. Consequently, the size of the particle is reduced, and the total particle area per unit volume decreases. This occurs because the chloride ion has a strong bond with the H_2O , and free water is not available to enter the clay and hydrate effectively. In muds in which the clay is aggregated, the viscosity is low.

The relationship between the type and concentration of the salt in the water determines the point at which aggregation (inhibition) will occur:

- Sodium chloride (NaCl) 400 mEq/L
- Calcium chloride (CaCl_2) 20 mEq/L
- Aluminum chloride (AlCl_3) 20 mEq/L

It may be inferred that the higher the chloride content and the higher the valence of the cation salts in solution, the more the clay will be inhibited from swelling. It is also true that the tendency of the dispersed clays to revert to an aggregated (inhibited) state is measurable.

Dispersion

The subdivision of particles from the aggregated state in a fluid (water) to a hydrated colloid particle is the dispersing of that particle. In freshwater dispersion, the clay platelets drift about in an independent manor or in very small clusters. There are times when the platelets configure in random patterns. This usually occurs in a static condition and is termed *gel strength of dispersed clay*. The random movement and drifting of a positively charged edge toward a negatively charged face happens slowly in a dispersed state. When bentonite is in a dispersed state, the positive ion cloud presents an effective “shield” around the clay and sometimes slows this effect. The ionized Na^+ surrounds the clay to form a weak crystalline barrier.

Dispersed clay state is characterized by

- High viscosity
- High gel strength
- Low filtrate

Flocculation (NaCl)

The most common cause of flocculation of clays in the field is the incorporation of NaCl in to a fresh water mud. When the Na^+ content is raised toward 1%, the water becomes more positively charged. The ionized envelope cloud that “protected” the platelet is of a lower charge than the bulk water. The positive Al^{3+} edge joins with the oxygen face, and the drift of edge to face is accelerated.

The viscosity rises, and water loss is uncontrollable when the clay flocculates edge to face in a “House of Cards structure,” and the increase in viscosity and water loss is dramatic. As the NaCl content increases to 5%, the free water is tied up by the chloride ion, and the ion and the clays collapse and revert to the aggregated state. The water is removed from the clay platelet body.

When the NaCl content increases to 15% to 30% by weight, the agglomerates flocculate into large edge to face groups. This leads to extreme viscosities and very poor fluid loss control. This also depends on the solids content. In diluted suspensions, the viscosity usually is reduced by increasing salt concentrations, and clay platelets are in the aggregated state. Viscosity will go through a “hump.”

Deflocculation (Chemical Dispersion)

One way to deflocculate, or chemically disperse, a clay platelet is with a large molecule having many carboxyl and sulfonate anions at scattered intervals on the cellulose chain. In deflocculated or chemically dispersed muds, the viscosity will be lower than it was in the flocculated state.

Lignosulfonate works to deflocculate by the anionic charges that latch onto the positive edges of the clay platelet. The remainder of this huge (flat) cellulosic molecule is repelled from the negative clay face and rolls out from the edges.

The edge-to-face flocculation that occurred becomes virtually impossible. The polyanionic encapsulator can be rendered neutral if the pH drops below 9.5. The NaCl flocculant is still present in the solution, but its flocculating effects are rendered ineffective if the pH is maintained above 9.5.

Flocculation (Calcium)

When calcium is induced into a drilling fluid, its solubility depends on the pH of the water in the fluid. The double-positive charge on the calcium ion will attract itself to the face of the bentonite platelet at an accelerated rate, because this attraction is far superior to the sodium's ability to retain its place on the clay face. The divalent calcium ions will still partially hydrate, but the amount of water is less around the clay platelet. This will allow flocculation to occur much faster, because there is little water structure around the clay in this situation.

Calcium can cause flocculation in the same manner as salt (NaCl) in that edge-to-face groupings are formed. Calcium is a divalent cation, so it holds onto two platelet faces, which causes large groups to form, and then the edge-to-face grouping to take hold. Because calcium (Ca^{2+}) has a valence of 2, it can hold two clay platelets tightly together, and the flocculation reaction starts to happen at very low concentrations. To achieve flocculation with salt (NaCl), it takes 10 times the concentration for the edge-to-face groupings to form.

In the flocculated state, a dispersant (thinner) will work to separate the flocculating ions and encapsulate the platelets by mechanical shear. This is a short-term answer to the problem, however, because the contaminating ion is still active in the system, and it must be reduced to a normal active level for drilling to continue.

Deflocculation (Calcium Precipitation)

The most effective way to remove the flocculating calcium ion from the system is to chemically precipitate it. Two common chemicals can be used to accomplish removal of the calcium ion. They are Na_2CO_3 (soda ash) and NaHCO_3 (bicarbonate of soda). Because calcium is lodged between two platelets and holding them together, the two

chemicals will, with mechanical help, bond together with the flocculant calcium as shown in the formula below:

Lime + Sodium Bicarbonate
→ Calcium Carbonate + Caustic + Water

Calcium sulfate + Sodium carbonate
→ Calcium carbonate + Sodium sulfate

In the previous chemical equation, calcium is precipitated and rendered inert. There is no longer a possible flocculating calcium ion to deal with.

Inhibition (NaCl)

When a water solution contains more than 12,000 mg/l of NaCl, it can inhibit clays from swelling or hydrating. This happens because the sodium ion content is high in the water, and the sodium ions on the clay face cannot leave to allow space for the water to enter the clay platelet. The chloride ion has an ability to tightly hold onto water molecules, which leaves few free ions to envelope or surround the clay. When the clay (aggregation) platelet does not hydrate, the state is the same as it is in the sack. In this instance, the ion is controlling the swelling of clays and is referred to as *inhibition*.

Controlling these various clay states in water-base drilling fluids is important for the success of any well using this chemistry. It can be said that flocculation causes and increases viscosity and that aggregation and deflocculation decrease viscosity.

4.5.3.8 WATER-BASE MUDS

A water-base drilling fluid is one that has water as its continuous or liquid phase. The types of drilling fluids are briefly described in the following sections.

Freshwater muds are generally lightly treated or untreated muds having a liquid phase of water, containing small concentrations of salt, and having a pH ranging from 8.0 to 10.5. Freshwater muds include the following types.

Spud Muds

These muds are prepared with available water and appropriate concentrations of bentonite and/or premium commercial clays. They are generally untreated chemically, although lime, cement, or caustic soda is occasionally added to increase viscosity and give the mud a fluff to seal possible lost return zones in unconsolidated upper hole surface formations. Spud muds are used for drilling the surface hole. Their tolerance for drilled solids and contaminants is very limited.

Natural Mud

Natural or native muds use native drilled solids incorporated into the mud for viscosity, weight, and fluid loss control. They are often supplemented with bentonite for added stability and water loss control. Surfactants can be used to aid in controlling mud weight and solids buildup. Natural muds are generally used in top hole drilling to mud-up or to conversion depth. They have a low tolerance for solids and contamination.

Saltwater Muds

Muds ordinarily are classified as saltwater muds when they contain more than 10,000 mg/L of chloride. They may be further classified according to the amount of salt present and/or the source of makeup water (see Table 4.5.3):

Amount of chloride in mg/L

1. Saturated salt muds (315,000 ppm as sodium chloride)
2. Salt muds (over 10,000 mg/L chloride but not saturated)

Source of make-up water

- A. Brackish Water
- B. Sea Water

Saltwater muds may be purposely prepared, or they may result from the use of salty makeup water, from drilling into salt domes or stringers, or when saltwater flows are encountered. Saltwater muds include the following types.

Seawater or Brackish Water Muds

These muds are prepared with available makeup water, both commercial and formation clay solids, caustic soda, and lignite and/or a lignosulfonate. CMC is usually used for fluid loss control, although concentration of lignites

and lignosulfonates are also often used for this purpose. Viscosity and gel strength are controlled with caustic soda, lignosulfonate, and/or lignites. Soda ash is frequently used to lower the calcium concentration. CMC or lignosulfonates are used for water loss control, and pH is controlled between 8.5 to 11.0 with caustic soda. Seawater muds and brackish or hard water muds are used primarily because of the convenience of makeup water, usually open sea or bays. The degree of inhibitive properties varies with the salt and calcium concentration in the formulated fluid.

Saturated Salt Muds

Saturated salt water (natural or prepared) is used as makeup water in these fluids. Prehydrated bentonite (hydrated in freshwater) is added to give viscosity, and starch is commonly used to control fluid loss. Caustic soda is added to adjust the pH, and lignosulfonates are used for gel strength control. Occasionally, soda ash may be used to lower filtrate calcium and adjust the pH. Saturated salt muds are used to drill massive salt sections (composed mainly of NaCl) to prevent washouts and as a work-over or completion fluid. Freshwater bentonite suspensions are converted by adding NaCl to reach saturation. Conversion is carried out by diluting the freshwater mud to reduce the viscosity “hump” seen in breakovers. Saturated salt muds usually are used at mud weights below 14.0 lb/gal.

Composition of NaCl mud

- Brine NaCl
- Density — salt, barite, calcium carbonate or hematite
- Viscosity — CMC HV, Prehydrated bentonite, XC-polymer (xanthan gum)
- Rheology — lignosulfonate
- Fluid Loss — CMC LV or PAC (polyanionic cellulose)
- pH – P_f (alkalinity) — caustic potash or caustic soda

Chemically Treated Mud (No Calcium Compounds)

This type of mud is made up of a natural mud that has been conditioned with bentonite and treated with caustic soda and lignite or lignosulfonate (organic thinner). No inhibiting ions are found in this type of fluid.

Lignite/Lignosulfonate Mud

This fluid is prepared from freshwater and conditioned with bentonite. Lignosulfonate is added as a thinner and lignite for filtration control and increased temperature stability. CMC or PAC may be used for additional filtration control when the bottom-hole temperature does not exceed 121°C (250°F). This type of mud is applied at all mud weights and provides a relatively low pH system (pH values for calcium lignosulfonates will be 10.0–11.0). This type of fluid is stable at reasonably high temperatures (325°F) and has good resistance to contamination.

TABLE 4.5.3 Seawater Composition

Constituent	Parts per Million	Equivalent Parts per Million
Sodium	10440	454.0
Potassium	375	9.6
Magnesium	1270	104.6
Calcium	410	20.4
Chloride	18970	535.0
Sulfate	2720	57.8
Carbon dioxide	90	4.1
Other constituents	80	n/a

Calcium Treated Muds

Calcium-treated fluids are prepared from any low or high pH mud by the addition of appropriate amounts of lime or gypsum, caustic soda, and thinner (lignite or lignosulfonate). Calcium-treated muds include lime and gypsum muds.

Lime Muds

Lime muds include low- and high-lime muds. They are prepared from available muds by adding calcium lignosulfonate, lignite, caustic soda or KOH, lime, and a filtration-control material, PAC or starch. Caustic soda is used to maintain the filtrate alkalinity (P_f values) and lime to control the mud alkalinity (P_m values) and excess lime. Lime muds offer resistance to salt, cement, or anhydrite contamination even at high mud weights.

Gypsum Mud

Commonly called “gyp muds,” they are prepared from freshwater and conditioned with bentonite or from available gel and water mud. Caustic soda is added for pH control. Gypsum, lignosulfonate, and additional caustic soda are added simultaneously to the mud. CMC may be added for filtration control. This fluid is used for drilling in mildly reactive shale or where gypsum or anhydrite must be drilled. It resists contamination from cement or salt. Use is limited by the temperature stability of the filtration control materials, CMC (250°F ±).

4.5.3.9 Special Muds

In addition to the most common mud systems discussed previously, there are other muds that do not fall neatly into one category or another in the classification scheme.

Low-Density Fluids and Gaseous Drilling Mud (Air-Gas Drilling Fluids)

The basic gaseous drilling fluids and their characteristics are presented in [Table 4.5.4](#).

This system involves injecting air or gas downhole at the rates sufficient to attain annular velocity of 2,000 to 3,000 ft/min. Hard formations that are relatively free from water are most desirable for drilling with air-gas drilling fluids. Small quantities of water usually can be dried up or sealed off by various techniques [6].

Air-gas drilling usually increases drilling rate by three or four times over that when drilling with mud, as well as one-half to one-fourth the number of bits are required. In some areas, drilling with air is the only solution; these are (1) severe lost circulation, (2) sensitive producing formation that can be blocked by drilling fluid (skin effect), and (3) hard formations near the surface that require the use of an air hammer to drill.

There are two major limitations with using air as a drilling fluid: large volumes of free water and size of the hole. Large water flows generally necessitate converting to another type of drilling fluid (mist or foam). Size of the hole determines a volume of air required for good cleaning. Lift ability of air depends annular velocity entirely (no viscosity or gel strength). Therefore, large holes require an enormous volume of air, which is not economical.

Mist Foam Drilling Fluids

Misting involves the injection of air and mud or water and foam-making material. In the case of “water mist,” only enough water and foam is injected into the air stream to clear the hole of produced fluids and cuttings. This unthickened water can cause problems due to the wetting of the exposed formation, which can result in sloughing and caving of water-sensitive shale into the wellbore. Mud misting, on the other hand, coats the walls of the hole with

TABLE 4.5.4 Gaseous Drilling Fluid Systems

Type of Fluid	Density, ppg	PH	Temp. Limit °F	Application Characteristics
Air/gas	0	—	500	{ High-energy system. Fastest drilling rate in dry, hard formations. Limited by water influx and hole size.
Mist	0.13–0.8	7–11	300	{ High-energy system. Fast penetration rates. Can handle water intrusions. Stabilizes unstable holes (mud misting).
Foam	0.4–0.8	4–10	400	{ Very-low-energy system. Good penetration rates. Excellent cleaning ability regardless of hole size. Tolerates large water influx.

a thin film and has a stabilizing effect on water-sensitive formations. A mud slurry that has proved adequate for most purposes consists of 10 ppb of bentonite, 1 ppb of soda ash, and less than 0.5 ppb of foam-stabilizing polymer such as high-viscosity CMC. If additional foam stability is needed, additional foamer is used [6].

Nondispersed (Low-Solids) Muds

The term *low-solids mud* covers a wide variety of mud types, including clear water (fresh, salt, or brine), oil-in-water emulsions, and polymer or biopolymer fluids (muds with polymer and no other additives).

Extended Bentonite Muds

Low-solids nondispersed mud is generally prepared from freshwater with little or no drilled solids and bentonite, along with a dual-action polymer for extending the bentonite and flocculating drilled solids. This type of mud is designed for low-solids content and to have low viscosity at the bit for high drilling rates. The polymers used greatly increase the viscosity contributed by the bentonite and serve as flocculants for native clay solids, making them easier to remove by solids-control equipment. These polymers or bentonite extenders permit the desired viscosity to be maintained with about half of the amount of bentonite normally required. No deflocculant is used, so a flocculated system is maintained. The flocculation and lower solids content permit the mud to have a relatively low viscosity at the bit and at the bottom of the hole, where shear rates are high, and a relatively high viscosity at the lower shear rates in the annulus for good hole cleaning. One problem with this type of fluid is that filtration rates are fairly high, because the solids are flocculated and their quantity is low. This means that they do not pack tightly in the filter cake. Sodium polyacrylates or small amounts of CMC may be added for filtration control.

The temperature limitation of extended bentonite fluids is 200–275°F. Other benefits include improved hydraulics and less wear on bits and pump parts.

Inhibitive Salt/Polymer Muds

An *inhibitive mud* is one that does not appreciably alter a formation once it has been cut by the bit. The term covers a large number of mud systems, among them saltwater muds with more than 10,000 mg/L of sodium chloride, calcium-treated muds (lime and gyp), and surfactant-treated muds. Under the category of inhibiting salt/polymer muds, however, we are speaking specifically about muds containing inhibitive salts such as KCl, NaCl, or diammonium phosphate along with complex, high-molecular-weight polymers. In these muds, prehydrated bentonite and polymer are added for viscosity and gel strength, polyanionic cellulose (PAC) or CMC are added for fluid loss control, and

corrosion inhibitors and oxygen scavengers often are used to protect tubular goods. These muds are used for drilling and protecting water-sensitive formations and are good for minimizing formation damage due to filtrate invasion when the formation contains hydratable clay solids. Good hole cleaning and shear thinning are characteristics of these fluids. High-solids concentrations cannot be tolerated, however, making good solids control very important. Temperature limitations of 200–250°F are also characteristic. Among the muds of this type is KCl/lime mud. This mud system uses pre-hydrated bentonite or KCl for inhibition, lignosulfonate and/or lignite as a thinner, KOH (caustic potash) or caustic soda for alkalinity, lime for alkalinity and inhibition, and polymers such as CMC or PAC for filtration control.

Surfactant Muds

Surfactant muds were developed primarily to replace calcium-treated muds when high temperature becomes a problem. The term *surfactant* means surface-acting agent, or a material that is capable of acting on the surface of a material. In drilling muds, surfactants are additives that function by altering the surface properties of the liquid and solid phases of the mud or by imparting certain wetting characteristics to the mud. The composition of the surfactant mud system tends to retard hydration or dispersion of formation clays and shales. The pH of these muds is kept from 8.5 to 10.0 to give a more stable mud at higher temperatures.

The surfactant mud usually encountered is a lignite surfactant mud system. This mud is made up from freshwater using bentonite, lignite, and the surfactant. Small amounts of defoamer may be required with the addition of the lignite. The pH of this mud is maintained within closely fixed limits (8.5 – 10.0) for maximum solubility of the thinner (lignite). Tolerance to salt, gyp, and cement contamination is limited. To retain satisfactory flow properties at high temperatures, the clay content of the mud must be kept low (1–1.6 CEC capacity) through the use of dilution and solids-control equipment. The combination of lignite with surfactant in this mud enables its use at extremely high bottom-hole temperatures. This is due to the temperature stability of lignite and the effect of the surfactant in providing viscosity control and minimizing gel strength development at higher temperatures.

High-Temperature Polymer Muds

Development of a high-temperature polymer system evolved from a need for a mud system with low solids and nondispersive performance at higher temperatures.

System capabilities:

- Good high-temperature stability
- Good contaminant tolerance

- Can formulate temperature stable nondispersed polymer mud system
- Can be used in wide variety of systems for good shale stability
- Minimum dispersion of cuttings and clays
- Flexibility of general application

Application of the high-temperature polymer system primarily consists of five products: (1) polymeric deflocculant, (2) acrylamide copolymer, (3) bentonite, (4) caustic soda or potassium hydroxide, and (5) oxygen scavenger. Barite, calcium carbonate, or hematite is then used as a weighting agent.

The polymeric deflocculant is a low-molecular-weight, modified polyacrylate deflocculant used to reduce rheological properties of the system. It differs from lignosulfonates in that it does not require caustic soda or an alkaline environment to perform. Limited amounts of the polymer may be used in low-mud-weight systems, but larger additions will be needed at higher mud weights and when adding barite to increase the fluid density.

The backbone of the system is an acrylamide copolymer used to control fluid loss. In freshwater systems, 1 to 2 lb/bb will be the range required to control the API fluid loss. In seawater systems, the concentration will range from 4 to 5 lb/bbl. HPHT fluid loss can also be controlled with the polymer. It is not affected by salinity or moderate levels of calcium. At higher concentrations of contaminants, some increase in viscosity will result.

Caustic soda and/or potassium hydroxide are alkaline agents used to control the pH of the system. Either is used to maintain the system pH between 8.3 and 9.0.

Oxygen scavengers serve two purposes in this system. First, because of the low pH characteristic of the system, it should be added to protect the drill pipe. (Run corrosion rings in the drill pipe to determine treatment rates for the corrosion that may be occurring.) Second, as the temperature of the mud exceeds 300°F, any oxygen present will react with the polymers and reduce their efficiency. Additional treatment will be required to replace affected or degraded polymers.

New Generation Water-Based Chemistry

Several companies have developed water-base fluids that provide the inhibition formerly seen only when using oil-base fluids. Novel chemistry such as sodium or potassium silicates, membrane-efficient water-base muds, and highly inhibiting encapsulating polymers make these new systems unique and high in performance. Product development in the area of highly inhibitive polymers will no doubt result in the total replacement of invert emulsions. The need to provide more environmentally acceptable products drive the research and development of many drilling fluids by vendors around the world.

Oil-Base Mud Systems and Nonaqueous Fluids (NAF)

Oil-base muds are composed of oil as the continuous phase, water as the dispersed phase, emulsifiers, wetting agents, and gellants. Other chemicals are used for oil-base mud treatment, such as degellants, filtrate reducers, and weighting agents.

The oil for an oil-base mud can be diesel oil, kerosene, fuel oil, selected crude oil, mineral oil, vegetable esters, linear paraffins, olefins, or blends of various oils. There are several desired performance requirements for any oil:

- API gravity = 36° – 37°
- Flash point = 180°F or above
- Fire point = 200°F or above
- Aniline point = 140°F or above

Emulsifiers are very important in oil-base mud because water contamination on the drilling rig is very likely and can be detrimental to oil mud. Thinners, on the other hand, are far more important in waterbase mud than in oil-base mud; oil is dielectric, so there are no interparticle electric forces to be nullified.

The water phase of oil-base mud can be freshwater or various solutions of calcium chloride (CaCl₂), sodium chloride (NaCl), or formates. The concentration and composition of the water phase in oil-base mud determines its ability to solve the hydratable shale problem.

The external phase of oil-base mud is oil and does not allow the water to contact the formation; the shales are thereby prevented from becoming wet with water and dispersing into the mud or caving into the hole.

The stability of an emulsion mud is an important factor that has to be closely monitored while drilling. Poor stability results in coalescence of the dispersed phase, and the emulsion will separate into two distinct layers. Presence of any water in the HPHT filtrate is an indication of emulsion instability.

The advantages of drilling with emulsion muds rather than with water-base muds are

- High penetration rates
- Reduction in drill pipe torque and drag
- Less bit balling
- Reduction in differential sticking

Oil-base muds are generally expensive and should be used when conditions justify their application. As in any situation, a cost-benefit analysis should be done to ensure that the proper mud system is selected. Oil-based fluids are well suited for the following applications:

- Drilling troublesome shales that swell (hydrate) and disperse (slough)
- Drilling deep, high-temperature holes in which water-base muds solidify

- Drilling water-soluble formations such as salt, anhydride, carnallite, and potash zones
- Drilling the producing zones

For additional applications, oil muds can be used

- As a completion and workover fluid
- As a spotting fluid to relieve stuck pipe
- As a packer fluid or a casing pack fluid

Drilling in younger formations such as “gumbo,” a controlled salinity invert fluid is ideally suited. Gumbo, or plastic, flowing shale encountered in offshore Gulf of Mexico, the Oregon coast, Wyoming, West Africa, Venezuela, the Middle East, Western Asia, and the Sahara desert, benefits from a properly designed salinity program. Drilling gumbo with water-base mud shale disperses into the mud rapidly, which reduces the drilling rate and causes massive dilution of the mud system to be required. In some cases, the ROP must be controlled to prevent plugging of the flowline with hydrated “gumbo balls.” Solids problems also are encountered with water-based fluid drilling gumbo such as bit balling, collar balling, stuck pipe, and shaker screens plugging.

Properly designed water-phase salinity invert fluids will pull water from the shale (through osmosis), which hardens the shale and stabilizes it for long-term integrity.

Generally, oil-base mud is to delivered to the rig mixed to the desired specifications. In some cases, the oil-base mud can be mixed on location, but this process can cost expensive rig time. In the latter case, the most important principles are (1) to ensure that ample energy in the form of shear is applied to the fluid and (2) to strictly follow a prescribed order of mixing. The following mixing procedure is usually recommended:

1. Pump the required amount of oil into the tank.
2. Add the calculated amounts of emulsifiers and wetting agent. Stir, agitate, and shear these components until adequate dispersion is obtained.
3. Mix in all of the water or the CaCl₂-water solution that has been premixed in the other mud tank. This requires shear energy. Add water slowly through the submerged

guns; operation of a gun nozzle at 500 psi is considered satisfactory. After emulsifying all the water into the mud, the system should have a smooth, glossy, and shiny appearance. On close examination, there should be no visible droplets of water.

4. Add all the other oil-base mud products specified.
5. Add the weighting material last; make sure that there are no water additions while mixing in the weighting material (the barite could become water wet and be removed by the shale shakers).

When using an oil-base mud, certain rig equipment should be provided to control drilled solids in the mud and to reduce the loss of mud at the surfaces:

- Kelly valve—a valve installed between the Kelly and the drill pipe will save about one barrel per connection.
- Mud box—to prevent loss of mud while pulling a wet string on trips and connections; it should have a drain to the bell nipple and flow line.
- Wiper rubber—to keep the surface of the pipe dry and save mud.

Oil-base mud maintenance involves close monitoring of the mud properties, the mud temperature, and the chemical treatment (in which the order of additions must be strictly followed). The following general guidelines should be considered:

- A. The mud weight of an oil mud can be controlled from 7 lb/gal (aerated) to 22 lb/gal. A mud weight up to 10.5 lb/gal can be achieved with sodium chloride or with calcium chloride. For densities above 10.5 lb/gal, barite, hematite, or ground limestone can be used. Calcium carbonate can be used to weight the mud up to 13 lb/gal; it is used when an acid-soluble solids fraction is desired, such as in drill-in fluids or in completion/workover fluids. Iron carbonate may be used to obtain weights up to 19.0 lb/gal when acid solubility is necessary (Table 4.5.5).
- B. Mud rheology of oil-base mud is strongly affected by temperature. API procedure recommends that the mud temperature be reported along with the funnel viscosity.

TABLE 4.5.5 Estimated Requirements for Oil Mud Properties

Mud Weight, ppg	Plastic Viscosity, cP	Yield Point, lbs/sq ft ²	Oil-Water Ratio	Electrical Stability
8–10	15–30	5–10	65/35–75/25	200–300
10–12	20–40	6–14	75/25–80/20	300–400
12–14	25–50	7–16	80/20–85/15	400–500
14–16	30–60	10–19	85/15–88/12	500–600
16–18	40–80	12–22	88/15–92/8	Above 600

The general rule for maintenance of the rheological properties of oil-base muds is that the API funnel viscosity, the plastic viscosity, and the yield point should be maintained in a range similar to that of comparable-weight water muds. Excessive mud viscosity can be reduced by dilution with a base oil or with specialized thinners. Insufficient viscosity can be corrected by adding water (pilot testing required) or by treatment with a gellant, usually an organophilic clay or surfactant.

- C. Low-gravity solids contents of oil-base muds should be kept at less than 6% v/v. Although oil muds are more tolerant for solids contamination, care must be taken to ensure that solids loading does not exceed the recommended guidelines. A daily log of solids content enables the engineer to quickly determine a solids level at which the mud system performs properly.
- D. Water-wet solids is a very serious problem; in severe cases, uncontrollable barite setting may result. If there are any positive signs of water-wet solids, a wetting agent should be added immediately. Tests for water-wet solids should be run daily.
- E. Temperature stability and emulsion stability depend on the proper alkalinity maintenance and emulsifier concentration. If the concentration of lime is too low, the solubility of the emulsifier changes, and the emulsion loses its stability. Lime maintenance has to be established and controlled by alkalinity testing. The recommended range of lime content for oil-base muds is 0.1 to 4 lb/bbl, depending on base oil being used. Some of the newer ester-base muds have a low tolerance for hydroxyl ions; in this case, lime additions should be closely controlled.
- F. CaCl_2 content should be checked daily to ensure the desired levels of inhibition are maintained.
- G. The oil-to-water ratio influences funnel viscosity, plastic viscosity, and HTHP filtration of the oil-base mud. Retort analysis is used to detect any change in the oil-water ratio, because changes to the oil-water ration can indicate an intrusion of water.
- H. Electrical Stability is a measure of how well the water is emulsified in the continuous oil phase. Because many factors affect the electrical stability of oil-base muds, the test does not necessarily indicate that a particular oil-base muds, the test does not necessarily indicate that a particular oil-base mud is in good or in poor condition. For this reason, values are relative to the system for which they are being recorded. Stability measurement should be made routinely and the values recorded and plotted so that trends may be noted. Any change in electrical stability indicates a change in the system.
- I. HTHP filtration should exhibit a low filtrate volume (< 6 ml). The filtrate should be water free; water in the filtrate indicates a poor emulsion, probably caused by water wetting of solids.

4.5.3.10 Environmental Aspects of Drilling Fluids

Much attention has been given to the environmental aspects of the drilling operation and the drilling fluid components. Well-deserved concern about the possibility of polluting underground water supplies and of damaging marine organisms, as well as effects on soil productivity and surface water quality, has stimulated widespread studies on this subject.

Drilling Fluid Toxicity

There are three contributing mechanisms of toxicity in drilling fluids: chemistry of mud mixing and treatment, storage and disposal practices, and drilled rock. The first group conventionally has been known the best because it includes products deliberately added to the system to build and maintain the rheology and stability of drilling fluids.

Petroleum, whether crude or refined products, should not be added to water-base muds. Adequate substitutes exist and are economically viable for most situations. Levels of 1% or more of crude oil may be present in drilled rock cuttings, some of which will be in the mud.

Common salt, or sodium chloride, is also present in dissolved form in drilling fluids. Levels up to 3,000 mg/L of chloride and sometimes higher are naturally present in freshwater muds as a consequence of the salinity of subterranean brines in drilled formations. Seawater is the natural source of water for offshore drilling muds. Saturated-brine drilling fluids become a necessity when drilling with water-base muds through salt zones to get to oil and gas reservoirs below the salt. In onshore drilling, there is no need for chlorides above these background levels. Potassium chloride has been added to some drilling fluids as an aid to controlling problem shale formations. Potassium acetate or potassium carbonate are acceptable substitutes in most of these situations.

Heavy metals are present in drilled formation solids and in naturally occurring materials used as mud additives. The latter include barite, bentonite, lignite, and mica (sometimes used to control mud loss downhole). There are background levels of heavy metals in trees that carry through into lignosulfonate made from them.

Attention has focused on heavy metal impurities found in sources of barite. Proposed U.S. regulations would exclude many sources of barite ore based on levels of contamination. European and other countries are contemplating regulations of their own.

Chromium lignosulfonates are the biggest contributions to heavy metals in drilling fluids. Although studies have shown minimal environmental impact, substitutes exist that can result in lower chromium levels in muds. The less-used chromium lignites (trivalent chromium complexes) are similar in character and performance, with less chromium.

TABLE 4.5.6 Toxicity Difference between Active and Waste Drilling Fluids

Toxicant	Active Mud	Detection Rate	Reserve Pit	Detection Rate, %
Benzene	No	—	Yes	39
Lead	No	—	Yes	100
Barium	Yes	100	Yes	100
Arsenic	No	—	Yes	62
Fluoride	No	—	Yes	100

Nonchromium substitutes are effective in many situations. Typical total chromium levels in muds are 100–1000 mg/L.

Zinc compounds such as zinc oxide and basic zinc carbonate are used in some drilling fluids. Their function is to react out swiftly sulfide and bisulfide ions originating with hydrogen sulfide in drilled formations. Because human safety is at stake, there can be no compromising effectiveness, and substitutes for zinc have not seemed to be effective. Fortunately, most drilling situations do not require the addition of sulfide scavengers.

Indiscriminate storage and disposal practices using drilling mud reserve pits can contribute toxicity to the spent drilling fluid. The data in Table 4.5.6 is from the EPA survey of the most important toxicants in spent drilling fluids. The survey included sampling active drilling mud (in circulating system) and spent drilling mud (in the reserve pit). The data show that the storage disposal practices became a source of the benzene, lead, arsenic, and fluoride toxicities in the reserve pits because these components had not been detected in the active mud systems.

The third source of toxicity in drilling discharges are the cuttings from drilled rocks. A study of 36 cores collected from three areas (Gulf of Mexico, California, and Oklahoma) at various drilling depths (300 to 18,000 ft) revealed that the total concentration of cadmium in drilled rocks was more than five times greater than the cadmium concentration in commercial barites. It was also estimated, using a 10,000-ft model well discharge volumes, that 74.9% of all cadmium in drilling waste may be contributed by cuttings, but only 25.1% originate from the barite and the pipe dope.

Mud Toxicity Test for Water-Base Fluids

The only toxicity test for water-base drilling fluids having an EPA approval is the Mysid bahia shrimp bioassay. The test was developed in the mid-1970s as a joint effort of the EPA and the oil industry. The bioassay is a test designed

to measure the effect of a chemical on a test population of marine organisms. The test is designed to determine the water-leachable toxicity of a drilling fluid or mud-coated cutting. The effect may be a physiological or biochemical parameter, such as growth rate, respiration, or enzyme activity. In the case of drilling fluids, lethality is the measured effect. For the Mysid test, all fluids must exceed a 30,000 concentration of whole mud mixed in a 9:1 ratio of synthetic seawater.

Nonaqueous Fluid (NAF) and Drilling Fluid Toxicity

Until the advent of synthetic-based invert emulsion fluids in the early 1990s, the discharge of NAF was prohibited due the poor biodegradability of the base oils. In 1985, a major mud supplier embarked on a research program aimed at developing the first fully biodegradable base fluid. The base fluid would need to fulfill a number of criteria, regarded as critical to sustain drilling fluids performance while eliminating long-term impact on the environment:

- Technical performance — the fluid must behave like traditional oil-base muds and offer all of their technical advantages
- The fluid must be nontoxic, must not cause tainting of marine life, not have potential to bioaccumulate, and be readily biodegradable.

Research into alternative biodegradable base fluids began with common vegetable oils, including peanut, rapeseed, and soy bean oils. Fish oils such as herring oil were also examined. However, the technical performance of such oils was poor as a result of high viscosity, hydrolysis, and low temperature stability. Such performance could only be gained from a derivative of such sources, so these were then examined.

Esters were found to be the most suitable naturally derived base fluids in terms of potential for use in drilling fluids. Esters are exceptional lubricants, show low toxicity, and have a high degree of aerobic and anaerobic biodegradability. However, there are a vast number of fatty acids and alcohols from which to synthesize esters, each of which would have unique physical and chemical properties.

After 5 years of intensive research, an ester-based mud that fulfilled all of the design criteria was ready for field testing. This fluid provided the same shale stabilization and superior lubricity as mineral oil-based mud but also satisfied environmental parameters. The first trial, in February 1990, took place in Norwegian waters and was a technical and economic success. Since then, over 400 wells have been drilled world wide using this ester-base system, with full approval based on its environmental performance. This history of field use is unrivalled for any synthetic drilling fluid on a global basis, and no other drilling fluid has been researched in such depth. The research program included

- Technical performance testing using oil-base mud as a baseline
- Toxicity to six marine species, including water column and sediment reworker species
- Seabed surveys
- Fish taint testing
- Aerobic and anaerobic biodegradability testing
- Human health and safety factors

The release of ester-base fluids onto the market marked the beginning of the era of synthetic-base invert drilling fluids. Following the success of esters, other drilling fluids were formulated that were classed as synthetics, these fluids included base oils derived from ethylene gas and included linear alpha olefins, internal olefins, and poly-alpha olefins.

Summary of Flashpoint and Aromatic Data

With the introduction of synthetic-base muds into the market, the EPA moved to provide guidelines on the quality and quantity of the synthetic oils being discharged into the Gulf of Mexico. In addition to the water column aquatic testing done for water-base fluids, the EPA set forth guidelines for examining toxicity to organisms living in the sediments of the seafloor. A *Leptocheirus* sedimentary reworker test was instituted in February of 2002 for all wells being drilled with synthetic-base muds to examine how oil-coated cuttings being discharged into the Gulf of Mexico would impact the organisms living on the seafloor.

Two standards were set forth to govern the discharge of synthetic-base muds. A *stock standard* test is required for the base oil looking at the biodegradability of a synthetic

base oil and as well as a new test for the *Leptocheirus* sedimentary reworker. This stock standard is done once per year to certify that the base oils being used are in compliance with the regulation.

When a well is drilled with a synthetic-base mud, monthly and end-of-well tests are required for the *Mysid* and *Leptocheirus*, organisms to ensure that the synthetic-base oil being used meets a certain standard of environmental performance. There are two standards that can be used for these annual and well-to-well tests: an ester standard and a C16-C18 Internal Olefin standard.

The test used as a standard is based on the type of base oil being tested against a similarly approved standard. Base oils that are less toxic and highly biodegradable would be compared with esters, while all others would have to meet or exceed the C16-C18 IO standard (Figure 4.5.11 and Table 4.5.7).

With synthetic-based muds being widely used in the Gulf of Mexico, especially in deep water, controlling the quality of these materials is extremely important to the environment.

From US-EPA 2001 NPDES General Permit for New and Existing Sources in the Offshore Subcategory of the Oil and Gas Extraction Category for the Western Portion of the Outer Continental Shelf of the Gulf of Mexico (GMC290000) 66 Fed. Reg. No. 243, p. 65209, December 18, 2001.

4.5.4 Completion and Workover Fluids

Completion and workover fluids are any fluids used in the completion of a well or in a workover operation. These

FIGURE 4.5.11 Base fluid type.

TABLE 4.5.7 Aromatic Content Standards

	Fluids Meeting Internal Olefin Standard	Performance of New Blended-Base Fluid
Base fluid biodegradation	Equal to or better than a 65:35 blend of C16-C18 internal olefin in a 275-day test. Tested once per year. Ratio of IO result compared with base fluid must be calculated at 1.0 or less.	Ratio = 0.8
Leptocheirus base fluid toxicity	Ten-day Leptocheirus LC50 must be equal to or less toxic than a 65:35 blend of C16-C18 internal olefin tested at least annually. Ratio of IO result compared with base fluid must be calculated at 1.0 or less	Ratio = 0.8
PAH content of base fluid	High-performance liquid chromatography/UV-EPA method 1654 must give a PAH (as phenanthrene) content of less than 10 ppm	Below 1 ppm limit of detection

Summary of permit requirements and performance of blended drilling fluid, base fluid against those permit mandated C16–18 Internal olefin standards.

From US-EPA (2001) NPDES General Permit for New and Existing Sources in the Offshore Subcategory of the Oil and Gas Extraction Category for the Western Portion of the Outer Continental Shelf of the Gulf of Mexico (GMG290000) 66 Fed. Reg. No. 243, p. 65209, December 18, 2001.

fluids range from low-density gases such as nitrogen to high-density muds and packer fluids. The application and requirements vary for each fluid.

Workover fluids are fluids used during the reworking of a well after its initial completion. They may be gases such as nitrogen or natural gas, brine waters, or muds. Workover fluids are used during operations such as well killing, cleaning out a well, drilling into a new production interval, and plugging back to complete a shallower interval.

Completion fluids are used during the process of establishing final contact between the productive formation and the wellbore. They may be a water-base mud, nitrogen, oil mud, solids-free brine, or acid-soluble system. The most significant requirement is that the fluid does not damage the producing formation and does not impair production performance.

Packer fluids are fluids placed in the annulus between the production tubing and casing. Packer fluids must provide the required hydrostatic pressure, must be nontoxic and noncorrosive, must not solidify or settle solids out of suspension over long periods of time, and must allow for minimal formation damage.

Various types of fluids may be used for completion and workover operations:

1. Oil fluids
 - a. Crude
 - b. Diesel
 - c. Mineral oil
2. Clear water fluids
 - a. Formation salt water
 - b. Seawater

- c. Prepared salt water such as calcium chloride, potassium chloride or sodium chloride salt and zinc, calcium, or sodium-based bromides
3. Conventional water-base mud
4. Oil-base or invert emulsion muds

Completion or workover fluids may be categorized as

1. Water-base fluids containing oil-soluble organic particles
2. Acid-soluble and biodegradable
3. Water base with water-soluble solids
4. Oil-in-water emulsions
5. Oil-base fluids

Three types of completion or workover fluids are

1. Clear liquids (dense salt solutions)
2. Weighted suspensions containing calcium carbonate weighting material, a bridging agent to increase the density above that of saturated solutions
3. Water-in-oil emulsions made with emulsifiers for oil muds

Clear liquids have no suspended solids and can be referred to as solids-free fluids. Weighted suspensions are fluids with suspended solids for bridging or added density. These fluids can be referred to as solids-laden fluids.

For solids-free fluids, water may be used in conjunction with a defoamer, viscosifier, stabilized organic colloid, and usually a corrosion inhibitor. Solids-free completion and workover fluids have densities ranging from 7.0 to 19.2 pounds per gallon (ppg) (0.84 – 2.3 SG).

Solids-laden fluids may be composed of water, salt, a defoamer, suspension agent, stabilized organic colloid, pH stabilizer, and a weighting material/bridging agent.

4.5.4.1 Solids-Free Fluids

Brines used in completion and workover applications may be single-salt brines, two-salt brines, or brines containing three different salt compounds.

4.5.4.2 Single-Salt Brines

Single-salt brines are made with freshwater and one salt such as potassium chloride, sodium chloride, or calcium chloride. They are the simplest brines used in completion and workover fluids. Because they contain only one salt, their initial composition is easily understood. Their density is adjusted by adding either salt or water. Single-salt brines are available in densities of up to 11.6 ppg and are the least expensive brines used in completions.

Potassium chloride (KCl) brines are excellent completion fluids for water-sensitive formations when densities over (9.7 ppg)(1.16 SG) are not required. Corrosion rates are reasonably low and can be reduced even more by keeping the pH of the system between 7 and 10 and using corrosion inhibitors (1% by volume). Sodium chloride is one of the most used single-salt brines. Advantages of sodium chloride brines are low cost and wide availability. Densities up to 10.0 ppg are achievable for this single-salt brine. Calcium chloride (CaCl₂) brines are easily mixed at densities up to 11.6 ppg (1.39 SG). Sodium bromide brines can be used when the density of a calcium chloride brine is desired, but the presence of acid gas is possible. Sodium bromide has low corrosion rates even without the use of corrosion inhibitors. Although these brines are more expensive than CaCl₂ brines, they are useful in CO₂ environments.

4.5.4.3 Two-Salt Brines

The basic ingredient of calcium chloride/calcium bromide brines

(CaCl₂/CaBr₂) is a calcium bromide solution that ranges in density from 14.1 to 14.3 ppg (1.72 SG); the pH range is 7.0 to 7.5. The density of CaBr₂ brine can be increased by adding calcium chloride pellets or flakes. However, a 1.81 S.G. CaCl₂/CaBr₂ solution crystallizes at approximately 65°F (18°C). CaCl₂/CaBr₂ brine can be diluted by adding a CaCl₂ brine weighing 11.6 ppg (1.39 SG). The corrosion rate for CaCl₂/CaBr₂ is no more than 5mm per year on N-80 steel coupons at 300°F (149°C). If a corrosion inhibitor is desired, a corrosion inhibitor microbistat is recommended.

The viscosity of CaCl₂/CaBr₂ brine can be increased by adding liquefied HEC viscosifier. Reduction in filtration may be obtained by the addition of CaCO₃ weighting

material/bridging agent or by increasing the viscosity with polymeric materials.

There is not much of a crystallization problem with calcium chloride/calcium bromide brines at densities between 11.7 and 13.5 ppg (1.40 and 1.62 SG). However, the heavier CaCl₂/CaBr₂ brines require special formulation in cold weather applications.

4.5.4.4 Three-Salt Brines

Three-salt brines such as calcium chloride/calcium bromide/zinc bromide brines are composed of CaCl₂, CaBr₂, and ZnBr₂. At high temperatures, corrosion rates in brines containing ZnBr₂ are very high and can result in severe damage to equipment. For use at high temperatures, the brine should be treated with corrosion inhibitors. The corrosion rate of the treated brine is usually less than 3 mm per year.

4.5.4.5 Classification of Heavy Brines

Properties and Characteristics of Completion and Workover Fluids

Although the properties required of a completion or workover fluid vary depending on the operation, formation protection should always be the primary concern.

Density

The first function of a completion or workover fluid is to control formation pressure. (Table 4.5.8). The density should be no higher than necessary to accomplish that function. Increased density can be obtained by using weighting materials such as calcium carbonate (CaCO₃), iron carbonate (FeCO₃), barite (BaSO₄), or by using soluble salts such as NaCl, KCl, NaBr, CaCl₂, CaBr₂, or ZnBr₂. The Table 4.5.9 below shows the specific weight range and acid solubility of each type of solids-laden fluid.

TABLE 4.5.8 Expansibility of Heavy Brine at 12,000 psi from 24° to 92°C or 76° to 198°F

Compressibility of Brine	Heavy Brine at 198°F Density SG – lb/gal	198°F at 2,000–12,000 psi (lb/gal/1,000 psi)
NaCl	1.14–9.49	0.019
CaCl ₂	1.37–11.46	0.017
NaBr	1.50–12.48	0.021
CaBr ₂	1.72–14.30	0.022
ZnBr ₂ /CaBr ₂ /CaCl ₂	1.92–16.01	0.022
ZnBr ₂ /CaBr ₂	2.31–19.27	0.031

TABLE 4.5.9 Solids-Laden Fluids

Weight Materials	Pounds/gallon	Acid Solubility
CaCO ₃	10–14	98%
FeCO ₃	10–18	90%
Barite	10–21	0%

Solids – Laden Fluids

The density of a brine solution is a function of temperature. When measured at atmospheric pressure, brine densities decrease as temperature increases.

Viscosity

In many cases, the viscosity of the fluid must be increased to provide lifting capacity required to bring sand or cuttings to the surface at reasonable circulating rates. A popular viscosifier for completion and workover fluids is hydroxyethylcellulose (HEC). It is a highly refined, partially water soluble, and acid-soluble polymer with very little residue when acidized. Other materials used as viscosifiers include guar gums and biogums (xanthan). Although these materials are applicable in certain instances, they do not meet the acid or water-solubility standards of HEC. HEC is the most common viscosifier for all types of brines.

In some cases, solids must be suspended at low shear or static conditions. Available alternatives include clays and polymers. The most widely used suspension agent in completion and workover fluids is xanthan gum.

Suspension or Filtration Control: Filtration

In most applications, some measure of filtration control is desirable. The standard approach to filtration control in completion and workover fluids is the use of property sized calcium carbonate particles for bridging in conjunction with colloidal size materials such as starch or CMC. The reason for the popularity of calcium carbonate is that it is acid soluble and can be removed. In some cases, oil-soluble resins are used as bridging agents, as are sized salts when used in saturated salt brines.

The seasonal ambient temperature must be considered when selecting a completion or workover fluid. If the temperature drops too low for the selected fluid, the fluid will crystallize or freeze. Each brine solution has a point at which crystallization or freezing occurs. Two definitions are important: FCTA, or first crystal to appear, is the temperature at which the first crystal appears as a brine is cooled. LCTD, or last crystal to dissolve, is temperature at which the last salt crystal disappears as the brine is allowed to warm. Although this type of visual check may be somewhat

inexact, it is an important part of the analysis of brines. Once the crystallization point of a fluid is determined, you can be reasonably sure that the fluid is safe at a temperature equal to or higher than the crystallization point. The FTCA and LCTD are run under normal-pressure conditions; pressure can greatly alter the formation of crystals in a brine, and more sophisticated tests are required to determine this value.

Special brine formulations are used to accommodate seasonal changes in temperature. Summer blends are fluids appropriate for use in warmer weather. Their crystallization points range from approximately 7–20°C₂ (45°F–68°F). Winter blends are used in colder weather or colder climates and have crystallization points ranging from approximately 20° F (– 6°C) to below 0°F (– 18°C). At times, a crystallization point between those of summer and winter blends is desirable. Special formulations are then used to prepare fluids that can be called fall, spring, or intermediate blends.

At first, it may seem practical to consistently formulate fluids having lower than necessary, and therefore safe, crystallization points. Although this approach may be easier, it is likely to be much more expensive. Generally, the lower the crystallization point, the more the fluid costs. If you provide a fluid having a crystallization point much lower than necessary, you are likely to be providing a fluid with a considerably higher cost than necessary. This is just one of numerous factors to consider when selecting a fluid that is both effective and economical.

Preparing Brines

The typical blending procedure for NaCl and KCl brines is to begin with the required volume of water and then add sacked salt. Calcium chloride/calcium bromide brines and calcium chloride/calcium bromide/zinc bromide brines require special blending procedures.

Calcium Chloride/Calcium Bromide Solutions

The ingredients in CaCl₂/CaBr₂ solutions must be added in a specific order. The necessary order of addition is as follows:

1. Start with the CaBr₂ brine.
2. Add sacked CaCl₂.
3. Allow approximately 45 minutes for most of the sacked CaCl₂ to dissolve.

Calcium Chloride/Calcium Bromide/Zinc Bromide Solutions

For CaCl₂/CaBr₂/ZnBr₂ solutions using 15.0 ppg (1.80 SG) CaCl₂/CaBr₂ brine and 19.2 ppg (2.28 SG) CaBr₂/ZnBr₂, the proper order of addition is as follows:

1. Start with the 15.0 ppg (1.80 SG) CaCl₂/CaBr₂ brine.
2. Add the 19.2 ppg (2.28 SG). CaBr₂/ZnBr₂ brine.

Rules of thumb for blending of brines

1. DO NOT CUT SACKS. Exception: CaBr₂ brines from 11.6 to 15.1 ppg.
2. An increase of CaBr₂ decreases the crystallization temperature for CaBr₂ brines.
3. An increase of ZnBr₂ decreases the crystallization temperature in any blend.
4. A decrease in crystallization temperature increases the cost of the fluid.
5. Do not mix fluids containing divalent ions (Ca²⁺, Zn²⁺) with fluids containing monovalent ions (Na⁺, K⁺). Precipitation may occur.
6. Do not increase the pH of CaBr₂ or ZnBr₂ fluids or precipitation may occur.
7. Do not add large volumes of water to CaBr₂ or ZnBr₂ brines or precipitation may occur.

Fluid Selection

A good approach to selecting a fluid is to decide what functions the fluid is to perform and then select a base fluid and additives that will most effectively do the job. The first decision in selecting a fluid is identification of the required functions or properties. The next step is the selection of the type of fluid to be used. The properties or functions of the fluid dictate the type of fluid to be used. If the decision is made in reverse order, a poor performance is likely to result.

Completion and Workover Fluids Weighting Materials

Calcium Carbonate

Calcium carbonate is available in five grades: 5, 50, 150, 600, and 2,300. At least 50% of the particles in each grade are large than the size (μm) indicated by the number. Other grind sizes can be made available.

Typical Physical Constants

Hardness (Mohr's scale)	3
Specific gravity	2.7
Bulk density, lb/ft ³ , or ppg	168.3 or 22.5

Typical Chemical Composition

Total carbonates (Ca ²⁺ , Mg ²⁺)	98.0% (min)
Total impurities (Al ₂ O ₃ , Fe ₂ O ₃ , SiO ₂ , Mn)	2.0% (max)

TABLE 4.5.10 Specified, Gravity and Specific Weight of Common Materials

Material	Specific gravity	lb/gal	lb/bbl
Barite	4.2–4.3	35.0–35.8	1470–1504
Calcium carbonate	2.7	22.5	945
Cement	3.1–3.2	25.8–26.7	1085–1120
Clays and/or drilled solids	2.4–2.7	20.0–22.5	840–945
Diesel oil	0.84	7.0	294
Dolomite	2.8–3.0	23.3–25.0	980–1050
Feldspar	2.4–2.7	20.0–22.5	840–945
Fresh water	1.0	8.33	350
Galena	6.5	54.1	2275
Gypsum	2.3	19.2	805
Halite (rock salt)	2.2	18.3	770
Iron	7.8	65.0	2730
Iron oxide (hematite)	5.1	42.5	1785
Lead	11.4	95.0	3990
Limestone	2.7–2.9	22.5–24.2	945–1015
Slate	2.7–2.8	22.5–23.3	945–980
Steel	7.0–8.0	58.3–66.6	2450–2800

CaCO₃ (5) (93% will pass through a 325 mesh) can be used alone or with (Fe₂ (CO₃)₃) to increase the densities of freshwater or brine fluids beyond their saturation limits. It may also be used to increase the density of oil base fluids (Table 4.5.10).

CaCO₃ (5) can be used instead of clays to provide wall cake buildup for acid-soluble fluids.

It may also be used as an acid-soluble bridging agent for formations having pore sizes up to 15 μm.

CaCO₃ 50, 150, 600, and 2,300 grades are recommended for use as bridging agents for lost circulation problems, in squeeze mixtures, and in other similar applications. The particle size distribution is maintained in the slurry to provide effective bridging at the surface of the pay zone.

Acid solubility

CaCO₃ is 98% soluble in 15% HCl solution. One gallon of 15% HCl dissolves 0.83 kg or 1.84 lb of CaCO₃.

Bridging agent

Normal treatment is 2.27 to 5 kg (5 to 10 ppb) of the appropriate grade(s). From 5% to 10% of the material added

should have particle size at least one third of the formation pore diameter.

Iron Carbonate

Iron carbonate is used to achieve densities in excess of 14.0 ppg in (1.68 SG) solids-laden systems. The maximum density of a CaCO₃ fluid is approximately 14.0 ppg (1.68 SG) and the maximum density of iron carbonate fluids is 17.5–18.0 ppg (2.10–2.16 SG). For weighting fluids in the 13.0–16.5 ppg (1.56–1.98 SG) range, a blend is recommended.

The following precautions should be considered when using iron carbonate:

1. Iron carbonate is only 87% acid soluble, and after acidizing, 13% of the solids added may be left to plug the formation or may be flushed out, depending on the size and distribution of the formation flow channels.
2. *Mud acid, a combination of hydrofluoric acid and hydrochloric acid, should not be used with iron carbonate.* The hydrofluoric acid reacts with iron carbonate to produce insoluble salts of acidic and basic nature (iron fluoride and iron hydroxide). When using iron carbonate, use only hydrochloric acid.

4.5.5 Safety Aspects of Handling Brines

4.5.5.1 Potassium Chloride

Toxicity

No published data indicate that potassium chloride is a hazardous material to handle. It is toxic only if ingested in very large amounts. It is considered a mild irritant to the eyes and skin. Inhalation of potassium chloride dust leaves a taste and causes mild irritation to mucous membranes in the nose and throat. Potassium is toxic to the Mysid shrimp used for aquatic toxicity testing in U.S. Federal waters. Potassium levels over 4% will likely fail the 30,000 ppm minimum required for discharge.

Safety precautions

Prolonged contact with skin and eyes should be avoided. Inhalation of potassium chloride dust should be avoided as much as possible. Eye protection should be worn according to the degree of exposure, and dust masks should be used in severe dusting conditions. Personal protective equipment (PPE) should always be used when mixing or handling brines and all fluids used in drilling and completions operations.

First Aid Measures

The following first aid measures should be used:

1. For contact with eyes, flush promptly with plenty of water for 15 minutes.

2. For contact with skin, flush with plenty of water to avoid irritation.
3. For ingestion, induce vomiting and get medical attention.
4. For inhalation, if illness occurs, remove the person to fresh air, keep him or her warm, and quiet, and get medical attention.

4.5.5.2 Sodium Chloride

Toxicity

There are no published data indicating that salt is a hazardous material to handle. Sodium chloride is considered a mild irritant to the eyes and skin. Inhalation of dust leaves a taste and causes mild irritation to mucous membranes in the nose and throat.

Safety Precautions

Prolonged contact with skin and eyes should be avoided. The inhalation of sodium chloride dust should be avoided as much as possible. Eye protection should be worn according to the degree of exposure, and dust masks may be needed in severe exposure.

First Aid Measures

The following first aid measures should be used:

1. For contact with eyes, flush promptly with plenty of water for 15 minutes.
2. For contact with skin, flush with plenty of water to avoid irritation.

4.5.5.3 Calcium Chloride

Toxicity

Three to five ounces of calcium chloride may be a lethal dose for a 45-kg (100-pound) person. However, calcium chloride is not likely to be absorbed through the skin in toxic amounts. Strong solutions are capable of causing severe irritation, superficial skin burns, and permanent eye damage. Normal solutions cause mild irritation to eyes and skin, and dust may be irritating.

Safety Precautions

Contact with eyes and prolonged skin contact should be avoided. Clean, long-legged clothing must be worn. Hand and eye covering may be required, depending on the severity of possible exposure. For severe exposure, chemical goggles and a dust respirator should be worn. Cool water (27°C, 80°F or cooler) should always be used when dissolving calcium chloride. Because of an exothermic reaction, calcium chloride can burn bare hands if solids have been added. Barrier creams should always be used when handling

brines such as calcium chloride, calcium bromide, and zinc bromide.

First Aid Measures

The following first aid measures should be used:

1. For contact with eyes and skin, flush promptly with plenty of water for 15 minutes. Get medical attention in the event of contact with eyes. Remove contaminated clothing, and wash before reuse.
2. For inhalation, if illness occurs, remove the person to fresh air, keep him or her warm and quiet, and get medical attention.
3. For ingestion, induce vomiting, and get medical attention.

4.5.5.4 Calcium Bromide

Toxicity

There are no published data indicating that calcium bromide is a hazardous material to handle. However, it is considered toxic when ingested in large amounts. It is also a mild irritant to the skin and eyes. Inhalation results in irritation of the mucous membranes in the nose and throat. Because of an exothermic reaction, calcium bromide fluid can burn bare hands when sacked CaBr_2 is added to the solution. Burns caused by these fluids are the result of a chemical reaction with moisture on the skin.

Safety Precautions

Prolonged contact with the skin and eyes should be avoided. Clean, long-legged clothing and rubber boots should be worn. Eye protection should be worn and a dust respirator used for severe exposure. Contaminated clothing should be changed. Barrier creams should always be used when handling these brines.

First Aid Measures

The following first aid measures should be used:

1. For contact with eyes and skin, flush promptly with plenty of water.
2. For inhalation, if illness occurs, remove the victim to fresh air, keep him or her warm and quiet, and get medical attention.
3. For ingestion, induce vomiting, and get medical attention.

Environmental Considerations

Local regulations should be observed. Care should be taken to ensure that streams, ponds, lakes, or oceans are not polluted with calcium bromide.

4.5.5.5 Zinc Bromide

Toxicity

There are no published data indicating that zinc bromide is a hazardous material to handle. It is considered toxic when ingested in large amounts. Zinc bromide is also a severe irritant to the skin and eyes. Inhalation results in irritation of mucous membranes in the nose and throat. Because of an exothermic reaction, zinc bromide fluid can burn bare hands if sacked materials have been added. Never expose eyes to zinc bromide; blindness can occur.

Safety Precautions

Contact with skin and eyes should be avoided. Long-legged clothing and proper eye protection should be worn. Barrier creams should always be used when handling zinc bromide brines. Rubber boots and rubber protective clothing also is suggested. Contaminated clothing should be washed off or changed, because contact with the skin can cause burns.

First Aid Measures

1. For contact with eyes and skin, flush promptly with plenty of water. Wash skin with mild soap, and consider seeking medical attention.
2. For inhalation, if illness occurs, remove victim to fresh air, kept him or her warm and quiet, and get medical attention.
3. For ingestion, induce vomiting, and get medical attention.

Environmental Considerations

Local regulations should be observed, and care should be taken to avoid polluting streams, lakes, ponds, or oceans. Regulations in the United States prohibit the discharge of zinc into federal waters. Zinc bromide fluids should be disposed of in the same manner as oil fluids.

Safety Rules of Thumb

1. Do not wear leather boots.
2. Wear eye goggles for CaCl_2 , CaBr_2 , and ZnBr_2 .
3. Wear rubber gloves underneath regular gloves while tripping.
4. Wear slicker suits while tripping pipe in most brines.
5. Wash off CaCl_2 or ZnBr_2 spills within 15 minutes; reapply barrier creams.
6. Change clothes within 30 minutes for CaCl_2 and within 15 minutes for CaBr_2 or ZnBr_2 if a spill occurs.
7. Do not wear shoes or boots for more than 15 minutes if they have CaCl_2 , CaBr_2 , or ZnBr_2 spilled in them.
8. Use pipe wipers when tripping.

TABLE 4.5.11 Drilling Fluids Contaminants Removal

Contaminant To Be Removed	Chemical Used To Remove Contaminant	Conversion Factor mg/L (Contaminant) × Factor = lb/bbl Chemical to Add
Ca ²⁺	Soda ash	0.000925
Ca ²⁺	Sodium bicarbonate	0.000734
Mg ²⁺	Caustic soda	0.00115
CO ₃ ⁻²	Lime	0.00043
HCO ₃ ⁻¹	Lime	0.00043
H ₂ S	Lime	0.00076
H ₂ S	Zinc carbonate	0.00128
H ₂ S	Zinc oxide	0.000836

4.5.6 Preventing Contamination

4.5.6.1 Brine Filtration

Filtration is a critical step if a well is to produce at its full potential and remain on line for a longer period. Although filtering can be expensive and time consuming, the net production can be enough to pay the difference in only a matter of days.

Filtration can be defined as the removal of solids particles from a fluid. Because these particles are not uniform in size, various methods of removal must be used (Table 4.5.11).

Filtration has evolved from the surface filtering systems with low-flow volumes to highly sophisticated systems. Regardless of which system is used, a case for filtering fluid can be made for every well completed, every workover, and every secondary recovery project.

The purpose of filtering any fluid is to prevent the downhole contamination of the formation with undesirable solids present in the completion fluid. Contamination can impact production and shorten the productive life of the well. Contamination can occur during perforating, fracturing, acidizing, workover, water flooding, and gravel packing of a well. Any time a fluid containing solids is put into the wellbore, a chance of damaging the well exists.

Contaminants in fluids come in many sizes and forms. Cuttings from drilling operations, drilling mud, rust, scale, pipe dope, paraffin, undissolved polymer, and any other material on the casing or tubing string contributes to the solids in the fluid. At times, it is virtually impossible, because of particle size, to remove all of the solids from the fluid, but by filtering, the chance of success can be increased almost to 100%.

How clean does the fluid need to be? What size particle do we need to remove? Typically, the diameter of the grains of sand is three times the size of the pore throat, assuming the sand is perfectly round. Particles greater than one-third the diameter of the pore throat bridge instantly on the throat and do not penetrate the formation. These particles represent a problem, but one that can be remedied by hydraulic fracturing of the well and blowing the particles from the perforation tunnels, by perforation washing tools, or by acid. Particles less than one-tenth the diameter pass through the throat and through the formation without bridging or plugging. However, particles between one-third and one-tenth the pore throat diameter invade the formation and bridge in the pore throat deeper in the formation. These particles cause the serious problems because, with the pore throats plugged and no permeability, acid cannot be injected into the formation to clean the pore throats. Suggested guidelines for the degree of filtration are

Formation sand size (mesh)	Filtration level (μm)
11.84	40
5.41	80
2.49	2.09

In various stages of the completion process, we are faced with fluids contaminated by a high concentration of particles over a wide range of sizes. To maintain production, the best filtering process should use a number of steps to remove contaminants, starting with the largest and working down to the smallest. This includes, in order of use, shale shaker or linear motion shaker, desilter, centrifuge, and cartridge filters.

In summary, successful completions primarily depend on following a set procedure without taking shortcuts and on good housekeeping practices. A key element in the entire process is using clean fluids, which is made possible in large part through filtration techniques.

4.5.6.2 Cartridge Filters

Each field, formation and well site has unique characteristics and conditions. These include reservoir rock permeabilities, pore sizes, connate fluid composition, downhole pressures, and so on. These conditions dictate the brine composition and level of clarity needed for a proper completion, which determine the level of filtration needed to achieve the fluid clarity level required.

Disposable cartridge filters are widely available around the world. They can be used alone, in combination (series),

or in tandem with other types of filtration equipment. When very large particles or high solids concentrations are present, conventional solids control equipment should be used as prefilters if they are thoroughly washed and cleaned before use. After the filtration requirement is established, the goal becomes one of optimizing a filtration system design. This involves putting together a properly sized and operated system of prefilters and final filters to meet the filtration efficiency objective at the lowest operating cost. Cartridge filters are available in different configurations and various materials of construction. Filter media include yarns, felts, papers, resin-bonded fibers, woven-wire cloths, and sintered metallic and ceramic structures.

The cartridge is made of a perforated metal or plastic tube, layered with permeable material or wrapped with filament to form a permeable matrix around the tube. Coarser particles are stopped at or near the surface of the filter, and the finer particles are trapped within the matrix. Pleated outer surfaces are used to provide larger surface areas. Cartridge filters are rated by pore sizes such as 1, 2, 4, 10, 25, and 50 μm , which relate to the size of particles that the filter can remove. This rating is nominal or absolute, depending on how the cartridges are constructed. A nominally rated filter can be expected to remove approximately 90% of the particles that are larger than its nominal rating. Actually, solids larger than the rating pass through these filters, but the concentration of the larger particles is reduced. High flow rates and pressures cause their efficiencies to fall. They must be constantly monitored and changed when they begin to plug, or the fluid will begin to bypass the filters.

Absolute rated filters achieve a sharp cutoff at its rated size. They should remove all the particles larger than their rating and generally become plugged much faster than nominally rated cartridges. Cartridge filters are most often used downstream of other filters for final clarification.

4.5.6.3 Tubular Filters

Tubular filters consist of a fabric screen surrounding a perforated stainless steel tube. Dirty fluid flows from the outside, through the fabric, where solids are stopped, and the filtrate passes into the center tube. The fabric can remove particles down to 1 to 3 μm . Because the solids are trapped on the outside surface of fabric, the element is easy to backwash and clean. Backwashing is accomplished by changing the valving and forcing clean brine back through the filter in the opposite direction. In 8–15 seconds, the element can be filtering again.

4.6 DRILL STRING: COMPOSITION AND DESIGN

Section reviewed by Bill Lyons and Tom Wadsworth

4.6.1 History: Drill String Versus Drill Stem

The term “drill string” is the oil field “slang” term used by most of the personnel in the modern oil and gas drilling industry. The term describes a single assembly of components, starting from the bottom of the borehole with the drill bit, then the drill collars, then any heavy weight or thick-walled drill pipe, and then the stands of conventional the drill pipe that suspend the entire drill string from the drilling rig at the surface (see [Figure 4.6.1](#)). At the surface the top tool joint of the top conventional drill pipe is threaded to either a kelly or to a top drive system either of which provides the power to rotate the entire drill string, which in turn allows the drill bit to destroy the bottomhole formation rock to advance the depth of the borehole. The API standards literature use the term “drill stem” which comes from the early days of the oil field drilling operations when the primary drilling was carried out with cable tool rigs [1,2].

Prior to the creation of the API in 1919, early petroleum operators used cable tool rigs to drill the majority of oil and gas wells in the Ohio, Pennsylvania and West Virginia areas in the late 1800s and into the early 1900s. These were usually shallow wells at around 2000 ft in depth or less. These cable tool rigs were also used in the early 1900s for the initial oil and gas exploration and production successes in the East Texas and Western Louisiana areas where the well depths were near 3000 ft.

The new rotary drilling technology was invented by the French in the late 1880s as a water well drilling technology. This technology was introduced into oil and gas drilling operations in the USA in 1901, but this newer method of drilling was not in general use in the US oil and gas sedimentary basins until the 1920s. At that time nearly all of the oil and gas wells that had been drilled in the USA had been drilled using cable tool rigs. Rotary drill rigs starting their domination of oil and gas well drilling in the 1940s and from then on this new drilling technology became the technology of choice into the present day [1,2].

Cable tool drilling technology is still in use today around the world but is primarily used to drill shallow water wells

FIGURE 4.6.1 Typical drill-stem assembly [4].

to supply fresh water to remote populations. The cable tool technology uses a short section of rigid solid steel bar (about 20–30 ft in length) with a pointed chisel like bit configuration on its bottom end which breaks up the formation rock when this unique tool is dropped repeatedly on the bottom the borehole. This cable tool rigid bar bit is called the “drill stem” and is hung at the bottom end of the long drilling line cable which is suspended from one end of the spudding (or walking) beam of the cable tool rig. The spudding beam is operated by the bullwheel on the cable tool rig floor [3]. As the bullwheel is turned the spudding beam pivots and allows the end with the drilling line cable attached to move up and down and make repeated drops of the drill stem bit to break up the rock formation at the bottom of the hole and advance the borehole depth.

Rotary drilling technology went through rapid innovation and development here in the USA during the 1920s and 1930s. In particular, the vice grip pipe wrench like rotary table was replaced with the square kelly. Also the

use of “conventional” drill pipe to provide WOB was replaced by the development of specialized thick-walled pipe joints that could be threaded together and placed just above the drill bit to provide the needed WOB. These new thick-walled pipe components are called the drill collars. The modern API Standards describing today’s downhole rotary drilling equipment have retained the old drill stem term from cable tool days to describe the entire length of downhole steel tubular components from the drill bit at the bottom of the assembly and continue to the surface to either the kelly/rotary table or to the top drive system (see Figure 4.6.1) [4,5].

4.6.1.0.1 Purpose of the Drill String

As can be seen in Figure 4.6.1 the main components of the downhole portion of the drill string are; the drill bit, the drill collars, and drill pipe which reach to the surface kelly or top drive on the drilling rig. The purpose of the drill string is to; (1) control the weight that will be placed on the drill

bit by using the weight of the drill collars (by holding the remainder of the drill string in tension with the hoisting system), (2) transmit torque and rotation to the top of the drill string which in turn rotates the heavily weighted drill bit at the bottom of the drill string (with the kelly/rotary table or with the top drive system), (3) conveys drilling fluid through the inside of the drill string to the drill bit to carry cuttings away from the rock face (with the mud pumps or air compressors), and (4) provides control of borehole direction (with tactical placement of stabilizers).

4.6.1.0.2 Components of the Drill String

Figure 4.6.1 shows a typical drill string to drill a vertical well in drill land operations from rotary table equipped drilling rig in a mature sedimentary basin. This figure shows simple example drill string composed of just the drill bit, bit sub, crossover sub, drill collars, and drill pipe. These are the standard components of the typical land operation vertical well drill string. In this figure the bottom-hole-assembly (BHA) is the lower portion of the drill string, namely, the drill bit and the drill collars. The drill pipe is attached to the top of the BHA and the top joint of the drill pipe is made up to the kelly and the kelly via the rotatory table provides the rotary power to the entire drill string. The entire drill string rotates the drill bit to advance the near vertical borehole. Newer drilling rigs are equipped with a top drive system, the top joint of the drill pipe would be made up to the bottom threading of the quill of the top drive system (this connection is often through a slip-sub). Depending on the land operation location, the drill string will have subsurface safety valve subs (SSSV) placed in the drill sting at strategic positions that can block any back flow of drilling mud and/or reservoir fluids from any impending well control event while drilling operations are underway. These SSSVs have become mandatory in most land drilling jurisdictions and all offshore operations. Other drill string components for drilling operations are as follows:

- Stabilizers
- Reamers
- Bit and crossover subs
- Drilling jars
- Shock absorbing tools
- Magnetic drill collars
- LWD
- MWD
- Downhole motor
- Rotary steerable system (RSS)

4.6.2 Drill Collar

The term *drill collar* is derived from the short sub originally used to connect the drill bit to the drill pipe in the early days of vertical well rotary drilling operations. This is what

today we would call a *bit sub*. A modern drill collar for land operations is a Range 2 length approximately 30 ft. The purpose of drill collars is to allow the driller to place weight on the bit to give the bit the vertical force needed to allow the drill bit to be efficiently advanced deeper. This is the only component of the drill string that can be traditionally placed in compression. This vertical force on the bit together with rotational torque from the drill string rotary action and the circulating fluid are all required to complete a successful rotary drilled vertical well. The total length of drill collars in a drill string can be from a few 90 ft to as long as 900 ft. The length of the BHA in the typical drill string is ultimately dependent on the type of rock to be drilled, the drill bit type and size and the engineering requirements of the well purpose.

Drill collars are classified according to the shape of their cross section as round (i.e., conventional drill collars), spiral drill collars (i.e., spiral grooves machined in the collar outer surfaces), and square drill collars. Spiral drill collars are used for drilling formations in which the threat of downhole fluids differential pressure that can cause the drill collar smooth surface to be stuck to the exposed rock formation (e.g., “differential sticking”). The spiral grooves in the spiral collar outer surface thwarts the differential sticking threat during drilling operations. The square drill collar is used to increase the stiffness of the BHA which in turn allows the drilling operation to drill straighter vertical wells.

Conventional drill collars and spiral drill collars are fabricated with a uniform outside diameter. A lift sub is a rig tool approximately 2 ft long that makes up to the drill collar box at the top of the collar when the collar is stood vertical. The elevator engages the top of the lift sub to allow the collars to be made up to the BHA. To allow the drill collars to be held in the rotary table with the slips the drill collars must be held in the slips with a safety clamp must be placed on the top of the collar before the slips can engage and hole the collar in the rotary table. The dimensions and unit weights of the various conventional drill collars are given in Tables 4.6.1 [4–7].

4.6.2.1 Fabrication of Drill Collars

Nearly all drill collars are fabricated from blank solid seamless pipe. Therefore, drill collars are fabricated with a box and a pin tool joints machined into the two ends of a seamless pipe solid bank. Figure 4.6.1 shows a cut-away of a conventional drill collar placed between bit sub (below) and crossover sub (above). Modern drill collars for use in general service are usually fabricated from a chromium-molybdenum alloy AISI 41XX. The latter two XX denotes the carbon content in this steel alloy. This alloy can vary from AISI 4135, AISI 4137, AISI 4140, to AISI 4145 (carbon content of 0.35% to 0.45%) [5]. In general, the higher the carbon content the higher the yield stress and

TABLE 4.6.2 Mechanical Properties of Drill Collars, Subs and Stabilizers [5,7]

OD (in.)	Min. Yield (psi)	Min. Ten. Stren. (psi)	Min. Elongation (%)	Hardness (BHN)	Min. CVN (ft lbs)
≤ 6.875	1,10,000	1,40,000	13	285	40
≥ 7.000	1,00,000	1,35,000	13	285	40

the ultimate tensile strength failure, but the lower total elongation at tensile failure and the toughness indicating CVN impact ft-lb value. Thus, the more the carbon contents in the steel design, the less forgiving or brittle the steel becomes. Table 4.6.2 gives the typical mechanical properties of drill collar steel for ODs less than or equal to 6.875 in. Also given in Table 4.6.2 are the minimum mechanical properties for ODs of 7 in. or greater. Many drilling operations take place in fields that produce H₂S or other sour gases. The Ni-Mo-Nb-modified 4130 steel have proved to show very good SSC resistance. Also showing very good sour gas resistance are the families of chromium steels and stainless steels with chrome contents above 13%, and the chrome - nickel steels which also show very good sour gas resistance. In all of these steels low alloys, extra care must be taken to keep impurities out of the process and the steels must be cold rolled to assure small grain sizes. Since carbon content in sour gas resistant steels must be minimized, these steels will generally have a lower minimum yield stress and ultimate tensile strength capacity (e.g., with minimums of 80,000 psi and 95,000 psi, respectively) than their general service counterparts.

Specialized downhole tools like those given in the list above that are often included in most modern BHAs will use similar alloy steels for housings and other structural components are the same as those discussed above for drill collars [8,9].

4.6.2.2 Drill Collar Length Ranges

Table 4.6.3 gives the API Standard for *Length Range* designations for tubular manufactures all around the world. These designations are for both drill collars and for drill pipe. These designations allow tubular manufactures to produce tubulars with consistent specifications understandable by all OCTG suppliers, service companies and operators.

Range 1 tubulars for the fabrication of drill collars and drill pipe are designated for use by small land drilling rigs that are typically used for water well, environmental, and geotechnical drilling projects. Some oil and gas service companies also use these smaller drilling rigs with Range 1 drill collars and drill pipe for shallow maintenance operations.

Range 2 tubulars for the fabrication of drill collars and drill pipe are designated for use by typical land drilling

rigs for oil and gas drilling operations. These land drilling rigs are typically capable of pulling a stand of triples (e.g., three Range 2 drill collars or drill pipe joints). Smaller land drilling rigs capable of pulling a stand of double Range 2 drill collars or drill pipe joints are also used for limited shallow oil and gas drilling operations. There are also land drilling rigs that are fully automated that are capable of pulling single joints of Range 2 drill collars and drill pipe joints. These small fully automated rigs have become widely used in the drilling of new in-field wells in older reservoir production areas in North America.

Range 3 tubulars are designated for the fabrication of drill collars and drill pipe are designated for nearly exclusive use by offshore drilling rigs. The Range 3 drill collars and drill pipe are particularly important to these very expensive drilling operations since these larger offshore drilling rigs are capable of pulling three Range 3 drill collars or drill pipe joints. This capability of pulling triple allows these offshore drilling operations to be far more efficient in making trips into and out of the well.

Fabrication of the drill collar will start with a seamless thick-walled tubular produced by a steel mill that specializes in tubular products for a number of construction applications. Since these mills produce a seamless tubular from red hot ingots of steel. These ingots are rolled in the outside and a mandrel use to make the inside hole (the bore) through the tubular. Because the steel is red hot it is difficult to control the exact length of each tubular produced. This is why the length specification for each Range category in Table 4.6.3 allows the mills plenty of leeway to cut lengths for their objective production Range. Also, since the inside of the tubular cannot be rolled to a precise wall thickness, the wall thickness for nearly all seamless tubulars must be adjusted

TABLE 4.6.3 API Range Designations for Tubular Manufactures [4]

API Ranges	~Min. Length (ft)	~Max. Length (ft)
Range 1	18	22
Range 2	27	32
Range 3	38	46

for engineering calculations to a smaller number value than that sought in the tubular mill fabrication process.

4.6.2.3 Drill Collar Shouldered Connections

Drill collar threaded connections are machined in the two open ends of the mill fabricated thick-walled tubular (i.e., a box connection on one end and a pin connection on the other end, see Figure 4.6.1). Table 4.6.4 gives the most common connection sizes and types for common drill collar dimensions used by one prominent service company with worldwide oil and gas drilling operations [5, 11]. These are shouldered connections which allow the shoulders on each side of the connection to support most of the bending stress as the BHA is run through curved boreholes and doglegs. Table 4.6.4 connections are shown in the more current API Numbered Connection form. These numbered connections are basically redesigned older historically recognized API Standard connection designations (i.e., API IF where the IF stands for Internal Flush, API FH where the FH stands

for Full Hole, and API Reg where the Reg stands for Regular). The API Numbered Connections are basically redesigned API IF and API FH connections. The new API Numbered Connections have been designed to reduce the stress concentrations that were inherent in the original API IF and API FH designs. For the fabrication of drill collars, these connections are machined into the open ends of the tubular blank. The threads on the larger drill collar sizes are cold rolled in the thread roots to make these areas of the box and pin connection more resistant to fatigue damage and failure. All connection threads (box and pin) are phosphate-coated (or coated with similar coatings) to protect the threads from the environmental elements. Also these factory applied coatings will help prevent galling during initial connection makeup.

Most worldwide service companies and tubular fabrication facilities have developed proprietary connections for drill collars (and drill pipe tool joints). These proprietary connections are usually based on the standard API connections like those shown in Table 4.6.4 and other connections shown in References 5 and 7. The engineers in these companies have redesigned these API connections, or created new connections that have stress relief and sealing features that the companies have been able to patent or protect with trade secret laws. These industrial efforts have greatly multiplied the threaded connections that are available in the industry and nearly made the task of keeping an up to date accounting of all possible connections nearly impossible (see Reference 7). In essence, this proliferation of proprietary connections has become a great marketing tool for the worldwide service companies and primer tubular fabricators to retain their traditional customers.

TABLE 4.6.4 Drill Collar Typical Service Company Connections [5, 11]

DC Connections API Designation (in.)	Min. OD (in.)	Bore (in.)	BSR

API 8-5/8 Reg	11.000	3.000	2.78:1

4.6.2.4 Bending Stress Ratio

The mechanical failure of nearly all drill collars most typically occurs in one of the last thread root in the pin of a drill collar connection. This is due to the weakness of the a typical drill collar connection relative to the remainder of the drill collar itself when subjected to bending stresses which occur when the drill string (BHA) is passed through a directional radius turn or through a borehole dogleg. This connection pin weakness can be quantified with the bending stress ratio (BSR). The BSR is a very useful design tool that can be employed to assist in the design the BHA (and later on in this section in designing some limited other connections within the remainder of the drill string).

The BSR is the ratio of the bending section modulus of a connection box to the corresponding bending section modulus of the connection mating pin. The BSR is written as

$$BSR = \frac{Z_B}{Z_P} \quad (4.6.1)$$

TABLE 4.6.5 Recommended BSR Ranges for DCs and DPs [7]

Drill Collar OD (in.)	Traditional BSR Range	Recommender BSR Range
<6.000	2.25–2.75	1.8–2.5
6.000–7.875	2.25–2.75	2.25–2.75
>8.000	2.25–2.75	2.5–3.2

where Z_B is the bending stress section modulus (in.³),

Z_P is the bending stress section modulus (in.³).

Table 4.6.4 gives the BSR for the listed drill collar sizes. Table 4.6.5 gives the typical recommended BSR ranges for all drill collar sizes. Using the ranges in Table 4.6.5 and reviewing the BSRs of the connections given in Table 4.6.4, it is evident in this limited list that there are several drill collar connections violate the recommendations in Table 4.6.5, namely:

- DC 5.00 in. × 2.500 in. with an NC 38 connection
- DC 6.500 in. × 2.250 in. with an NC 46 connection
- DC 6.500 in. × 2.8125 in. with an NC 46 connection
- DC 6.750 in. × 2.250 in. with an NC 46 connection
- DC 7.250 in. × 2.8125 in. with an NC 50 connection

This would indicate that these drill collars should not be used in a drill string for direction borehole or a well in crooked hole country.

4.6.2.5 Selecting Drill Collar Sizes

Selection of the appropriate OD and ID of drill collars is a multifaceted engineering task. Probably the most important method of selecting the drill collar sizes is to study the results from any offset wells that had been drilled in similar rock formations of the basin. An approximate analytical method can be used also. The most important factors in selecting drill collar size are

1. Drill bit size.
2. Coupling OD of the casing or liner to be set in the borehole.
3. Formation tendency to produce sharp changes in the hole deviation and direction.
4. Hydraulic program.
5. Assume there is a possibility of having to wash-over a failed drill collar connection with a drill string lost in the borehole.

To avoid an abrupt change in hole deviation (which may make it difficult or impossible to run casing) when drilling in crooked-hole areas with an unstabilized drill bit and drill collars, the required outside diameter of the drill collar place right above the bit can be approximated from the following equation:

$$OD_{dc} = 2OD_{cc} - D_{bit} \quad (4.6.2)$$

where OD_{bit} is outside diameter of drill bit (in.),

OD_{cc} is the outside diameter of the casing coupling (in.),

OD_{dc} is the outside diameter of drill collars (in.).

Table 4.6.6 can also be used to determine the recommended maximum drill collar ODs for common borehole sizes drilled into soft rock formations (usually in immature sedimentary basins) and hard rock formations (usually in mature sedimentary basins).

4.6.2.6 Drill Collar Shouldered Connection Makeup Torques

Table 4.6.7 gives the makeup torques for all the selected drill collar sizes and associated connections shown in Table 4.6.4. The rotary shouldered connections must be made up with a high enough torque to prevent the made up shoulders from separating under the various downhole loading conditions. Shoulder separation can occur when rotating the BHA in high angle directional boreholes or in doglegs, when drill collars buckle due to compressive loads in the BHA, or when high tensile loads are applied to the BHA. The shoulders of the box and pin threaded components are the only seal in a connection (see Figure 4.6.2) [10, 12]. The threads themselves do not seal because they are designed with clearance between the crest of one thread and the root of its mating thread groove. The clearance acts as a channel for thread compound and small solid particles that could be in the drilling fluid. Another reason to prevent shoulder separation is because when the shoulders of the box no longer takes any of the bending forces then the total bending forces are transferred to the pin of that connection. This is why nearly all drill collar failures start with a fracture at one of the pin thread root grooves. To ensure that the shoulders will stay together during operations then equal and oppose forces between each shoulder component must be high enough to create a compressive stress on each shoulder face capable of offsetting any bending at the connection that might occur when the drill collar buckled or is rotated through a borehole dogleg. This required compression shoulder load is generated by the makeup

Hole Size (in.)	Soft Formations *	Hard Formations **
4.750	2.125 × 1.250	3.500 × 1.500
5.875–6.125	4.125 × 2.000	4.750 × 2.000
6.500–6.750	4.750 × 2.250	5.000 × 2.000
7.625–7.875	6.000 × 2.8125	6.000 (or 6.500) × 2.000
8.500–8.750	6.250 (or 6.500) × 2.8125	6.750 (or 7.000) × 2.250

torque. Standard makeup torque for most drill collar rotary shouldered connections is a torque which results in a stress level in the weaker of the pin or box of 66,000 psi or 60,000 psi (depending on the drill collar minimum yield stress, see Table 4.6.2). This makeup torque is in essence a requirement to create a maximum stress in the pin or box of no greater than 60% of the minimum yield stress of the drill collar steel. The location where these stress calculations are to be assessed on the pin and box are specific and are shown in Figure 4.6.2. The cross-sectional area of pin is measured at a plane perpendicular to the pin axis at 3/4 in. from its makeup shoulder (see Figure 4.6.2). The cross-sectional area of the box is measured at a plane perpendicular to the box axis at a distance of 3/8 in. from its makeup shoulder (see Figure 4.6.2) [5, 10].

4.6.3 Drill Pipe

The major portion of the drill string is composed of drill pipe. Early rotary drilling rigs that operated up through the 1930s utilized improvised drill pipe that were basically production and casing tubulars with separate threaded couples. In the late 1930s new drill pipe designs appeared that would be the forerunners of the present modern drill pipe. The unique innovations in these new drill pipe designs were shouldered tool joint connections that are friction welded to opposite ends of a tube body (i.e., denoted as “drill pipe tube body”). The standard drill pipe today as in the past are designed to be in tension only. The drill collars are the only major components in the drill string that are placed in compression to provide weight on the bit.

4.6.3.1 Modern Drill Pipe

Figure 4.6.3 shows a cut-a-way of a typical standard weight drill pipe. Standard drill pipe consists of three components: (1) the tube body, (2) the treaded pin tool joint welded to one end of the tube body, and (3) the threaded box tool joint welded to the other end of the tube body. Before the tool joints are friction welded to the tube body, the tube body is upset, or forged, on each end to increase the wall thickness near the ends of the tube body. After the upsetting process, the tube body is heat treated to the proper grade strength. The length categorizations for drill pipe are described by the API designations given in Table 4.6.5. Most drill pipe tube body components are made from steel materials similar to AISI 4125/30 seamless tube mill product (see References 4 and 10). Like many industries, the petroleum industry utilizes steel grade system to identify the tube body steel of the drill pipe. This allows the steel tube body mills around the world to have more flexibility in producing the

tube body components for the fabrication of all drill pipe products.

Most tool joints are made from materials similar to AISI 4240 steel forgings, tubing, or bars. All tool joints are heat treated to the same material yield strength of approximately 120,000 psi, regardless of the intended API drill pipe grade (tube body) classification of the final product.

Table 4.6.8 gives the list dimensions and mechanical properties of the various drill pipe sizes categories. Table 4.6.9 gives the specifications of the tube body component and thereby the final product drill pipe steel grade designation of the drill pipe final product. The drill pipe size is the OD of the pipe tube body. The following items are required to completely identify an individual length of drill pipe [4, 10]:

- Pipe size is the pipe OD (in., mm).
- Pipe nominal unit weight or nominal unit mass (lb/ft, kg/m).

The section modulus, Z_b , of the box should be $2\frac{1}{2}$ times greater than the section modulus, Z_p , of the pin in a drill collar connection. On the right side of the connection are the spots at which the critical area of both the pin (A_p) and box (A_b) should be measured for calculating torsional strength.

FIGURE 4.6.2 The drill collar connection. [12].

- *Pipe grade* is defined as the minimum yield strength.
- *Pipe upset* is the type of wall increase at the two ends of the tube body prior to the welding on of the two tool joints (either; IU—internal upset, EU—external upset, IEU—internal external upset).

Also in Table 4.6.8 are ranges of adjusted unit weights for the present industrial inventory of commercial available drill pipe [5, 7]. The API standard steel grades and non-API of drill pipe body elements are given in Table 4.6.9. This table gives the values of yield strength (minimum and maximum) and tensile strength (minimum). Within each adjusted unit weight range drill pipe size (tube body OD) and nominal unit weight (lb/ft) category there are drill pipe available in most of the grades given in Table 4.6.9. A particular adjusted unit weight of a given drill pipe design is the value that is used for actual engineering calculations such as weight of the drill string and the buoyant weight of

the drill string that are critical information for well planning and follow-on drilling operations.

It is interesting to note that in the DS-1 Standard Volume 2 which provides the industry with the most complete listing of the various manufactures drill pipe products, that in the common API 5 in., nominal weight 19.50.

4.6.3.2 Drill Pipe Adjusted Unit Weight

Because there has been a proliferation of drill collar and drill pipe manufactures around the world in the past two decades, there is a large variety of drill pipe for engineering planners to select from when planning a future well drilling operations. The ranges of adjusted unit weight values shown in Table 4.6.8 reflect the variety of drill pipe tool joint sizes and thread styles (for the shouldered connections) that are available for each size (tube body OD) and nominal unit weight (lb/ft) category. For example, within a drill pipe size (tube body OD) and nominal unit weight (lb/ft), an API Grade E 75 (tube body) drill pipe will likely have tool joints that have smaller ODs than the tool joints that are used for an API Grade S135 (tube body) drill pipe. Therefore, the adjusted unit weight for the API Grade E75 will be less than the adjusted unit weight for the API Grade S135 drill pipe. These drill pipe tool joint shouldered connections will be similar or the same as those shown in Table 4.6.4 and 4.6.7 for drill collars. The manufacturers overall design requirements for most drill pipe categories given in Table 4.6.8 are to require that the tensile strength of the tool joints and its threaded connections be greater than the tensile strength of the drill pipe tube body. Although an accurate adjusted unit weight value for a given drill pipe design is certainly desirable for the engineer to have to complete an engineering design for a future well, it is not always possible to have that accurate adjusted unit weight value. Any slowdown in drilling activity with prolonged stacking of drilling equipment will make future determination of an accurate adjusted unit weight of inventoried drill pipe less certain. Therefore, it may be necessary to estimate the adjusted unit weight value from incomplete records of the origin and history of a given drill pipe inventory.

FIGURE 4.6.3 Typical standard drill pipe cut-a-way.

4.6.3.3 Drill Pipe Tension and Torsional Capacities

As was discussed above, nearly all drill pipe mechanical design dictates that the tube body is the weak link in both tension capacity and in torsional capacity. The term capacity is defined as the load (tension, torsion, or combined loads) that will produce a normal stress or a von Mises equivalent stress equal to the minimum yield stress of the drill pipe tube body grade.

Tables 4.6.10 and 4.6.11 gives the tension and torsional capacities for the drill pipe tube body component for the

three categories of inventory drill pipe. These are API Class 1 (New) drill pipe, API Premium Class drill pipe, and Class 2 drill pipe. These categories are predicated on the amount of wear that is incurred on the weakest link of the drill pipe design, the drill pipe tube body.

1. *API Class 1 (New)* drill pipes are unused drill pipe that are obtained directly from the tubular manufacturers. Nearly all drill pipe tube bodies are manufactured by a process that requires that the center inside opening of the tubular are formed by a mandrel that is forced through the center of the hot ingot of steel material as

TABLE 4.6.9 DP Tube Body Yield, Tensile, and Endurance Stresses [5]

Grade	Min. Yield Strength (psi)	Max. Yield Strength (psi)	Min. Tensile Strength (psi)	Min. Endurance Limit (psi)
API E 75	75,000	1,05,000	1,00,000	30,000
API X 95	95,000	1,25,000	1,05,000	32,000
API G 105	1,05,000	1,35,000	1,15,000	34,000
API S 135	1,35,000	1,65,000	1,45,000	36,000
Non-API 140*	1,40,000	1,65,000	1,50,000	NP
Non-API 150*	1,50,000	1,65,000	1,60,000	NP
Non-API 165*	1,65,000	NP	1,75,000	NP

*Note: These are non-API Grades developed by several steel tubular mills and drill pipe manufacturers (e.g., Grant Prideco, Tenaris, HiLong, VAM, Drilco).
NP - Not published.

the outside of the tubular is rolled to shape an accurate OD. The forming of the inside with the mandrel are not as accurate a process as the rolling of the OD. Thus, for new manufactured drill pipe, the wall thickness along the tube body can be 87.5% (or greater) of the API specified wall thickness values given in Table 4.6.8 can be classified as API Class 1 (New) [4,5].

2. *API Premium Class* are used drill pipes that are classified in that category by certified pipe inspectors. These inspectors are contracted by the either an operating company, or a service company, or other oil field entity (e.g., equipment rental company) to ascertain the wear to the OD of the tube body and in some high quality inspections, the wear to the OD of the tool joints. In addition to wear to the outer surfaces, the inspectors inspect for box and pin thread damages and tool joint shoulder damages. These inspections take place when an entire drill string has been removed from a well where the drill string has been used to drill a section of the borehole. There is a variety of inspection intensity levels that can be contracted. This inspection process and levels of intensities are detailed in T. H. Hill's DS-1 Standard, Volume 4 [8]. For the API Premium Class designation, the drill pipe tube body shall have no position on the tube body has a wall thickness wear of less than 80% of the specified wall thicknesses given in Table 4.6.8 [4,5]. Obviously, any drill pipe that does not pass inspection is removed from that drill string inventory and is reclassified as API Class 2 drill pipe.
3. *API Class 2* drill pipes are that last category of used drill pipe that API recommends for use in the drilling of deep wells. These drill pipe are classified by certified

pipe inspectors. The main difference in this inspection is that the API Class 2 requires that no position on the tube body has wall thickness wear less than 70% of the specified wall thicknesses given in Table 4.6.8 [4, 5]. When drill pipe is classified with wear less than 70% of its specified wall thickness it is sold as scrap metal or sold to water well drillers or geotechnical well drillers for shallow drilling operation.

4.6.3.4 Drill Pipe Tool Joint Make-up Torques

The drill pipe connections are very thick-walled components. The connections are basically the tool joints. The tool joints are designed to be threaded (box to pin) connections that can take the tension and torsion loads beyond what the drill pipe tube body can safely resist. In order for the tool joints to resist these drill string tension and torsion loads, the threaded shouldered connections must be made up on the rig floor with the proper torque in order to have the appropriate stresses in the box, pin and shouldered interfaces to resist the anticipated drill string loads. As in drill collar make up torque requirements, standard makeup torque for most rotary shouldered drill pipe connections is a torque which results in a stress level in the weaker of the pin or box of 72,00 psi which is assuming that all tool joints steels have a minimum yield stress of 120,00 psi. This makeup torque is in essence a requirement to create a maximum stress in the pin or box of no greater than 60% of the minimum yield stress of the tool joint steel.

Many of the drill pipe manufactures that have proprietary steel grades (e.g., 140,00, 150,00, and 165,00 psi) and proprietary connection designs usually utilize tool joint

*Non-API drill pipe.
NA140, NA150, NA165 are proprietary non-API grades of steel.

steels that have minimum yield stresses up to 140,000 psi in order to provide a better match for the tube body steels. To obtain more information on these proprietary products the reader needs to review the manufacturers catalogs and/or online web sites of these vendors.

As was done in the discussion of the drill collars, only a limited selection of API tool joint connections and their respective make-up torques have been given in [Tables 4.6.12a](#) and [4.6.12b](#). For consistency these API numbered connections are the same as those shown in [Table 4.6.7](#).

4.6.3.5 Heavy Weight and Thick-walled Drill Pipe

In the early 1960s the oil and gas drilling industries expanded their interest in carrying out high angle directional drilling operations. This initial interest in developing more efficient directional drilling technologies was driven by the petroleum industry's early successes in offshore exploration and production operations. High-angle directional drilling (extended reach or long radius, medium radius and short radius) requires that substantial portions of the drill string to be placed in compression (see Sections 10, 11, and 12). Therefore, over the past 40 years there has been a concerted effort by the service and operating companies to develop new drill pipe designs that will allow compression loadings together with bending flexibilities. This industry wide effort initially led to the development of heavy weight drill pipe (HWDP) in the early 1970s. The HWDP designs were essentially drill collars with their waist sections trimmed (i.e., reduced wall thickness). [Figure 4.6.4](#) shows an example cut-a-way of a typical HWDP [11, 12]. The HWDPs have proved to be very successful and essential drill string components for directional drilling operations that have taken place both offshore and in land operations over the past four decades. All HWDP are proprietary products offered by a variety of service companies and tubular manufactures.

A new comer to this new style drill pipe development effort is the thick-walled drill pipe (TWDP). This new product is fabricated like a standard API drill pipe in that the thicker-walled tube body is welded to its two separate box and pin tool joints. In general, these TWDP can have tube body steel MYS up to 150,000 psi and tool joint steel MYS from 120,000 psi and up to 140,000 psi. These new high-strength TWDP have also become very useful for completion working strings in complex highly directional drilling wellbores.

[Table 4.6.13](#) shows the basic wall thickness differences between the standard drill pipe, the TWDP, and the HWDP for one of the most commonly used drill pipe sizes, namely; the standard API 5 in. drill pipe, nominal 19.50 lb/ft, with a NC 50 connection. As can be seen in the table the wall

thickness for the standard API drill pipe is 0.362 in. (non-compression capable drill pipe), the TWDP wall thickness is 0.750 in. (compression capable), and HWDP wall thickness is 1.00 in. (compression capable).

[Table 4.6.14](#) shows specifications for typical HWDP for OD size from 3-1/2 in. to an OD size of 6-5/8 in. In general, HWDP are fabricated with tube body steel components with MYS of 55,000 psi and tool joints with MYS of 10,000 or 11,000 psi. The unique value of the HWDP designs is derived from the low MYS for the HWDP tube body component. This allows that these HWDP tube body components to plastically deform under unusually high bending loads and not fail or fracture and separate the drill string itself. Low MYS steels are very forgiving and can deform to as high as 30% strain values. These HWDP components if deformed plastically during a directional drilling operation and retrieved from the well are straightened and reused.

4.6.4 Drill String Design Examples

The basics of drill string design will be demonstrated by carrying out the step by step engineering calculations that lead to the design for a simple directional drilling drill string to drill the final openhole section of the well to receive the production casing string.

4.6.4.0.1 Well and Rig Data:

- [Figure 4.6.5](#) shows a schematic of the example wellbore trajectory profile.
- API 9-5/8 in., nominal 43.50 lb/ft, Grade P-110, casing string, run from the surface to a setting depth for the intermediate casing shoe at 6000 ft MD.
- 8-1/2 in. diameter PCD drill bit to drill the section from the casing shoe (at 6000 ft MD) to the 11,000 ft TVD target formation. Drilling is to be in mainly soft to medium formations.
- Kick off depth: 4500 ft TVD
- Build rate of medium radius borehole is 6° per 100 ft of arc.
- Mud weight for the drilling of the 8-1/2 in. production borehole is estimated to be 11.0 ppg.
- Required maximum weight on the drill WOB) bit anticipated to be 35,000 lbs.
- Margin of Over Pull (MOP) to be used for drilling the production section wellbore is 50,000 lbs.
- Rig rotary table slips length 16 in.

4.6.4.0.2 Available Inventory Equipment:

- 20 joints of 6-1/2 in. x 2-13/16 in. standard drill collars (unit wt. 91. lb/ft), NC50.
- 50 joints of 5 in. x 3 in. HWDP (wt. 50.1 lb/ft). NC50.

*Based on MYS of 55,000 psi

- 350 joints of API 3-1/2 in., nominal 13.3 lb/ft (adjusted wt. 13.93 lb/ft), Grade E75, Class 2, EU NC 38, tool joints 4-3/4 in. × 2-11/16 in.
- 320 joints of API 4 in., nominal 14.00 lb/ft (adjusted wt. 15.34 lb/ft), Grade X95, Premium Class, IU NC 40, tool joints 4-3/4 in. × 2-11/16 in.

4.6.4.0.3 Bottom Hole Assembly (BHA)

Bit, bit sub, two 6-1/2 in. × 2-13/16 in. drill collars, stabilizer, two 6-1/2 in. × 2-13/16 in. drill collars, stabilizer, two 6-1/2 in. × 2-13/16 in. drill collars, stabilizer, crossover sub to HWDP. Assume that the bit, bit sub, stabilizers and cross-over sub are equal to a total of 15 ft of drill collars unit weight in lb/ft equivalent.

4.6.4.0.4 Directional Plan

Directional plan for the production borehole to the target is to drill 6° per 100 ft build section starting at the KOP at 4500 ft to an angle of inclination from vertical of 31° (see Figure 4.6.5). After drilling this curved section with a

downhole steerable motor and MWD the drill string is to be designed to extend the 8-1/2 in. borehole from the EOB and holding the inclination angle of 31° to the target formations at TVD 11,000 ft.

4.6.4.0.5 Design Factors

- BHA neutral point design factor ($NP_{BHA} = 0.85$).
- Drill pipe published tension capacity values (New, Premium, Class 2) reduction factor = 0.90 (Note that this API standard reduction factor for the tension capacity of the tube body is a result of the 87.5% minimum wall thickness of published tube body value that API tubing mills are allowed to use when forming the seamless tube body).

Step 1: Determine the MD of the cased and open 8-1/2 in. borehole from surface to target (see Figures 4.6.5 and 4.6.6).

Measured length of arc, L_{arc} , below KOP to an inclination angle of 31° is

$$L_{arc} = \left(\frac{31^\circ}{6^\circ}\right) 100 = 516.7\text{ft} \quad (4.6.2)$$

The radius of the arc is

$$R = \left(\frac{100}{6^\circ}\right) \left(\frac{180^\circ}{\pi}\right) = 954.9\text{ft}$$

FIGURE 4.6.5 Schematic of drill string design example.

FIGURE 4.6.6

This classifies the directional section of the well as a medium radius (see Sections 4.10–4.12).

Length of vertical depth, d_{arc} , in the arc is

$$\sin 31^\circ = \left(\frac{d_{\text{arc}}}{954.9} \right) \quad (4.6.3)$$

Solving for d_{arc} gives

$$d_{\text{arc}} = 954.9 (\sin 31^\circ) = 491.9\text{ft} \quad (4.6.4)$$

Vertical depth, d_{EOB} , to EOB is

$$d_{\text{EOB}} = 11000 - 4500 - 491.9 = 6008.1\text{ft} \quad (4.6.5)$$

Measured length of borehole from EOB to target, $L_{\text{EOB/T}}$, is

$$\cos 31^\circ = \left(\frac{6008.1}{L_{\text{EOB/T}}} \right) \quad (4.6.6)$$

Solving for $L_{\text{EOB/T}}$ gives

$$L_{\text{EOB/T}} = \left(\frac{6008.1}{\cos 31^\circ} \right) = 7009.2\text{ft} \quad (4.6.7)$$

Measured length of proposed borehole and, therefore, the drill string, L_{ds} , is

$$L_{\text{ds}} = 4500.0 + 516.7 + 7009.2 = 12026\text{ft} \quad (4.6.8)$$

Step 2: Determine the BHA Length, L_{BHA} , and the BHA air weight, W_{BHA} .

The length of the drill bit, bit sub, drill collars, stabilizers, and crossover sub section of the BHA, $L_{\text{dc/ss}}$, is

$$L_{\text{dc/ss}} = 15 + 3(62) = 201\text{ft} \quad (4.6.9)$$

The air weight of, $L_{\text{dc/ss}}$, is

$$W_{\text{dc/ss}} = (91)(201) = 18291\text{lb} \quad (4.6.10)$$

The equation for determining the length of drill collars in a BHA are presented in API RP7G and the DS-1 Volume 2. This equation is [5,7]

$$L_{\text{dc}} = \left[\frac{\text{WOB}}{\cos \alpha \text{NPk}_b w_{\text{dc}}} \right] \quad (4.6.11)$$

k_b is the buoyancy factor (at MW = 11. ppg, $k_b = 0.832$).

Equation 4.6.11 can be modified to account for the example requirement for the rigid drill collar section of the BHA. Such a modified equation allows for the

determination of the length of the HWDP for the BHA needed for the WOB requirement. This modified equation for determining the length of the HWDP is

$$L_{\text{HWDP}} = \left[\frac{\text{WOB}}{\cos \alpha \text{NPk}_b w_{\text{HWDP}}} \right] - \left[\frac{W_{\text{dc}}}{w_{\text{HWDP}}} \right] \quad (4.6.12)$$

For the example Equation 4.6.12 gives

$$L_{\text{HWDP}} = \left[\frac{35000}{\cos 31^\circ (0.85)(0.832)(50.1)} \right] - \left[\frac{18291}{50.1} \right]$$

$$L_{\text{HWDP}} = 787.6\text{ft} \quad (4.6.13)$$

The number of HWDP stands are obtained by dividing 787.6 ft by 93 ft and rounding up. This yields

$$L_{\text{HWDPstd}} = \left(\frac{787.6}{93} \right) = 8.5$$

$$L_{\text{HWDPstd}} = 9.0 \text{ stands} \quad (4.6.14)$$

The actual measured length of, L_{HWDPact} , is

$$L_{\text{HWDPact}} = (93)(9.0) = 837\text{ft} \quad (4.6.15)$$

The air weight of the HWDP section of the drill string, W_{HWDPact} , is

$$W_{\text{HWDPact}} = (50.1)(837) = 41934\text{lb} \quad (4.6.16)$$

The length of the BHA, L_{BHAact} , is

$$L_{\text{BHAact}} = L_{\text{dc/ss}} + L_{\text{HWDPact}} = 201 + 837 = 1038\text{ft} \quad (4.6.17)$$

The air weight of the BHA, W_{BHAact} , is

$$W_{\text{BHAact}} = W_{\text{dc/ss}} + W_{\text{HWDPact}} \quad (4.6.18)$$

$$W_{\text{BHAact}} = 18291 + 41934 = 60225\text{lb} \quad (4.6.19)$$

Step 3: Determine the order of the inventory drill pipe in the drill string design. The required length of the drill pipe, L_{dp} , needed in the drill string design is

$$L_{\text{dp}} = L_{\text{ds}} - L_{\text{BHA}} = 12026 - 1038 = 10988 \text{ ft} \quad (4.6.20)$$

The maximum length of API 3-1/2 in. needed to support the weight of the BHA, is determined from the following equation [5,7]

$$L_{\text{dp}} = \frac{(0.9P_t) - \text{MOP}}{w_{\text{dp}} k_b} - \frac{w_{\text{dc}} L_{\text{dc}}}{w_{\text{dp}}} \quad (4.6.21)$$

Equation 4.6.21 can be modified to determine what length of each of the drill pipe in the inventory can be used in the drill pipe section of the drill string. From Table 4.6.10 the tensile capacity for the API 3-1/2 in., nominal 13.30 lb/ft (adjusted wt. 13.93 lb/ft), Grade E75, Class 2 is found to be 183,398 psi. Also from Table 4.6.10 the tensile capacity for the API 4 in., nominal 14.00 lb/ft (adjusted wt. 15.34 lb/ft), Grade X95, Premium Class is found to be 283,963 psi. The weakest drill pipe, namely the API 3-1/2 in. drill pipe, needs to be run at the bottom of the drill pipe section of the drill string (i.e., just above the BHA). The API 4 in. drill pipe, the stronger drill pipe in inventory, is to be run at the top of the drill string. The maximum length of the API 3-1/2 in. drill pipe, L_{dp1} , that can be placed in the drill string design just above the BHA is (from a modified Equation 4.6.21) is

$$L_{dp1} = \frac{[(0.9)(183398)] - 50000}{(13.93)(0.832)} - \frac{60225}{13.93}$$

$$L_{dp1} = 5600.2 \text{ ft} \tag{4.6.22}$$

The number of API 3-1/2 in. drill pipe stands are obtained by dividing 5600.2 ft by 93 ft and rounding down. This yields

$$L_{dp1} = \left(\frac{5600.2}{93} \right) = 60.2$$

$$L_{dp1} = 60.0 \text{ stands} \tag{4.6.23}$$

The actual measured length of L_{dp1act} is

$$L_{dp1act} = (93)(60.0) = 5580 \text{ ft} \tag{4.6.24}$$

The air weight of L_{dp1act} is

$$W_{dp1act} = (13.93)(5580) = 77729 \text{ lb} \tag{4.6.25}$$

The required length of L_{dp2req} at the top of the drill string to reach the surface is

$$L_{dp2req} = L_{ds} - L_{BHAact} - L_{dp1act}$$

$$= 12026 - 1038 - 5580 = 5408 \text{ ft} \tag{4.6.26}$$

Equation 4.6.21 is used to determine the API 4 in. drill pipe capability to support the entire buoyant weight of the drill string. This is

$$L_{dp2cap} = \frac{[(0.9)(283963)] - 50000}{(15.34)(0.832)} - \frac{60225 + 77729}{15.34}$$

$$L_{dp2cap} = 7055 \text{ ft} \tag{4.6.27}$$

Since the L_{dp2cap} (7055 ft) is greater than L_{dp2req} (5408 ft) then the inventory API 4 in. drill pipe can be used to complete the drill string.

The number of API 4 in. drill pipe stands are obtained by dividing 5408 ft by 93 ft and rounding down. This yields

$$L_{dp2} = \left(\frac{5408}{93} \right) = 58.2$$

$$L_{dp2} = 58.0 \text{ stands} \tag{4.6.28}$$

The actual measured length of L_{dp2act} is

$$L_{dp2act} = (93)(58.0) = 5394 \text{ ft} \tag{4.6.29}$$

The air weight of L_{dp2act} is

$$W_{dp2act} = (15.34)(5394) = 82744 \text{ lb} \tag{4.6.30}$$

The total air weights of the drill string, the total buoyant weights of the drill string, lengths of sections, measured depths to top of drill string sections, and their respective buoyant tension loads are summarized in Table 4.6.15.

Step 4: Determine the air weight and buoyant weight of the drill string when hanging in the slips of the rotary table. Also, determine whether this drill string can be supported in the rig rotary table by 16 in slips. Table 4.6.15 above

TABLE 4.6.15 Summary of Example Drill String Lengths, MDs, Wts, and Tension Loads

gives the summary of the drill string design results which are needed to carry out slip crush calculations.

Slip crush calculations: When a drill string is hung in the slips in the rotary table the possibility exists that the axial load on the drill pipe body that is supporting the axial load can be crushed due to high hoop stresses, σ_{η} , created by the axial load in that short cylindrical section of the pipe body. The slip crush problem can be analyzed using the approximate relationship between the pipe body hoop stress, σ_h , caused by the slips, and the pipe body tensile axial stress, σ_t , caused by that axial load. This approximate relationship is [13]

$$\frac{\sigma_h}{\sigma_t} = \left[1 + \frac{Dk}{2L_s} + \left(\frac{Dk}{2L_s} \right)^2 \right]^{1/2} \quad (4.6.31)$$

where D is the outside diameter of the drill pipe (in.), L_s is the length of the slips (in.), and k is the lateral load factor which is a function of the length of the slip and the coefficient of friction between the pipe and the slips. Table 4.6.16 gives the values of the σ_h/σ_t ratio that can be calculated from Equation 4.6.31 for different combinations of drill pipe diameters, length of slips, and coefficient of friction. At the top of the example drill string design is the API 4 in., nominal 14.00 lb/ft, Grade X95, Premium Class, IU NC40. During the drilling operation to drill to the target formations this API 4 in. drill pipe will be placed in the slips and must support the entire buoyant of the drill string. Table 4.6.15 shows the anticipated maximum buoyant weight of the drill string at the TVD is expected to be 183,621 lb. The drilling rig has 16 in. slips. The

coefficient friction between the drill pipe and the slips will be assumed to be 0.10. Use a slip crush design factor $DF_{sc} = 1.15$. The rated tensile load capacity for this drill pipe body is 283,963 lbs (see Table 4.6.10). The useful load capacity is

$$ULC = \frac{283963}{1.15}$$

$$ULC = 246924 \text{ lb} \quad (4.6.32)$$

From Table 4.6.16 the σ_h/σ_t ratio for the example combination of $D = 4$ in. and $L_s = 16$ in. is 1.29. Therefore, the applied lateral load for the σ_h is

$$ALL = (1.29) 183621 = 236871 \text{ lb} \quad (4.6.33)$$

Since hoop stress and tensile stress are both applied over the same cross-sectional area of the drill pipe tube body and since $ALL < ULC$ then drill string buoyant weight of 183,621 lb can be safely supported by the 16 in. slips in the rig rotary table.

Step 5: In the event of an operational necessity such as a stuck drill string, it is often necessary to determine the surface torque limit that might be applied to the drill string at the surface while the string is also under a constant tension load applied by the drawworks. In these stuck drill string situations, the buoyancy forces are usually not effective since the buoyant force is dispersed into the formation that has ensnared the drill string. Therefore, the tension force that is usually applied to pull up on the drill string to aid in releasing the string is the only tension force (through the entire length of the drill string) in the string. To aid in the releasing the drill string a rotary table or top drive torque is often also applied at the rig floor. This creates a combined stress analysis situation within the steel components of the drill string. The weakest links in the drill string are usually the drill pipe tube body. In this example case, this would be the tube bodies in each of the API 4 in. drill pipe joints and the tube bodies in each of the API 3-1/2 in. drill pipe joints.

To evaluate the combined stress load capacity of drill pipe tube bodies of the API 4 in. drill pipe and the tube bodies of the API 3-1/2 in. drill pipe in the drill string the maximum distortion energy ductile metal failure theory is used to determine the limiting conditions between the applied tension force (the pull up force) at the top of the drill string) and the applied torsion force (also at the top of the drill string). This failure theory is currently known as the either the equivalent stress or the von Mises stress, σ_{vm} , combined stress equation [14]. One of the more general forms of this failure theory is

$$\sigma_{vm}^2 = \left(\frac{1}{2}\right) \left[(\sigma_z^2 - \sigma_t^2)^2 + (\sigma_t^2 - \sigma_r^2)^2 + (\sigma_r^2 - \sigma_z^2)^2 + 6\tau^2 \right] \quad (4.6.34)$$

where σ_z is the axial tension stress (psi),
 σ_t is the tangential stress (psi),
 σ_r is the radial stress (psi)
 τ is the shear stress (psi).

Considering the condition where the tube body is acted upon by an axial tension force (P) that creates a normal axial stress σ_z and a twisting or torque action (T) that creates a shear stress τ in the tubing body. Therefore, σ_z and τ become the following:

$$\sigma_z = \frac{P}{A} \quad (4.6.35)$$

$$\tau = \frac{T}{Z} \quad (4.6.36)$$

where P is axial tension (lbs),

A is the tube body cross-sectional area (in.²),

T is torque (in. lb)

Z is polar section modulus (in.³),

The polar section modulus is

$$Z = \frac{2J}{D_{od}} \quad (4.6.37)$$

where J is polar moment area which is

$$J = \left(\frac{\pi}{32}\right) \left[D_{od}^4 + D_{id}^4 \right] \quad (4.6.38)$$

and D_{od} is the outside tube body diameter (in.),

D_{id} is the inside tube body diameter (in.).

Substituting Equations 4.6.35–4.6.38 into Equation 4.6.34 and solving for the applied torque, T, gives

$$T = \frac{\left(\frac{2J}{D_{od}}\right)}{\sqrt{3}} \left[(Y_m)^2 - \left(\frac{P}{A}\right)^2 \right]^{0.5}$$

The above equation can be written in oil field units as

$$Q_T = \frac{0.096167J}{D_{od}} \sqrt{Y_m^2 - \frac{P^2}{A^2}} \quad (4.6.39)$$

where Q_T is applied torque (ft lb).

Equation 4.6.39 is used to evaluate the surface applied torque limitations can be determined for applied tension forces that might be necessary to release a stuck pipe. This

equation can be used to determine the torque limitations for the API 4 in. drill pipe at the top of the example drill string for the tension forces of 50,000 lb, 75,000 lb and 100,000 lb. For the API 4 in. drill pipe the equation values are

$$\begin{aligned} D_{od} &= 4.00 \text{ in.} \\ D_{id} &= 3.340 \text{ in.} \\ A &= 3.8048 \text{ in.}^2 \\ Y_m &= 95000 \text{ psi} \\ J &= 12.915 \text{ in.}^4 \\ P &= 50000 \text{ lb} \end{aligned}$$

and Equation 4.6.39 yields

$$\begin{aligned} Q_T &= \frac{0.096167 (12.915)}{4.0} \sqrt{(95000)^2 - \frac{(50000)^2}{(3.8048)^2}} \\ Q_T &= 29210 \text{ ft lb} \end{aligned} \quad (4.6.40)$$

The equation can also be used to determine the torque limitations for the API 3-1/2 in. drill pipe below the API 4 in. drill pipe in the example drill string for the tension forces of 50,000 lb, 75,000 lb and 100,000 lb. For the API 3-1/2 in. drill pipe the equation values are

$$\begin{aligned} D_{od} &= 3.50 \text{ in.} \\ D_{id} &= 2.764 \text{ in.} \\ A &= 3.6209 \text{ in.}^2 \\ Y_m &= 75000 \text{ psi} \\ J &= 9.002 \text{ in.}^4 \\ P &= 50000 \text{ lb} \end{aligned}$$

and for this case Equation 4.6.39 yields

$$\begin{aligned} Q_T &= \frac{0.096167 (9.002)}{3.5} \sqrt{(75000)^2 - \frac{(50000)^2}{(3.6209)^2}} \\ Q_T &= 18551 \text{ ft lb} \end{aligned} \quad (4.6.41)$$

Table 4.6.17 gives the summary of the torque limitations for both the API 4 in. drill pipe tube body and the API 3-1/2 in. drill pipe tube body. The example drill string is a tapered string with the API 4 in. drill pipe at the top and the API 3-1/2 in. drill pipe below the API 4 in. and the BHA below the API 3-1/2 in. drill pipe. The weakest drill pipe in tension, the API 3-1/2 in., is again shown in Table 4.6.17 to be the weakest in torque limits for all the proposed applied tensions.

TABLE 4.6.17 DP Tube Torque Limits with Tension

DP Size (in.)	Min. Yield Torque (ft lb)	Pull Tension (lb)		
		50,000	75,000	1,00,000
		Torque Limits (ft lb)		
API 4.0	29,498	29,210	28,860	28,350
API 3-1/2	18,551	18,230	17,830	17,250

Step 6: Figure 4.6.5 shows the trajectory profile of the borehole of the drill string design example. In this example design the plan is for a directionally drilled arc with a build rate of 6 ° per 100 ft of arc to a final inclination angle of 31°. This build rate requires a radius of curvature of 955.0 ft. At the required inclination angle the arc is 515.7 ft long through a vertical drop of 491.9 ft. This portion of the well is to be cased with API 9-5/8 in., nominal 43.50 lb/ft (id = 8.755 in.), Grade P-110 casing set at 6000 ft MD. This is to be accomplished prior to the example drill string being deployed to drill the hold section from the casing shoe to the target at 12,026 ft MD (11,000 TVD). This means the drill string components (drill collars and drill pipe) will be exposed to additional bending stresses as the tool joints and drill pipe bodies are rotated through the 516.7 ft of arc that is cased and has an inside diameter of 8.755 in. These additional bending stresses will be cyclic and therefore the steel components will be fatigue failures. As was stated earlier in this section, fatigue failures of drill string components are the cause of the majority of downhole drill string mechanical problems. In what follows is a simple method of assessing the initial fatigue tendencies of connection pins, boxes, and tube bodies to fatigue failures.

The bending normal stress, σ_b , is defined as [14]

$$\sigma_b = \frac{M c}{I} \quad (4.6.42)$$

where M is the applied moment (lb in.),

c is the distance from the centerline to the outer fiber (in.),

I is the moment area modulus of the pipe cross section (in.⁴).

The radius of the bend caused by the moment is defined as

$$\frac{M}{EI} = \frac{1}{R_b} \quad (4.6.43)$$

Substituting Equation 4.6.43 into Equation 4.6.42 yields

$$\sigma_b = E \frac{c}{R_b} \quad (4.6.44)$$

Equation 4.6.44 can give an initial value for the cyclic stress for individual components in the drill string proposed design and the overall stress and cyclic stress can be compared with the known endurance stress level of the steel grade or alloy of the component.

The API 4 in. drill pipe tube body additional cyclic bending stress is approximately

$$\sigma_b = (30 \times 10^6) \left(\frac{2.0}{(12)(955.0)} \right) = 5236 \text{ psi} \quad (4.6.45)$$

The drill string buoyant weight on the top of the API 4 in. drill pipe body is 183,621 lb (see Table 4.6.15). The cross-sectional area of the pipe tube body is 3.8048 in.². Thus, the normal stress due to the tension load is

$$\sigma_t = \frac{183621}{3.8048} = 48222 \text{ psi} \quad (4.6.46)$$

The potential fatigue stress levels are the combination of the two stresses which can be approximately

$$\sigma_{\text{chigh}} = 48222 + 5236 = 53458 \text{ psi} \quad (4.6.47a)$$

$$\sigma_{\text{clow}} = 48222 - 5236 = 42986 \text{ psi} \quad (4.6.47b)$$

Table 4.6.9 gives the fatigue endurance stress for API Grade X95 drill pipe tube body steel as 32,00 psi. Since both the cyclic stresses in Equations 4.6.47a and 4.6.47b exceed the endurance stress limit for the drill pipe tube body steel grade then more detailed fatigue analysis should be carried out on this component. This type of analysis is beyond the scope of this handbook. T.H. Hill's DS-1 Standard, Drill Stem Design and Operation, Volume 2 has a very detailed fatigue analysis that provides a step by step process that an engineer can follow to complete the fatigue for this and the other components of a this and other drill strings [7].

The API 3-1/2 in. drill pipe tube body additional cyclic bending stress is approximately

$$\sigma_b = (30 \times 10^6) \left(\frac{1.75}{(12)(955.0)} \right) = 4582 \text{ psi} \quad (4.6.48)$$

The drill string buoyant weight on the top of the API 3-1/2 in. drill pipe body is 114,778 lb (see Table 4.6.15). The cross-sectional area of the pipe tube body is 3.6209 in.². Thus, the normal stress due to the tension load is

$$\sigma_t = \frac{114778}{3.6209} = 31699 \text{ psi} \quad (4.6.49)$$

The potential fatigue stress levels are the combination of the two stresses which can be approximately

$$\sigma_{\text{chigh}} = 31699 + 4582 = 36281 \text{ psi} \quad (4.6.50a)$$

$$\sigma_{\text{clow}} = 31699 - 4582 = 27117 \text{ psi} \quad (4.6.50b)$$

Table 4.6.9 gives the fatigue endurance stress for API Grade E75 drill pipe tube body steel as 30,00 psi. Since only one of the cyclic stresses in Equations 4.6.50a and 4.6.50b exceeds the endurance stress limit for the drill pipe tube body steel grade then this tube body may not fail the operation. However, it would be prudent to carry out the full analysis using the T.H. Hill's fatigue analysis in DS-1, Volume 2 [7].

4.6.5 Conclusions

This section has presented some simplification and abbreviations in the traditional data available to the drill string designer. The most important being the presentation of the adjusted unit weights in Table 4.6.8 as ranges of values. This was done because of the proliferation worldwide manufacturers of quality drill pipe and many with proprietary steel grades and designs of tool joint threads. Very few industrial standard documentation publishers have been able to keep up with the listing of these new products and all their design details. The only apparent current list is in T.H. Hill's DS-1, Volume 2 [7]. As the oil and the gas industry experiences this latest slow down, there is a concern that the adjusted unit weight information for many of these stacked drill pipe inventories maybe lost or at the least misplaced or misread. In such a situation, the range of adjusted unit weights could be valuable for a future drill string designer.

Here is how a future drill string designer might use the adjusted unit weight range values given in Table 4.6.8 for an actual design and compare the results with the drill string design analysis given in Section 4.6.3 above (which used the actual published adjusted unit weights for the API 3-1/2 in. and the API 4 in. the inventory drill pipe).

4.6.5.1 Using the Range Values

The range of unit adjusted weight values for the API 3-1/2 in., nominal 13.30 lb/ft (all steel grades) is listed in Table 4.6.8 as 13.40 lb/ft–15.67 lb/ft. This range encompasses six drill pipe steel grades (API E75, API X95, API G105, API S135, and proprietary 140 and 150) [5, 7].

The range of unit adjusted weight values for the API 4 in., nominal 14.00 lb/ft (all steel grades) is listed in Table 4.6.8 as 14.19–17.08 lb/ft. This range encompasses six drill pipe steel grades (API E75, API X95, API G105, API S135, and proprietary 140 and 150) [5,7].

These are progressively higher steel minimum yield strength grades which will, in turn, would require progressively stronger tool joints in order to ensure that the weak link in each drill pipe design remains the drill pipe tube body and not the tool joints. Since the great majority of tool joints are fabricated from steel with minimum yield strength of 120,000 psi, this will require progressively more steel volume in the tool joints (usually via increased ODs). Therefore, it is assumed that this relationship is reflected in the range values and can estimate the allocation of this increase in adjusted unit weight values between the six grades of steel.

API 3-1/2 in. Estimated Adjusted Unit Weight

The adjusted unit weight increase allocated to each of the six steel grades is estimated to be approximately the same for each of the six grades. This allocation will be

$$\Delta_{auw1} = \frac{(15.67 - 13.40)}{6} = 0.3783 \text{ lb / ft}$$

Therefore, the E75 grade estimated adjusted unit weight range can be

$$R_{E75} = 13.40 + 0.3783 = 13.78 \text{ lb / ft} \quad (4.6.51)$$

It has been assumed that the estimate this sought is in the high end of the applicable range.

API 4 in. Estimated Adjusted Unit Weight

The adjusted unit weight increase allocated to each of the six steel grades is estimated to be approximately the same for each of the six grades. This allocation will be

$$\Delta_{auw2} = \frac{(14.19 - 17.08)}{6} = 0.4817 \text{ lb / ft}$$

Therefore the X95 grade estimated adjusted unit weight range can be

$$R_{X95} = 14.19 + 0.4817 + 0.4817 = 15.87 \text{ lb / ft} \quad (4.6.52)$$

It has been assumed that the estimate this sought is in the middle of the applicable range.

4.6.5.2 Comparisons

The estimated adjusted unit weights for the API 3-1/2 in., nominal 13.30 lb/ft drill pipe and the API 4 in., nominal 14.40 lb/ft drill pipe given in Equations 4.6.51 and 4.6.52 are used to recalculate the drill pipe lengths for the example drill string design that was carried out above in Section 4.6.3. These results are compared to the results obtained using the actual published adjusted unit weights given in Table 4.6.15.

Table 4.6.18 gives results for the example drill string design using the estimated adjusted unit weights of Equations 4.6.51 and 4.6.52. Comparing the summary in Table 4.6.18 with those in Table 4.6.15, it is found that the drill pipe stands numbers and lengths are the same in both summaries. The only differences in the summaries are the total weights of the drill string designs (both air weight and buoyant weight). The total weights in Table 4.6.18 (estimate adjusted unit weights) are approximately 2000 lb greater than those in Table 4.6.15 (the actual published adjusted weights).

4.7 BITS AND DOWNHOLE TOOLS

Section reviewed by Graham Mensa-Wilmot

4.7.1 Roller Cone Drill Bits

A wide variety of rotary bit designs is available from a number of manufacturers. Each of these is intended to provide optimal performance in specific formations and in particular drilling environments. Bit designers must anticipate formational and environmental influences into their designs. To accomplish this, manufacturers meticulously collect information on the operation of all bits with the purpose of enhancing the performance efficiency of their respective designs. Modern drill bits incorporate significantly different cutting structures and use vastly improved materials from those that were used just a few years ago. As a result, the performance efficiency of bit designs has improved systematically through the years. Variations in operating practices, types of equipment used, and hole conditions can require design adjustments, and manufacturers usually work closely with drilling companies to ensure that opportunities for design revision are expeditiously identified and implemented.

4.7.1.1 Bit Design

Rotary drill bits are designed to

- Accurately cut gage throughout the life of the bit
- Provide stable and vibration free operation at the intended rotational speed and weight on bit (WOB)
- Function at a low cost per foot drilled
- Have a long downhole life that minimizes requirements for tripping

To achieve these goals, bit designers must consider many factors. Among these are the formation to be drilled and the drilling environment, expected rotary speed, expected WOB, hydraulic arrangements, and anticipated dull conditions from both abrasion and impact. The bit body, cone configurations, and cutting structures are design focal points, and metallurgical, tribological, and hydraulic considerations also have significant influence on design solutions.

4.7.1.1.1 Basic Roller Cone Design Principles

The performance of a drill bit is influenced by the environment in which it operates. Operating choices such as applied WOB, rotary speed, and hydraulic arrangements all have important implications on the way in which bits are designed and on their operating performance.

Environmental factors such as the nature of the formation to be drilled, hole depth and direction, characteristics of drilling fluids, and the way in which a drill rig is operated are also of critical importance to bit performance and design. Engineers consider these factors for all designs, and every design begins with close cooperation between the designer and the drilling company to ensure all applicable inputs contribute to the bit's design.

Design activities are principally focused in four general areas: material selection for the bit body and cones, geometry and type of cutting structure to be employed, mechanical operating requirements, and hydraulic requirements. The dimensions of a bit at the gage (outside diameter) and pin (arrangement for attachment to a bottom hole assembly) are fixed, usually by industry standards, and resultant design dimensions always accommodate them (Figure 4.7.1).

FIGURE 4.7.1 Roller cone bit general nomenclature.

Structural Materials

Steels are selected that have appropriate yield strength, ability to harden, impact resistance, machineability, heat-treated properties, and ability to accept hardfacing without damage. Materials are described in more detail later.

Cutting Structure Arrangements

Cutting structures must be designed to provide efficient penetration of the formations to be drilled and accurately cut gage. The cutting structure must also prevent the bottom hole from contacting bit body structures (Figure 4.7.2). Cutting structures are described in more detail later.

Bearing, Seals, and Lubrication Design

The importance of roller cone bit bearing reliability cannot be understated. In an operational sense, bearings, seals, and lubrication arrangements function as a unit and their designs are closely interrelated (Figure 4.7.3). Bearing systems must function normally under high loads from WOB, in conditions of large impact loads, while immersed in abrasive and chemical laden drilling fluids, and in some cases in relatively high temperature environments (bearings, seals, and lubrication are described in more detail later).

Hydraulic Arrangements

Hydraulic configurations are designed so as to efficiently remove cuttings from the cutting structure and bottom hole and evacuate all cuttings efficiently (Figure 4.7.4).

4.7.1.1.2 Design Methods and Tools

How Teeth and Inserts “Drill”

To understand design parameters for roller cone bits, it is first necessary to understand how roller cone bits drill. Two quite different types of drilling action take place. The first

FIGURE 4.7.3 Bearing, seal, and lubrication system.

FIGURE 4.7.2 Typical roller cone bit cutting structure.

FIGURE 4.7.4 Hydraulic flow around bit body.

FIGURE 4.7.5 Cutting actions for roller cone bits.

of these is a crushing action that takes place when weight applied to the bit forces its inserts (or teeth), into the formation. The second is a skidding, gouging type of action that partly results because the axis of cone rotation is slightly angled to the axis of bit rotation. Skidding and gouging also takes place because rotary motion of the bit does not permit a penetrated insert to rotate out of the crushed zone it has created without a certain amount of lateral force. The axis of cone rotation more dramatically produces the skidding-plowing action, but both effects contribute to cutting action (Figure 4.7.5).

Bentson Bit Design Method

The bit geometry and cutting structure engineering method of H. G. Bentson, reported in his paper entitled “Roller Cone Bit Design,” has since 1956 been the root from which most roller cone bit design methods have been based [1]. Although modern engineering techniques and tools have advanced dramatically from those used in 1956, Bentson’s method is still the basis from which the design process has been derived. It continues to be useful as a background explanation of elements of bit design and is outlined later.

Bit Diameter and Available Space

The first consideration in the physical design of a roller cone bit is one of bit diameter, or to use other words, of available space. Every element of a rock bit must be confined within a circle representative of the hole to be drilled (Figure 4.7.6). The American Petroleum Institute has issued a specification establishing permissible tolerances for standard bit diameters [2]. In plan view, these prescribed diameters each inscribe a circle that is the maximum permissible diameter for a roller cone bit of a given size. Designers then use all available space within the circle or diameter when designing a bit.

Most geometric and mechanical features of a bit are tied to the bit’s circular cross-section. For example, the size of journals, bearings, cones, and hydraulic and lubrication features are collectively governed by circular cross-section. Individually, the sizing of the various elements can, to an extent, be varied. An increase in the physical size of one element will necessitate a corresponding decrease in one or more of the others, however. Proportions between component parts such as a cone and a bearing are a compromise between bearing dimensions, in which larger usually has advantages, and cone shell thickness, in which increased thickness is, again, generally advantageous. The design of the final assembly of mating journals, bearings, and cones involves an even more complex array of compromises. Repositioning or altering size or shape of a single component nearly always requires subsequent additional changes in one or more of the other features. In smaller bits, finding good compromises can be difficult because of their shortage of available space.

FIGURE 4.7.6 Confinement of three-cone bit elements within bit diameter.

FIGURE 4.7.7 Effect of journal angle on bit cones.

Journal Angle

The term *journal angle* describes the angle formed by a line perpendicular to the axis of the bit and the axis of the bit leg journal (Figure 4.7.7). Journal angle is usually the first element in a roller cone bit design. It is introduced into design to optimize bit insert (or tooth), penetration into the formation being drilled; generally, bits with relatively small journal angles are best suited for drilling in softer formations while those with larger angles perform best in harder formations.

Cone Geometry

Cone shape is another critical design element and the relationship between cones is such that a change in shape or size of one cone always affects adjacent cones (Figure 4.7.7).

Cone Offset Angle

To increase the skidding-gouging action, bit designers generate additional working force by skewing (or offsetting) the centerlines of the cones so they do not intersect at a common point on the bit. The angle of skew is called the *cone offset angle*. Cone offset forces a cone to turn within the limits of the hole, rather than on its own axis.

Cone offset angle is the horizontal distance between the axis of a bit and the vertical plane through the axis of its journal. Offset is a dimension measured from the journal centerline to the bit centerline. The line segment representing the amount of offset is perpendicular to both journal and bit centerlines. Offset is established by moving the centerline of a cone away from the centerline of the bit in such a way that a vertical plane through the cone centerline is parallel to the vertical centerline of the bit.

Basic cone geometry is directly affected by increasing or decreasing either the journal angle or the offset angle and a change in one of the two requires a compensating change in the other. For example, an increase in the journal angle requires an offsetting decrease in the cone offset angle.

Skidding-gouging improves penetration in soft and medium formations at the expense of increased insert or tooth wear. Bit designers limit the use of offset so results just meet requirements for formation penetration. In abrasive formations, offset can reduce cutting structure service life to an impractical level. As a result, bits designed for abrasive applications typically use small offsets that minimize skidding-gouging action.

Teeth and Inserts

Tooth and insert design is primarily governed by

Structural requirements for the insert or tooth
Formation requirements such as penetration, impact, abrasion, and stickiness

With borehole diameter and knowledge of formation requirements, the designer selects (or designs new), structurally satisfactory inserts that provide the optimal insert or tooth pattern necessary to efficiently drill the formation.

Factors that must be considered to design an efficient insert or tooth and establish an advantageous bottom-hole pattern include

Bearing assembly arrangement
Cone offset angle
Journal angle
Cone profile angles
Insert or tooth count
Insert or tooth spacing

When these requirements have been satisfied, remaining space can be allocated to insert or tooth contour and a cutting structure geometry that is best suited for the formation.

In general, the physical appearance of cutting structures designed for soft, medium, and hard formations can be readily recognized by the length and geometric arrangement of their inserts.

Additional Design Criteria

With the exception of journal angle and offset values, the previous discussion of fundamental design has described roller cone bit design factors imposed by geometric limitations. Basic design criteria relate to more arbitrary factors that are primarily a function of previous experience. These include design criteria such as

- Clearance between inserts or teeth and features on adjacent cones
- Bottom-hole coverage
- Cone-shell thickness
- Bearing configuration

A typical insert or tooth design layout for a roller cone bit intended for use in medium-hard formations, to which these design criteria have been applied is shown in Figure 4.7.8. Because the design incorporates an offset, cone sections lie in parallel planes, one above the other, by an amount that is a calculated function of offset value. Design work of this sort is usually accomplished through three-dimensional modeling.

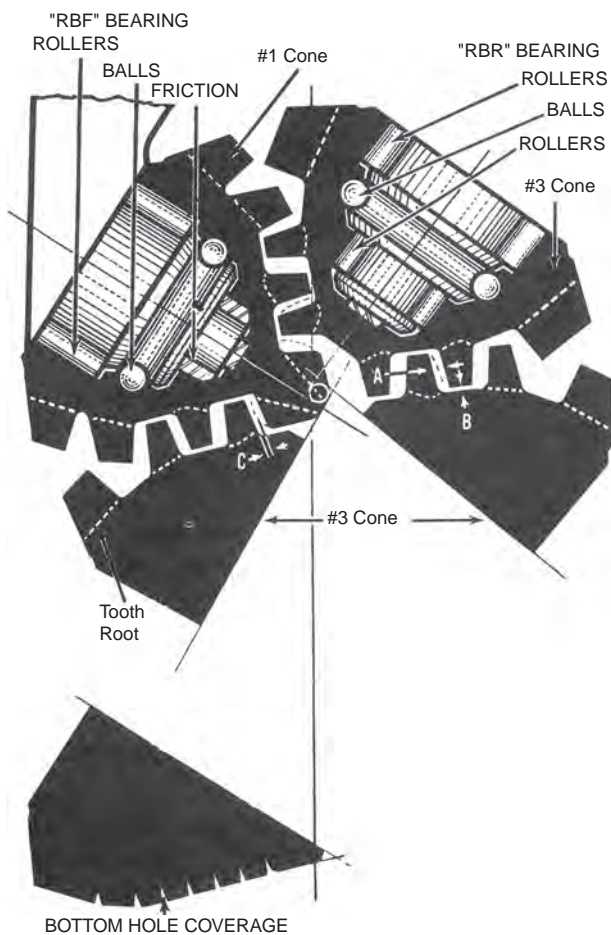

FIGURE 4.7.8 Insert or milled tooth bit design showing clearances, bottom-hole coverage, cone-shell thickness, and bearing configuration.

Insert or tooth clearances relative to adjacent cones must be closely controlled. Within limits, these clearances are maintained to the smallest possible dimension to gain maximum use of space. Excessive clearance results in inadequate bottom-hole coverage and accelerated wear on inserts or teeth. Excessive dimensions sacrifice insert or tooth depth, cone-shell thickness, and permissible bearing size. Insufficient clearance can cause interference between adjacent cones.

The composite view of the cones shown later the cone cluster is required to determine the bottom-hole coverage. This layout presents an overall check on the general insert or tooth spacing and is required for proper engineering of insert or tooth balance and insert or tooth arrangement. Spaces representing uncut bottom are kept to a minimum and, within limits, are balanced. If these spaces are kept uniform and within the dimensional limits shown, teeth on an offset bit will wipe away any uncut bottom.

Cone-Shell Thickness

Cone-shell thickness is of crucial importance from a strength standpoint. Insufficient shell thickness can result in cone failure and loss of downhole components. Varying shell thicknesses are used for different bit types, but design engineers always adhere to established minimum values (Figure 4.7.9).

Bearings Factors

In operation, radial loads are supported by the outer and inner bearings. The primary function of the ball bearings in roller cone bits is to secure cones to leg journals; under certain loadings, however, ball bearings can also help resist thrust loading although this is not their purpose (Figure 4.7.10).

Design criteria for roller cone bit bearing structures are critical. Bearings must routinely withstand extremely high values of unit and impact loading. Under the most adverse loading and lubrication conditions, bearing life is expected to exceed that of the inserts. Correct physical proportions for a cutting structure must be established to achieve this. Within the limited space available, overly large roller and ball bearings necessitate reduced journal diameters. This condition decreases wear life of the journal and increases its potential for fatigue failure. Conversely, excessive journal diameters require the use of smaller rollers and balls that will fail more readily under compression loads.

Length-to-diameter ratios of bearing rollers must fall within engineered limits. Rollers that do not have proper proportions tend to skew in their race or fail from beam loading. Roller and ball race flange thicknesses must be adequate to eliminate failure under the severest conditions. Balance between these elements must be maintained to prevent excessive wear or premature failure by one of them.

FIGURE 4.7.9 Failed cone shell.

FIGURE 4.7.10 Typical roller bearing system.

Conversely, the number of inserts or teeth must be few enough so that, when worn, sufficient unit force can still be applied to cause bit penetration.

Relatively larger bearings can be installed in hard formation bits because their shorter inserts or teeth consume less available cone space. Increased bearing size enables

bearings to withstand the larger weights on bit required to drill hard formations.

4.7.1.1.3 Design as Applied to Cutting Structure

To this point, fundamentals of roller cone bit design common to all bit types have been discussed. The design of a bit for use in a specific category of formations requires the application of additional design factors, including

- Journal angle and offset values
- Rolling characteristics of the cones
- The effect of insert or tooth depth on bearing-structure size

The application of these design factors is best exemplified by comparison of two illustrations (Figure 4.7.11). The cutting structure on the left is designed for the softest formation types, that on the right for formations that are harder.

The action of bit cones on a formation is of prime importance to achieving a desirable penetration rate and other performance attributes. Soft-formation bits require a gouging-scraping action. Hard-formation bits require

FIGURE 4.7.11 Cutting structure for soft (left) and hard (right) formations.

a chipping-crushing action. These actions are primarily governed by the degree to which the cones roll and the degree to which they skid. Maximum gouging-scraping (soft-formation) actions require a significant amount of skid. Conversely, a chipping-crushing (hard-formation) action requires that cone roll approaches the “true roll” condition and skids very little.

For soft formations, a combination of the smallest journal angle, largest offset angle, and greatest variation in cone-profile angles. These develop a cone action that skids more than it rolls. Conversely, hard formations require a combination of the largest journal angle, no offset, and least variation in the cone profile. These will result in a cone action that closely approaches true roll with no skidding (Figure 4.7.12).

Relationships of Bearing Size, Insert or Teeth Dimensions, and Cone Shell

Cone insert or tooth length (the two are not exactly the same but have the same effect) affects bearing-structure size. Insert length describes the required shell thickness value for the drilled hole in which an insert is supported. Within the confine of available space, longer teeth are achieved by reducing cone shell thickness.

Soft-formation bits require the use of longer inserts or teeth. This usually requires an offsetting reduction in bearing-structure size. Viewed from the opposite perspective, the size of required cone and bearing structures can be a limiting factor for insert or tooth length. Hard-formation bits require shorter inserts or teeth. In this case, space

available will permit incorporation of relatively larger bearing structures.

Inserts or Teeth and the Cutting Structure

Because formations are not homogeneous, sizable variations exist in their drillability and have a large impact on cutting structure geometry. For a given WOB, wide spacing between inserts or teeth results in improved penetration and in relatively higher lateral loading on the inserts or teeth. Closely spacing inserts or teeth reduces loading at the expense of reduced penetration. The design of inserts and teeth, themselves, depends largely on the hardness and drillability of the formation. Penetration of inserts and teeth, cuttings production rate, and hydraulic requirements are interrelated as shown in Table 4.7.1.

Formation and cuttings removal impact cutting structure design. Soft, low compressive strength formations require long, sharp, and widely spaced inserts or teeth. Penetration rate in this type of formation is partially a function of insert or tooth length and maximum insert or tooth depth must be used. Limits on the magnitude of maximum insert or tooth length are dictated by minimum requirements for cone-shell thickness and for bearing-structure size. Insert or tooth spacing must be sufficiently large to ensure efficient cleaning and cutting removal.

Requirements for hard, high-compressive-strength formation bits are usually the direct opposite of those for soft-formation types. Inserts are shallow, heavy, and closely spaced. Due in part to the abrasiveness of most hard formations and, in part, to the chipping action associated

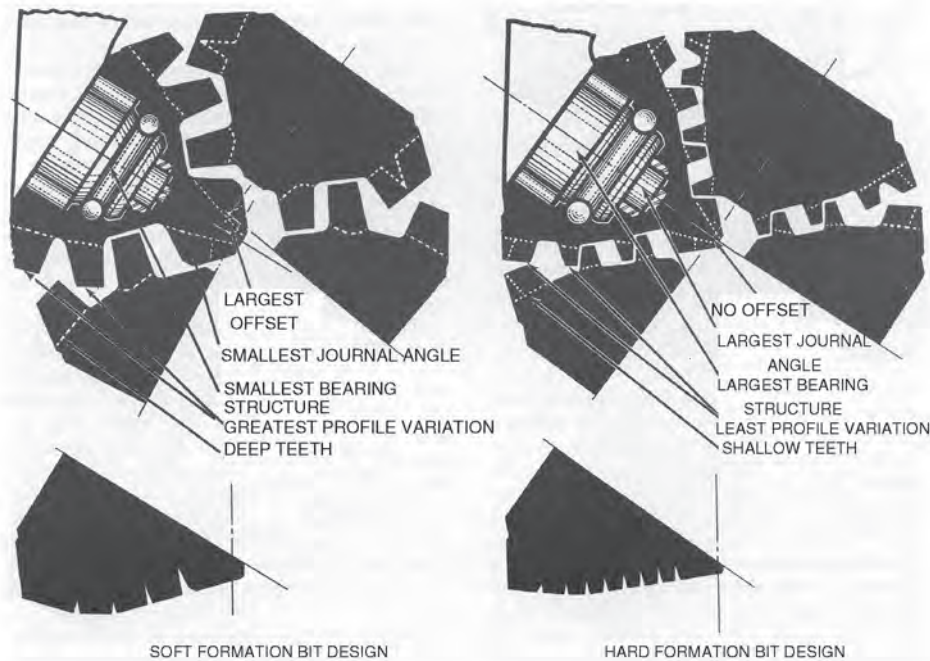

FIGURE 4.7.12 Cutting structure for soft (left) and hard (right) formations.

TABLE 4.7.1 Interrelationship between Inserts & Teeth, Hydraulic Requirements and the Formation

Formation Characteristics	Insert/Tooth Spacing	Insert/Tooth Properties	Penetration & Cuttings Production	Cleaning/Hydraulic Flow Rate requirement
Soft	Wide	Long & Sharp	High	High
Medium	Relatively Wide	Shorter & Stubbier	Relatively High	Relatively High
Hard	Close	Short & Rounded	Relatively Low	Relatively Lower

**FIGURE 4.7.13** Comparison of softer IADC 437X (left) and harder 837Y (right) cutting structures.

with drilling hard formations, the teeth must be closely spaced (Figure 4.7.13). This distributes loading widely to minimize insert or tooth wear rates and limit lateral loading on individual teeth. At the same time, inserts are stubby and milled tooth angles large to withstand heavy WOB loadings required to overcome high formation compressive strength. Close spacing often limits the size of inserts or teeth.

In softer and, to some extent, medium hardness formations, formation characteristics are such that provisions for efficient cleaning require careful attention from designers. If cutting structure geometry does not promote cuttings removal, bit penetration will be impeded and force the rate of penetration to decrease. Conversely, successful cutting structure engineering encourages both cone shell cleaning and cuttings removal.

Variations in downhole conditions and operating limitations often require use of different bit types even though drillability of the formations may be similar. Crooked-hole problems, for example, generally necessitate use of reduced WOB and higher rotary speeds. A different bit type may be required from that for the same formation under conditions that permit heavier weight and lower rotary speed. Weight on bit or rotary-speed limitations imposed by other factors would have a similar effect on the bit-type requirements. Knowledge of these design factors and their application to specific bit types is important to making productive bit choices.

The Mechanics of Roller Cone Bit Design

Modern roller cone bit design requires sophisticated engineering software tools. Such tools integrate many separate design and manufacturing related functions including CAD/CAM, preparation of bills of material, and error checking. These rely extensively on three dimensional modeling that allows the design engineer to flexibly and efficiently construct very complex assemblies. Software also has the capability to evaluate models against existing standards and to add new features to existing standards. Models can be structurally evaluated using advanced simulation methods such as Finite Element Modeling and software verifies that parts, assemblies, and drawings comply with established modeling standards and design practices. All of this takes place in a single, seamless environment (Figure 4.7.14).

1. Structural Analysis

Product evaluations, under static and dynamic conditions are conducted by design engineers. This is done to ensure operational safety, as well as product reliability and efficiency, from structural and vibrations perspectives.

Separately, finite element solutions for solid models automatically mesh with design environments or according to specifications (Figure 4.7.15). These allow interactive refinement that enables designers to quickly evaluate

FIGURE 4.7.14 Three dimensional engineering modeling.

FIGURE 4.7.15 Finite element modeling.

different configurations under a variety of environmental and geometric conditions.

Computational Fluid Dynamics

Computational Fluid Dynamics is also closely integrated with modern engineering software tools to provide simulation of drilling fluid flows around the bit. Some software incorporates fluid flow simulation into the design process (Figure 4.7.16). As parts or assemblies are being designed, engineers can perform simulations directly into the geometry created in their CAD system. The need for physical prototype testing is greatly reduced by these hydraulic tools. Physical testing produces only “go or no-go” answers, whereas software provides analytical insight. Modern tools increase flow efficiencies for drilling fluids and lower the cost of hydraulic engineering relative to empirical methods used in the relatively recent past.

Advanced Engineering Methods

Bit design is undergoing very rapid evolution. The refined products of modern engineering tools, are being linked to practical expertise and formal scientific research regarding materials, geometries, hydraulic performance, and operating conditions in the environment of real formations. This real world approach is suggesting a great number of exceptionally efficient, innovative roller cone bit design solutions such as that shown in Figure 4.7.17.

An example of advanced engineering methods used by a leading bit manufacturer has several steps:

1. Identify and obtain samples of rock in which drilling will take place.
2. Under conditions that duplicate drilling by simulation (downhole confining pressure, WOB, and rotation speed), measure penetration and abrasive characteristics of the rock.
3. Under conditions that duplicate drilling in a hydraulics simulator (Flow and nozzle arrangements) measure hydraulic characteristics of cutting removal and bit cleaning properties.
4. Process mechanical testing data with proprietary software to deliver bit design outputs. This research method predicts rate of penetration at a given rotary speed, optimal WOB, and rock formation properties. By its use, bit profile design; bottom-hole pattern; insert or tooth sharpness, shape, and counts; journal angle; and, required cone offset can all be optimized.

4.7.1.1.4 Materials Design

Materials properties are a crucial aspect of roller cone bit performance. Components must be resistant to abrasive wear, erosion, and impact loading. Metallurgical characteristics such as heat treatment properties, weldability,

FIGURE 4.7.16 Computational fluid dynamics.

FIGURE 4.7.17 Bit designs.

capability to accept hardfacing without damage, and machineability all figure into the eventual performance and longevity result for a bit. Physical properties for bit components are contingent on the raw material from which the component is made, the way that material has been processed, and of the type of heat treatment that has been applied to it. Steels employed in roller cone bit components are all melted to exacting chemistries, cleanliness, and interior properties. All are wrought because of grain structure refinements obtained by the rolling process.

Most manufacturers begin with forged blanks for both cones and legs because of further refinement and orientation of microstructure that results from the forging process.

Material specifications for legs and cones are different. Structural requirements and the need for abrasion or erosion resistance are different for legs and cones. Further, different sections of a component often require different physical properties. Leg journal sections, for example, require high hardenabilities that resist wear from bearing loads whereas the upper portion of legs are configured to provide high tensile strengths that can support large structural loads.

Legs and cones are commonly made for forged blanks. Forgings have superior metallurgical structures compared with those for components machined from wrought stock. The forging process increases metal density and orients metal grain structure to result in optimal load-bearing capabilities (Figure 4.7.18). Forgings are manufactured

FIGURE 4.7.18 Wrought-vs-forged grain structure.

FIGURE 4.7.19 Roller cone bit leg forging (three required).

from wrought materials, whose properties were previously described.

Roller cone bit legs and cones are manufactured from low alloy steels. Legs are made of a material that is easily machinable before heat treatment, is weldable, has high tensile strength, and is capable of being hardened to a relatively high degree. Cones are made from materials that can be easily machined when soft, are weldable when soft, and can be case hardened to provide resistance to abrasion, and erosion (Figure 4.7.19).

4.7.1.1.5 Inserts and Wear-Resistant Hardfacing Materials

Tungsten carbide is one of the hardest materials known to man. This hardness makes it extremely useful as a cutting and abrasion resisting material for roller cone bits. The compressive strength of tungsten carbide is much greater than its tensile strength. It is a material whose usefulness is to be gained only within design arrangement that ensure compressive loading while protecting against shear and tension. Tungsten carbide bearing inserts are the most popular material for drill bit cutting elements. Hardfacing materials containing tungsten carbide grains are the standard for protection against abrasive wear on bit surfaces.

When most say “tungsten carbide,” they do not refer to the chemical compound (WC), but rather to a sintered composite of tungsten carbide grains imbedded in and metallurgically bonded to a ductile matrix, or binder phase. Such materials are included in a family of materials called *cermets* or *ceramic-metal*. Binders support tungsten carbide grains and provide tensile strength. Because of binder, cutters can be formed into useful shapes that orient tungsten carbide grains so they will be loaded under compression. Tungsten carbide cermets can also be polished to a very smooth finish that reduces sliding friction. By control of grain size and binder content, the hardness and strength of these materials can be tailored to yield optimal properties for individual applications.

The most common binder metals for use with tungsten carbide are iron, nickel, and cobalt. These materials are related on the periodic table of elements and have an affinity for tungsten carbide (cobalt has the greatest affinity). Tungsten carbide cermets normally have binder contents in the range 6% to 16% by weight. Because tungsten carbide grains are metallurgically bonded to the binder, there is no porosity at boundaries between the binder and grains of tungsten carbide and the cermet is less subject to damage by shear and shock.

4.7.1.1.6 Properties of Tungsten Carbide Composites

The process of designing cermet properties makes it possible to exactly match a material to the requirements for a given drilling application. Tungsten carbide particle size (normally 2 to 6 μm), shape, and distribution and binder content (as a weight percent) affect composite material hardness, toughness, and strength. Generally, increasing binder content for a given tungsten carbide grain size causes the hardness to decrease and fracture toughness to increase. Conversely, increasing tungsten carbide grain size affects hardness and “toughness.” Smaller tungsten carbide particle size and reducing binder content produces higher hardness, higher compressive strength and better wear resistance. In general, cermet grades are developed in a range in which hardness and toughness vary oppositely with changes in either particle size or binder content. In any case, subtle variations in tungsten carbide content, size, distribution, and porosity can markedly affect material performance (Figure 4.7.20).

The photomicrograph (Figure 4.7.21) shows a magnified, polished section of a tungsten carbide, with cobalt binder. The tungsten carbide grains in the photomicrograph appear as trapezoids and triangles. Average grain size is nominally 5 μm with a binder content of 10% by weight.

FIGURE 4.7.20 Hardness, toughness, and wear resistance of cemented tungsten carbide.

FIGURE 4.7.21 Photomicrograph of a WC-Co composite.

Dual-Composite (DC) Tungsten Carbide Inserts

DC tungsten carbide is a new class of carbide that improves fracture toughness limitations associated with conventional tungsten carbide grades. The material is characterized by large tungsten carbide particles that are manufactured in a multi-stage process and by a microstructure that is more homogeneous than conventional cemented tungsten carbides. DC tungsten carbide increases fracture toughness by as much as 50% over tough, cemented tungsten carbide grades without affecting wear performance and, in some cases, have improved both toughness and wear resistance.

DC tungsten carbide maximizes fracture toughness by increasing mean separation between tungsten carbide particles. This results in a more homogenous distribution of tungsten carbide particles and a larger amount of the toughness providing cobalt binder around and between adjacent tungsten carbide composite granules. Wear improvement results from the large tungsten carbide grains. Because of the toughness and thermal conductivity of binder content in DC carbides, they have superior resistance to thermal

damage. This combination of properties is well suited to high ROP drilling in soft to medium formations [5–7].

Diamond-Enhanced Tungsten Carbide Inserts

Diamond-enhanced inserts (DEI) are frequently used to prevent wear in the highly loaded, highly abraded gage area of bits or in all insert positions if drilling conditions are difficult. They are composed of polycrystalline diamond compact (usually called PDC), which is chemically bonded, synthetic diamond grit supported in a matrix of cemented tungsten carbide. PDC has both higher compressive strength and higher hardness than cemented tungsten carbide. Diamond materials are largely unaffected by chemical interactions with rock and are less sensitive to heat than cemented tungsten carbides. These properties make it possible for diamond-enhanced materials to function normally in drilling environments in which cemented tungsten carbide grades deliver disappointing or unsatisfactory results (Figure 4.7.22) [6, 7, 9].

When designing diamond-enhanced inserts, incorporation of higher diamond densities increases impact resistance and ability to economically penetrate abrasive formations. As would be expected, increasing diamond density increases insert cost. In the past, diamond-enhanced inserts have been available only in symmetric shapes. The first of these was the semi-round top insert. Today, some manufacturers have developed processes that make it possible to produce complex, diamond-enhanced insert shapes.

Cellular Diamond Inserts

Cellular diamond is an innovative new insert material that places exceptionally high diamond densities at the work point of an insert. Cellular diamond is a polycrystalline diamond compact organized in long strand-like cells (Figure 4.7.23). It has a honeycomb structure when viewed from the end that can be seen without magnification. The interior of the cells is composed of diamond grit in a tungsten carbide cermet matrix. Boundaries between cells

Comparison of Diamond, Polycrystalline Diamond, and Tungsten Carbide Materials					
	Knoop Hardness (Kg/mm ²)	Coefficient of Friction	Coefficient of Thermal Expansion (10 ⁻⁴ /°C)	Density (g/cm ³)	Fracture Toughness (Kic)
Tungsten Carbide (6% Co)	1475	0.2	4.3–5.6	14.95	10.8
Polycrystalline Diamond, (PCD)	5000–8000	0.08–0.15	1.5–3.8	3.80–4.10	6.1–8.9
Natural Diamond	6000–9000	0.05–0.10	0.8–4.8	3.52	3.4

FIGURE 4.7.22 Comparison of DEI and WC+Co Properties.

FIGURE 4.7.23 Cellular diamond microstructure.

FIGURE 4.7.24 Pitted cellular diamond insert showing crack inhibition.

are cemented tungsten carbide. The columnar nature of cellular diamond inhibits the propagation of cracking.

A particular advantage of cellular diamond material is that its geometry and structure can be engineered and scaled for particular applications. For example, complex insert shapes that previously could not have been diamond enhanced now are protected by cellular diamond [6].

If there is local damage to a cellular diamond insert, the nature of the cellular structure inhibits formation of cracks, resulting only in localized pitting. Similar damage to tungsten carbide inserts would eventually lead to their failure (Figure 4.7.24). Pitting does not have significant adverse effects on insert performance and does not cause insert failure.

As expected of a diamond-enhanced insert, resistance to abrasion is far superior to that for tungsten carbide. Figure 4.7.25 shows a comparative dull test bit that employed both diamond-enhanced tungsten carbide and cellular diamond gage inserts in a difficult environment.

Tungsten Carbide Hardfacing

Hardfacing materials are designed to provide wear resistance (abrasion, erosion and impact), for the bit. To be effective, they must be resistant to loss of material by flaking, chipping, and bond failure with the bit and are designed with these structural requirements in mind, as well. Hardfacing is used to provide wear protection on the lower (shirttail), area

FIGURE 4.7.25 Comparative cellular diamond performance on a failed experimental dull.

of all roller cone bit legs, and as a cutting structure material on milled tooth bits (Figure 4.7.26).

Hardfacing is most commonly, manually deposited by oxyacetylene welding. A hollow steel tube containing appropriately sized grains of tungsten carbide is held in a flame until the steel rod melts and bonds through surface

FIGURE 4.7.26 Typical hardfacing applications.

melting with the bit feature being hardfaced. In the process, tungsten carbide grains flow as a solid, with melted steel from the rod, onto the bit. The steel solidifies around the tungsten carbide particles, firmly attaching them to the bit.

4.7.1.1.7 Cutting Structure Design

Principals

Roller cone bits drill soft formations differently than hard formations. Soft formations are drilled by penetration of the insert or tooth followed by a prying action as the cutting element is rotated during cone revolution. Cuttings from deeply penetrated, soft formations are large and the volume of cuttings produced is high, and rate of penetration is high. Hard formations are difficult to penetrate with available weights on bit and insert or tooth structures appropriately sized for use in roller cone bits. To overcome these problems, hard structures are drilled with blunt inserts or teeth that crush rather than penetrate the formation. Chips are small, volume of cuttings is small, and rate of penetration is low.

Inserts or teeth for soft and hard formation drilling are as different as their means of drilling suggest. Soft formation inserts or teeth are as long as available space permits. The limit for external length is established later the point at which interferences with adjacent cones or cutting structures would occur. Soft formation inserts are desirably

sharp. There are limits on sharpness as well, of course. There must be sufficient structure to ensure reasonable expectations for insert or tooth life. In this regard, use of inserts can result in a relatively sharper cutting structure than milled teeth. In any event, the extent of sharpness and the rate of penetration it promises are a compromise with requirements for bit life, limitations on tripping, and other operational factors.

Hard formation inserts or teeth are primarily designed with only structural considerations in mind. They have blunt profiles that can withstand large, crushing loads. These loads are decreased through use of a relatively higher number of inserts or teeth to focus WOB on the largest possible number of inserts. Dome-shaped inserts, often of compression- and abrasion-resistant diamond-enhanced materials, withstand these punishing conditions and are the preferred choice for extreme conditions. [Figure 4.7.27](#) compares soft and hard formation cutting structures.

Tungsten Carbide Insert Design

The design of tungsten carbide inserts takes the properties of both tungsten carbide materials and the geometric efficiency for drilling of a particular rock formation into account. Softer materials require geometries that are long and sharp to encourage rapid penetration. Impact loads are low but abrasive wear can be high. Hard materials are drilled more by a crushing and grinding action than by penetration. Impact loads and abrasion can be very high. Tough materials, such as carbonates, are drilled by a gouging action and can sustain high impact loads and high operating temperatures. Variations in the way that drilling is accomplished, and rock formation properties govern the shape and grade of the correct tungsten carbide inserts to be selected.

The shape and grade of tungsten carbide inserts is influenced by their respective location on a cone. Inner rows of inserts function differently from outer rows. Inner rows have relatively lower rotational velocities about both the cone and bit axes. As a result, they have a natural tendency to gouge and scrape rather than roll. Inner insert rows generally use softer, tougher insert grades that best withstand crushing, gouging, and scraping actions. Gage inserts are commonly constructed of harder, more wear resistant grades that best withstand severe abrasive wear. It can be seen that as requirements at a specific bit location dictate, the designer must be prepared to provide different solutions. Fortunately, a large range of insert geometries, sizes, and grades through which bit performance can be optimized are available ([Figure 4.7.28](#)) [11].

Gage Cutting Structure

The most critical cutting structure feature is the gage row. Gage cutting structures must cut both the bottom of the hole and its outside diameter. Because of the severity of gage demands on a bit, both milled tooth and insert type bits can

FIGURE 4.7.27 Soft and hard formation cutting structures.

FIGURE 4.7.28 Insert types.

employ tungsten carbide or diamond-enhanced inserts on the gage. Under abrasive conditions, severe wear or gage-rounding is common, and at high rotary speeds, the gage row can experience temperatures that lead to heat checking, chipping, and eventually breakage.

Special Cutting Structure Features

Special cutting features include heel row cutters and ridge cutter inserts.

Heel Row Cutters

The high rotary speeds and side-loading forces generated by steerable systems can cause bits to prematurely become under gage. To counteract this, specially shaped tungsten carbide side-cutting chisel elements keep the bit in-gage longer without interfering with the steerability of the bit. In unusually abrasive conditions, use of semi-round top diamond-enhanced inserts on the heel minimize wear and ensure full gage holes. All insert bits and many milled tooth bits employ tungsten carbide or diamond-enhanced inserts on the heel (Figure 4.7.29).

Ridge Cutter Inserts

When drilling soft formations with insert type bits, it is fairly common to have uncut ridges develop between cutter rows. Ridges can become sufficiently high that they

FIGURE 4.7.29 Typical heel row inserts.

contact the bit cone impeding penetration and causing abrasive wear. Cutting structures intended for use in soft drilling environments commonly employ ridge cutter inserts to break up ridges that might develop. Ridge cutters are small inserts located between the principal cutter rows (Figure 4.7.30).

4.7.1.1.8 Hydraulic Features

Nozzles, Bosses, and Flow Tubes

Drilling fluids circulate through a drill string to nozzles at the bit and back to a reserve pit via the system annulus. They provide three crucial functions to drilling: cleaning

FIGURE 4.7.30 Ridge cutter application.

the cutting structure, cuttings removal from the hole bottom and efficient cuttings evacuation. The hydraulic energy that causes fluid circulation is one of only three variable energy inputs (WOB, rotary speed, and hydraulic flow), available on a drill rig for optimization of drilling performance.

Many roller cone bit options such as nozzle selection, flow tubes, vectored flow tubes, and center nozzle ports help optimize hydraulic performance. These hydraulic features give alternatives to drilling operators for precise placement of hydraulic energy according to needs at the well bottom.

Generating cuttings is the first step needed to achieve high penetration rates; cleaning cuttings from the cone and from the hole bottom and lifting them through the annulus to the rig reserve pit is the remaining part of a hydraulic solution. Computer modeling supported by laboratory testing is the most common approach to development and verification of hydraulic designs. Efficient velocity profiles deliver hydraulic energy where it is most needed, particularly in cases in which drilling flow rates are compromised.

Normally, several different nozzles can be interchangeably used with the provided boss size on a particular bit. Nozzles are commonly classified into standard, extended, and diverging categories (Figure 4.7.31). Extended nozzles release the flow at a point closer than standard to the hole bottom. Diverging nozzles release flows in a wider than normal, lower velocity stream. They are primarily designed for use in center jet installations [10].

Extended Nozzles

Extended nozzles reduce flow dissipation, increase flow velocity at the impingement point, and increase hydraulic energy delivered to the well bottom. Higher impingement pressures help dislodge cuttings from the bottom and move them away from the bit. Higher velocity fluids are less likely to entrain surrounding fluids and to pull them back into the

FIGURE 4.7.31 Typical standard, diffused, and extended nozzles showing a steel retainer and tungsten carbide wear insert.

cones. This minimizes cuttings regrind and improves rates of penetration. Extended nozzles are particularly useful in marginal hydraulic environments and high overbalance applications.

Flow Tubes

Flow Tubes are extended nozzle tubes designed for use in high flow applications of up to 300GPM per nozzle. They are either welded attachments or are directly incorporated into bit leg forgings. Flow tubes accept both standard and extended nozzles and improve overall hydraulic efficiency by placing flow discharge energy nearer to the hole bottom. Flow tubes are particularly useful for directional wells in which hydraulic performance is critical. Flow tubes generally increase bit life by reducing abrasive wear from cuttings regrind and can be used in conjunction with most nozzles (Figure 4.7.32).

Vectored Flow Tubes

Vectored flow tubes are a generally available option. Vectored flows discharge, at an angle to bit centerline, onto the preceding cone face to enhance cone cleaning. They are

Flow Tube
with extended Nozzle

FIGURE 4.7.32 Flow tube.

particularly beneficial in intervals with sticky formations or in motor runs in which available hydraulic energy at the bit is limited (Figure 4.7.33).

Diverging Nozzles

Diverging nozzles spread the fluid stream as it leaves the nozzle. Cross-sectional area at the discharge orifice is increased to cause the flow rate to decelerate into a wide,

low velocity spray. Dispersed, low pressure center nozzle flows improve cone cleaning in the cone apex areas and reduce tendencies toward bit balling without increasing potential for cone shell erosion. Dispersed center flows can also contribute to reductions in the loss of nose and middle row inserts by improving insert cleaning in the cone apex area.

For maximum benefit of a diverged center flow, approximately 20% of total hydraulic flow should be programmed through the center jet; 10% or less is generally too little to be effective while 30% or more erodes the cone area excessively.

Center Nozzles

Center nozzles are installed on the vertical centerline of a bit to provide a discharge onto the apex area of the three roller cones and enhance cone cleaning. Center nozzles are typically standard equipment on bit larger than 16 in.

Blank Nozzles

A plug that is used to close or block a fluid discharge port on a roller cone bit. Blank nozzles are threaded and can be field installed. They are typically used to create cross-flow configurations in bit nozzling.

Asymmetric Nozzle Configurations and Cross-flow

A bit has a symmetric nozzle configuration when three nozzles, at the same level on the periphery of a bit, of the same size and type are installed 120° to each other. A bit with an asymmetric nozzle configuration has at least two different nozzle sizes or types installed around the periphery of the bit.

When the fluid from a nozzle impinges on the well bottom, it moves away from the point of impingement in a 360°, fanlike spray. A boundary is formed where the fluid from two different jets meet. The fluid at these boundaries creates stagnant zones known as *dead zones*. In the case of a symmetric nozzle configuration, dead zones occur under the middle part of the cones (Figure 4.7.34). In an asymmetric

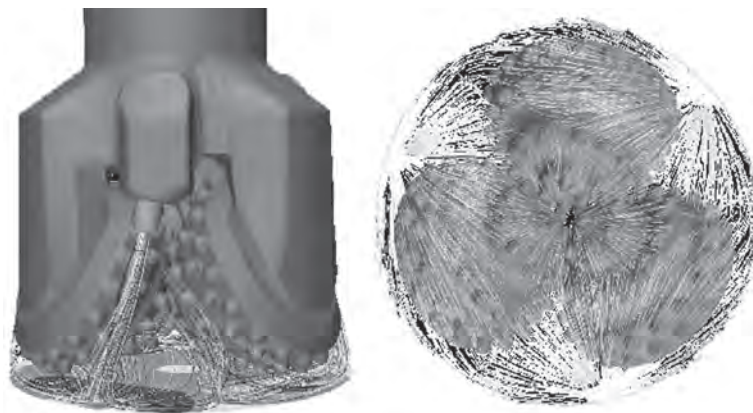

FIGURE 4.7.33 Vectored flow tube.

FIGURE 4.7.34 Symmetric and asymmetric flow.

nozzle configuration, the dead zones move away from the impingement zone of the larger jet and toward that of the smaller jet. This has the benefit of moving a stagnation zone away from the middle of the cone. Asymmetric flows ensure that cuttings do not become impounded under a bit causing the inefficiencies of regrind, lower rates of penetration, and erosion wear to the bit.

Cross-flow is a subset of asymmetric nozzle sizing in which one jet is installed with a blank. The blanked side of the bit leaves a natural exit path for the fluid from the opposing two jets. The flow from the remaining two jets sweeps under two of the cones to improve bottom-hole cleaning and chip removal (Figure 4.7.35).

Hydraulic Computation

Hydraulic computation requires a knowledge of hydraulic nomenclature and energy, fluid velocity, and system pressure loss.

Hydraulic Nomenclature:

- A_n = Area of a nozzle (sq in)
- BHCP = Bottom hole circulating pressure (psi)
- C_r = Chip rate (fpm)
- ECD = Effective circulating density (lb/gal)
- d_c = Chip diameter (in) (use 0.25)
- D_h = Hole diameter (in)
- D_j = Diameter of a nozzle (in)
- HSI = Bit hydraulic horsepower (sq in.)
- ID_p = Pipe inside diameter (in.)
- I_f = Jet impact force (lb)
- L = Pipe or hole depth (ft)
- OD_p = Pipe outside diameter (in)
- P_c = Density of a rock chip (lb/gal) use 21
- P = Fluid density (lb/gal)
- PV = Plastic viscosity (cp)
- Q = Flow rate (gpm)
- V_a = Annulus fluid velocity (fpm)
- V_{ca} = Annulus critical velocity (fps)

FIGURE 4.7.35 Cross flow test.

- V_{cp} = Pipe bore critical velocity (fps)
- V_p = Pipe bore fluid velocity (fpm)
- V_n = Jet velocity (fps)
- V_s = Slip rate (fpm)
- YP = Yield Point (lb/100 ft.)
- ΔP_a = Annulus pressure loss (psi)
- ΔP_b = Jet nozzle pressure loss (psi)
- ΔP_p = Bore pressure loss (psi)
- μ = Bingham plastic effective viscosity (cp)

Hydraulic Energy

Energy is the rate of doing work. A practical aspect of energy is that it can be transmitted or transformed from one form to another; for example from an electrical form to a mechanical form by a motor. A loss of energy always occurs during transformation or transmission. In drilling fluids, energy is called hydraulic energy or, commonly, hydraulic horsepower.

The basic equation for hydraulic energy is

$$HHP = \frac{(P)(Q)}{1714} \tag{4.7.1}$$

in which

HHP = Hydraulic horsepower

- P = Pressure (psi) (or kPa)
- Q = Flow rate (gal/min) (or L/min)
- 1714 = Conversion of (psi-gal/min) to HHP
(or kPa – L/min) = 44,750

Rig pumps are the source of hydraulic energy carried in the drilling fluids. This hydraulic energy is commonly called the total hydraulic horsepower or pump hydraulic horsepower.

$$HHP_t = \frac{(P_t)(Q)}{1714} \tag{4.7.2}$$

in which

- HHP_t = Total hydraulic energy (hydraulic horsepower)
- P_t = Actual or theoretical rig pump pressure (psi)

See prior equation for metric conversion.

The rig pump pressure (P_t) is the same as the total pressure loss or the system pressure loss. HHP_t is the total hydraulic energy (rig pump) required to counteract all the friction energy (loss) starting from the Kelly hose

(surface line) and Kelly, down the drill string, through the bit nozzles, and up the annulus, at a given flow rate (Q).

Bit hydraulic energy is the energy needed to counteract frictional energy (loss) at the bit, or can be expressed as the energy expended at the bit.

$$HHP_b = \frac{(P_b)(Q)}{1714} \quad (4.7.3)$$

See prior equation for metric conversion.

Fluid Velocity

The general formula for fluid velocity is

$$V = \frac{Q}{A} \quad (4.7.4)$$

in which

- V = Velocity (ft/min) or (m/min)
- Q = Flow rate (gal/min) or (L/min)
- A = Area of flow (ft²) (or m²)

The average velocity of a drilling fluid passing through a bit’s jet nozzles is derived from the fluid velocity equation:

$$V_j = \frac{(0.32086)(Q)}{A_n} \quad (4.7.5)$$

in which

- V_j = Average jet velocity of bit nozzles (ft/sec) (or m/sec)
- A_n = Total bit nozzle area (in²) (or cm²)

Nozzle sizes are expressed in 32nd of an inch (inside diameter) increments. Examples are 9/32 in. and 12/32 in. The “32nd” is usually not mentioned, but understood to be in 32nd of an inch. For example, 9/32-in. and 12/32-in. nozzle sizes are, respectively, expressed as 9 and 12.

The impact force of the drilling fluid at velocity (V_{j1}) can be derived using Newton’s Second Law of Motion, force equals mass times acceleration. Assuming all the fluid momentum is transferred to the bottom of the hole:

$$I_j = (0.000518)(MW)(V_j) \quad (4.7.6)$$

in which

- I_j = Impact force of nozzle jets (lb of force) (or k)
- MW = Mud weight (lb/gal) (or kg/L)
- Q = Flow rate (gal/min) (or L/min)
- V_j = Average jet velocity from bit nozzles (ft/sec) (or m/sec)

System Pressure Loss

Pressure losses inside the drill string basically result from turbulent conditions during drilling. Viscosity has very little effect on pressure losses in turbulent flow. At higher Reynolds numbers, a larger variation results only in a small variation in the friction factor. The calculated pressure loss equations are based on turbulent flow and are corrected for mud weight instead of viscosity.

$$\Delta P = P_b = \frac{(MW)(Q)^2}{(10858)(A_n)^2} \quad (4.7.7)$$

in which

- A_n = Total combined area of the bit nozzles (in.²) (or cm²)
- MW = Mud weight (lb/gal) (or kg/L)
- P_b = Bit nozzle jets pressure loss (psi) (or kPa)
- Q = Flow rate (gal/min) (or L/min)

Practical Hydraulic Guidelines

The following table is a summary of accepted, starting hydraulics configurations (Table 4.7.2).

4.7.1.2 *Roller Cone Bit Components*

4.7.1.2.1 **Bearing, Seal, and Lubrication Systems**

Roller cone bearing systems are designed to be fully operational when the cutting structure of the bit is worn out. To achieve this standard of bearing performance, modern goals for seal and bearing system life are for a million or more revolutions of a bit without failure, compared with 500,000 or fewer revolutions in the recent past. To achieve these advances, there is a major concentration of research into bearing, seal, and lubricant designs and into materials that can improve seal and bearing life.

TABLE 4.7.2 Rules of Thumb for Optimization of Roller Cone Bit Hydraulic Performance

1. Use mini-extended nozzles except in severe balling conditions.
2. Use asymmetric nozzle configurations.
3. Configure nozzles for cross flow.
4. Re-evaluate and optimize hydraulics as applications and equipment change.
5. Design the hydraulic program to address requirements of key lithologies in the bit run.
6. Run center jets in sediments that have bit balling tendencies.
7. Use diffusing center-jets to minimize cone erosion and fluid wash.

Roller cone bits primarily use two types of bearings: roller bearings, and, journal bearings (sometimes called friction bearings). Each type is normally composed of a number of separate components, including: primary bearings, secondary bearings, seal system, features that resist thrust loading, cone retention balls, and the lubrication system (Figure 4.7.36).

FIGURE 4.7.36 Roller bearing features.

Primary bearings, the main load-bearing component, are normally as large as possible within the limits of available space. Secondary bearings are smaller, reduced diameter, bearings located adjacent to the apex area of a cone. Secondary bearings provide additional load-bearing capability in an area too small in diameter for the primary bearings. Primary and secondary bearings can be roller bearings or journal bearings. It is common for a bearing system to be composed of combinations of the two, such as a primary roller bearing and secondary journal bearing.

Seals prevent the entrance of cuttings and drilling fluids into the bearing system and prevent lubricant from escaping the bearing system. Thrust washers are located on the end of leg journals and between the primary and secondary bearing surfaces to resist axial loading. Most roller cone bits incorporate what appears to be a ball type bearing. This is the cone retention locking system rather than a bearing. The bearing balls are the bit feature that retains cones on their mating journals. The lubrication system contains the stock of lubricant that will, throughout the life of the bearing system provide lubrication to bearings and seals. Each of these features is described in more detail later.

Roller Bearing Systems

Roller bearings are a common bit bearing system because they can reliably support large loads and generally perform well in the drilling environment (Figure 4.7.37).

FIGURE 4.7.37 Typical roller bearing arrangement.

To enhance bearing life, leading manufacturers continually research bearing materials, sizing and shape. Bearing rollers tend to be loaded more at the ends than in the middle. This tends to cause spalling at the static contact point. To avoid damage from end-loads, rollers are sometimes contoured so the central portion of the roller has a slightly larger diameter than the ends forcing uniform load distribution across the entire roller length. Rollers of this type are called contoured rollers. They lower bearing operating temperatures and reduce bearing fatigue.

Bearings are commonly manufactured to precise roller tolerances (0.0005 in.) ensure uniform load distribution and are in some cases individually matched to increase bearing life. These improve bearing efficiency and help control temperature. Precise tolerances, in conjunction with contoured rollers, significantly increase bearing capacity compared with previous bearing systems, making it possible for bits to function normally under higher weights on the bit and rotary speeds and still provide longer bearing life.

Journal Bearing Systems

Journal bearings consist of at least one rotating surface separated by a film of lubricant. The surfaces are specially designed so that the lubricant film keeps them separated; were they to touch, mating bearing components would gall or possibly even fuse. Journal bearings are generally inexpensive to manufacture and, when functioning properly, are very efficient. A comparison of roller bearing and journal bearing assemblies is presented in Figure 4.7.38.

Hydrodynamic Lubrication

Journal bearings are able to function efficiently and avoid wear because of a hydrodynamically generated film of lubricant that separates the rotating surfaces. The thickness of this lubricant film depends on the following variables:

- Radial clearance between the leg journal and cone
- Radius of the leg journal
- Lubricant viscosity
- Rotational velocity of the cone
- Applied load

So long as the hydrodynamic conditions exist to create a lubricating film between the two rotating surfaces, the life of a journal bearing is virtually limitless. If the film breaks

down for any reason (e.g., high loads, low speeds, low viscosity), the bearing surfaces will come into contact with each other, and a phenomenon called *boundary lubrication* takes place. Film thickness decreases as rotational speed decreases or as bearing loading increases.

In hydrodynamic lubrication, heat generated is a function of lubricant viscosity, applied load, and relative speed between cone and journal. As bearing temperature increases, lubricant viscosity and film thickness decrease creating a potential for journal bearing malfunction. Heat generated varies with the square of the speed. A twofold increase in bearing rotational speed produces a fourfold increase in the generation of heat in the bearings. In larger bits, heat generation can be significant and large bearing design must include provisions for removal of heat from the bearing area.

Boundary Lubrication

Boundary lubrication takes place in a transition between hydrodynamic lubrication and metal-to-metal contact in which there is no lubricant film at all. This transition exists because of surface roughness existing on the journal and cone bearing surfaces.

Peaks in surface roughness are called *asperities*. Asperities exist on all machined surfaces; even mirror finishes do not eliminate microscopic asperities on a bearing surface.

As a hydrodynamic film thins due to speed, load or viscosity, asperities touch and boundary lubrication occurs. The degree to which they can be expected to touch varies. Bearing materials are carefully selected so that damage that will be done to a bearing by asperity interaction is minimized. The surfaces are designed so that a polishing effect is produced and improved, “worn-in” performance results.

In boundary lubrication, heat generated is a function of lubricant film strength, applied load, and the metallurgical properties of the cone and journal surfaces. Rough surfaces generate more heat than those that are smooth, and hard surfaces generate more heat than the soft. As a high pressure lubricating film becomes thinner, asperity interaction increases. Heat generated by boundary lubrication is greater than that generated by hydrodynamic lubrication and will eventually cause bearing failure.

FIGURE 4.7.38 Comparison of journal and roller bearing arrangements.

Design of Journal Bearings

Journal bearings must be designed to provide a balanced bearing geometry, adequate journal strength, and maximize the thickness of the high pressure lubricating film developed during hydrodynamic lubrication. Surface areas, journal and cone diameters, and clearances between journal and cone are factors that affect the thickness of lubricating films (Figure 4.7.39).

The metallurgy of the bearing must be balanced to minimize heat generation during boundary lubrication. Cone-bearing surfaces are steel. Soft, silver-plated, sleeves are installed on the journal. Silver polishes easily and minor surface irregularities from machining are quickly smoothed. This ensures low friction operation, and uniform lubricant flow over the bearing surface.

Manufacturing tolerances must be precise so that surfaces run true to their design condition. Roundness of journal and cone surfaces is important. If any part of a bearing is out of round, the effectiveness of the lubrication regime will be adversely affected.

Journal Bearing Materials

Specifically formulated, high tensile strength and ductile metal alloys are used for journal bearing sleeves and thrust washers (Figure 4.7.40). Tensile strength provides load-bearing and high-rotational-speed capabilities; ductility increases impact resistance. These alloys are specifically designed to minimize the effect of asperity deformation on bearing performance. Surfaces are commonly silver plated because the softness of silver lends itself to smoothing

under asperity deformation. Bearing smoothness encourages hydrodynamic lubrication, resulting low-friction, low-temperature operation and long bearing life.

Open Bearing Systems

Air-cooled, nonsealed roller bearings are commonly used for air drilling applications. When air, gas, or mist is used as a drilling fluid, such as blast hole drilling in open pit mines, nonsealed roller bearing bits are used. Open bearing designs rely on drilling fluid for cooling, cleaning, and lubrication of the bearings. If water is injected into the air or gas, bits are equipped with a water separator to prevent water in contact with loaded bearing surfaces and thereby reduce their life. Backflow valves prevent cuttings suspended in water from backing up through the bit into the drill pipe when the flow of air or gas is interrupted.

Seal Systems

In general, seal systems are classified as either static or dynamic. Roller cone bits use both types of seals. Dynamic seals involve sealing across surfaces that are moving in relationship to one another, as would be the case for a bearing seal. Seal parts or surfaces that do not move in relationship to one another during bit operation, such as the seal between a hydraulic nozzle and the bit to prevent leakage around the joint, are static seals.

Roller cone bearing seals operate in an exceptionally harsh environment. Drilling mud and most cuttings are extremely abrasive. Drilling fluids often contain chemicals, and operating temperatures can be sufficiently high to break down the elastomers from which seals are made. Pulses

FIGURE 4.7.39 Typical journal bearing system.

FIGURE 4.7.40 Typical journal bearing sleeve.

often occur in downhole drilling fluids that apply lateral loading on seals that must be resisted.

Bearing Seals

On a purely practical level, bearing seals have two functions: to prevent foreign materials such as mud, cuttings, chemicals, and water from entering the bearings and to prevent bearing lubricant stocks from escaping the bit.

Visualize the difference in the nature of these two duties. On the interior side, the seal is excluding clean, functional lubricant from escaping the bit, whereas on the exterior side, the seal is excluding dirt and chemicals from penetrating the bit. The separation of these two extremely different functions takes place at a small point between the two sides of a seal. If either of the functions breaks down, the bearings and the bit could be destined for damage or failure. These facts cause most bit manufacturers to aggressively engage in sealing research.

Seal Definitions

In a rotating bearing, two working sides of a seal are respectively called the energizer, and, the dynamic wear face. These two parts are directly opposite, one to the other, with the energizing portion bearing on the gland and the dynamic wear face bearing against the rotating unit. For the energizing portion of the seal to function properly, it must have a surface against which to react. This is provided by a channel called a seal gland.

The wearing portion of the seal must have the capability to withstand the heat and abrasion generated as the rotating surface passes over it. The energizer, when functioning correctly, is not a high wear area. Ideally, it simply bears against the gland and provides the pushing energy that keeps the wear surface firmly in contact with the rotating unit.

O-Rings

Donut-shaped O-rings are used in many roller cone bit applications. O-rings are manufactured from elastomers

(i.e., synthetic rubbers) that withstand the temperatures, pressures, and chemicals encountered in the drilling environment. They are a traditional but still consistently reliable seal system.

An O-ring is installed in a seal gland to form a seal system. The gland holds the O-ring in place and is sized so the O-ring is compressed between the gland and the bearing hub at which sealing is required. This compression, typically 9% to 12% in rock bits, is the sealing force between the gland and hub. It firmly presses the interior wall of the O-ring against the hub and the exterior diameter of the O-ring against the gland. This latter force tends to prevent the seal from turning in the gland and experiencing wear on the outer surfaces from rotating contact with the gland (Figure 4.7.41).

Many roller cone bits use traditional O-ring seal systems. In some cases, O-ring seal efficiency is enhanced by innovative glands, such as a V shape, designed to increase energization entropy as load increases (Figure 4.7.42). The two-point contact between the V-surface and O-ring effectively prevents seal rotation. This arrangement also responds particularly well to the periodic pulse loadings that are often propagated through drilling fluids. If a pulse occurs, in either direction, it moves the O-ring in the direction in which the pulse is moving. As this movement develops, geometry of the V surface causes a wedge-like action against the O-ring that increases seal energization.

Shaped, Bi-material Seals

As with all parts of a modern roller cone bit, new materials and engineered shapes play a large role in seal performance. Different materials are combined to optimize energization and resist seal wear. These would include a highly entropic, soft elastomer to provide energization and a very hard elastomer or polymer fabric in the dynamic wear area. Seal shape is engineered to geometrically optimize energization and wear resistance. The modern seal solution shown later

FIGURE 4.7.41 O-Ring and gland.

FIGURE 4.7.42 O-Ring with modern “V” Type gland.

is shaped so a small contact area on the energization side increases pressure at the point of contact with the gland and prevents undesirable seal rotation. The dynamic wear portion of the seal is a relatively large surface resulting in low pressure on the wear area. This encourages low running temperatures and wear rates (Figure 4.7.43).

Dual-seal systems optimize the two sealing functions, excluding entry of contaminants into the bearing system and preventing loss of lubricant from the system (Figure 4.7.44). The individual seal that prevents contaminant entry is called the secondary seal. As one looks at the seal and bearing system, the secondary seal is the farther of the two seals from the bearings. The seal that prevents system lubricant loss is called the primary seal; it is located closest to the bearing. The design, both shape and composition, of primary and secondary seals is very different. Dynamic wear surfaces for the pair are individually optimized to the different environments in which they work. Because

FIGURE 4.7.43 Cross-section of modern bi-material seal.

FIGURE 4.7.44 Typical dual-seal system.

the cavity between the primary and secondary seals is filled with lubricant under pressure, an added impedance to the entry of foreign solids and fluids into the bearing is introduced. Single seal systems must provide both sealing functions with a single seal.

Twin seals stand up well under cycling and uneven bit loading. Seal integrity is maintained in harsh drilling environments such as high rotational speeds, high weights on bit, high dogleg severity, high mud weights, and deep, hot environments.

Lubrication of Seals

Seals must be lubricated to prevent high wear rates and excessive temperatures that could lead to seal material failures. Lubricant for the bearings also serves to lubricate the seals.

4.7.1.2.2 Lubrication Systems and Lubricants

Lubricants play a vital role in bearing performance. They provide lubrication for both bearings and seals, and they provide a medium for heat transfer away from the bearings. In popular dual-seal bearing systems, lubricant between primary and secondary seals further serves as an additional sealing element by impeding the migration of foreign matter that may penetrate the primary seal. To achieve these functions, lubricants are specially engineered and continually improved. Lubrication systems are engineered to provide reserve storage, positive delivery to the bearing system, capacity for thermal expansion, and pressure equalization with fluids on the bit exterior.

Lubrication systems include a resupply reservoir sufficiently large to ensure availability of lubricant for all lubrication functions throughout the life of the bit. A small positive pressure differential in the system ensures flow from reservoir to bearings. The system is vented to equalize internal and external reservoir pressures. Without equalization, a pressure differential between bit exterior and interior could be sufficient to cause seal damage and bearing failure.

Lubricants

High drilling temperatures and high pressures in the lubrication system, together with the potential of exposure to water and chemicals, require high performance from lubricants. Most bit lubricants are specially formulated. Leading bit manufacturers employ scientists to develop and test lubricants. Superior lubricants are stable to temperatures above 300°F, and many also function normally at temperatures down to about 0°F. They are also hydrophobic (i.e., repel water) and retain their stability if water succeeds in penetrating the bit, and are resistant to chemicals normally found in drilling fluids. Superior lubricants are environmentally safe and do not contain lead additives that have traditionally been included to help resist high pressures.

Lubricant Supply

Roller cone bits typically contain one lubricant reservoir in each leg (Figure 4.7.45). For a three-cone bit there are three reservoirs. Each must have the capacity for sufficient reserves of lubricant for operation of the bearing assembly it serves throughout the bit's life.

Reservoirs are more complex than most would expect. As temperatures in a bit rise, lubricants expand thermally. Some lubrication systems vent over-volumes resulting from thermal expansion to the bit exterior. Better designs, however, include extra capacity in the lubricant reservoir to accept expansion volumes without necessity for loss of lubricant by venting. Reservoirs are also a point at which heat removed from the bearings by means of the lubricant can be dissipated.

Well-designed reservoirs always include pressure relief capacity. Pressure beyond a set point is relieved. An over pressure condition in the reservoir system will cause a

FIGURE 4.7.45 Typical roller cone bit lubricant reservoir.

pressure relief valve to lift and release grease until the undesirable differential pressure is equalized. Such releases are rarely required.

Pressurization, Pressure Equalization, and Relief

The column of drilling fluids and cuttings, contained in a well, exert very high pressures on a bit operating at the well bottom. These high pressures are applied to the seal system. They are resisted by lubricant in the seal and bearing system. At installation, lubricant is at atmospheric pressure and it cannot provide significant resistance to well bottom pressures. Internal lubrication system pressures in well-designed systems accordingly equalize themselves with external bit pressures to prevent seal failure. Equalization is accomplished by two small valves installed in the bit. Seal gap compensation valves equalize any pressure differential that may occur between the primary and secondary seals in dual-seal systems (Figure 4.7.46), and lubricant reservoir dome vent valves. Twin seal systems require a secondary pressure equalization valve that prevents formation of a pressure differential between the seals.

Typical, high-performance lubrication systems establish positive lubricant flows to the bearings. The reservoir is also equipped with a rubber diaphragm open to contact with drilling fluids. When the bit is tripped toward the well bottom, drilling fluid is forced through a small opening in the dome of the bit onto the diaphragm at the hydrostatic pressure of the fluid column. This causes the diaphragm

to deflect inward into the reservoir thereby pressurizing the lubricant. As lubricant is consumed or escapes through the seal system, this pressure causes lubricant to flow to the bearings.

4.7.1.2.3 Protective Features

Design engineers give a good deal of consideration to means by which roller cone bit legs can be protected from abrasive wear. Quality bits are shipped with hardfacing protection in the shirttail area. A number of additional protective features are commonly added, depending on abrasive severity (such as the extremes of horizontal or high angle wells, bent motor subs and housings, formations prone to caving, and inadequate hole cleaning). These include hardfacing on the upper leg, use of flush mounted tungsten carbide inserts in the leg, use of exposed tungsten carbide or semi-round top diamond-enhanced inserts in a variety of patterns, and lug pads equipped with carbide or diamond-enhanced inserts (Figures 4.7.47 and 4.7.48).

4.7.1.3 Special Purpose Designs

4.7.1.3.1 Mono-cone Bits

Mono-cone bits were first used in the 1930s because they have a number of theoretical advantages. In practice, the design has not been broadly used. Bit research, encouraged by advances in cutting structure materials, continues to

FIGURE 4.7.46 Pressure equalization.

FIGURE 4.7.47 Leg protection.

keep this concept in mind because it has the room for extremely large bearings and has a very low cone rotation velocities that suggest potential for long bit life. Although they are of obvious general interest, these are particularly advantageous in smaller diameter bits in which bearing sizing presents significant engineering problems. Mono-cone bits drill efficiently at lower torques than those required by three-cone bits. This combination of characteristics are promising for small diameter bits and for motor driven directional applications (Figure 4.7.49).

Mono-cone bits drill differently from three-cone bits. Drilling properties can be similar to both beneficial crushing properties of roller cone bits and shearing action of PDC bits. Cutting structure research focuses partly on

FIGURE 4.7.48 Typical lug pad with tungsten carbide inserts.

exploitation of both mechanisms encouraged by the promise of efficient shoe drill-outs and drilling in formations with hard stingers interrupting otherwise “soft” conditions.

The design provides ample space to enable nozzle placements for efficient bottom hole and cutting structure cleaning. Ample space also permits the use of large inserts.

Unlike three-cone bits, most mono-cone inserts cut gage. This renders the bit under gage as inserts wear. Modern, ultra-hard cutter materials properties can almost certainly extend insert life and expand the range of applications in which this design could be profitable.

4.7.1.3.2 Two-Cone Bits

Two cone bit designs are another product whose origin lies well into the past. The first roller cone patent, issued in August 1909, covered a two-cone bit. Two cone bits have a reputation for drilling straight wells. As with mono-cone

FIGURE 4.7.49 Mono-cone bit.

FIGURE 4.7.50 Two-cone bit.

bits, two cone bits have available space for larger bearings and rotate at lower speeds than three-cone bits. Bearing and seal life for a particular bit diameter is greater than for a comparable three-cone bit. Two cone bits, while not common, are available and used in special applications (Figure 4.7.50). More importantly, their advantages always keep them in mind for research and incorporation of modern materials into the design could renew interest in them.

The cutting action of two-cone bits similar to that of three-cone bits but the nature of cutting structure geometry is such that fewer inserts simultaneously contact the hole bottom. Penetration per insert is, accordingly, increased providing a particularly beneficial result in applications in which capabilities to place WOB are limited.

The additional space available in two cone designs has several advantages. It is possible to have large cone offset angles that produce increased scraping action at the gage. Space also enables excellent hydraulic characteristics by room for placement of nozzles close to the bottom. It also allows for use of large inserts or teeth that can extend bit life or efficiency.

Two cone bits do have a tendency to bounce and vibrate. This characteristic is especially a concern for directional drilling. This and advances in three-cone bearing life and cutting structures, cause use of two cone bits to be presently uncommon. Good designers have not forgotten them, however; the concept has advantages that cannot be ignored. As

with many roller cone bit designs, modern materials and engineering capabilities frequently resolve problems that have been troublesome in the past.

4.7.1.4 Roller Cone Bit Nomenclature

Roller cone bits are generally classified as either tungsten carbide insert bits or milled tooth bits. To assist in comparison of similar products from various manufacturers, the International Association of Drilling Contractors (IADC) has established a unified, bit classification system for the naming of drill bits. This system is described later.

4.7.1.4.1 IADC Roller Cone Bit Classification Method

The IADC Roller Cone Bit Classification is an industry wide descriptive standard for description of milled tooth and insert type roller cone bits. It is a coding system based on key design and application related criteria. The presently used version was introduced in 1992 using criteria that were cooperatively developed by drill bit manufacturers under the auspices of the Society of Petroleum Engineers [3].

IADC Classification

The IADC classification system is a four-character design and application related code. The first three characters are always numeric; the last character is always alphabetic. The first digit refers to bit series, the second to bit type, the third to bearings and gage arrangement, and the fourth (alpha) character to bit features.

Examples of IADC 135M, 447X, and 637Y bits can be seen in the following photograph (Figure 4.7.51). These IADC codes represent the following bits and environments:

- 135M: Soft formation (1), milled tooth bit (3); roller bearings with gage protection (5); motor application (M)
- 447X: Soft formation (4), insert bit (4); friction bearings with gage protection (7); chisel type inserts (X)
- 637Y: Medium-hard (6), insert bit (3); friction bearing with gage protection (7); conical type inserts (Y)

Series

Series, the first character in the IADC System, defines general formation characteristics and divides milled tooth and insert type bits. Eight Series (or categories) are used to describe roller cone rock bits.

Series 1, 2, and 3 apply to milled tooth bits. Series 4, 5, 6, 7, and 8 apply to insert type bits. The higher the series number, the harder or more abrasive is the rock type. Series 1 represents the softest (easiest drilling applications) for milled-tooth bits. Series 3 represents the hardest and most abrasive applications for milled tooth bits. Series 4 represents the softest (easiest drilling applications) for insert type bits. Series 8 represents very hard and abrasive applications for insert-type bits.

FIGURE 4.7.51 IADC codes.

Unfortunately, rock hardness is not clearly defined by the IADC System. The meaning of “hard” sandstone or “medium-soft” shale, for example are subjective and open to a degree of interpretation. Information should, accordingly, be used only in a descriptive sense; actual rock hardness will vary considerably depending on factors such as depth, overbalance and hydrostatic pressure, porosity and other factors that are difficult to quantify (Table 4.7.3).

Type

The second character in the IADC Categorization System represents bit type, insert, or milled tooth and describes a degree of formation hardness. Types range from 1 through 4.

Bearing Design and Gage Protection

The third IADC character defines both bearing design and gage protection. IADC defined seven categories of bearing design and gage protection. These are

1. Nonsealed roller bearing (also known as open bearing bits)
2. Air-cooled roller bearing (designed for air or foam or mist drilling applications)
3. Nonsealed roller bearing, gage protected

4. Sealed roller bearing
5. Sealed roller bearing, gage protected
6. Sealed friction bearing
7. Sealed friction bearing, gage protected

Gage protected indicates only that a bit has some feature that protects or enhances the gage of the bit. It does not specify the nature of the feature. For example, increased tooth count, modified insert shape or material, and diamond-enhanced inserts can all be categorized as gage protection.

Included Features

The fourth character used in the system defines the features available. IADC considers this category to be optional. This alpha character is not always recorded on bit records but is commonly used within bit manufacturer’s catalogs and brochures. IADC categorization assigns and defines 16 identifying features (Table 4.7.4). Only one alphabetic feature character can be used under IADC rules. As bit designs commonly combine several of these features, the most significant feature is normally listed.

Limitations of IADC Classification

When using IADC coding, keep in mind that it is the bit manufacturer’s responsibility to create IADC codes for their bit designs. There is no independent authority monitoring coding. Given the subjectivity of the system, this can put into question whether a bit has been properly positioned.

Bit designs can vary substantially within a single IADC code; three 7⁷/₈-in. insert type bits using a manufacturer’s model designations of A, B, and C, are categorized within the IADC Classification as 517 despite large differences in the bits. Insert count for the inner row cutting structure increases by 30% from A to C (50 versus 65 inserts) and by 18% for the outer rows. This variation in insert counts could have a substantial impact on performance in a particular application and points out a weakness in the IADC Coding System (Figure 4.7.52).

It is very important to understand that an IADC coding does not limit the drilling application for a particular bit. The following paragraph from the IADC/SPE clearly highlights this point: “The fact that each bit has a distinct code does not mean that it is limited to drilling only the narrow

TABLE 4.7.3 Typical Compressive Strengths of Common Rock Types

Hardness	UCS (psi)	Examples
Ultra-Soft	<1000	gumbo, clay
Very Soft	1000–4000	unconsolidated sands, chalk, salt, claystone
Soft	4000–8000	coal, siltstone, schist, sands
Medium	8000–17,000	sandstone, slate, shale, limestone, dolomite
Hard	17,000–27,000	quartzite, basalt, gabbro, limestone, dolomite
Very Hard	>27,000	marble, granite, gneiss

range of formations defined by a single box on the chart. All bits, within reason, drill effectively in both softer and harder formations than specified by the IADC code. Competitive products with the same IADC code are built for similar applications but they may be quite different in design detail, quality and performance” [4].

4.7.1.5 IADC Roller Cone Bit Dull Grading

The International Association of Drilling Contractors (IADC), in conjunction with the Society of Petroleum Engineers (SPE), has established a systematic method by which the cause for bit failures can be clearly communicated. The

intent of the system is to facilitate and accelerate product and operating development based on accurately recorded experience. This system is referred to as Dull Grading. The Dull Grading Protocol requires a systematic evaluation of specific bit areas, reports the reason why the bit was removed from service, and provides a standard method for reporting.

Partly as a result of dull analyses, bit design processes and product operating efficiencies evolve quite rapidly. Engineers identify successful design features that can be reapplied and unsuccessful features that must be corrected or abandoned; manufacturing units receive feedback on product quality; sales personnel migrate performance gains and avoid duplication of mistakes between similar applications, and so forth. All bit manufacturers require the collection of dull information for every bit run.

4.7.1.5.1 IADC Eight-Point Dull Grading System

The IADC Eight-Point Dull Grading System reviews bit wear in four general categories: Cutting Structure, Bearings and Seals, Gage, and Remarks. These, and their subcategories, are described by the following graphic (Figure 4.7.53). Dull Grading for diamond and PDC matrix bits differs from that for roller cone bits in the way that cutting structures are measured and graded. When grading a diamond or PDC bit, specific measurement rules appropriate to that group must be used.

Cutting Structure Grading (T)

For dull grading purposes, cutting structures are subdivided into four subcategories: inner rows, outer rows, major dull characteristic of the cutting structure, and location on the face of the bit where the dull characteristic occurs. Figure 4.7.54 provides information on insert or tooth row identification and the convention for reporting their wear.

T			B	G	REMARKS		
1	2	3	4	5	6	7	8
CUTTING STRUCTURE				B	G	REMARKS	
Inner Rows (I)	Outer Rows (O)	Dull Char. (D)	Location (L)	Brng. Seal (B)	Gage 1/16 (G)	Other Dull (O)	Reason Pulled (R)

FIGURE 4.7.53 IADC dull grading system.

FIGURE 4.7.54 Identifying insert and milled tooth rows.

Insert or Tooth Height Measurement

Measurements of cutting structure condition requires an evaluation of bit tooth or insert wear status. Wear is reported using an eight-increment wear scale in which minimal wear is represented by the notation T1, and 100% worn is represented by T8 (Figure 4.7.55).

General Rule for Cone Identification

Typically, the #1 cone contains the centermost cutting element. On some bits, the #1 and #3 cones both appear to have the centermost cutting element; in general, the cone with the greatest distance between the A and B rows is the #1 cone. Cones #2 and #3 follow the #1 cone in a clockwise

direction. This rule does not correctly define the first cone for some modern bits, however, and it may be necessary to verify with the manufacturer.

Inner Rows Cutting Structure (I)

Dull grading begins with evaluation of wear on the inner rows of inserts or teeth, that is, with the cutting elements not touching the wall of the hole bore. Grading involves measurement of combined inner rows structure reduction due to loss, wear, and breakage using the measurement method described previously.

Outer Rows Cutting Structure (O)

The second step is the outer rows of inserts or teeth, that is, those that touch the wall of the hole bore. Grading involves measurement of combined outer rows teeth or insert structure reduction due to loss, wear, and breakage using the measurement method described previously.

Cutting Structure Dull Characteristic (D)

The cutting structure dull characteristic is the observed characteristic that is most likely to limit further usage of the bit in the intended application. A two-letter code is used to indicate the major dull characteristics of the cutting structure. These codes are listed in Table 4.7.4.

FIGURE 4.7.55 Tooth height measurement.

TABLE 4.7.5 Roller Cone Bit Dull Location Codes

Code	Description	Code	Description
N	Nose Row	1	Cone #1
M	Middle Row	2	Cone #2
G	Gage Row	3	Cone #3
A	All Rows		

Location (L)

A two-letter code is also used to indicate the location of the wear or failure that necessitated removal of the bit from service. These codes are listed in Table 4.7.5.

Bearings and Seals Grading (B)

IADC provides separate protocols for estimation of bearing and seal wear in nonsealed and sealed bearing assemblies.

Estimating Wear on Nonsealed Bearings

For nonsealed bearings, wear is estimated on a 0 to 8 linear scale (0 is new, 8 is 100% expended.)

Estimating Wear on Sealed Bearings

A checklist for seal and bearing system condition is provided in Table 4.7.6. The grading protocol is

If no seal problems are encountered, use the grading code E.

If either any component in the assembly has failed, use the grading code F.

TABLE 4.7.6 Roller Cone Bit Bearing/Seal Evaluation Check List

Condition	Acceptable Condition
Ability to rotate cone	Rotates normally
Cone spring-back	Spring-back exists
Seal squeak	Seal squeak exists
Internal sounds	No internal noises exist
Weeping grease	No lubricant leaks exist
Shale burn	No shale burn exists
Shale packing	If packing exists, remove before measuring
Gaps at the back-face or throat	No bearing gaps exist
Inner or outer bearing letdown	No bearing letdown exists

If any portion of the bearing is exposed or missing, it is considered an ineffective assembly; again use the grading code F.

Use grading code N if it is not possible to determine the condition of both the seal and the bearing.

Grade each seal and bearing assembly separately, by cone number (If grading all assemblies as one, report the worst case.)

Gage Grading (G)

The Gage Category of the Dull Bit Grading System is used to report an under gage condition for cutting elements intended to touch the wall of the hole bore. For diamond and PDC bits only, gage is measured with a nominal ring gage (API specifications for nominal ring gages for roller cone bits have not been issued).

Undergage increments of $\frac{1}{16}$ in. are reported. If a bit is $\frac{1}{16}$ in. under gage, the gage report is “1.” If a bit is $\frac{1}{8}$ in. ($\frac{2}{16}$ in.) undergage, the gage report is “2.” If a bit is $\frac{3}{16}$ in. undergage, the gage report is “3,” and so forth. Round to the nearest $\frac{1}{16}$ in. Gage rules apply to cutting structure elements only. Measurement are taken at the closer to gage of either the gage or heel cutting elements (Figure 4.7.56).

For two-cone bits, gage is the measured distance from the closer to gage of the gage or heel elements. For bits with bearing or seal failures, out of gage amount can be measured provided that cones do not have axial or radial movement. If nominal ring gages are not available, the true gage condition cannot be determined.

Remarks

The Remarks category is more important than its title implies. It enables explanation of dull characteristics that do not correctly fit into other categories, and it is the category in which the reason why a bit was removed from service is confirmed.

FIGURE 4.7.56 Measuring out of gage.

Other Dull Characteristics (O)

Other dull characteristics can be used to report dull characteristics other than those reported under “Cutting Structure Dull Characteristics (D).” Codes for “Other Dull Characteristics” are shown in [Table 4.7.7](#).

Reason Pulled (R)

Codes for “Reason Pulled” are shown in [Table 4.7.8](#).

4.7.1.6 Roller Cone Bit Economics

No matter what or how good a new product or method may be to a drilling operation, the final result is always measured in terms of cost per foot or meter. Lowest cost per foot indicates to drilling engineers and supervisors which products to use in each situation. Reduced costs lead directly to higher profits or, in some cases, to the difference between profit and loss.

For those in administration, engineering, manufacturing, and sales, cost calculations are used to evaluate the effectiveness of any product or method, new or old. Because drilling costs are so important, everyone involved should know how to make a few simple cost calculations.

For example, the cost of a PDC bit can be up to twenty times the cost of a mill tooth bit and up to four times the cost of a tungsten carbide insert bit. The choice of either, the PDC bit, a milled tooth bit, or an insert roller cone bit must be economically justified by its performance. Occasionally,

HR	Hours on bit	WO	Washout in drill string
LIH	Left in Hole		

this performance justification is accomplished by simply staying in the hole longer or drilling faster.

The main reason for using a bit, however, is that it saves money on a cost-per-foot basis. A PDC bit, to be economical, must make up for its additional cost by either drilling faster or staying in the hole longer. Because the bottom line on drilling costs is dollars and cents, a bit's performance is based on the cost of drilling each foot of hole.

Break-even analysis on a bit is the most important aspect of an economic evaluation. A break-even analysis is necessary to determine if the added bit cost can be justified for a particular application.

The break-even point for a bit is simply the footage and hours needed to equal the cost per foot that would be obtained on a particular well if the bit were not used. To get the break-even, a good offset well must be used for comparative purposes.

If the following bit record were used, we could determine if a bit would be economical ([Table 4.7.9](#)).

4.7.1.7 Example of Offset Well Performance

Total rotating time = 212.5 hr

Total trip time = 54.3 hr (Tripping rate is computed at 1000 ft/hr on average. This rate depends on rig type and operation.)

Rig operating cost = \$300/hr

Total bit cost = \$16,148

Total footage = 3,380 ft

TABLE 4.7.9 Bit Record

Bit Size (in.)	Type	Bit Cost	Depth Out (ft.)	Footage Drilled (ft.)	Hours	ROP
8½	FDS+	\$2,820	9,618	756	26	29.1
8½	FDT	\$1,848	10,271	653	24	27.2
8½	FDG	\$1,848	10,699	428	22	19.5
8½	F2	\$4,816	11,614	915	71.5	12.8
8½	F2	\$4,816	12,242	628	69	9.1
Total:		\$16,148		3,380	212.5	Avg: 15.9

Therefore, the offset cost per foot for this interval (8,862 to 12,242 ft) is calculated using the standard cost-per-foot equation:

$$C = \frac{R * (T + D) + B}{F} \quad (4.7.8)$$

in which

C = drilling cost per foot (\$/ft)

R = rig operating cost (\$/hr)
(Plus add-on equipment, such as downhole motor.)

T = trip time (hr)

D = drilling time (hr)

B = bit cost (\$)

F = footage drilled (ft)

Using the data provided in the earlier example, the cost per foot is

$$C = \frac{(212.5 + 54.3)\$300 + \$16,148}{3,380} = 28.46 \text{ \$/ft.}$$

When determining if an application can be suitable for a bit, the offset performances are given but the performance of the bit must be estimated. We must assume the footage the bit will drill or the penetration rate it will obtain. If the footage is assumed, then we use the following formula to calculate the break-even ROP:

$$ROP = \frac{R}{C - (RT + B)/F} \quad (4.7.9)$$

in which

R = rig operating cost (\$/hr)

C = offset cost per foot (\$)

T = trip time of bit (hr)

B = bit cost (\$)

F = assumed bit footage (ft)

In the previous example

$$R = \$300$$

$$C = \$28.46$$

$$T = 12 \text{ hr}$$

$$B = \$18,300$$

$$F = 3,380 \text{ ft}$$

Therefore

$$ROP = \frac{\$300}{\frac{\$28.46 - (300 \times 12 + \$18,300)}{3,380 \text{ ft}}} = \$13.7 \text{ ft/hr}$$

The bit must drill the 3,380 ft at a penetration rate of 13.7 ft/hr to equal the offset cost per foot of \$28.46 for the same 3,380 ft.

If a penetration rate is assumed, use the following equation to calculate the break-even footage:

$$F_{BE} = \frac{RT + B}{C - (R/ROP)} \quad (4.7.10)$$

In the previous example, if we assume a penetration rate of 20 ft per hour, we have

$$F_{BE} = \frac{\$300 \times 12 + \$18,300}{\$28.46 - 300/20}$$

In this case, the bit must drill 1,627 ft to attain the break-even point.

4.7.1.8 Roller Cone Bit Glossary

Abrasive wear

wearing away by contact friction between two surfaces in relative motion to one another.

Air bit

a type of roller cone bit that uses compressed air or natural gas for cooling and cuttings removal.

Air drilling

a method of rotary drilling that uses compressed air, instead of water or mud, as the drilling fluid.

Bit gauge

a circular ring used to determine whether a bit has the correct outside diameter.

Bit record

a report that lists each bit used during a drilling operation, and reporting on wear using the IADC Dull Grading protocol.

Bit run

placing a bit on the bottom of a hole, drilling the prescribed amount of hole, or until it wears out, and pulling it from the hole.

Cellular diamond

extruded strands of Polycrystalline Diamond Compact encased within a tungsten carbide with binder that are bundled into groups, shaped, and used as a high performance cutting element.

Cone

usually conically shaped, rotating components of a roller cone bit that support the teeth or insert type cutting elements that penetrate the formation during drilling.

Cone alignment

the way in which roller cones are aligned with a bit's center axis.

Cone angle

the face angle of a bit cone.

Cone speed

the rotational velocity at which a roller cone bit cone rotates about its centerline. Three-cone bit cone rotation speed is normally higher than bit rotation speed; one cone bit rotation speed is normally lower than bit rotational speed.

Drilling fluid

fluids circulated in a well to clean and cool the bit and remove cuttings.

Erosion wear

surface wear caused by fluid born abrasives. For example, drilling fluids used in conjunction with cuttings removal from roller cone bits can cause severe erosion of exposed cone surfaces.

Gage or Gauge

the diameter of a bit or a hole drilled by a bit.

Gage area

the outside diameter of a bit that drills the wall of a well.

Gage row

the inserts or teeth in the outermost row on the cones of a bit. The gage row determines a hole's gage or diameter.

IADC

International Association of Drilling Contractors.

Impingement angle

with respect to roller cone bits, the angle at which a drilling fluid flows from a bit nozzle strikes the well bottom.

Inner bearings

bearings that lie near the apex of a roller cone (also called secondary or thrust bearing).

Insert

a tungsten carbide shape used as a cutting element on roller cone bits.

Journal

that portion of a roller cone bit leg that supports the bearing system, lubrication system, and cone retention system for one of the bits cones.

Journal bearing

a type of roller cone bit bearing designed to rotate on a film of lubricant rather than on roller type bearings.

Leg

a three-cone bit component comprising one third of the bit (120° of arc) when viewed in plan view. Three legs are assembled to complete a bit. Each leg contains a journal that supports the bearing system, seals, lubrication system, and cone retention system for one of the bit's three cones.

Milled-tooth bit

a roller cone bit in which the cutting elements are rows of hardfaced steel teeth.

Mono-cone bit

a type of roller cone bit in which a single semi-hemispherical cutting device rotates as the bit drills.

Offset

a roller cone bit term describing an engineered orientation of the cone axes so they do not intersect at the bit centerline. Offset prevents free rolling of the cone and sets up a skidding action that improves drilling efficiency.

Outer bearings (or primary bearings)

the main bearings of a roller cone bit that are located near the open end of a cone.

Out-of-gage bit

a bit whose diameter is more or less than that specified for the hole to be drilled.

Out-of-gage hole

a hole that is smaller or larger than the specified diameter of the hole to be drilled.

Rate of penetration (ROP)

a commonly used measure of drilling rate, normally expressed in terms of feet or meters per hour.

Rotary speed

the rotational velocity at which a bit turns about its centerline.

Sealed bearing

a type of bearing that is not exposed to the drilling fluids. Seals prevent drilling fluid from entering the bearings.

Shirttail

the rounded bottom portion of a roller cone bit leg.

Three-cone bit

a type of roller cone bit composed of three, rotating, intermeshing cones.

Tungsten carbide

a compound of tungsten with carbon. This term often refers to a composite material composed of tungsten carbide grains cemented with a metallic binder such as cobalt, nickel, or iron that is used for cutting and resisting abrasion.

TCI bit

a type of roller cone bit using tungsten carbide inserts for cutting elements.

Two-cone bit

a type of roller cone bit composed of two, cone-shaped cutting devices that rotate as the bit drills.

Undergage bit

a bit whose outside diameter is less than the specified minimum for a well.

Weight on bit (WOB)

force, normally expressed in pounds or kilograms, applied to bit in the direction of the bit centerline.

4.7.2 Diamond Matrix Bits**4.7.2.1 Diamond-Impregnated Core Bits**

Diamond matrix bits are being employed to a greater extent because of the advancements in mud motors. High rpms can destroy roller cone rock bits very quickly. On the other hand, diamond bits rotating at high rpm usually have longer life since there are no moving parts.

4.7.2.2 Diamond-Impregnated Core Bit Selection

The industry is moving to a new selection method for diamond-impregnated core bits based on the Mohs hardness scale. Advancements in metallurgy and diamond coating technologies have improved impregnated bits in relation to different rock types. On the low end of the Mohs scale, selection of a low-series bit is ideal, and the opposite is true at the upper end (Figure 4.7.57). In addition to the scale, a bit may be made specifically to cut abrasive or competent rock formations. The Mohs scale appears to be the new standard, because the selection criteria have scientific methodology for determining the right bit for the job, as opposed to the older color coded system [11].

4.7.2.3 Diamond Selection

Diamonds used as the cutting elements in the bit metal matrix have the following advantages:

1. Diamonds are the hardest material.
2. Diamonds are the most abrasion-resistant material.
3. Diamonds have the highest compressive strength.
4. Diamonds have a high thermal conductivity.

Diamonds also have some disadvantages as cutting elements: they are very weak in shear strength, have a very low shock impact resistance, and can damage or crack under extremely high temperatures.

FIGURE 4.7.57 Sample Alpha α bit product line as available in series 1 through 10 (courtesy of the Boart Longyear Company).

When choosing diamonds for a particular drilling situation, there are basically three things to know. First, the quality of the diamond chosen should depend on the formations being drilled. Second, the size of the diamond and its shape will be determined by the formation and anticipated penetration rate. Third, the number of diamonds employed is dictated by the formation and anticipated penetration rate.

There are two types of diamonds, synthetic and natural. Synthetic diamonds are man made and are used in PDC STRATAPAX type bit designs. STRATAPAX PDC bits are best suited for extremely soft formations. The cutting edge of synthetic diamonds are round, half-moon shaped or pointed.

Natural diamonds are divided into three categories. First are the carbonate or black diamonds. These are the hardest and most expensive diamonds. They are used primarily as gage reinforcement at the shockpoint. Second are the West African diamonds. These are used in abrasive formations and usually are of gemstone quality. About 80% of the West African diamonds are pointed in shape and, therefore, 20% are the desirable spherical shape. Third are the Congo or coated diamonds. These are the most common category. Over 98% of these diamonds are spherical by nature. They are extremely effective in soft formations. The other 2% are usually cubed shaped, which is the weakest of the shapes available.

By studying specific formations, diamonds application can be generalized as follows:

- Soft, gummy formations—Congo, cubed shaped
- Soft formation—large Congo, spherically shaped

- Abrasive formation—premium West Africa
- Hard and abrasive—Special premium West Africa

Diamond Bit Design

Diamond drill bit geometry and descriptions are given in Figure 4.7.58 [18]. Diamond core bit geometry and descriptions are given in Figure 4.7.59 [9].

Diamond bits have several design parameters, which include face layout and profile geometry. Face layouts drive fluid course geometries and configurations, which are deemed critical for product performance. In most instances, profiles are classified as round, parabolic, tapered, and flat crown. Profile geometry selection for diamond bits is primarily based on formation characteristics, in terms of formation hardness and abrasiveness. In most instances, profiles for hard and abrasive formations tend to be more parabolic. Additionally, directional drilling objectives also influence profile selection for diamond bits.

Cone angles and throat depth dictate the bit best suited for stabilization. Cone angles that are steep (60° to 70°), medium (80° to 90°), or flat (100° to 120°) are best suited for highly stable, stable, and fracturing formation, respectively.

Diamond drill bits with special designs and features include

1. Long gage bits, used on downhole motors for drilling ahead in vertical boreholes.
2. Flat-bottom, shallow-cone bit designs, used on sidetracking jobs or in sidetracking jobs with downhole motors.

FIGURE 4.7.58 Diamond drill bit nomenclature (courtesy of Hughes Christensen).

3. Deep cones having a 70° apex angle are normally used in drill bits to give built-in stability and to obtain greater diamond concentration in the bit-cone apex.

Diamond Bit Hydraulics

The hydraulics for diamond bits should accomplish rapid removal of the cuttings, and cooling and lubrication of the diamonds in the bit metal matrix.

Bit Hydraulic Horsepower

An effective level of hydraulic energy (hydraulic horsepower per square inch) is the key to optimum bit performance. The rule-of-thumb estimate of diamond bit hydraulic horsepower HP_h and penetration rates is shown in Table 4.7.10. The bit hydraulic horsepower is dependent upon the pressure drop across the bit and the flowrate.

Bit Pressure Drop

The pressure drop across the bit is determined on the rig as the difference in standpipe pressure when the bit is on bottom, and when the bit is off bottom, while maintaining constant flowrate.

Maximum Drilling Rate

In fast drilling operations (soft formations), the maximum penetration rate is limited by the maximum pressure available at the bit. This is the maximum allowable standpipe pressure minus the total losses in the circulating system.

Optimum Pump Output

In harder formations where drilling rates are limited by maximum available bit weight and rotary speed, the optimum value of flow rate should be adjusted to achieve the

FIGURE 4.7.59 Diamond core bit nomenclature (courtesy of Hughes Christensen).

TABLE 4.7.10 Bottomhole Hydraulic Horsepower Required for Diamond Drilling [2]

Penetration Rate, ft/hr	1-2	2-4	4-6	6-10	over 10
Hydraulic Horsepower Required, HP_H /sq. inch	1-1.5	1.5-2	2-2.5	2.5-3	3-3.5

bit hydraulic horsepower required. The minimum pump discharge required to maintain annular velocity and bit cooling is shown in Figure 4.7.60.

Hydraulic Pumpoff

The bit pressure drop acts over the bit face area between the cutting face of the bit and the formation and tends to lift the bit off the bottom of the hole. This force is large at the higher bit hydraulic horsepower being utilized today and in some

FIGURE 4.7.60 Pump discharge for diamond bits [9]. (courtesy of Hughes Christensen).

cases may require additional bit weight to compensate. For example, the pumpoff force on an $8 \frac{7}{16}$ in. diamond bit having a pressure drop across the bit of 900 psi would be about 6,000 lb.

The hydraulic pumpoff force F_{po} (lb) can be approximated by [4]:

$$F_{po} = 1.29 (\Delta P_b) (d_h - 1) \quad (4.7.11)$$

for the radial flow watercourse design bits, and

$$F_{po} = 0.32 (\Delta P_b) (d_h - 1) \quad (4.7.12)$$

for cross-flow watercourse system (refer to IADC classification of fixed-cutter bits).

4.7.2.4 Diamond Bit Weight on Bit and Rotary Speed

Weight on Bit

Drilling weight should be increased in increments of 2,000 lb as the penetration rate increases. As long as no problems are encountered with the hydraulics and torque, weight can be added. However, when additional weight is added and the penetration rate does not increase, the bit may be balling up, and the weight on the bit should be decreased.

Rotary Speed

Diamond bits can usually be rotated at up to 150 rpm without any problem when hole conditions and drill string design permit. Rotary speeds of 200 and 300 rpm can be used with stabilized drill strings in selected areas. Diamond bits have also operated very successfully with downhole motors at 600 to 900 rpm. The actual rotary speed limits are usually imposed by safety.

4.7.2.5 Core Bits

Most core barrels utilize diamonds as the rock cutting tool. There are three types of core barrels.

Wireline Core Barrel Systems

The wireline system can be used for continuous drilling or coring operations. The inner barrel or the drill plug center of the core bit can be dropped from the surface and retrieved without pulling the entire drill string.

Marine Core Barrels

Marine barrels were developed for offshore coring where a stronger core barrel is required. They are similar to the conventional core barrels except that they have heavier outer tube walls.

Rubber Sleeve Core Barrels

Rubber sleeve core barrels are special application tools designed to recover undisturbed core in soft, unconsolidated formations. As the core is cut, it is encased in the rubber sleeve that contains and supports it. Using face discharge ports in the bit, the contamination of the core by circulating fluid is reduced. The rubber sleeve core barrel has proven to be a very effective tool, in spite of the fact that the rubber sleeve becomes weak with a tendency to split as the temperature increases about 175°F.

Core Barrel Specifications

Core barrel sizes, recommended make-up torques, maximum recommended pulls and recommended fluid capacities are shown in Tables 4.7.11 and 4.7.12 [9].

TABLE 4.7.11 Core Barrels: Recommended Makeup Values [9]

Core Barrel Size	3.5×1.75	4.12×2.12	4.50×2.12	4.75×2.62	5.75×3.50	6.25×3	6.25×4	6.75×4	8.0×5.25	
Recommended Make up Torque foot-pounds	1,700 to 2,050	3,000 to 3,600	5,000 to 6,000	4,050 to 4,850	7,400 to 8,800	14,900 to 17,800	8,150 to 9,800	9,900 to 12,000	19,000 to 22,700	
Pounds Line Pull for Different Length Tong Levers	60"	375	660	1,100	890	1,620	3,270	1,795	2,190	4,170

4.7.2.6 Weight on Bit and Rotary Speed for Core Bits

Weight on Bit

Figure 4.7.61 shows the drilling weights for diamond core bits in various formations. These are average values determined in field tests [9]. The proper weight on the bit for each core run can be determined by increasing the bit weight in steps of 1,000 to 2,000 lb, with an average speed of 100 rpm. Coring should be continued at each interval while carefully observing the penetration rate. Optimum weight on the bit has been reached when additional weight does not provide any further increase in penetration rate or require

FIGURE 4.7.61 Bit weight for core bits (courtesy of Hughes Christensen).

excessive torque to rotate the bit. Using too much weight can cause the diamonds to penetrate too deeply into a soft formation with an insufficient amount of mud flow able to pass between the diamonds and the formation, resulting in poor removal of the cuttings. The core bit could clog or even burn, and penetration rate and bit life will be reduced. In harder formations, excessive weight will cause burning on the tips of the diamonds or shearing with a resulting loss in salvage.

Rotary Speed

The best rotational speed for coring is usually established by the limitations of the borehole and drill string. The size and number of drill collars in the string and the formation being cored must be considered when establishing the rotational speed. Figure 4.7.62 shows the recommended rotating speed range for optimal core recovery in different formations [8]. Concern should also be given to the harmonic vibrations of the drill string. Figure 4.7.63 gives critical rotary speeds that generate harmonic vibrations.

4.7.2.7 Polycrystalline Diamond Compacts (PDC) Bits

PDC bits get their name from the polycrystalline diamond compacts used for their cutting structure. The technology that led to the production of STRATAPAX drill blanks grew from the General Electric Co. work with polycrystalline manufactured diamond materials for abrasives and metal working tools. General Electric Co. researched and developed the STRATAPAX (trade name) drill blank in 1973 and Christensen, Inc. used these in PDC bit field tests. The bits were successfully applied in offshore drilling in the North Sea area in the late 1970s and in on-shore areas in the United States in the early 1980s. In some areas, the PDC bits have out-drilled roller rock bits, reducing overall cost per foot by

FIGURE 4.7.62 Recommended rotary speed for core bits [8] (courtesy of Hughes Christensen).

FIGURE 4.7.63 Critical rotary speed for core bits [10] (courtesy of API).

30% to 50% and achieving four times the footage per bit at higher penetration rates. [11, 12].

On a worldwide basis, drag bits operated in soft and medium-hardness formations have set performance records for single-run footage (>22,000 ft), cumulative footage (>18,000 ft in 26 runs), and single-run penetration rate (>2,200 ft/hr) [13]. This success has motivated continuing efforts to expand the range of applications for drag bits to increasingly harder formations. Laboratory studies indicate that PDC drag bits can outperform conventional rollerbits in hard rock when they are operated under conditions that minimize frictional heat generation and bit chatter [14]. Field test have confirmed that a properly controlled standard PDC drag-bit design is capable of drilling an extended hard-rock interval at a high rate of penetration. [15].

Figure 4.7.64 shows the major components and design of the PDC bit. Typical polycrystalline diamond compacts are shown in Figure 4.7.65. The polycrystalline diamond compacts consist of a thin layer of synthetic diamonds on a tungsten carbide disk. These compacts are produced as an integral blank by a high pressure, high temperature process. The diamond layer consists of many tiny crystals bonded together at random orientations for maximum strength and wear resistance.

The tungsten carbide backing provides mechanical strength and further reinforces the diamond compact wear-resistant properties. During drilling, the polycrystalline diamond cutter wears down slowly with a self-sharpening effect. This helps maintain sharp cutters for high penetration-rate drilling throughout the life of the bit.

FIGURE 4.7.64 PDC bit nomenclature (courtesy of Strata Bit Corp). Source: Strata Bit Corporation, 600 Kenrick, Suite A-1, Houston, TX 77060 ph (713) 999-4530 unknown booklet of the company.

FIGURE 4.7.65 Polycrystalline diamond compacts [2] (courtesy of Hughes Christensen).

Variations in cutter design and processing parameters can strongly affect in-service cutter loads, wear, and durability. Geometric design variables include the diamond-table thickness, the cutting-edge chamfer design, and the diamond-table/tungsten-carbide interface configuration. Three nonplanar interface configurations are illustrated in

Figure 4.7.66. Material design variables for the diamond table itself include the binder composition and the distribution of diamond grain sizes. Manufacturing process variations can involve changes in pressure/temperature peaks and cycle history during high-pressure/high-temperature compaction. Appropriate adjustments in cutter design and processing can yield dramatic improvements in wear and/or impact performance [4.7.3].

PDC Bit Design

Figures 4.7.67 and 4.7.68 show typical PDC bits. Figure 4.7.67 is for soft formation. Figure 4.7.68 is for hard and abrasive formation [2].

Bit Body Material (Matrix)

There are two common body materials for PDC bits, steel and tungsten carbide. Heat-treated steel body bits are normally a “stud” bit design, incorporating diamond compacts on tungsten carbide posts. These stud cutters are typically secured to the bit body by interference fitting and shrink fitting and with brazing. Steel body bits also generally incorporate three or more carbide nozzles (often interchangeable) and carbide buttons on gauge. Steel body

FIGURE 4.7.66 Non planar interface configurations.

FIGURE 4.7.67 PDC bit designed for soft formations [2] (courtesy of Halliburton Drill Bits and Services).

FIGURE 4.7.68 PDC bit designed for hard and abrasive formations [2] (courtesy of Halliburton Drill Bits and Services).

bits have limitations of erosion of the bit face by the drilling mud and wear of the gauge section. Some steel body bits are offered with wear-resistant coatings applied to the bit face to limit mud erosion.

Greater bit design freedom is generally available with matrix body bits because they are “cast” in a mold like natural diamond bits. Thus, matrix body bits typically have more complex profiles and incorporate cast nozzles and waterways. In addition to the advantages of bit face configuration and erosion resistance with matrix body bits diamond compact matrix bits often utilize natural diamonds to maintain full gage hole. Matrix body bits generally utilize long, cylinder-shaped cutters secured to the bit by brazing.

Bit Profile

Bit profile can significantly affect bit performance based upon the influence it has on bit cleaning, stability, and hole deviation control. The “double-cone” profile will help maintain a straight hole even in crooked hole country. The sharp nose will attack and drill the formation aggressively while the apex and reaming flank stabilize the bit. This sharp profile may be more vulnerable to damage when a hard stringer is encountered as only the cutters on the sharp nose will support the impact loading. A shallow cone profile appears to be the easiest to clean due to the concentration of hydraulics on the reduced surface area of the bit face. This profile relies heavily upon the gage section for directional stability. The shallow cone profile will hold direction and angle with sufficient gauge length and proper stabilization of the bit.

Cutter Exposure

Figure 4.7.69 shows the types of cutter exposure on PDC bits [1]. Cutter exposure is the distance between the cutting edge and the bit face. Stud bits typically have full exposure that proves very aggressive in soft formation. In harder formations, less than full exposure may be preferred for added cutter durability and enhanced cleaning. Matrix body bits are designed with full or partial exposure depending on formation and operating parameters.

Cutter Orientation

Figure 4.7.70 shows the cutter orientation for typical PDC bits. The displacement of cuttings can be affected by side

FIGURE 4.7.70 Cutter orientation [2] (courtesy of Hughes Christensen).

and back rake orientation of the cutters. Back rake angle typically varies from 0 to -25° . The greater the degree of back rake, generally the lower the rate of penetration, but the greater the resistance to cutting edge damage when encountering a hard section. Side rake has been found to be effective in assisting bit cleaning in some formations by mechanically directing cuttings toward the annulus. Matrix body bits allow greater flexibility in adjusting cutter orientation for best drilling performance in each formation.

4.7.3 IADC Fixed Cutter Bit Classification System

The term fixed cutter is used as the most correct description for the broad category of non-roller-cone rock bits. The cutting elements may be comprised of any suitable material. To date, several types of diamond materials are used almost exclusively for fixed cutter petroleum drilling applications. This leads to the widespread use of the term "diamond" bits and PDC bits in reference to fixed cutter designs.

The IADC Drill Bits Subcommittee began work on a new classification method in 1985. It was determined from the outset that (1) a completely new approach was required, (2) the method must be simple enough to gain

widespread acceptance and uniform application, yet provide sufficient detail to be useful, (3) emphasis should be placed on describing the form of the bit, i.e., "paint a mental picture of the design", (4) no attempt should be made to describe the function of the bit, i.e., do not link the bit to a particular formation type or drilling technique since relatively little is certain yet about such factors for fixed cutter bits, (5) every bit should have a unique IADC code, and (6) the classification system should be so versatile that it will not be readily obsolete.

The resultant four-character diamond bit classification code was formally presented to the IADC Drilling Technology Committee at the 1986 SPE/IADC Drilling Conference. It was subsequently approved by the IADC Board of Directors and designated to take effect concurrent with the 1987 SPE/IADC Drilling Conference. A description of the 1987 IADC Fixed Cutter Bit Classification Standard follows [1]

Four characters are utilized in a prescribed order (Figure 4.7.71) to indicate seven fixed cutter bit design features: cutter type, body material, bit profile, fluid discharge, flow distribution, cutter size, and cutter density. These design traits were selected as being most descriptive of fixed cutter bit characteristics.

The four-character bit code is entered on an IADC-API Daily Drilling Report Form as shown in Figure 4.7.72. The space requirements are consistent with the four-character IADC roller bit classification code. The two codes are readily distinguished from one another by the convention that diamond bit codes begin with a letter, while roller bit codes begin with a number.

Each of the four characters in the IADC fixed cutter bit classification code are further described as follows:

Cutter Type and Body Material

The first character of the fixed cutter classification code describes the primary cutter type and body material (see Figure 4.7.71). Five letters are presently defined:

FIGURE 4.7.72 Fixed-cutter bit code entry in IADC-API Daily Report [1] (courtesy of SPE).

D—natural diamond/matrix body, M—PDC/matrix body, S—PDC/steel body, T—TSP/matrix body/O—other.

The term PDC is defined as “polycrystalline diamond compact.” The term TSP is defined as “thermally stable polycrystalline” diamond TSP materials are composed of manufactured polycrystalline diamond which has the thermal stability of natural diamond. This is accomplished through the removal of cobalt binder material and trace impurities and, in some cases, the filling of lattice structure pore spaces with a material of compatible thermal expansion coefficient.

The distinction of *primary* cutter types is made because fixed cutter bits often contain a variety of diamond materials. Typically one type of diamond is used as the primary cutting element while another type is used as backup material.

Profile

The number 1 through 9 in the second character of the fixed cutter classification code refer to the bit’s cross-sectional profile (Figure 4.7.73). The term profile is used here to describe the cross-section of the cutter/bottomhole pattern. This distinction is made because the cutter/bottomhole profile is not necessarily identical to the bit body profile.

Nine basic bit profiles are defined by arranging two profile parameters—outer taper (gage height) and inner concavity (cone height)—in a 3 × 3 matrix (Figure 4.7.74). The rows and columns of the matrix are assigned high, medium and low values for each parameter. Gage height systematically decreases from top to bottom. Cone height systematically decreases from left to right. Each profile is assigned a number.

Two versions of the profile matrix are presented. One version (see Figure 4.7.73) is primarily for the use of manufacturers in classifying their bit profiles. Precise ranges of high, medium, and low values are given. In Figure 4.7.73 gage height and cone height dimensions are normalized to a reference dimension which is taken to be the bit diameter for drill bits and the (OD-ID) for core bits. Figure 4.7.74 provides a visual reference which is better suited for user by field personnel. Bold lines are drawn as examples of typical bit profiles in each category. Cross-hatched areas represent the range of variation for each category. Each of the nine profiles is given a name. For example, “double cone” is the term used to describe the profile in the center of the matrix (code 5). The double-cone profile is typical of many natural diamond and TSP bits.

FIGURE 4.7.73 Bit profile codes for fixed cutter bits [1] (courtesy of SPE).

The number 0 is used for unusual bit profiles which cannot be described by the 3×3 matrix of Figure 4.7.73. For example, a “bi-center” bit which has an asymmetrical profile with respect to the bit pin centerline should be classified with the numeral 0.

Hydraulic Design

The numbers 1 through 9 in the third character of the fixed cutter classification code refer to the hydraulic design of the bit (Figure 4.7.75). The hydraulic design is described by two components: the type of fluid outlet and the flow distribution. A 3×3 matrix of orifice types and flow distributions defines 9 numeric hydraulic design codes. The orifice type varies from changeable jets to fixed ports to open throat from left to right in the matrix. The flow distribution varies from bladed to ribbed to open face from top to bottom. There is usually a close correlation between the flow distribution and the cutter arrangement.

The term *bladed* refers to raised, continuous flow restrictors with a standoff distance from the bit body of more than 1.0 in. In most cases cutters are affixed to the blades

so that the cutter arrangement may also be described as bladed. The term *ribbed* refers to raised continuous flow restrictors with a standoff distance from the bit body of 1.0 in. or less. Cutters are usually affixed to most of the ribs so that the cutter arrangement may also be described as ribbed. The term *open face* refers to nonrestricted flow arrangements. Open face flow designs generally have a more even distribution of cutters over the bit face than with bladed or ribbed designs.

A special case is defined: the numbers 6 and 9 describe the crowfoot/water course design of most natural diamond and many TSP bits. Such designs are further described as having either radial flow, crossflow (feeder/collector), or other hydraulics. Thus, the letters R (radial flow), X (cross flow), or O (other) are used as the hydraulic design code for such bits.

Cutter Size and Placement Density

The numbers 1 through 9 and 0 in the fourth character of the fixed cutter classification code refer to the cutter size and placement density on the bit (Figure 4.7.76). A 3×3 matrix

FIGURE 4.7.74 Nine basic profiles of fixed-cutter bits [1] (courtesy of SPE).

of cutter sizes and placement densities defines 9 numeric codes. The placement density varies from light to medium to heavy from left to right in the matrix. The cutter size varies from large to medium to small from top to bottom. The ultimate combination of small cutters set in a high density pattern is the impregnated bit, designated by the number 0.

Cutter size ranges are defined for natural diamonds based on the number of stones per carat. PDC and TSP cutter sizes are defined based on the amount of usable cutter height. Usable cutter height rather than total cutter height is the functional measure since various anchoring and attachment methods affect the “exposure” of the cutting structure. The most common type of PDC cutters, which have a diameter that is slightly more than $\frac{1}{2}$ in., were taken as the basis for defining medium size synthetic diamond cutters.

Cutter density ranges are not explicitly defined. The appropriate designation is left to the judgement of the

manufacturer. In many cases manufacturers build “light-set” and “heavy-set” versions of a standard product. These can be distinguished by use of the light, medium, or heavy designation which is encoded in the fourth character of the IADC fixed cutter bit code. As a general guide, bits with minimal cutter redundancy are classified as having light placement density and those with high cutter redundancy are classified as having heavy placement density.

4.7.3.1 Examples of Fixed-Cutter Bit Classification

Figure 4.7.77 shows a natural diamond drill bit which has a long outer taper and medium inner cone, radial flow fluid courses, and five to six stones per carat (spc) diamonds set with a medium placement density. Using the definitions in Figures 4.7.71, 4.7.73, 4.7.74 and 4.7.75, the characteristics of this bit are coded D 2 R 5 as follows:

HYDRAULIC DESIGN

	CHANGEABLE JETS	FIXED PORTS	OPEN THROAT
BLADED	1	2	3
RIBBED	4	5	6
OPEN FACED	7	8	9

ALTERNATE CODES
 R - RADIAL FLOW
 X - CROSS FLOW
 O - OTHER

FIGURE 4.7.75 Hydraulic design code for fixed-cutter bits [1] (courtesy of SPE).

CUTTER SIZE AND DENSITY

<u>SIZE</u>	<u>DENSITY</u>		
	light	medium	heavy
large	1	2	3
medium	4	5	6
small	7	8	9

0 – impregnated

<u>CUTTER SIZE RANGES</u>	<u>NATURAL DIAMONDS</u> stones per carat	<u>SYNTHETIC DIAMONDS</u> usable cutter height
large	< 3	> 5/8"
medium	3-7	3/8-5/8"
small	> 7	< 3/8"

CUTTER DENSITY IS DETERMINED BY MANUFACTURER

FIGURE 4.7.76 Code of cutter size and placement [1] (courtesy of SPE).

FIGURE 4.7.77 Example of natural diamond bit with radial flow hydraulic design [1] (courtesy of SPE).

Cutter/body type	D—natural diamond, matrix body
Bit profile	2—long taper, medium cone
Hydraulic design	R—open throat/open face radial flow
Cutter size/density	5—med. cutter size, med. placement density

Figure 4.7.78 shows a steel body PDC bit with standard-size cutters lightly set on a deep inner cone profile. This

bit has changeable nozzles and is best described as having a ribbed flow pattern although there are open face characteristics near the center and bladed characteristics near the gage. The IADC classification code in this case is S 7 4 4.

Figure 4.7.79 shows a steel body core bit with a long-taper, stepped profile fitted with impregnated natural diamond blocks as the primary cutting elements. The bit has no inner cone. Since there is no specific code for the natural

FIGURE 4.7.78 Example of steel body PDC bit with inverted profile [1] (courtesy of SPE).

FIGURE 4.7.79 Example of steel body impregnated core bit with face discharge flow [1] (courtesy of SPE).

diamond/steel body combination, the letter O (other) is used as the cutter type/body material code. The profile code 3 is used to describe the long outer taper with little or no inner cone depth. The hydraulic design code 5 indicates a fixed port, ribbed design. Finally, the number 0 is used for impregnated natural diamond bits. Therefore the complete IADC classification code for this fixed cutter bit is 0 3 5 0. Although the classification code for this bit does not explicitly indicate the cutter type and body material, it can be referred from the rest of the code that this is an impregnated natural diamond, nonmatrix body bit, in which case steel is the most likely body material.

4.7.3.2 Dull Grading for Fixed Cutter Bits

This section describes the first IADC standardized system for dull grading natural diamond, PDC, and TSP (thermally stable polycrystalline diamond) bits, otherwise known as fixed cutter bits [2]. The new system is consistent with the recently revised dull grading system for roller bits. It describes the condition of the cutting structure, the primary (with location) and secondary dull characteristics, the gage condition, and the reason the bit was pulled.

The format of the dull grading system is shown in Figure 4.7.80. For completeness, Figure 4.7.80 contains all of the codes needed to dull grade fixed cutter bits and roller

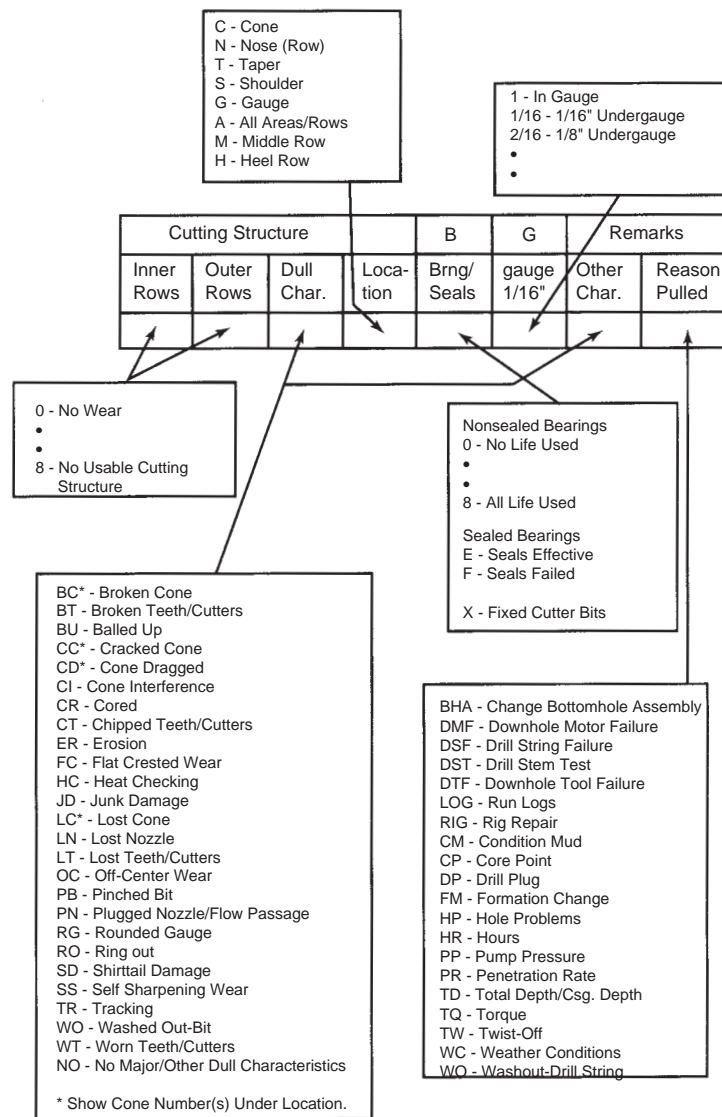

FIGURE 4.7.80 IADC bit dull grading codes—bold characters for fixed-cutter bits [18] (courtesy of SPE).

bits. Those codes which apply to fixed cutter bits are in boldface.

Eight factors about a worn fixed cutter bit can be recorded. The first four spaces are used to describe the cutting structure. In the first two spaces, the amount of cutting structure wear is recorded using the linear scale 0 to 8, based on the initial useable cutter height. This is consistent with grading tooth wear on roller bits. The amount of cutter wear represented by 0 through 7 is shown schematically in Figure 4.7.81. An 8 means there is no cutter left. This same scale is to be used for TSP and natural diamond bits, with 0 meaning no wear, 4 meaning 50% wear, and so forth.

The first space of the dull grading format is used for the cutting structure in the inner two-thirds of the bit radius, and the second space applies to the cutting structure in the outer one-third of the bit radius, as shown schematically in Figure 4.7.81. When grading a dull bit, the average amount of wear in each area should be recorded. For example, in Figure 4.7.81 the five cutters in the inner area would be graded a 2. This is calculated by averaging the grades of the individual cutters in the inner area as follows: $(4 + 3 + 2 + 1 + 0) / 5 = 2$. Similarly, the grade of the outer area would be a 6. On an actual bit the same procedure would be used. Note that for a core bit, the centerline in Figure 4.7.81 would be the core bit ID.

The third space is used to describe the primary dull characteristic of the worn bit; i.e., the obvious physical change from its new condition. The dull characteristics which apply to fixed cutter bits are listed in Figure 4.7.80.

FIGURE 4.7.81 Schematics of cutters wear [2] (courtesy of SPE).

FIGURE 4.7.82 Locations of wear on fixed-cutter bit [2]. (Courtesy of SPE).

The location of the primary dull characteristic is described in the fourth space. There are six choices: cone, nose, taper, shoulder, gauge, and all areas. Figure 4.7.82 shows four possible fixed cutter bit profiles with the different areas labeled. It is recognized that there are profiles for which the exact boundaries between areas are debatable and for which certain areas may not even exist. Notice that in the last profile there is no taper area shown. However, using Figure 4.7.83 as a guide, it should be possible to clearly define the different areas on most profiles.

The fifth space will always be an “X” for fixed cutter bits, since there are no bearings. This space can be used to distinguish dull grades for fixed cutter bits from dull grades for roller bits.

The measure of the bit gauge is recorded in the sixth space. If the bit is still in gauge, an “I” is used. Otherwise,

FIGURE 4.7.83 Schematic of common dull characteristics [2] (courtesy of SPE).

the amount the bit is undergauge is noted to the nearest $\frac{1}{16}$ of an inch.

The seventh space is for the secondary dull characteristic of the bit, using the same list of codes as was used for the primary dull characteristic. The reason the bit was pulled is shown in the eighth space using the list of codes shown in Figure. 4.7.80.

4.7.3.3 Downhole Tools

Downhole drilling tools are the components of the lower part of a drill string used in normal drilling operations such as the drill bits, drill collars, stabilizers, shock absorbers, hole openers, underreamers, drilling jars as well as a variety of drill stem subs.

As drill bits, drill collars and drill stem subs are discussed elsewhere, this section regards shock absorbers, jars, underreamers, and stabilizers.

4.7.3.4 Shock Absorbers

Extreme vertical vibrations throughout the drill string are caused by hard, broken or changing formations, and the drilling bit chafing against the bottom formation as it rotates.

In shallow wells, the drill string transmits the vibration oscillations all the way to the crown block of the drilling rig. The effects can be devastating as welds fail, seams split, and drill string connections break down under the accelerated fatigue caused by the vibrations. In deep holes, these vibrations are rarely noticed due to elasticity and dampening by the long drill string. Unfortunately, the danger of fatigue still remains and has resulted in many fishing operations.

The drill string vibration dampeners are used to absorb and transfer the shock of drilling to the drill collars where it can be borne without damaging or destroying other drill string equipment. Their construction and design vary with each manufacturer. To effectively absorb the vibrations induced by the drill bit, an element with a soft spring action and good dampening characteristics is required. There are six basic spring elements used: (1) vulcanized elastometer, (2) elastomeric element, (3) steel wool, (4) spring steel, (5) Belleville steel springs, and (6) gas compression.

Types of Shock Absorbers

Two of the eight commonly used commercial shock absorbers are described below.

Drilco Rubber Type

See Figure 4.7.84 and Table 4.7.13. Shock is absorbed by an elastometer situated between the inner and outer barrels. This shock absorbing element is vulcanized to the barrels. The torque has to be transmitted from the outer into the inner barrel. This tool is able to absorb shocks in axial or in radial directions. There is no need to absorb shocks in the torque because the drill string itself acts like a very good

FIGURE 4.7.84 Drilco rubber-spring shock dampener. (Courtesy of Smith International, Inc.).

shock absorber so the critical shocks are in axial directions. These tools cannot be used at temperatures above 200°F. Though they produce a small stroke the dampening effect is good [3].

Christenson Shock Eze

See Figure 4.7.85 [4]. A double action vibration and shock absorber employing Belleville spring elements immersed in oil.

FIGURE 4.7.85 Christensen's Shock Eze[1] (courtesy of Hughes Christensen).

The tool features a spline assembly that transmits high torque loads to the bit through its outer tube, while the inner assembly absorbs vibration through a series of steel-disc springs. The spring system works in both suspension and compression.

The high shock-absorbing capabilities of this tool are attained by compression of the stack of springs within a stroke of five inches. The alternating action of the patented spring arrangement provides a wide working range, under all possible conditions of thrust and mud pressure drop.

Placement of Shock Absorber in Drill String

Many operators have their own way of placing shock absorbers in the drill string (see Figure 4.7.86) [4]. In general, the optimum shock absorbing effect is obtained by running the tool as near to the bit as possible. With no deviation expected, the tool should be installed immediately above the bit stabilizer as shown in Figure 4.7.86C.

In holes with slight deviation problems, the shock absorber could be run on top of the first or second string stabilizer. For situations where there are severe deviation problems, the shock absorber should be placed as shown in Figures 4.7.86B and 4.7.86D.

For turbine drilling, it is recommended that the shock absorber be placed on top of the first stabilizer above the turbine as in Figure 4.7.86A.

4.7.4 Air Hammer Bits

Percussion air hammers have been used for decades in shallow air drilling operations. These shallow operations have been directed at the drilling of water wells, monitoring wells, geotechnical boreholes, and mining boreholes. In the past decade, however, the percussion air hammers have seen increasing use in drilling deep oil and natural gas wells. Percussion air hammers have a distinct advantage over roller cutter bits in drilling abrasive, hard rock formations.

The use of percussion air hammers (or down-the-hole air hammers) is an acceptable option to using rotating tri-cone or single cone drill bits for air and gas drilling operations. The air hammer utilizes an internal piston (or hammer) that is actuated by the compressed air (or other gas) flow inside the drill string. The internal piston moves up and down in a chamber under the action of air pressure applied either below or above the piston through ports in the inside of the air hammer. In the downward stroke, the hammer strikes the

bottom of the upper end of the drill bit shaft (via a coupling shaft) and imparts an impact load to the drill bit. The drill bit in turn transfers this impact load to the rock face of the bit. This impact load creates a crushing action on the rock face very similar to that discussed earlier in this section. But in this situation, the crushing action is dynamic and is more effective than the quasi-static crushing action of tri-cone and single cone drill bits. Therefore, air hammer drilling operations require far less WOB as comparable drilling operations using tri-cone or single cone drill bits.

The air hammer is made up to the bottom of the drill string and at the bottom of the air hammer is the air hammer bit. The air hammer drill string must be rotated just like a drill string that utilizes tri-cone or single cone drill bits. The rotation of the drill string allows the inserts (i.e., tungsten carbide studs) on the bit face to move to a different location on the rock face surface. This rotation allows a different position on the rock face to receive the impact load as the upper end of the hammer bit is struck by the hammer. In direct circulation operations, air flow passes through the hammer section, through the drill bit channel and orifices to the annulus. As the air passes into the annulus, the flow entrains the rock cuttings and carries the cuttings to the surface in the annulus. Direct circulation air hammers are available in a wide variety of outside housing diameters (3 inches to 16 inches). These air hammers drill boreholes with diameters from 3 5/8 inches to 17 1/2 inches.

There are also reverse circulation air hammers. These unique air hammers allow air pressure in the annulus to actuate the hammer via ports in the outside housing of the hammer. The reverse circulation air hammer bits are

designed with two large orifices in the bit face that allow the return air flow with entrained rock cuttings to flow to the inside of the drill string and then to the surface. Reverse circulation air hammers are available in larger outside housing diameters (6 inches to 24 inches). These air hammers drill boreholes with diameters from 7 7/8 inches to 33 inches. Figure 4.7.87 shows two typical air hammer bits that would be used with direct circulation air hammers. The larger bit (standing on its shank end) is an 8 5/8 inch diameter concave bit. The smaller bit (laying on its side) is a 6 inch diameter concave bit.

There are five air hammer bit cutting face designs. Figure 4.7.88a shows the profile of the drop center bit and Figure 4.7.88b shows the profile of the concave bit. Figure 4.7.89a shows the profile of the step gauge bit and Figure 4.7.89b. shows the profile of the double gauge bit. Figure 4.7.90 shows the profile of the flat face bit. These five bit cutting face designs are applicable for a variety of drilling applications from non-abrasive, soft rock formations to highly abrasive, very hard rock formations. The application of these five face designs are shown in Figure 4.7.91a, b.

In the past the air hammer manufacturers have provided the air hammer bits for their specific air hammers. This practice insured compatibility of bit with hammer housing. The increased air hammer use in drilling deep oil and natural gas recovery wells has attracted traditional oil field drill bit manufacturers to fabricate air hammer bits. Although the air hammer bit faces are somewhat uniform in design, the shafts are different for each air hammer manufacturer. The air hammer face and shafts are integral to the bit, thus,

FIGURE 4.7.86 Recommended placement of the Shock Eze [1] (courtesy of Hughes Christensen).

manufacturing air hammer bits is complicated. Fortunately, the air hammer has proven in the past decade to be very effective in drilling deep boreholes. This has given rise to competition among traditional drill bit manufacturers to provide improved air hammer bits for deep drilling operations. This competition has in turn resulted in an increase in the quality and durability of air hammer bits (over the traditional air hammer manufacturer-supplied air hammer bits) in the more hostile environments of the deep boreholes. Operational use of the air hammer will be discussed in detail in section 4.10.

4.7.5 Jars

Jarring is the process of transferring strain energy (*drill pipe stretch*) in the drill string to kinetic energy by releasing the

detent in the jar at a given overpull value. A jar is a hollow rod-telescoping cylinder with a detent mechanism that holds the rod in place or cocked position until a predetermined force or overpull valve is obtained. After the detent is released, the rod travels freely until it reaches the end of its stroke, where the jarring action occurs by a sudden impact of a hammer and anvil within the jar.

By definition, the detent is a mechanical device (e.g., catch, latch, collet, spring-operated ball) for positioning and holding one mechanical part in relation to another so that the device can be released by force applied to one of the parts.

4.7.5.1 Type of Jars

There are two general classes of jars: fishing jars and drilling jars.

FIGURE 4.7.87 Two typical air hammer bits with concave face ($8\frac{5}{8}$ inch diameter bit on end, 6 inch diameter on side) (courtesy of Rock Bit International Incorporated).

A fishing jar is used to free stuck drill string and is added to the drill string only when the string becomes stuck.

The drilling jar is used as a part of the drill string, mainly in the bottomhole assembly, (BHA) positioned either in height-weight drill pipe (Figure 4.7.92) or in drill collars (Figure 4.7.93) in most cases. Running drilling jars in the

BHA is insurance against loss time and money since the jarring process can begin immediately after the drill string becomes stuck. Note: Jars are not effective if the stuck point is located above the jar.

4.7.5.2 Drilling Jar Design

Drilling jars can be classified as mechanical or hydraulic, depending on the triggering method. A third design, which incorporates a hydraulic section for up jarring and a separate mechanical section for down jarring, is called hydro-mechanical.

Mechanical Jars

(Figure 4.7.94). Mechanical jars trigger by some variation of the spring-loaded mechanical detent principle. The detent releases as soon as a predetermined overpull is reached so that the only waiting time is that required to cycle the drawworks and stretch the drill pipe. With most mechanical drilling jars, triggering forces cannot be varied downhole, but those that do allow varied overpull downhole use drill pipe torque to control the triggering overpull. This method normally becomes less predictable as hole drag becomes high.

Hydraulic Drilling Jars

(Figure 4.7.95). The operating principle of the conventional hydraulic drilling jar is explained by McGill (SPE 1968). A piston is pulled through a close-fitting bore, causing hydraulic fluid to flow from a high-pressure side to the low-pressure side around the piston. When the piston moves from the close-fitting area of the bore into the area of the larger diameter, the fluid can flow freely around the piston and the jar releases. This provides a time delay, which can be used to stretch the drill pipe to any desired tensile overpull or to apply weight to the jar to jar down within the range of the particular jar. The ability to vary the overpull can be useful in many jarring operations.

This type of hydraulic delay frequently generates heat at a rate that cannot dissipate because this design requires a long metering stroke. This long metering stroke is necessary to allow for changes in the piston/bore radial clearance. The heat build-up in the jar may necessitate periodically stopping the jarring action to allow the jar fluid to cool.

FIGURE 4.7.88 Air hammer bit face profile designs, a) drop center bit, and b) concave bit (courtesy of AB Sandvik Rock Tools).

FIGURE 4.7.89 Air hammer bit face profile designs, a) step gauge bit, b) double gauge bit (courtesy of AB Sandvik Rock Tools).

FIGURE 4.7.91b Hybrid Bit (Kymera) - combination of PDC and Roller Cones (courtesy of Hughes Christensen – BHI).

To minimize the heat build-up problem, a hydraulic drilling jar with a time delay/mechanical release detent was designed.

The operating principle of the hydraulic delay/mechanical release jar is explained by R. W. Evans (SPE 1990). The metering function of this type of jar is separated from the triggering function by using a separate valve to

control the triggering. When jarring, the mandrels move in response of the drawworks while the housing remain stationary. Two pistons that oppose each other to define a high-pressure chamber resist the movement of the mandrels in either direction. The metering orifice allows hydraulic fluid to slowly bleed through the piston until the triggering valves are mechanically opened. This delay or metering

FIGURE 4.7.92 Jars positioned in heavy-weight drill pipe.

time is designed to allow the operator sufficient time to pull to the desired overpull or apply adequate weight to the jar for a downward action before the triggering valves to open. Like the conventional hydraulic jar, both types do not require presetting or adjustment before running in the well. The overpull and downward jarring forces and directions are controlled from the rig floor.

4.7.6 Underreamers

The term *underreaming* has been used interchangeably with *hole opening*. Underreaming is the process of enlarging the hole bore beginning at some point below the surface using a tool with expanding cutters. This permits lowering the tool through the original hole to the point where enlargement of the hole is to begin.

FIGURE 4.7.93 Jars positioned in drill collars.

Hole opening is considered as opening or enlarging the hole from the surface (or casing shoe) downward using a tool with cutter arms at a fixed diameter.

Thus, the proper name for the tools with expandable cutting arms is underreamers. The cutting arms are collapsed in the tool body while running the tool in the hole. Once the required depth is reached, mud circulation pressure moves the cutters opening for drilling operation. Additional pressure drop across the underreamer orifice gives the operator positive indication that the cutter arms are extended fully and the tool is underreaming at full gauge.

Underreamer Design

There are two basic types of underreamers: (1) roller cone rock-type underreamers and (2) drag-type underreamers. The roller cone rock-type underreamers are designed for

FIGURE 4.7.94 Dailey L.I. Mechanical drilling jar (Courtesy of Weatherford International).

FIGURE 4.7.95 Dailey Hydraulic drilling jar (Courtesy of Weatherford International).

FIGURE 4.7.96 Types of Underreamers (Courtesy of Smith International, Inc).

FIGURE 4.7.98 Rock-type underreamer nomenclature (courtesy of Smith International, Inc.).

all types of formations depending upon the type of roller cones installed. The drag-type underreamers are used in soft to medium formations. Both types can be equipped with a bit to drill and underream simultaneously. This allows for four different combinations of underreamers as shown in Figure 4.7.96. Nomenclature of various under-reamer designs are shown in Figures 4.7.97, 4.7.98, 4.7.99, and 4.7.100.

Underreamer Specifications

Tables 4.7.14 through 4.7.17 [2] show specifications for the four different types of Smith International, Inc. underreamers. Table 4.7.14 shows the specifications for the six standard models of reamaster underreamers. Table 4.7.15 shows the specifications for the nine standard models of drilling-type underreamers, Table 4.7.16 shows the specifications for the ten standard models of Rock-Type underreamers and Table 4.7.17 shows the specifications for the eight standard models of drag-type underreamers.

Underreamer Hydraulics

Pressure losses across the underreamer nozzles (orifice) are shown in Figures 4.7.101 and 4.7.102 [1]. These pressure drop graphs can be used for pressure losses calculations (given pump output and nozzles) or for orifice (nozzle) selection (given pump output and pressure loss required).

4.7.6.1 Stabilizers

Drill collar stabilizers are installed within the column of drill collars. Stabilizers guide the bit straight in vertical-hole drilling or help building, dropping, or, maintaining hole angle in directional drilling. The stabilizers are used to

1. provide equalized loading on the bit
2. prevent wobbling of the lower drill collar assembly
3. minimize bit walk
4. minimize bending and vibrations that cause tool joint wear
5. prevent collar contact with the sidewall of the hole
6. minimize keyseating and differential pressure.

FIGURE 4.7.102 Pressure drop across underreamer (rock-type (RTU) and drag-type underreamers with one nozzle) (courtesy of Smith International, Inc.).

The condition called “wobble” exists if the bit centerline does not rotate exactly parallel to and on the hole centerline so the bit is tilted.

Stabilizer Design

There are three commonly used stabilizer designs.

Solid-Type Stabilizers

(Figure 4.7.103). These stabilizers have no moving or replaceable parts, and consist of mandrel and blades that can be one piece alloy steel (integral blade stabilizer) or blades welded on the mandrel (weld-on blade stabilizer). The blades can be straight or spiral, and their working surface is either hardfaced with tungsten carbide inserts or diamonds [2,3].

Sleeve-Type Stabilizers

(Figure 4.7.104). These stabilizers have replaceable sleeve that can be changed in the field. There are two types of sleeve-type stabilizers: the rotating sleeve-type stabilizer (Figure 4.7.104A [2]) and the nonrotating sleeve-type stabilizer (Figure 4.7.104B [4]). Rotating sleeve-type stabilizers have no moving parts and work in the same way as solid-type stabilizers. Nonrotating sleeve-type stabilizers have a nonrotating rubber sleeve supported by the wall of the borehole. The rubber sleeve stiffens the drill collar string in packed hole operations just like a bushing.

Reamers

(Figures 4.7.105 and 4.7.106). Reamers are stabilizers with cutting elements embedded in their fins, and are used to maintain hole gage and drill out doglegs and keyseats

in hard formations. Because of the cutting ability of the reamer, the bit performs less work on maintaining hole gauge and more work on drilling ahead. Reamers can be used as near-bit stabilizers in the bottomhole assembly or higher up in the string. There are basically three types of reamer body:

- Three-point bottom hole reamer. This type of reamer is usually run between the drill collars and the bit to ensure less reaming back to bottom with a new bit.
- Three-point string reamer. The reamer is run in the drill collar string. This reamer provides stabilization of the drill collars to drill a straighter hole in crooked hole country. When run in the string, the reamer is effective in reaming out dog-legs, keyseats and ledges in the hole.
- Six-point bottom hole reamer. This type of reamer is run between the drill collars and the bit when more stabilization or greater reaming capacity is required. Drilling in crooked hole areas with a six-point reamer has proven to be very successful in preventing sharp changes in hole angles.

Reamers are either open bearing design or sealed bearing design with pressure compensation. Open bearing design reamers are used for standard applications. Sealed bearing design reamers are used in more demanding conditions where extended reamer life is required.

Application of Stabilizers

Figure 4.7.107 illustrates three applications of stabilizers, pendulum, fulcrum, and lock-in (stiff) hook-up.

FIGURE 4.7.103 Solid-type stabilizers (courtesy of Smith International and Baken Hughes INTEQ).

FIGURE 4.7.104 Sleeve-type stabilizers. (A) Rotating sleeve-type stabilizer (Servco). (B) Grant cushion stabilizers (nonrotating sleeve-type stabilizer) (courtesy of Smith International).

FIGURE 4.7.105 Open bearing design (m-60/62) reamer, 3-point and 6-point types (courtesy of Smith International, Inc.).

FIGURE 4.7.106 Sealed bearing design (Borrox 85) reamer, 3-point and 6-point types (courtesy of Smith International, Inc.).

FIGURE 4.7.107 Applications of stabilizers in directional drilling.

The stiff hookup consists of three or more stabilizers placed in the bottom 50 to 60 ft of drill collar string. In mind crooked hole conditions, the stiff hookup will hold the deviation to a minimum. In most cases, deviation will be held below the maximum acceptable angle. In severe conditions, this hookup will slow the rate of angle buildup, allowing more weight to be run for a longer time. This method prevents sudden increases or decreases of deviation, making dog-legs less severe and decreasing the probability of subsequent keyseats and other undesirable hole conditions. The stiff hookup is beneficial only until the maximum acceptable angle is reached. The pendulum principle should then be used.

To employ pendulum effect in directional drilling, usually one stabilizer is placed in the optimum position in the drill collar string. The position is determined by the hole size, drill collar size, angle of deviation and the weight on the bit. A properly placed stabilizer extends the suspended portion of the drilling string (that portion between the bit and the point of contact with the low side of the hole). The force of gravity working on this extended portion results in a stronger force directing the bit toward vertical so the well trajectory returns to vertical.

To employ fulcrum effect one stabilizer is placed just above the bit and additional weight is applied to the bit. The configuration acts as a fulcrum forcing the bit to the high side of the hole. The angle of hole deviation increases (buildup) as more weight is applied.

To employ a restricted fulcrum effect one stabilizer is placed just above the bit while second stabilizer is placed above the nonmagnetic drill collar. The hookup allows a gradual buildup of inclination with no abrupt changes.

To prevent key-seating one stabilizer is placed directly above the top of drill collars. The configuration prevents drill collars wedging into a key seat during tripping out of the hole.

To prevent differential sticking across depleted sands stabilizers are placed throughout the drill collar string. The area of contact between drill collars and hole is reduced, thus reducing the sticking force.

4.8 DRILLING AND COMPLETION FLUIDS HYDRAULICS

Section reviewed by Bill Lyons

4.8.1 Rheological Classification of Drilling Fluids

Experiments performed on various drilling muds have shown that the shear stress-shear rate characteristic can be represented by one of the functions schematically depicted in Figure 4.8.1. If the shear stress-shear rate diagram is a straight line passing through the origin of the coordinates, the drilling fluid is classified as a Newtonian fluid, otherwise it is considered to be non-Newtonian [1-3].

The following equations can be used to describe the shear stress-shear rate relationship:

Newtonian fluid

$$\tau = \mu \left(-\frac{dv}{dr} \right) \quad (4.8.1)$$

Bingham plastic fluid

$$\tau = \tau_y + \mu_p \left(-\frac{dv}{dr} \right)^n \quad (4.8.2)$$

Power law fluid

$$\tau = K \left(-\frac{dv}{dr} \right)^n \quad (4.8.3)$$

Herschel and Buckley fluid

$$\tau = \tau_y + K \left(-\frac{dv}{dr} \right)^n \quad (4.8.4)$$

where τ = shear stress

v = the velocity of flow

dv/dr = shear rate (velocity gradient in the direction perpendicular to the flow direction)

μ = dynamic viscosity

τ_y = yield point stress

μ_p = plastic viscosity

K = consistency index

n = flow behavior index

The dynamic viscosity (μ), yield point stress (τ_y), plastic viscosity (μ_p), consistency index (K), and flow behavior index (n) are usually determined with the Fann rotational viscometer. The Herschel and Buckley fluid model is not considered further in this text.

FIGURE 4.8.1 Shear stress-shear rate diagram: (a) Newtonian fluid, (b) Bingham plastic fluid, (c) Power law fluid, (d) Herschel-Buckley fluid.

4.8.2 Mud Flow Regimes

The flow regime (i.e., whether laminar or turbulent) can be determined using the Reynolds number. In general, the Reynolds number, Re , is calculated in consistent units from

$$Re = \frac{dvp}{\mu} \quad (4.8.5)$$

where d = diameter of the fluid conduit
 v = velocity of the fluid
 ρ = density of fluid
 μ = viscosity

In oilfield engineering units

$$Re = \frac{928d_e\bar{v}\gamma}{\mu} \quad (4.8.6)$$

where d_e = equivalent diameter of a flow channel (in.)
 \bar{v} = average flow velocity (ft/sec)
 γ = drilling fluid specific weight (lb/gal)
 μ = Dynamic viscosity (cp)

The equivalent diameter of the flow channel is defined as

$$d_e = \frac{4(\text{flow cross-sectional area})}{\text{wetted perimeter}} \quad (4.8.7)$$

For flow in the i.d. of the workstring, $d_e = d$, and for annular flow, $d_e = d_1 - d_2$,

where d = inside diameter of the pipe (in.)
 d_1 = larger diameter of the annulus (in.)
 d_2 = larger diameter of the annulus (in.)

The flow changes from laminar to turbulent in the range of Reynolds numbers from 2,100 to 4,000 [3,4]. In laminar flow, the friction pressure losses are proportional to the average flow velocity. In turbulent flow, the losses are proportional to the velocity to a power ranging from 1.7 to 2.0.

The average flow velocity is given by the following equations:

For flow inside circular pipe

$$\bar{v} = \frac{q}{2.45d^2} \quad (\text{ft/sec}) \quad (4.8.8)$$

For flow in an annular space between two circular pipes

$$\bar{v} = \frac{q}{2.45(d_1^2 - d_2^2)} \quad (\text{ft/sec}) \quad (4.8.9)$$

where q = mud flow rate (gpm)

For non-Newtonian drilling fluids, the concept of an effective viscosity* can be used to replace the dynamic viscosity in Equation 4.8.5.

For a Bingham plastic fluid flow in a circular pipe and annular space, the effective viscosities are given as [3,4].
For pipe flow

$$\mu_e = \mu_p + 6.66 \left(\frac{\tau_y d}{\bar{v}} \right) (Cp) \quad (4.8.10)$$

For annular flow

$$\mu_e = \mu_p + 4.99 \left(\frac{\tau_y (d_1 - d_2)}{\bar{v}} \right) (Cp) \quad (4.8.11)$$

For a power law fluid, the following formulas can be used.

For pipe flow

$$\mu_e = \left(\left(\frac{1.6\bar{v}}{d} \right) \left(\frac{3n+1}{4n} \right) \right)^n \left(\frac{300Kd}{\bar{v}} \right) (Cp) \quad (4.8.12)$$

For annular flow

$$\mu_e = \left(\left(\frac{2.4\bar{v}}{(d_1 - d_2)} \right) \left(\frac{2n+1}{3n} \right) \right)^n \left(\frac{200K(d_1 - d_2)}{\bar{v}} \right) (Cp) \quad (4.8.13)$$

The plastic viscosity (μ_p), yield point stress (τ_y), flow behavior index (n), and consistency index (K) are mud rheological properties that are typically calculated from the experiments performed on the drilling mud in a rotational viscometer. When these data are available, the following equations can be used:

$$\mu_p = \theta_{600} - \theta_{300} (c_p) \quad (4.8.14)$$

$$\tau_y = \theta_{300} - \mu_p \left(\text{lb}/100 \text{ ft}^2 \right) \quad (4.8.15)$$

$$n = 3.32 \log \frac{\theta_{600}}{\theta_{300}} \quad (4.8.16)$$

$$K = \frac{\theta_{300}}{(511)^n} \left(\text{lb}/100 \text{ ft}^2 \text{ s}^{-n} \right) \quad (4.8.17)$$

where θ_{600} = viscometer reading at 600 rpm

θ_{300} = viscometer reading at 300 rpm

Example

Consider a well with the following geometric and operational data:

Casing $9\frac{5}{8}$ in., unit weight = 40 lb/ft, ID = 8.835 in.
Drill pipe: $4\frac{1}{2}$ in., unit weight = 16.6 lb/ft, ID = 3.826 in.
Drill collars: $6\frac{3}{4}$ in., unit weight = 108 lb/ft, ID = $2\frac{1}{2}$

in. Hole size: $8\frac{1}{2}$ in. Drilling fluid properties: $\theta_{600} = 68$, $\theta_{300} = 68$, density = 10 lb/gal, circulating rate = 280 gpm.

Calculate Reynolds number for the fluid (1) inside drill pipe, (2) inside drill collars, (3) in drill collar annulus, and (4) in drill pipe annulus.

To perform calculation, a Power law fluid is assumed.

Flow behavior index (use Equation 4.8.16) is

$$n = 3.32 \log \frac{68}{41} = 0.729$$

Consistency index (use Equation 4.8.17) is

$$K = \frac{41}{(511)^{0.729}} = 0.433 \text{ lb}/100 \text{ ft}^2 \text{ s}^{-0.729}$$

The average flow velocities are

For inside drill pipe (use Equation 4.8.8)

$$\bar{v} = \frac{280}{2.45 (3.826)^2} = 7.807 \text{ (ft/sec)}$$

For inside drill collars

$$\bar{v} = \frac{280}{2.45 (2.25)^2} = 22.58 \text{ (ft/sec)}$$

In drill collar annulus (in open hole) use Equation 4.8.3.

$$\bar{v} = \frac{280}{2.45 (8.5^2 - 6.75^2)} = 4.282 \text{ (ft/sec)}$$

In drill pipe annulus (in the cased hole)

$$\bar{v} = \frac{280}{2.45 (8.835^2 - 4.5^2)} = 1.977 \text{ (ft/sec)}$$

The effective viscosities are

For inside the drill pipe (use Equation 4.8.12)

$$\mu_e = \left(\frac{(1.6) (7.807) (3) (0.729) + 1}{3.826 (4) (0.729)} \right)^{0.729} \times \left(\frac{(300) (0.433) (3.826)}{7.807} \right) = 160.9 \text{ cp}$$

For inside drill collars

$$\mu_e = \left(\frac{(1.6) (22.575) (3) (0.729) + 1}{2.25 (4) (0.729)} \right)^{0.729} \times \left(\frac{(300) (0.433) (2.25)}{22.575} \right) = 104.5 \text{ cp}$$

For in drill collar annulus (use Equation 4.8.13)

$$\mu_e = \left(\frac{(2.4) (4.282) (2) (0.729) + 1}{8.5 - 6.75 (3) (0.729)} \right)^{0.729} \times \left(\frac{(200) (0.433) (8.5 - 6.756)}{4.282} \right) = 140.1 \text{ cp}$$

* Also called equivalent or apparent viscosity in some published works.

In the drill pipe annulus

$$\mu_e = \left(\frac{(2.4)(1.977)(2)(0.729) + 1}{8.835 - 4.5} \frac{(3)(0.729)}{(3)(0.729)} \right)^{0.729} \times \left(\frac{(200)(0.433)(8.835 - 4.5)}{1.977} \right) = 233.6 \text{ cp}$$

Reynolds number (use Equation 4.8.6)

For inside the drill pipe

$$Re = 928 \frac{(3.826)(7.807)(10)}{(160.9)} = 1723$$

For inside drill collars

$$Re = 928 \frac{(2.25)(22.575)(10)}{(104.5)} = 4511$$

In the drill collar annulus

$$Re = 928 \frac{(8.5 - 6.75)(4.282)(10)}{(140.1)} = 496$$

In the drill pipe annulus

$$Re = 928 \frac{(8.835 - 4.5)(1.977)(10)}{(233.6)} = 340$$

4.8.3 Principle of Additive Pressures

Applying the conservation of momentum to the control volume for a one-dimensional flow conduit, it is found that [3,4].

$$\rho A \frac{dv}{dt} = -A \frac{dp}{dl} - P_w \tau_w - A \rho g \cos \alpha \quad (4.8.18)$$

where ρ = fluid density

A = flow area

dv/dt = acceleration (total derivative)

v = flow velocity

τ_w = average wall shear stress

P_w = wetted perimeter

g = gravity acceleration

α = inclination of a flow conduit to the vertical

dP/dl = pressure gradient

l = length of flow conduit

For a steady-state flow, Equation 4.8.18 is often written as an explicit equation for the pressure gradient. This is

$$\frac{dP}{dl} = -\frac{P_w}{A} \tau_w - \rho v \frac{dv}{dl} - \rho g \cos \alpha \quad (4.8.19)$$

The three terms on the right side are known as frictional, accelerational (local acceleration) and gravitational components of the pressure gradient. Or, in other words, the total

pressure drop between two points of a flow conduit is the sum of the components mentioned above. Thus,

$$\Delta P = \Delta P_F + \Delta P_A + \Delta P_G \quad (4.8.20)$$

where ΔP_F = frictional pressure drop

ΔP_A = accelerational pressure drop

ΔP_G = gravitational pressure drop (hydrostatic head)

Equation 4.8.21 expresses the principle of additive pressures. In addition to Equation 4.8.21, there is the equation of state for the drilling fluid.

Typically, water based muds are considered to be incompressible or slightly compressible. For the flow in drill pipe or drill collars, the acceleration component (ΔP_A) of the total pressure drop is negligible, Equation 4.8.20 can be reduced to

$$\Delta P = \Delta P_F + \Delta P_G \quad (4.8.21)$$

Equations 4.8.19 through 4.8.22 are valid in any consistent system of units.

Example

The following data are given:

- Pressure drop inside the drill string = 600 psi
- Pressure drop in annular space = 200 psi
- Pressure drop through the bit nozzle = 1,600 psi
- Hole depth = 10,000 ft
- Mud density = 10 lb/gal

Calculate

- bottomhole pressure
- pressure inside the string at the bit level (above the nozzles)
- drill pipe pressure

Because the flow in the annulus is upward, the total bottomhole pressure is equal to the hydrostatic head plus the pressure loss in the annulus. Hydrostatic head (psi) is calculated as follows [1,3,4]:

$$P_{\text{hyd}} = 0.052 \rho L \text{ psi} \quad (4.8.22)$$

where ρ = density (lb/gal)

L = length of pipe (ft)

Therefore,

$$P_{\text{bottom}} = 0.052(10)(10,000) + 200 = 5,400 \text{ psi}$$

Pressure inside the drill string above the nozzle, p_{is} (psi),

$$p_{\text{is}} = 5,400 + 1,600 = 7,000 \text{ psi}$$

Drill pipe pressure (also known as standpipe pressure), P_{dp} (psi)

$$p_{dp} = 7,000 + 600 - (0.052)(10)(10,000) = 2,400 \text{ psi}$$

Note that the drill pipe pressure is a sum of all the pressure losses in the circulating system.

4.8.4 Friction Pressure Loss Calculations

4.8.4.1 Laminar Flow

For pipe flow of Bingham plastic type drilling fluid, the following can be used:

$$\Delta p = \frac{\mu_p Lv}{1500d^2} + \frac{\tau_y L}{225d} \quad (4.8.23)$$

Corresponding equation for a Power law type drilling fluid is

$$\Delta p = \left[\left(\frac{1.6v}{d} \right) \left(\frac{3n+1}{4n} \right) \right]^n \frac{KL}{300d} \quad (4.8.24)$$

For annular flow of Bingham plastic and Power law fluids, respectively,

$$\Delta p = \frac{\mu_p Lv}{1000(d_1 - d_2)^2} + \frac{\tau_y L}{200(d_1 - d_2)} \quad (4.8.25)$$

and

$$\Delta p = \left[\left(\frac{2.4v}{(d_1 - d_2)} \right) \left(\frac{2n+1}{3n} \right) \right]^n \frac{KL}{300(d_1 - d_2)} \quad (4.8.26)$$

4.8.4.2 Turbulent Flow

Turbulent flow occurs if the Reynolds number as calculated above exceeds a certain critical value. Instead of calculating the Reynolds number, a critical flow velocity may be calculated and compared to the actual average flow velocity [1].

The critical velocities for the Bingham plastic and Power law fluids can be calculated as follows:

For a Bingham plastic fluid

$$v_c = \frac{1.08\mu_p + 1.08\sqrt{\mu_p^2 + 9.256(d_1 - d_2)^2\tau_y\rho}}{(d_1 - d_2)} \text{ (ft/min)} \quad (4.8.27)$$

For a power law fluid

$$v_c = \left[\frac{3.878 \times 10^4 K}{\rho} \right]^{1/(2-n)} \times \left[\left(\frac{2.4}{(d_1 - d_2)} \right) \left(\frac{2n+1}{3n} \right) \right]^{n/(2-n)} \text{ (ft/min)} \quad (4.8.28)$$

In the case of pipe flow, for practical purposes, the corresponding critical velocities may be calculated using Equation 4.8.27 and 4.8.28, but letting $d_2 = 0$.

Note: the critical flow velocity is in ft/min instead of the customary ft/sec.

In turbulent flow the pressure losses, Δp (psi), can be calculated from the Fanning equation [3,4].

$$\Delta p = \frac{f\gamma Lv^2}{25.8d} \quad (4.8.29)$$

where f = Fanning factor

L = length of pipe, ft

The friction factor depends on the Reynolds number and the surface conditions of the pipe. There are numerous charts and equations for determining the relationship between the friction factor and Reynolds number. The friction factor can be calculated by [3,4].

$$f = 0.046 \text{ Re}^{-0.2} \quad (4.8.30)$$

Substituting Equation 4.8.7, 4.8.8, and 4.8.30 into Equation 4.8.29 yields [4]

For pipe flow

$$\Delta p = \frac{7.7 \times 10^{-5} \bar{\gamma}^{0.8} q^{1.8} \mu_p^{0.2} L}{d^{4.8}} \quad (4.8.31)$$

For annular flow

$$\Delta p = \frac{7.7 \times 10^{-5} \bar{\gamma}^{0.8} \mu_p^{0.2} q^{1.8} L}{(d_1 - d_2)^3 (d_1 + d_2)^{1.8}} \quad (4.8.32)$$

Example

The wellbore, drill string and drilling fluid data from the previous example are used. Casing depth is 4,000 ft. Assuming a drill pipe length of 5,000 ft and a drill collar length of 500 ft, find the friction pressure losses,

For flow inside the drill pipe, the critical flow velocity is

$$v_c = \left[\frac{3.878 \times 10^4 (0.433)}{10} \right]^{1/(2-0.729)} \times \left[\left(\frac{2.4}{3.826 - 0} \right) \left(\frac{2(0.729) + 1}{3(0.729)} \right) \right]^{0.729/(2-0.729)} \times \text{(ft/min)}$$

$$v_c = 283 \text{ ft/min} = 4.72 \text{ ft/sec}$$

Recall $v = 7.807 \text{ ft/sec}$, because $v > v_c$ the flow is turbulent therefore Equation 4.8.31 is chosen to calculate the pressure loss p_1 .

$$\Delta p_1 = \frac{7.7 \times 10^{-5} (10^{0.8}) (280^{1.8}) (27^{0.2}) 5000}{3.826^{4.8}} \text{psi}$$

$$\Delta p_1 = 190 \text{ psi}$$

Note use of equation 4.8.14 to determine the plastic viscosity.

For flow inside the drill collars, it is easy to check that the flow is also turbulent and thus the pressure loss is

$$\Delta p_2 = \frac{7.7 \times 10^{-5} (10^{0.8}) (280^{1.8}) (27^{0.2}) 500}{2.25^{4.8}} \text{psi}$$

$$\Delta p_2 = 243 \text{ psi}$$

For annulus flow around the drill collars

To calculate the critical velocity, Equation 4.8.28 is used

$$v_c = \left[\frac{3.878 \times 10^4 (0.433)}{10} \right]^{1/(2-0.729)} \\ \times \left[\left(\frac{2.4}{8.5 - 6.75} \right) \left(\frac{2(0.729) + 1}{3(0.729)} \right) \right]^{0.729/(2-0.729)} \text{ (ft/min)}$$

$$v_c = 442 \text{ (ft/min)} = 7.36 \text{ ft/sec}$$

The average velocity around the collars is 4.282 ft/sec, as calculated in the previous example. Therefore, the flow is laminar and Equation 4.8.25 is selected to calculate the pressure drop Δp_3

$$\Delta p_3 = \left[\left(\frac{2.4 (4.282)}{(8.5 - 6.75)} \right) \left(\frac{2(0.729) + 1}{3(0.729)} \right) \right]^{0.729} \\ \times \frac{0.433 (500)}{300 (8.5 - 6.75)} \text{psi}$$

$$\Delta p_3 = 6.06 \text{ psi}$$

For annulus flow around the drill pipe in the open hole section.

It is found from Equation 4.8.28 that the flow is laminar, thus Equation 4.8.25 can be used with the average annular velocity found from Equation 4.8.9.

$$\bar{v} = \frac{280}{(2.45 (8.5^2 - 4.5^2))} = 2.19 \text{ ft/sec}$$

$$\Delta p_4 = \left[\left(\frac{2.4 (2.19)}{(8.5 - 4.5)} \right) \left(\frac{2(0.729) + 1}{3(0.729)} \right) \right]^{0.729} \\ \times \frac{0.433 (1000)}{300 (8.5 - 4.5)} \text{psi}$$

$$\Delta p_4 = 0.479 \text{ psi}$$

For annulus flow around the drill pipe in cased section.

Using Equation 4.8.28 it is determined that the flow is also laminar in the cased hole, therefore Equation 4.8.26 is used again.

$$\Delta p_5 = \left[\left(\frac{2.4 (1.977)}{(8.835 - 4.5)} \right) \left(\frac{2(0.729) + 1}{3(0.729)} \right) \right]^{0.729} \\ \times \frac{0.433 (4000)}{300 (8.835 - 4.5)} \text{psi}$$

$$\Delta p_5 = 1.5 \text{ psi}$$

Therefore, the total frictional pressure loss is

$$\Delta p_f = \Delta p_1 + \Delta p_2 + \Delta p_3 + \Delta p_4 + \Delta p_5$$

$$\Delta p_f = 94.7 + 243 + 6.06 + .48 + 1.5 = 346 \text{ psi}$$

4.8.4.3 Pressure Loss Through Bit Nozzles

Assuming steady-state, frictionless (due to the short length of the nozzles) drilling fluid flow, Equation 4.8.19 is written

$$\rho v = \frac{\partial v}{\partial l} = \frac{\partial p}{\partial l} \quad (4.8.33)$$

Integrating Equation 4.8.33 assuming incompressible drilling fluid flow (ρ is constant) and after simple rearrangements yields the pressure loss across the bit Δp_b (psi) which is

$$\Delta p_b = \frac{\rho v^2}{2} \quad (4.8.34)$$

Introducing the nozzle flow coefficient of 0.95 and using field system of units, Equation 4.8.34 becomes

$$\Delta p_b = \frac{\bar{\gamma} v^2}{1,120} \quad (4.8.35)$$

or

$$\Delta p_b = \frac{\bar{\gamma} v^2}{10,858 A^2} \quad (4.8.36)$$

where v = nozzle velocity in ft/s

q = flow rate in gpm

$\bar{\gamma}$ = drilling fluid density in lb/gal

A = nozzle flow area in in.²

If the bit is furnished with more than one nozzle, then

$$A = A_1 + A_2 + A_3 + \dots A_n \quad (4.8.37)$$

where n is the number of nozzles, and

$$d_{en} = \sqrt{d_1^2 + d_2^2 + \dots d_n^2} \quad (4.8.38)$$

where d_{en} is the equivalent nozzle diameter.

Example

A tricone roller rock bit is furnished with three nozzles with the diameters of $\frac{9}{32}$, $\frac{10}{32}$ and $\frac{12}{32}$ in. Calculate the bit pressure drop if the mud weight is 10 lb/gal and flowrate is 300 gpm.

Nozzle equivalent diameter is

$$d_{\text{en}} = \sqrt{\left(\frac{9}{32}\right)^2 + \left(\frac{10}{32}\right)^2 + \left(\frac{12}{32}\right)^2} = 0.5643 \text{ in.}$$

and the corresponding flow area is

$$A = \frac{\pi}{4} (0.5643)^2 = 0.2493 \text{ in.}^2 \quad (4.8.39)$$

The pressure loss through bit nozzles is

$$\Delta p_b = \frac{(10)(300)^2}{10858(0.2493)^2} = 1334 \text{ psi}$$

4.8.5 Underbalanced Drilling

Section reviewed by Michael Lorenz

4.8.5.1 Definitions

When drilling for oil and natural gas deposits, the most important function of the drilling fluid is to control the inflow of formation fluids that could enter the wellbore annulus. When the specific gravity of the drilling fluid has been engineered to provide a bottomhole pressure in the borehole annulus that precisely counters the pore pressure of the formation fluids that could enter the wellbore annulus, the drilling operation is called *balanced*. When the specific gravity of the drilling fluid has been engineered to provide a bottomhole pressure in the borehole annulus that is slightly higher than the pore pressure of the formation fluids, the drilling operation is called *overbalanced*. When the specific gravity of the drilling fluid has been engineered to provide a bottomhole pressure in the borehole annulus that is lower than the pore pressure of the formation fluids, the drilling operation is called *underbalanced* [5–7]. This is sometimes referred to as *flowdrilling*. Having drilled a well using underbalanced techniques, it is important to complete the well underbalanced. If the underbalanced drilling operation is not followed by completions efforts using underbalanced techniques, formation damage may still occur due to poor completions practices.

For a general guideline, when drilling and completing wells into the actual producing rock formations, underbalanced drilling (and completion) techniques are restricted to geologic provinces that have producing formations with pore pressures of the order of approximately 2500 psi or less. From a practical standpoint, this restricts underbalanced drilling and completions to infill production wells in oil and natural gas fields that have significant production

history. However, there are numerous drilling operations where underbalanced drilling techniques are utilized in both exploratory and early development wells when upper zones with troublesome rock formations are encountered. Thus, underbalanced drilling and completion techniques have broad applications throughout the oil and natural gas (and geothermal steam and water) resource recovery industry.

4.8.5.2 Drilling Operations

In oil and natural gas producing wells that have relatively low pore pressures, overbalanced drilling operations created *formation damage* by forcing the drilling mud particles and rock cutting fines into the producing rock formation pores thereby clogging the pores of formation rock in the vicinity of the open borehole. This formation damage reduces the flow of oil and/or natural gas to the wellbore when the well is completed and produced. Great costs are incurred by operating companies to reduce the effects of formation damage in wells that have been drilled with conventional overbalanced methods (e.g., hydraulic fracturing and acidizing).

Producing oil and natural gas geologic provinces become depleted as they are produced. This depletion is in both volume of oil or gas available for production and in reservoir pressure. To reduce the effects of formation damage, infill drilling and completion operations are carried out in these provinces, the new wells are increasingly being drilled and completed using underbalanced drilling techniques. The use of underbalanced drilling and completion techniques is generally confined to the drilling and completion of the rock formations that will produce oil and/or natural gas. Underbalanced drilling operations allow the oil and/or natural gas to flow into the wellbore as drilling process progresses through these producing rock formations. Special surface production equipment must be in place in order to safely collect these produced fluids and control (via metering) the volumetric flow rate of these fluids (together with the drilling fluid) into the wellbore at the bottom of the well. The metering of these volumetric flow rates is critical to the control of any underbalanced drilling operation. These metering measurements are used to continuously adjust the magnitude of the difference between the pore pressure of the openhole exposed producing formation and the pressure at that formation due to the circulating drilling fluid.

4.8.5.3 Air and Gas Drilling

Air and gas drilling refers to the use of compressed air (or other gases) as the circulating drilling fluid for rotary drilling operations. The majority of these drilling operations use compressed air as the circulating drilling fluid.

In some oil and natural gas recovery drilling operations it is necessary to drill with a gas that will not support downhole combustion. This is particularly the case when drilling in or near the hydrocarbon producing formations. This objective has been realized by using natural gas or inert atmospheric air (air stripped of most oxygen) as drilling gases. Natural gas from pipelines has been used as a drilling gas since the 1930's. The use of inert air as a drilling gas is a recent technological development [6]. Drilling location deployable equipment units are available to the oil and natural gas resource recovery industry. These units are also called "nitrogen generators." The units strip most of the oxygen content from the compressed air output from standard positive displacement primary compressors (rotary or reciprocation piston compressors). These inert air generating field units have only been in use for a few years.

The basic planning steps for the drilling of a deep well with compressed gases are as follows [6]:

1. Determine the geometry of the borehole section or sections to be drilled with air or other gases (i.e., openhole diameters, the casing or liner inside diameters, and depths).
2. Determine the geometry of the associated drill strings for the sections to be drilled with air or other gases (i.e., drill bit size and type, the drill collar size, drill pipe size, and maximum depth).
3. Determine the type of rock formations to be drilled and estimate the anticipated drilling rate of penetration. Also, estimate the quantity and depth location of any formation water that might be encountered.
4. Determine the elevation of the drilling site above sea level, the temperature of the air during the drilling operation, and the approximate geothermal temperature gradient.
5. Establish the objective of the air (or other gas) drilling operation:
 - To eliminate loss of circulation problems,
 - To reduce formation damage,
 - To allow formation fluids to be produced as the formation is drilled.
6. Determine whether direct or reverse circulation techniques will be used to drill the various sections of the well.
7. Determine the required approximate minimum volumetric flow rate of air (or other gas) to carry the rock cuttings from the well when drilling at the maximum depth.
8. Select the contractor compressor(s) that will provide the drilling operation with a volumetric flow rate of air that is greater than the required minimum volumetric flow rate (use a factor of safety of at least 1.2).
9. Using the compressor(s) air volumetric flow rate to be injected into the well, determine the bottomhole and surface injection pressures as a function of drilling depth (over the interval to be drilled). Also, determine the maximum power required by the compressor(s) and the available maximum derated power from the prime mover(s) (see Section 3.1, Chapter 3).
10. Determine the approximate volume of fuel required by the compressor(s) to drill the well.
11. In the event formation water is encountered, determine the approximate volumetric flow rate of "mist" injection water needed to allow formation water or formation oil to be carried from the well during the drilling operation.
12. Determine the approximate volumetric flow rate of formation water or formation oil that can be carried from the well during the drilling operation (assuming the injection air will be saturated with water vapor at bottomhole conditions).

The circulation system for an air (or other gas) drilling operation is a typical compressible fluid flow calculation problem. In these problems, the pressure and temperature is usually known at the exit to the system. In this case, the exit is at the end of the blowline. At this exit, the pressure and temperature are the local atmospheric pressure and temperature at the drilling location. The calculation procedures for air drilling circulation problems are to start at these known exit conditions and work upstream through the system. In these calculations, the volumetric flow rate must be assumed or known. If compressors are used to provide compressed air, then the volumetric flow rate is the sum of the outputs of all the primary compressors (see Section 3.4).

The methodology outline above has been successful in predicting bottomhole and injection pressures with an accuracy of about 5%. In order to attain this accuracy, it is necessary to consider all major and minor flow losses in the circulating system, and to account for any water or other incompressible fluids being carried from the well by the air or gas drilling fluid.

Bottomhole Pressure

The perfect gas law is used as the basis of the air and gas drilling equations presented. The perfect gas law can be written as (see Section 3.4, "Compressors")

$$\frac{P}{\gamma} = \frac{RT}{S_g} \quad (4.8.40)$$

where

- P is pressure (lb/ft² absolute, or N/m² absolute),
- γ is specific weight (lb/ft³, or N/m³),
- T is absolute temperature (°R, or K),

R is the universal gas constant (53.36 lb-ft/lb-°R, or 0.0074529.28 N-m/N-K),
S_g is the specific gravity of the gas.

The equation for the pressure in the air (or gas) flow at the entrance end to the blooey line (just after the Tee from the annulus) can be approximated by

$$P_b = \left[\left(f_b \frac{L_b}{D_b} + K_t + \sum K_v \right) \left(\frac{\dot{w}_g^2 R T_r}{g A_b^2 S_g} \right) + P_{at}^2 \right]^{0.5} \tag{4.8.41}$$

where

- P_b** is the pressure at the entrance to the blooey line (lb/ft² absolute, or N/m² absolute).
- P_{at}** is the atmospheric pressure at the exit to the blooey line (lb/ft² absolute, or N/m² absolute).
- f_b** is the Darcy-Wiesbach friction factor for the blooey line.
- L_b** is the length of the blooey line (ft, or m).
- D_b** is the inside diameter of the blooey line (ft, or m).
- K_t** is the minor loss factor for the Tee turn at the top of the annulus.
- K_v** is the minor loss factor for the valves in the blooey line.
- ẇ_g** is the weight rate of flow of gas (lb/sec, or N/sec).
- A_b** is the cross-sectional area of the inside to the blooey line (ft², or m²).
- T_r** is the average temperature of the gas flow in the blooey line (°R, or K)

The approximate value of the **K_t** can be determined from [Figures 4.8.2 and 4.8.3](#).

FIGURE 4.8.2 Dimensions of the blind Tee at top of annulus.

FIGURE 4.8.3 Flow resistance coefficient for the blind Tee at top of annulus.

The friction factor is determined from the empirical von Karman relationship. This relationship is

$$f_b = \left[\frac{1}{2 \log_{10} \left(\frac{D_b}{e} \right) + 1.14} \right]^2 \tag{4.8.42}$$

where **e** is the approximate absolute roughness of the blooey line inside surface (ft, or m).

For direct (conventional) circulation for air and gas drilling, the bottomhole pressure in the annulus is given by

$$P_{bh} = \left[\left(P_{at}^2 + b_a T_{av}^2 \right) e^{\frac{2a_a H}{T_{av}}} - b_a T_{av}^2 \right]^{0.5} \tag{4.8.43}$$

where

P_{bh} is the bottomhole pressure in the annulus (lb/ft² absolute, or N/m² absolute). (This pressure can also be the pressure at the bottom of any calculation interval with a uniform cross-sectional flow area.)

P_{at} is the pressure at the top of the annulus (lb/ft² absolute, or N/m² absolute). (This is the atmospheric pressure when the calculation interval starts at the top of the well. However, it is the pressure at the bottom of the calculation interval of the interval above if numerous

intervals with various cross-sectional flow areas are being considered.)

T_{av} is the average temperature of the calculation interval ($^{\circ}R$, or K).

H is the length (or height) of the calculation interval (ft, or m).

The constants a_a and b_a are

$$a_a = \left(\frac{S_g}{R} \right) \left[1 + \left(\frac{\dot{W}_s}{\dot{W}_g} \right) \right] \quad (4.8.44)$$

and

$$b_a = \frac{f}{2g(D_h - D_p)} \left(\frac{R}{S_g} \right) \frac{\dot{W}_g^2}{\left(\frac{\pi}{4} \right)^2 (D_h^2 - D_p^2)^2} \quad (4.8.45)$$

where

f is the Darcy-Wiesbach (or Moody) friction factor for the annulus (this can be a weighted average if the annulus has dissimilar surfaces).

g is the acceleration of gravity (i.e., 32.2 ft/sec², or 9.81 m/sec²)

\dot{w}_s is the weight rate of flow of the solids (lb/sec, or N/sec).

\dot{w}_g is the weight rate of flow of gas (lb/sec, or N/sec).

D_h is the inside diameter of the annulus borehole (ft, or m).

D_p is the outside diameter of the pipe in the annulus (ft, or m).

The values of \dot{w}_s and \dot{w}_g are determined from

$$\dot{W}_s = \frac{\pi}{4} D_h^2 \gamma_w S_s \kappa \quad (4.8.46)$$

and

$$\dot{W}_g = \gamma_g Q_g \quad (4.8.47)$$

where

γ_w is the specific weight of the water (62.4 lb/ft³, or 9810 N/ft³).

γ_g is the specific weight of the gas (lb/ft³, or N/ft³).

S_s is the specific gravity of the solids cuttings.

Q_g is the volumetric flow rate of gas at reference pressure and temperature conditions (ft³/sec, or m³/sec).

κ is the drilling rate of penetration (ft/sec, or m/sec).

The compressed air or other gas flowing through the annulus is assumed to be wholly turbulent, therefore, the friction factor is determined from the empirical von Karman

relationship for annulus flow. This relationship for the annulus is [8]

$$f = \left[\frac{1}{2 \log_{10} \left(\frac{D_h - D_p}{e_{av}} \right) + 1.14} \right]^2 \quad (4.8.48)$$

where e_{av} is the average absolute roughness of the annulus surfaces (ft, or m).

The average annulus open hole absolute roughness can be determined from a surface area weight average relationship between the inside openhole surface area and its roughness and the outside surface area of the drill string and its roughness. The weight average relationship is [4]

$$e_{av} = \frac{e_{oh} D_h^2 + e_p D_p^2}{D_h^2 + D_p^2} \quad (4.8.49)$$

The openhole borehole inside surface absolute roughness can be approximated from Table 4.8.1. The outside absolute roughness of the outside of the steel pipe is usually taken as 0.00015 ft [5].

Minimum Volumetric Flow Rate

The minimum volumetric flow rate can be approximated by determining the volumetric flow rate that will give a minimum kinetic energy per unit volume in the annulus equal to 3.0 lb-ft/ft³ (or 141.9 N-m/m³). This is usually at

TABLE 4.8.1 Openhole Wall Approximate Absolute Roughness for Rock Formation Types [6]

Rock Formation Types	Surface Roughness (ft)
Competent, low fracture Igneous (e.g., granite, basalt) Sedimentary (e.g., limestone, sandstone) Metamorphic (e.g., gneiss)	0.001 to 0.02
Competent, medium fracture Igneous (e.g., granite, basalt) Sedimentary (e.g., limestone, sandstone) Metamorphic (e.g., gneiss)	0.02 to 0.03
Competent, high fracture Igneous (e.g., breccia) Sedimentary (e.g., sandstone, shale) Metamorphic (e.g., schist)	0.03 to 0.04

the section of the annulus that has the largest cross-sectional area. The kinetic energy per unit volume is

$$KE = \frac{1}{2} \frac{\gamma_g}{g} V^2 \quad (4.8.50)$$

where

KE is the kinetic energy per unit volume (lb-ft/ft³, or N-m/m³).

V is the velocity of the gas in the annulus (ft/sec, or m/sec).

Drill Bit Orifices or Nozzles

Gas flow through an orifice or nozzle constriction can be either sonic or subsonic. These flow conditions depend upon the critical pressure ratio. The critical pressure ratio is the relationship between the downstream pressure and the upstream pressure. This ratio is a function of the properties of the gas and is given by [8]

$$\left(\frac{P_2}{P_1}\right)_c = \left(\frac{2}{k+1}\right)^{\frac{k}{k-1}} \quad (4.8.51)$$

where

P₁ is the upstream pressure (lb/ft² absolute, or N/m² absolute).

P₂ is the downstream pressure (lb/ft² absolute, or N/m² absolute).

k is the ratio of specific heats of the gas.

The flow conditions through the constriction are sonic if

$$\left(\frac{P_2}{P_1}\right)_c \leq \left(\frac{2}{k+1}\right)^{\frac{k}{k-1}} \quad (4.8.52)$$

The flow conditions through the constriction are subsonic if

$$\left(\frac{P_2}{P_1}\right)_c \geq \left(\frac{2}{k+1}\right)^{\frac{k}{k-1}} \quad (4.8.53)$$

If the gas flow through the orifice or nozzle throats is sonic, the pressure above the drill bit inside the drill string can be determined from

$$P_{ai} = \frac{\dot{w}_g T_{bh}^{0.5}}{A_n \left[\left(\frac{gkS_g}{R}\right) \left(\frac{2}{k+1}\right)^{\frac{k+1}{k-1}} \right]^{0.5}} \quad (4.8.54)$$

where

P_{ai} is the pressure above the drill bit inside the drill string (lb/ft² absolute, or N/m² absolute).

A_n is the total flow area of the orifices or nozzles (ft², or m²).

T_{bh} is the temperature of the gas at the bottom of the borehole (°R, or K).

If the gas flow through the orifice or nozzle throats is subsonic, the pressure above the drill bit inside the drill string can be determined from

$$P_{ai} = P_{bh} \left[\frac{\left(\frac{\dot{w}_g}{A_n}\right)^2}{2g \left(\frac{k}{k-1}\right) P_{bh} \gamma_{bh}} + 1 \right]^{\frac{k}{k-1}} \quad (4.8.55)$$

where γ_{bh} is the specific weight of the gas at bottomhole conditions (lb/ft³, or N/m³).

Injection Pressure

The pressure above the bit at the bottom of the inside of the drill string is used as the initial pressure for a sequence of calculations that determine the pressure at the top of each section of drill string having constant cross-section. The pressure at the top of each section is used as the initial pressure for the section above. This procedure is used until the injection pressure is determined. The injection pressure is obtained from [6]

$$P_{in} = \left[\frac{P_{ai}^2 + b_i T_{av}^2 \left(e^{\frac{2a_i H}{T_{av}}} - 1 \right)}{e^{\frac{2a_i H}{T_{av}}}} \right]^{0.5} \quad (4.8.56)$$

where

P_{in} is the injection pressure into the inside of the drill string (lb/ft² absolute, or N/m² absolute). (This pressure can also be the pressure at the top of any calculation interval with a uniform cross-sectional flow area.)

The constants a_i and b_i are

$$a_i = \frac{S_g}{R} \quad (4.8.57)$$

and

$$b_i = \frac{f}{2gD_i} \left(\frac{R}{S_g}\right)^2 \frac{w_g^2}{\left(\frac{\pi}{4}\right)^2 D_i^4} \quad (4.8.58)$$

where

D_i is the inside diameter of the constant cross-section section (ft, or m).

Water Injection

Water is injected into the volumetric flow rate of air (or other gases) flowing from the compressors to the top of the inside of the drill string for three important reasons:

TABLE 4.8.2 Typical Approximate Additives Volumes per 20 bbl of Water for Unstable Foam Drilling (actual commercial product volumes may vary)

Additives	Volume per 20 bbl of Water
Foamer	4.2 to 8.4 gal
Polymer	1 to 2 quarts
Corrosion Inhibitor	0.5 gal

- Saturate the air or other gas with water vapor at bottomhole annulus pressure and temperature conditions
- Eliminate the stickiness of the small rock cuttings flour generated by the advance of the drill bit
- Assist in suppressing the combustion of the mixture of produced hydrocarbons and oxygen rich air

Water injection (with additives) is accomplished with a liquid pump that injects water into the compressed gas flow line to the well. The liquid pump draws its water from a liquid suction tank. The typical additives are corrosion inhibitors, polymer, and a foaming agent. The foaming agent causes the gas/liquid mixture to develop into an unstable foam as the mixture passes through the bit orifices. Table 4.8.2 gives a typical additives mixture used to create unstable foam drilling. “Mist drilling” was the old term used to describe the practice of injecting water (with additives) into the compressed gas to the well. Later it was found that a foaming agent improved the hole cleaning effectiveness of water injection. The water injection practice is now known as “unstable foam drilling” [6].

Saturation of Gas

Water is injected into the air or other circulation gases at the surface in order to saturate the gas with water vapor at bottomhole conditions. The reason this is done is to assure that the circulation gas as it flows out of the drill bit orifices into the annulus will be able to carry formation water coming into the annulus as whole droplets. If the gas entering the annulus is not saturated, the gas will use its internal energy to convert the formation water to vapor. This will reduce the capability of the gas to expand as it enters the annulus. If the gas cannot expand properly, it will not create adequate gas flow velocity in the annulus to carry cuttings (and formation water) to the surface. Water saturated gas will carry formation water to the surface as droplets.

The empirical formula for determining the saturation of various gases including air can be found in a variety of chemistry handbooks and other literature. The empirical formula for the saturation pressure of air, p_{sat} , can be written as [9]

$$P_{\text{sat}} = 10^{\left[6.39416 - \left(\frac{1750.286}{217.23 + 0.555t_{\text{bh}}}\right)\right]} \quad (4.8.59)$$

where P_{sat} is saturation pressure of the air at annulus bottomhole conditions (psia) and t_{bh} is the temperature of the air at annulus bottomhole conditions ($^{\circ}\text{F}$). The approximate volumetric flow rate of injected water to an air drilling operation is determined by the relationship between the above saturation pressure and the bottomhole pressure in the annulus, and the weight rate of flow of gas being injected into the top of the inside of drill string. Thus, the flow rate of injected water, q_{iw} , is determined from [9]

$$q_{\text{iw}} = \left(\frac{P_{\text{sat}}}{P_{\text{bh}} - P_{\text{sat}}}\right) \left(\frac{3600}{8.33}\right) \dot{w}_{\text{g}} \quad (4.8.60)$$

where q_{iw} is the volumetric flow rate of injected water (gal/hr) and P_{bh} is the pressure at annulus bottomhole conditions (psia)

Eliminate Stickiness

The next higher volumetric flow rate of injected water is that amount needed to eliminate borehole stickiness. As the drill bit advances in some types of rock formations, the cutting action of the bit creates rock cuttings and a small amount of “rock flour”. Rock flour are very small rock particles that act mechanically very much like the flour one cooks with in the kitchen. If a borehole is originally dry, the circulation gas will efficiently carry the rock cutting particles and the rock flour up the annulus to the surface as the drill bit is advanced (this is called “dust drilling”). If a water bearing formation is penetrated, formation water will begin to flow into the annulus. When the water combines with rock flour, the flour particles begin to stick to each other and the borehole wall. This is very much like placing cooking flour in a bowl and putting a small amount of water in with it and mixing it. The cooking flour will become sticky and nearly impossible to work with a spoon. In the open borehole, the slightly wetted rock flour sticks to the nonmoving inside surface of the borehole. Because gas flow eddy currents form just above the top of the drill collars, “mud rings” develop from this sticky rock flour at this location on the borehole wall. These mud rings can build up and create a constriction to the annulus gas flow. This constriction will in turn cause the injection pressure to increase slightly (by 5 to 10 psi) in a matter of a minute or so. This rather sharp increase in pressure should alert the driller that mud rings are forming due to an influx of formation water (or perhaps even crude oil). If mud rings are allowed to continue to form they will begin to resist the rotation of the drill string (since cuttings are not being efficiently remove from the well). This in turn will increase the applied torque at the top of the drill string and increase the danger of a drill string torque failure. Also, the existence of mud rings creates a confined chamber of high pressure gas. If hydrocarbon rock formations are being penetrated, the potential for combustion in the chamber

increases. The solution to this operational problem is to begin to inject water into the circulation gas. Additional injected water (above that given by Equations 4.8.59 and 4.8.60) is needed to reduce the stickiness (in much the same way the cooking flour stickiness is reduced by adding more water). The amount of water added to eliminate the mud ring must be determined empirically and will be somewhat unique for each drilling operation.

The procedure for eliminating mud rings is as follows:

1. Begin injecting sufficient water to saturate the gas flow with water vapor.
2. Curtail drilling ahead but continue gas circulation.
3. Bring the rotations of the drill string up to about 100 rpm and lift the drill string up to the top of the drilling mast and lower it several times. This will allow the drill collars to smash into the mud ring structures and break them off the borehole wall.
4. Return to drilling ahead.
5. If the mud rings begin to form again (the injection pressure increases again), increase the water injection flow rate and repeat the above sequence.
6. Continue the above five steps until the volumetric flow rate of injected water reduces the stickiness of the rock flour so that the mud rings no longer form on the open borehole wall (this will be indicated by a return to a nearly constant gas injection pressure).

The typical injected water volumetric flow rate to eliminate rock flour stickiness in a $7\frac{7}{8}$ in. borehole would be of the order of approximately 2 to 10 bbl/hr.

Suppression of Hydrocarbon Combustion

The next higher volumetric flow rate of injected water is that needed to suppress the downhole combustion of hydrocarbons (e.g., downhole fire or explosion). This combustion is created when the advance of the drill bit gives a mixture of drilling air with produced oil, natural gas, and/or coal dust. The ignition spark is easily caused by the action of the steel drill bit cutters on the rock face at the bottom or the sides of the borehole. Figure 4.8.4 gives the ignition (ignition zone) parameters of pressure versus the percent mixture for natural gas mixed with standard atmosphere air (at ASME Standard Conditions) [10,11]. Increasing the water injection volumetric flow rate (with additives, particularly the foam agent) to the borehole wets down rock and steel surfaces reducing the risk of ignition sparks, and creates a bottom-hole foam that deprives the combustion process of unlimited source of oxygen. It is thought that the water injection can be successful in suppressing hydrocarbon combustion in vertical wells where the hydrocarbon producing rock formation section has a thickness of approximately 200 ft or less. Horizontal drilling in hydrocarbon bearing rock formations is considered quite risky because of the long time exposure of the spark producing drill bit.

In a drilling operation where air is being used as the drilling fluid, as the drill bit is advanced and hydrocarbon

FIGURE 4.8.4 Ignition mixture by volume of natural gas and atmospheric air.

bearing rock formations are about to be penetrated, the following steps should be taken to reduce the risk of downhole hydrocarbon combustion:

1. Drilling should be immediately stopped.
2. Air injection should be shut off and the gas flare monitored. If the flare is sustained by hydrocarbons from the well, the operator should note the wetness of the cuttings at the sample catcher (indicating water or distillate in the gas).
3. If the gas flare will not sustain or burn when the air is turned off, air can be turned back on, and water injection operations initiated, followed by careful bit advancement.
4. If the gas flare is sustained and/or the cuttings are wet, precautions must be taken to eliminate any mud rings before drilling forward. If water injection has not commenced, it should be initiated. With the air on and water injection operations underway, the drill string should be raised and lowered while rotating the drill string at approximately 100 rpm to smash any existing mud rings in the hole above the hydrocarbon bearing formations. If the injection pressure has not come down after this attempt to clear the mud rings, repeat the above sequence until the operator is satisfied that any mud rings have been successfully cleared. Once satisfied no existing mud rings are present in the borehole, carefully advance the drill bit through the hydrocarbon bearing formations.

Note that an alternative to the above is to switch the drilling gas to natural gas or liquid nitrogen.

There is a new technology that allows underbalanced drilling operations to be carried out using inert atmosphere. The technology is the development of large industrial membrane filters that strip most of the oxygen from the compressed air output of the primary compressors. The compressed inert air is either injected directly into the top of the drill string or injected into the top of the drill string after passing through the booster compressor.

4.9 WELL COMPLETION

Section reviewed by Michael Lorenz

4.9.1 Introduction

When the wellbore has been established by the drilling process, and the subsurface asset team has verified estimated reserves warrant production, the completion of the wellbore begins in earnest.

The well completion is the reservoir to wellbore connection and it must provide for this with the minimum flow resistance. The type of completion is dictated by the delivery potential of the reservoir and must suit the requirements of the project. The well completion is designed to last as long as there are economic reserves to recover in that location, and to leave some flexibility to make changes.

When does the completion actually begin? Though not a universal sentiment, many oil and gas professionals agree that any operation or process which has the potential to affect how well the oil and gas flows from the reservoir and into the wellbore, is actually a part of the completion process. During well work, there are sometimes competing objectives which those constructing the well are trying to

meet. And sometimes, the primary or most imperative goal is achieved with a somewhat detrimental effect on other, competing goals. An example of this could be if, when drilling through a pay zone, a kick is taken. In order to achieve the most important goal of well control, a heavy weight kill pill is pumped downhole in order to overcome the reservoir pressure of the kick, and to also inhibit its further flow during the completion of well drilling. Therefore, it is possible that the near wellbore area might have its permeability reduced which would likely reduce flow rate into the wellbore. It may also be possible to address this formation damage during the well completion process.

The goal of the completion process is to maximize the value of the well once it has been drilled. It is the completion process that fully prepares the well to flow and puts in place the equipment allowing the safe and economical production of the oil and gas, for which the well was drilled. These two statements imply there might be some benefit if the well is drilled with the final completion type fully considered and that wellbore placement can be used to assist with providing optimum completion efficiency.

Other important factors when planning for a completion are the ability to being able to fully characterize the formation, the type of production, the recovery mechanism(s), and the anticipated required well life. This information can have a significant impact on completion planning, and ultimately, on completion success.

4.9.2 Types of Completions

There are many different ways that a well can be completed. It seems that the number of completion methods is limited only by individual imagination. Indeed, additional completion methods have recently become prominent as industry has worked to bring additional, unconventional oil and gas to production. There will be more information about these methods later in this section.

Generally speaking, a completion starts as being either an open hole completion, or as a cased hole completion.

4.9.2.1 Open Hole Completions

For an open hole completion, casing is likely set at the top of a producing zone. The production interval is then drilled. This type of completion is normally used when the producing interval is strong and competent, so that it does not cave in or otherwise fail. It has also been used when an open hole gravel pack will be used. An open hole completion can be used in vertical, deviated or horizontal wells (Figure 4.9.1).

An advantage of an open hole completion is the fact that the entire formation interval is exposed to the wellbore, meaning the potential for a very productive well is inherent. A possible consideration when performing open hole completion planning is that once anything other than

FIGURE 4.9.1 Open hole schematic.

primary production enters the wellbore (gas or water for an oil well, water for a gas well), it is more difficult to isolate or shut off, in an open hole completion. Selective, within the zone, treatments are not as straightforward as in a cased hole. Sections of an open hole reservoir are more difficult to effectively isolate than they would be if the same interval was cased and cemented.

4.9.2.2 Cased Hole Completions

In a cased hole completion, an additional string of (production) casing is set down into the production interval once it has been drilled. The casing is cemented in place and this, along with the casing, provides for the potential for very effective isolation between producing intervals, if that would be required. The cemented casing is then perforated in the proper locations, in order to produce oil and gas into the wellbore. Most flowing wells are cased holes. This completion method can also be used in vertical, deviated and horizontal wellbores (Figure 4.9.2).

The obvious advantage to a cased hole completion is that the producing formation is provided with support by the casing and cement. Therefore, cased holes are typically used when the producing formation is not as strong and can fail easily during production, either initially or as the reservoir depletes.

Another advantage is that it is more straightforward to provide isolation of separate portions within the producing interval. This may be required during production, to remove or isolate unwanted producing fluids, and to more effectively stimulate specific reservoir sections.

Because all production must enter the wellbore through possibly restrictive holes in the casing, through the cement, and out into the formation, the potential for restricted

FIGURE 4.9.2 Cased hole schematic.

production in a cased hole well exists. Planning for optimized cased hole production is a very important process for each well.

4.9.3 Completion Operations

4.9.3.1 General

As mentioned earlier, there are many different types of completions, employing many different methods or steps. Because each completion operation costs money, operators are always looking for ways to optimize. Therefore, when appropriate, some of these descriptions are combined in certain wells, or not used at all. Also, specific steps or details within the operation are only included if they add potential additional value to the well's production, or if those steps are required for the safety of personnel performing the work and for the containment of the well.

4.9.3.2 Wellbore Clean-up and Displacement

Because most wells are drilled with some type of drilling mud, it is generally important to remove the mud from the wellbore prior to completion operations beginning. This does not happen in all cases, but often does. Drilling mud contains a large amount of solids. These solids will most of the time, impair the workings of completion equipment, and perhaps even impair the production of oil and gas into the wellbore. This is normally a very important process for cased hole wells, because of the possibility of solids plugging the perforations in the casing. Because of this, the drilling mud is pumped out of the wellbore, displaced directly with the completion fluid, or indirectly with some

sort of other clean, mostly solids-free fluid. The sides of the casing are also cleaned, so that mud residue is removed and the wellbore can hopefully, remain clean throughout the duration of the completion. The goal of this step is to have the wellbore filled with properly weighted completions brine, with as small amount of remaining solids as practical.

4.9.3.3 Formation Evaluation

Most formation evaluation has already been completed by this time in the drilling and completion of a wellbore. However, it might be that evaluation of the cement quality around the production casing has been planned after mud is removed from the well and replaced with the completion fluid. If that is the case, then cement evaluation can occur at this point. It is important to have a pretty good understanding of the likely isolation provided by the cement behind casing, as well as the top of cement. If the quality is judged to be less than required, remedial cementing can be done in the attempt to make it better. Remedial or squeeze cementing, involves perforating the casing in a limited area, and then breaking down or fracturing the formation and pumping additional cement out the perforations and into the formation. This attempt is made to provide additional cement isolation outside the casing.

In addition, if a workover operation is occurring instead of a brand new completion, then it is likely a cased hole evaluation log of some sort will also be run for the purpose of determining oil and water, oil and gas, and/or gas and water contacts. If run, these logs will be the basis for selecting casing perforation depths.

4.9.3.4 Lower Completion

The term “lower completion” is a broad term describing the parts of the completion operation pertaining to the processes and equipment installation within the reservoir section of either the cased or open hole.

In an open hole, this could mean that nothing additional is required after drilling it. It could also mean the installation of some sort of liner with provision for flow paths into the wellbore, or possibly the installation of a gravel packed screen. If equipment is run into the open hole, it will likely be anchored and sealed (perhaps with a packer) in the casing set and cemented above the production interval. This will help provide for the highest likelihood of long-lived well integrity.

For a cased hole, lower completion operations may include the following:

- Running and setting a sump packer
- Perforating the casing
- Running and installing some sort of sand control

If the productive interval has sufficient strength, both at present conditions, and in the future, with depletion, then the only lower completion step might be simply to perforate

the casing, before proceeding to the upper completion. In fact, it has become common in many instances, to include the perforating guns on the bottom of the upper completion assembly thereby combining several operations and possibly optimizing the time required to put the well on production. The production tubing along with the selected anchor and seal (packer), if any, with the perforating guns attached to the very bottom are all run in at once. The well is fully completed, production tree installed, and production lines and equipment installed. Once completed, the perforating guns are detonated, and they are designed to drop away, to the bottom of the well. At this point, the well is ready to be brought on production.

4.9.3.5 Upper Completion

If there is a separation between the lower completion and the upper completion, there is usually an anchor and a casing seal of some sort (possibly a packer) on the top of the lower completion that the upper completion connects to. Just as the lower completion is critical in establishing the hydraulic connection to reservoir fluids, the upper completion’s critical role is to insure long-term wellbore integrity so that the production fluids can be economically, reliably and safely produced to the surface, normally for as long as the reservoir will last. This is planned to be accomplished with no leaks or equipment failures.

The upper completion is designed to be able to safely, and with a designated safety factor, withstand the anticipated production loads that will occur over the life of the well. These loads typically include production and injection pressures and temperatures. During production, average wellbore temperature will increase, thereby causing the metallic tubing to get longer, adding to the force it and its anchor (if used) must withstand. During production, average wellbore pressure differential within the tubing will also likely increase. At the same time, during a well’s life, injection will also likely occur, causing cooling and a lowering of average wellbore temperature. This, along with applied pressure, also places loads on the tubing and anchors. In order to insure lifelong wellbore integrity, these loads must all be anticipated, and designed and accounted for when installing the upper completion.

4.9.3.6 Final Testing and Displacements

Completion planning should also include considerations pertaining to testing requirements, and in what condition, with what fluids installed, should the wellbore be left in. It is likely that the final fluids to be left in the well, both in the annulus and in the tubing, will be installed (circulated in) before upper completion operations are complete.

Also, if specific components of the upper completion are to be tested, this will also likely be done before the upper completion is finished.

The type and quantity of fluids left in the wellbore can significantly impact the long-term success of the well. The

fluid that is normally left in the annulus between the tubing and casing is called the packer fluid. It is specifically formulated to keep both the casing and production tubing with which it makes contact from corroding thereby assisting with long-term well integrity and reliability.

The fluid left in the production tubing could be completion fluid, or it could be something else designed to assist with initiating well production. Examples of this could be a drilling fluid base oil, or a lighter weight brine. This will provide for leaving the well in an underbalanced condition which greatly assists with the start of production.

Completion equipment critical to long-term wellbore integrity and reliability are often tested during the completion process. This equipment, if included, would be the production tubing, the production packer, production seal assemblies, and the safety valve. In many instances, the best practice testing method includes both a positive pressure test (pressuring up on the equipment) and a negative pressure test (lowering pressure above the equipment so that the pressure differential is in the direction of production, from below to above).

In some instances, the process of testing and establishing final wellbore condition is quite involved, leaving open the opportunity for optimizing the order of testing and other procedural steps so that the wellbore's long-term integrity is assured effectively and efficiently.

4.9.4 Completion Equipment

4.9.4.1 General

The types of equipment used in various completions widely vary depending on individual wellbore requirements and reservoir parameters. Some of the most common and likely to be run equipment are discussed here. Additional, more specific equipment will also be mentioned in subsequent sections.

4.9.4.2 Packers

There are many types of packers, designed for specific types and needs of completions. Generally, they perform the function of both an anchor and a seal. They can anchor the tubing, preventing movement. They also provide a seal between the outside of the tubing and the casing. This seal is used to prevent production fluids and pressures from reaching the top of the well outside of the tubing, and is a means of providing for reliability and long-lived wellbore integrity.

Packers can be set in open holes or cased holes. They can be for use with single or dual tubing strings. They can be run and set on electric line or on tubing or workstring.

As mentioned, packers can be used to isolate the annulus to provide a barrier, keeping production pressures and fluids from reaching the top of the well through the tubing/casing annulus. Packers are also used to isolate different production zones and assist with separating their production as required.

Packers can be set with mechanical force (weight and/or rotation). They can also be set with the application of hydraulic pressure.

Packers can be retrievable or permanent. A permanent packer can be very robust because, once set, it is not designed to ever release. Instead, if removal is ever required, milling/fishing is required. A typical hydraulic set, permanent packer is shown in Figure 4.9.3.

A retrievable packer is one that is designed to be easily retrieved, either with a straight pull on it, or with a straight pull on a retrieving tool run and latched into the packer.

An additional, more recent packer type that combines robust design and yet can still be removed from the wellbore without milling, is a removable packer. These packers typically require an internal part of the packer be cut with an electric line tool. These packers can then be removed with a straight pull.

Finally, packers that are designed to be run in critical, high-pressure, high-temperature applications will likely have their performance tested and verified in accordance with an accepted industry standard. The purpose of such testing is to insure the packer will reliably and with repeatability, perform at its rated pressure, temperature, and load ratings.

FIGURE 4.9.3 Hydraulic-set permanent production packer [1, Figure 10.14, p. 574].

4.9.4.3 Seal Assemblies

Some packers are designed to be run in and set separately from any tubulars. When this is done, the tubing may often still be required to seal and perhaps anchor inside the packer. When this occurs, a seal assembly can be run on the bottom of the tubing. This seal assembly is designed to seal inside the bore of the packer. It can also be designed to latch onto the packer so that it does not move. An example is shown in Figure 4.9.4.

4.9.4.4 Tubing

Tubing forms an integral part of most completions. If run, it is the conduit by which production fluids reach the surface. Its structural integrity during the entire life of the well is very important. Tubing must be designed to simultaneously withstand production pressures, temperatures, and induced axial forces and not leak. The tubing must also be compatible with the fluids it will be in contact with, both internally and externally.

Because the production tubing can be so critically important, a lot of time and effort also goes into insuring the proper connections are selected and tested, if necessary. For standard applications, the connection seal is established with the pipe dope, or an elastomer seal ring, or perhaps a combination of both. For critical, high-pressure applications, the connection seal is metal-to-metal, meaning that metal contact is required to effect a seal. It is often a requirement that this type of seal be qualified in accordance with an accepted industry standard. Whether or not such

FIGURE 4.9.4 Latching seal assembly [2,3; Figure 2.11, p. IV-55, PEH].

qualification is a requirement is normally established by the end user or also by the government authority with responsibility for the well. The purpose of the testing qualification is to verify and insure the connection reliably and repeatedly seals without leaking, under all loads conditions for which it is rated. It is normal for such connections to be rated the same as or greater than the tubing body itself.

4.9.4.5 Accessories

Completion accessory equipment can play a supporting yet very important role in safe and efficient completion and workover operations. This equipment provides additional operational flexibility and can sometimes make the difference between executing an expensive and risky operation, such as perforating a tubing string, and between a simple wireline operation to open a sliding sleeve (Figure 4.9.5).

Another completion accessory is a landing nipple. This normally has specifically designed ID's that are used to hold and seal plugs inside, for the purpose of providing isolation within the production tubing. A lock can be run inside of the landing nipple. Attached to it can be many different types of equipment, including plugs, chokes, check valves, pressure gauges, etc (Figure 4.9.6).

In addition to these, there are other additional accessory equipment, including flow couplings, blast joints, and wireline entry guides, to name a few.

4.9.4.6 Safety Valves

Safety valves run as part of the completion are a critical component of the completion. They are critical to providing containment in the event of a surface equipment malfunction or failure during production.

The subsurface safety valve is a fail-safe valve that is designed to close and prevent hydrocarbon release if something catastrophic occurs at surface. It is a normally closed valve, held open by surface applied hydraulic pressure. It can be run on tubing, or it can also be installed in a landing nipple (Figure 4.9.7).

Most modern completions use tubing retrievable safety valves, except where conditions and rates are benign.

4.9.5 Completion Type Descriptions

4.9.5.1 General

In addition to describing as cased or open hole, completions can also be characterized in other ways which describe the number of zones and the number of tubing strings run in the well.

4.9.5.2 Single Completions

A single tubing string provides the primary flow path for formation fluids to the surface. The packer is the primary seal to isolate the formation fluids and pressures from the

FIGURE 4.9.5 Sliding sleeves. [1, Figure 10.20].

tubing/casing annulus. This is a simple design with relatively low installation and maintenance costs (Figure 4.9.8).

4.9.5.3 Single Selective Completions

This is also a single completion string, but with multiple formation zones completed and capable of producing, either separately or simultaneously (co-mingled production). Normally, all productive intervals are perforated before the completion assembly is installed. Wireline plugs can be set in landing nipples to isolate zones from the bottom up. Sliding sleeves can be used to selectively open and close zones for production (Figure 4.9.9).

4.9.5.4 Dual Completions

Here, two tubing strings (that may or may not be the same size) are run in to allow separate, simultaneous produc-

tion from two producing intervals. This does provide for separate reservoir management. It is also a more complicated completion. Both zones are normally perforated first, and then the entire completion is run in. Both packers can be set at basically the same time (Figure 4.9.10). A dual completion requires the use of a dual surface production tree, which is capable of providing for simultaneous production from both tubing strings, as well as for surface containment.

4.9.5.5 Monobore Completions

A monobore completion is as it sounds—that is there is a single, uniform ID from the top of the well to the very bottom, including into the producing zone. The primary advantage to this type of completion is that its design facilitates effective, cost effective intervention. Because the

FIGURE 4.9.6 Nipple profile and lock. [1, Figure 10.17].

FIGURE 4.9.7 Tubing retrievable downhole safety valve. [1, Figure 10.9].

ID is basically the same, this means that in most cases, wireline or electric line is all that is required in order to isolate the existing producing zone, and complete another one. All work can be done through the existing production tubing, without having to pull it in order to service the

producing intervals. It is normally considered that a monobore completion will have a smaller ID, possibly causing a production flow restriction. However, if properly designed, a monobore completion can have a much larger ID, even equivalent to 5-1/2" tubing (Figure 4.9.11).

FIGURE 4.9.8 Single completion [2,3; Figure 2.23, p. IV-76, PEH].

FIGURE 4.9.10 Dual completion [2,3; Figure 2.25, p. IV-78, PEH].

FIGURE 4.9.9 Single selective completion [2,3; Figure 2.24, p. IV-77, PEH].

FIGURE 4.9.11 Monobore completion example [2,3; Figure 2.27, p. IV-81, PEH].

FIGURE 4.9.12 TAML multilateral classifications and types [1, Figure 12.18].

4.9.5.6 Other Types of Completions

Another type of completion worth mentioning here is a multilateral completion. This is a well with more than one bottom branch (lateral). Multilateral wells may be appropriate for multiple, compartmentalized reservoirs, or for reservoirs which are stacked, and would likely benefit from a highly deviated or horizontal completion. An additional driver for multilateral wells could be when surface

constraints are present, whether they be platform slots, or surface environment conditions.

Executing a multilateral well will likely be riskier than a single well. Therefore, this choice is one that should be carefully considered with input from a multi-disciplinary team.

Figure 4.9.12 is a graphic showing typical types and classifications of multilateral wells.

There are other types of completions, perhaps more specialized than these listed so far. They include underbalance completions, completions for heavy oil and steam injection, and completions for coal bed methane. If interested in these or others, please see the references.

4.9.6 Perforating

4.9.6.1 General

Perforating is primarily a cased hole completion process. It is the process by which holes are put into the casing and cement around the casing, so that the reservoir's production can flow into the well, and to the surface. The effectiveness of the perforating process can have a big impact on overall well productivity. It is therefore important to understand the factors that have the largest impact on the success of perforating operations.

4.9.6.2 Perforations

As mentioned, the objective of perforating is to be able to provide for flow from the reservoir into the wellbore. Figure 4.9.13 is an idealized schematic of a perforation.

Achieving holes like this through the casing and into the formation can provide for a very effective completion.

There are three parts to a perforating system and its explosive chain. They are the detonator, the detonating cord and the shaped charge. The explosive shaped charge develops intense pressure and penetrates the gun body, wellbore fluid, casing, cement and into the formation.

The perforating operation is one of the potentially most hazardous, due to the high explosives used. This requires strict attention to the care and handling of explosives, ensuring personnel are properly trained.

4.9.6.3 Perforating Basics

Components of the shaped charge are the liner, the main explosive and the primer (Figure 4.9.14).

An explosive detonating wave travels down the detonating cord, initiating the primer and detonating the main explosive. The exploding charge generates on the order of millions of psi, effectively causing the perforating jet to force its way through the gun case, annular fluid, casing, cement, and into the formation. It is the shape of the liner that focuses the explosion.

4.9.6.4 Types of Perforating Charges

There are two basic types of perforating charges. They can be characterized as big hole (BH) charges and deep penetrating (DP) charges. For perforations that will be filled with sand or proppant, BH charges are most appropriate. For completions in which there will not be sand control, DP charges will generally deliver the best performance (Figure 4.9.15).

In general, the shape of the liner primarily determines whether hole size or penetration depth is optimized.

In addition to this, charges can also be categorized by the type of explosive used (Figure 4.9.16).

Normally, RDX is used as the standard explosive in perforating guns. It is the most economical and is rated for use at bottom hole temperatures up to about 200 degrees F. However, as bottom hole temperatures increase, different explosives are recommended (Figure 4.9.17).

Finally, the amount of explosive used in each charge can vary, depending on the application and the size of the perforating gun. Generally speaking, perforating larger size casing will require higher explosive performance, implying larger amounts of explosives in each charge.

FIGURE 4.9.13 Typical perforation geometry [1, Figure 2.37, p. 501].

FIGURE 4.9.14 Perforating basics [4, p. 54]. Illustration copyright *Oilfield Review*, used with permission of Schlumberger.

Big Hole Charge

Deep Penetrating Charge

FIGURE 4.9.15 Types of shaped charges.

4.9.6.5 Perforating Guns

Perforating guns are generally also of two types—capsule and hollow carrier. The most likely conveyance method for capsule guns is via electric line. Hollow carrier guns can be conveyed with either electric line or with tubing/workstring (Figure 4.9.18).

Please note that with either gun, wellbore fluids and pressures are not allowed direct contact with the explosives.

Perforating guns can also be characterized by how the individual charges are oriented within the gun. This determines where the holes will be in the casing, and how many there will be per foot (Figure 4.9.19).

4.9.6.6 Perforating Conveyance Methods

There are multiple ways of performing perforating operations. For an introduction to some of the decision factors involved, see Figure 4.9.20.

4.9.7 Sand Control

4.9.7.1 General

A substantial number of oil and gas wells produce solid formation material, along with the oil and gas. Producing solids with oil and gas, especially at high rates, is not conducive to a safe and long-lived production well. The produced solids can very easily and in some cases, very quickly excessively erode the completion equipment, both downhole and at the surface, leading to leaks, and possible hydrocarbon spills and loss of containment. This possible

Abbreviation	Name	Formula	Comments
TNT	Trinitrotoluene	$C_6H_2(NO_2)_3CH_3$	Melts at 80°C (176°F) – therefore not suitable for downhole use
RDX	Research department composition X	$C_3H_6N_6O_6$	Most common downhole explosive
HMX	High molecular weight RDX	$C_4H_8N_8O_8$	Higher temperature version of RDX
HNS	Hexanitrostilbene	$C_{14}H_6N_6O_{12}$	Higher temperature stability, but reduced performance compared to HMX
PYX	Picrylamino-dinitro-pyridine	$C_{17}H_7N_{11}O_{16}$	Slightly reduced penetration compared to HNS, but very high temperature stability
TATB	Triaminotrinitrobenzene	$C_6H_6N_6O_6$	Not used on its own downhole. Common in missile systems! Very hard to detonate
HTX	High-temperature explosive	Combines HNS and TATB	Various different formulations possible; better penetration than HNS, with high temperature stability

FIGURE 4.9.16 Typical explosive types [1, Table 2.3, page 48].

FIGURE 4.9.17 Perforating explosive temperature stability [1, Figure 2.36, p. 49].

adverse consequence of producing solids with oil and gas has led to the development of methods designed to control solids production while still allowing efficient oil and gas production. A brief description of the major methods, along with relative advantages will be discussed.

4.9.7.2 Methods of Sand Control

Production Rate Restriction—Attempting to control sand production by reducing rate is a method that adds no

additional expense to well completion. However, it could possibly lead to the realization of reduced value from the well, if the rate reduction is excessive compared to what the well is capable of delivering.

Oriented or Selective Perforating—This method of sand control takes advantage of in-situ formation stresses and knowledge of the higher strength areas of the formation. Selective perforating shoots only the stronger sections of the formations as determined by logs and/or core samples. Oriented perforating shoots in the direction of maximum horizontal formation stresses. This can promote perforation tunnel stability. Of course, the ability to orient the perforating guns is critical. This method of sand control adds a little completion cost in the perforating operation. At the same time, there is still sand production risk since there is no physical sand barrier put in place.

In-Situ Consolidation—This method of sand control injects plastic resin or other chemical to consolidate and add strength to the formation. It is injected below frac pressure and is normally limited to short intervals. However, this may be a viable alternative and has been effective, if properly applied.

Stand-Alone Screens—This method of sand control provides a physical barrier to sand production. It is a requirement that the screen openings be properly sized for the expected formation particles being produced. If this method

FIGURE 4.9.18 Capsule and hollow carrier perforating guns [4, p. 70]. Illustration copyright *Oilfield Review*, used with permission of Schlumberger.

FIGURE 4.9.19 Common perforator phasing [Figure 4.8, p IV-158, PEH].

is not installed properly, the screens are likely to erode or plug or both, leading to a potential well failure. Sophisticated testing methods have been developed to enhance the success of the screen-only method. However, installation and initiating production still require careful planning in order to prevent premature failure.

Gravel Pack or Expandable Screens—Expandable screens are enhanced versions of standalone screens from the standpoint that the screens are designed to be expanded against the formation face in the open hole, or against the casing, in a cased hole. This provides the benefit of preventing excessive movement along the outside of the screen, by the formation particles. This can reduce the chances for erosion, and increase the likelihood of effective sand control.

Method	Advantages	Disadvantages
Tubing conveyed run with completion	No limit to weight of guns No limit to gun diameter except casing size. High underbalance is acceptable	Guns either left in place restricting access or extra sump and low hole angle required for gun drop off Consequences of misfire mean pulling the completion or switching to through tubing Guns are subject to high temperatures for longer
Drillpipe conveyed shoot and kill	No limit to weight or size of guns No sump required. Gun deployment is quick and reliable. No limit to underbalance	Perforation interval must be killed prior to gun retrieval leading to potential formation damage Permanent completion run with potential for surge/swab and ensuing well control problems
Wireline conveyed prior to running the completion	Gun size not restricted by a small completion. Most common with onshore wells	Underbalance is difficult or unsafe to achieve Perforations often made in a kill pill to control losses with resultant formation damage concerns Gun weight limited by strength of cable Limited pressure control capability
Through the permanent completion (wireline, coiled tubing or hydraulic workover unit)	Completion can be run in an isolated (unperforated) well Full pressure control in place for gun running and recovering Can be done independently of the rig (platform and land wells) Can relatively easily generate underbalance by flowing the well	Gun length limited by length of the lubricator. May require multiple runs Gun size restricted by the size of the completion restrictions

FIGURE 4.9.20 Perforating methods [1, Table 2.8, page 75].

A gravel pack is designed to fill the area around the screen with gravel or proppant. If in a cased hole, it is a design goal to also fill the perforations with proppant (Figure 4.9.21).

Generally speaking, the proppant or gravel pack sand is sized to contain for formation sand. The screen is sized to hold back the proppant or gravel, or the formation sand.

Frac Pack—This is an enhanced version of gravel pack sand control, and takes the gravel pack concept a step further by also initiating a stimulation fracture connected to the wellbore, and filling it with proppant. This can provide for a very effective, reliable and high-rate completion, while providing for robust sand control (Figure 4.9.22).

This is the most expensive sand control, but also the most effective from productivity and reliability standpoints.

FIGURE 4.9.21 Ideal open hole and cased hole gravel packs [2,3; Figure 5.4, p. IV-186, PEH].

4.9.8 Unconventional Completions

Unconventional wells are those oil and gas wells characterized by extremely low reservoir permeability's requiring significant stimulation in order to produce at economic rates. In a lot of cases, these producing formations are shale. Horizontal wells are drilled through these formations and then the wells are stimulated all along the horizontal length. The two main methods of horizontal multistage completions currently in use are cemented liner “plug and perf” and open hole multistage-fracturing systems.

Cemented Liner Multistage Fracturing—With this method, a production casing is cemented in place in the horizontal wellbore. Completion operations include setting bridge plugs, followed by perforating and then fracturing the perforated interval. This process is repeated for as many times as necessary to cover the horizontal section. When complete, the bridge plugs are drilled out, re-establishing reservoir connectivity to the wellbore. This method is relatively expensive and time consuming.

FIGURE 4.9.22 Frac Pack Geometry [1, Figure 3.50, p. 203].

FIGURE 4.9.23 Intelligent Well Upper Completion with Dual Zone Frac Packs [1, Figure 12.7, p. 647].

Open Hole Multistage Fracturing—With this system, multiple open hole packers, and frac ports/sleeves are run in the hole all at once. The open hole packers are all set simultaneously. Once this is done, the rig can leave. The frac ports/sleeves create openings between the packers. These tools can be opened hydraulically by dropping size-specific actuation balls into the system to shift the sleeve and expose the fracturing port. The balls create internal isolation between stages. All frac treatments are performed in a single, continuous pumping operation. Once the treatment is complete, the well can be flowed back immediately.

4.9.9 Intelligent Well Completions

The generally accepted definition of an intelligent well completion is a permanent system capable of collecting, transmitting and analyzing wellbore production and reservoir and completion integrity data, and enabling remote action to better control reservoir, well and production processes. Remote completion monitoring is defined as the ability of a system to provide data, obtained in or near the wellbore, without requiring access and entry for conventional intervention to the well. Remote completion control implies that information and instructions can be transmitted into the well to alter the position or status of one or more completion components. The primary objectives of these abilities are normally to maximize or optimize production and recovery, minimize operating costs and improve safety [1,2].

One of the most common intelligent well completion systems involves two remotely controlled valves and downhole pressure and temperature gauges. A common application includes multiple lower completion zones

requiring sand control. In the case of high-value completions, the sand control often means frac packed completions (Figure 4.9.23).

The design, testing, procurement, and installation of an intelligent well completion can add significant cost and complexity to planning and execution. Therefore, it is important to be able to understand and communicate the net value increase intelligent well execution will add to the producing asset. Figure 4.9.24 is a generalized flow chart describing the process for assessing intelligent well value determination.

To summarize, the team(s) charged with specifying well performance capabilities should be able to demonstrate the incremental value of intelligent well installation, just as well drilling and completion must be economically justified.

4.9.10 Artificial Lift

Artificial lift is the method of adding energy to the flow stream within the completion to increase the flow rate. Defined another way, the primary purpose of artificial lift methods is to lower the flowing bottom hole pressure so that the difference between it and the reservoir pressure is increased sufficiently to optimize production from the well. The most common methods of artificial lift are gas lift, rod pumps, electrical submersible pumps, progressive cavity pumps, plunger lift, and jet pumps. When designing the completion, it is apparent that consideration for the type of artificial lift to be used, must be included in completion design. A brief description of each method follows.

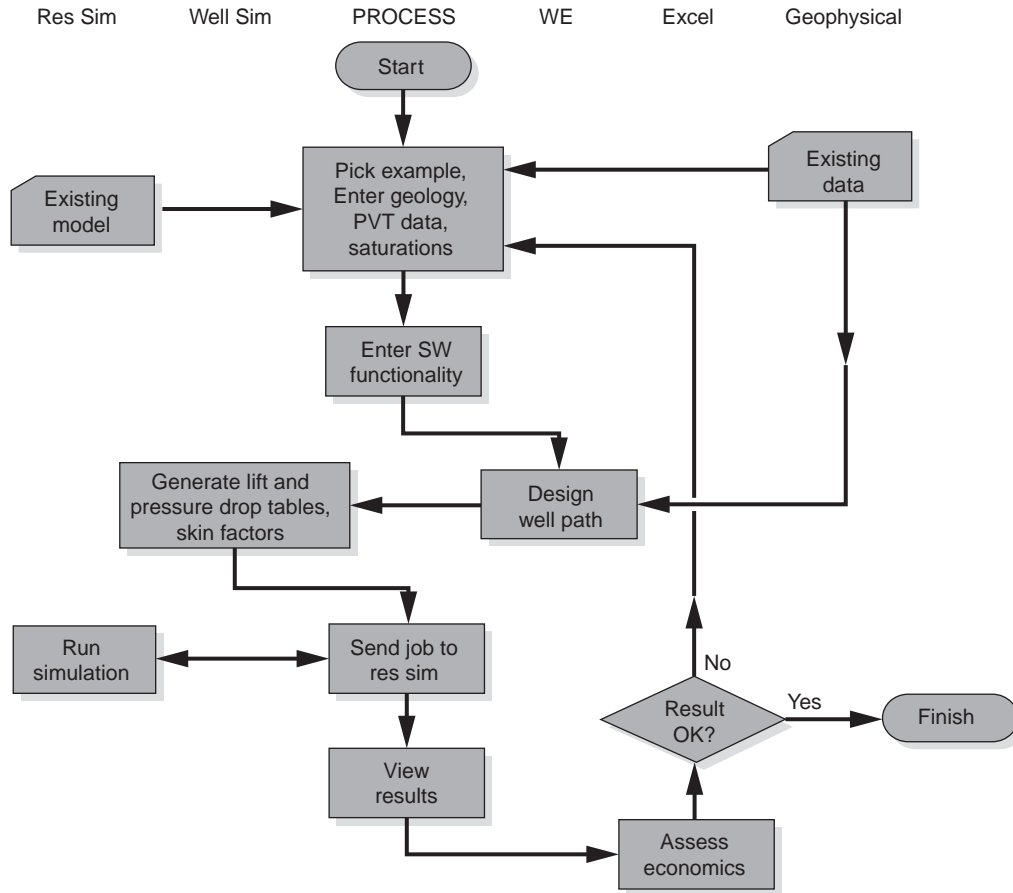

FIGURE 4.9.24 Generalized flow chart for intelligent well value determination [2,3; Figure 3.1, p. VI-117, PEH].

Gas Lift—Gas lift is the only form of artificial lift that does not require the use of a downhole pump. Instead, a gas lift mandrel is run as part of the completion tubing string. The mandrel includes a specifically sized gas opening with a specifically designed operating pressure (Figure 4.9.25).

The method works by injecting the optimum amount of gas based on reservoir pressure and PI. This method is the most common method offshore, and is the second most common method overall.

Rod Pump (Beam)—Rod pumps are the most common form of artificial lift, used mostly in land wells. They utilize a reciprocating rod to move a downhole pump. The downhole pump consists of a traveling and a standing valve, which each utilize a check valve to trap and mechanically lift the column of fluid to surface. This type of system handles gas and solids fairly well. Its use is common for low-volume producers.

Electrical Submersible Pumps (ESPs)—ESPs are routinely used onshore and for platform wells offshore. They

FIGURE 4.9.25 Gas lift system.

are very versatile, especially where high rates are required. ESP's are electrically powered via an electrical cable from the surface. They can be specifically sized for bottom hole pressure, reservoir PI and required drawdown.

Progressive Cavity Pumps—Progressive cavity pumps or PCP's are also powered from the surface with a drive unit to rotate a rod string and drive a downhole cavity pump. The pump consists of a rotor (polished helical-shaped rod) rotating inside the cavity of a stator (double-helical elastomer-liner cylinder), which causes fluid to become trapped in a moving cavity. These pumps are also good for handling gas and solids. They are best for low-volume producers, and, because of the rotating rod, are also limited in depth to about 6000 ft TVD.

Plunger Lift—Plunger lift systems utilize a standing valve and traveling plunger inside a tubing string. This allows reservoir fluid to accumulate on top of the plunger. Pressurized gas is periodically injected downhole below the plunger to push it up the production tubing, carrying a slug of reservoir fluid with it to the surface. Once the plug reaches the surface, the gas supply is shut off, allowing the plunger to fall back down to the standing valve. Naturally, this type of artificial lift requires a gas source. It doesn't handle solids that well, and tends to get stuck. This method is also best for low-volume wells.

Jet Pump—The jet pump utilizes a pressurized power fluid directed at high velocity through a downhole nozzle and across a venturi body. The resulting low-pressure zone downstream of the venturi allows reservoir fluids to be drawn in and mixed with the power fluid. The momentum of the combined power and reservoir fluid stream pushes the fluid column to the surface. There are no downhole moving parts. However a surface pump is required. This method has the worst lift efficiency of all artificial lift methods. It is marginal when handling solids and gas, but does have a wide range of production rates, from about 300 to 15,000 barrels of fluid per day.

4.9.11 Elements of Completion Design [1]

It is important to ensure that the completion design for a particular well is appropriate for the well. This includes consideration of current and anticipated well conditions, production rates, and longevity. Some basic steps to consider when planning and executing a well completion are:

Prepare a well statement of requirements—This document can be used to incorporate all the relevant and required data that has the potential to make a difference in the completion. This document should include reservoir and production data and an expectation of what the completion needs to achieve over its life.

Prepare a well basis of design—This document contains the main decisions made during the course of the completion design and their justification. It provides a historical record of considerations and decisions made, and can be used as an assurance review document to help insure the quality of the overall design. This document should be very detailed and include all elements driving and affecting any element of design, including metallurgy, ratings, sizes, equipment types, etc.

Completion procedure preparation and review—This is an acknowledged critical part of the completion design and preparation process since, in many cases, experienced personnel not directly associated with preparing for the completion have the opportunity to review and approve just about every aspect of the completion itself.

Post completion review—Equally important but often only superficially performed is the detailed, in-depth review of the performance of the completion installation process. Also included should be an assessment of how well the completion was designed, and how well its design met performance expectations. This sort of information can be very important to any person planning a later well completion or intervention.

4.9.12 Summary

This section discussing well completions is a very brief introduction to the vast body of knowledge encompassing them and their design considerations. Hopefully the information provided is successful in communicating that there is wide latitude in the complexity, cost, performance, reliability and longevity of completions. The selection of completion capabilities and performance should be driven by the reservoir. In other words, every piece of equipment, and every completion process should be able to be justified from the standpoint of personnel and environment safety, and economic return.

4.10 DIRECTIONAL DRILLING

Section reviewed by Francisco Sinisterra

4.10.1 Glossary of Terms used in Directional Drilling

The glossary of terms used in directional drilling [1] has been developed by the API Subcommittee on Controlled Deviation Drilling under the jurisdiction of the American Petroleum Institute Production Department's Executive Committee on Drilling and Production Practice. The most frequently used terms listed below.

Angle of inclination (angle of drift)

The angle, in degrees, taken at one or several points of variation from the vertical as revealed by a deviation survey, sometimes called the inclination or angle of deviation.

Angle of twist

The azimuth change through which the drillstring must be turned to offset the twist caused by the reactive torque of the downhole motor.

Anisotropic formation theory

Stratified or anisotropic formations are assumed to possess different drillabilities parallel and normal to the bedding planes with the result that the bit does not drill in the direction of the resultant force.

Azimuth

Direction of a course measured in a clockwise direction from 0° to 360°; also called bearing.

Back-torque

Torque on a drill string causing a twisting of the string.

Bent sub

Sub used on top of a downhole motor to give a non-straight bottom assembly. One of the connecting threads is machined at an angle to the axis of the body of the sub.

Big-eyed bit

Drill bit with one large-sized jet nozzle, used for jet deflection.

Bit stabilization

Refers to stabilization of the downhole assembly near the bit; a stabilized bit is forced to rotate around its own axis.

Borehole direction

Refers to the azimuth in which the borehole is heading.

Borehole directional survey

Refers to the measurements of the inclinations, azimuths and specified depths of the stations through a section of borehole.

Bottom-hole assembly (BHA)

Assembly composed of the drill bit, stabilizers, reamers, drill collars, subs, etc., used at the bottom of the drillstring.

Bottomhole location

Position of the bottom of the hole with respect to some known surface location.

Bottomhole orientation sub (BHO)

A sub in which a free-floating ball rolls to the low side and opens a port indicating an orientation position.

Build-and-hold wellbore

A wellbore configuration where the inclination is increased to some terminal angle of inclination and maintained at that angle to the specified target.

Buildup

That portion of the hole in which the angle of inclination is increased.

Buildup rate

Rate of change (°/100 ft) of the inclination angle in the section of the hole where the inclination from the vertical is increasing.

Clearance

Space between the outer diameter of the tool in question and the side of the drilled hole; the difference in the diameter of the hole and the tool.

Clinograph

An instrument to measure and record inclination.

Closed traverse

Term used to indicate the closeness of two surveys; one survey going in the hole and the second survey coming out of the hole.

Corrective jetting runs

Action taken with a directional jet bit to change the direction or inclination of the borehole.

Course

The axis of the borehole over an interval length.

Course bearing

The azimuth of the course.

Crooked-hole

Wellbore that has been inadvertently deviated from a straight hole.

Crooked-hole area

An area where subsurface formations are so composed or arranged that it is difficult to drill a straight hole.

Cumulative fatigue damage

The total fatigue damage caused by repeated cyclic stresses.

Deflection tools

Drilling tools and equipment used to change the inclination and direction of the drilled wellbore.

Departure

Horizontal displacement of one station from another.

Deviation angle

See "Angle of inclination."

Deviation control techniques

Fulcrum technique. Utilizes a bending moment principle to create a force on that the bit to counteract reaction forces that are tending to push the bit in a given direction.

Mechanical technique. Utilizes bottomhole equipment which is not normally a part of the conventional drillstring to aid deviation control. This equipment acts to force the bit to turn the hole in direction and inclination.

Packed-hole technique. Utilizes the hole wall to minimize bending of the bottomhole assembly.

Pendulum techniques. The basic principle involved is gravity or the "plumb-bob effect."

Directional drilling contractor

A service company that supplies the special deflecting tools, BHA, survey instruments and a technical representative to perform the directional drilling aspects of the operation.

Direction of inclination

Direction of the course.

Dogleg

Total curvature in the wellbore consisting of a change of inclination and/or direction between two points.

Dogleg severity

A measure of the amount of change in the inclination and/or direction of a borehole; usually expressed in degrees per 100 ft of course length.

Drag

The extra force needed to move the drillstring resulting from the drillstring being in contact with the wall of the hole.

Drainholes

Several high-angle holes drilled laterally form a single wellbore into the producing zone.

Drift angle

The angle between the axis of the wellbore and the vertical (see "Inclination").

Drop off

The portion of the hole in which the inclination is reduced.

Drop-off rate

Rate of change ($^{\circ}/100$ ft) of the inclination angle in the section of the wellbore that is decreasing toward vertical.

Coniometer

An instrument for measuring angles, as in surveying.

Gyroscopic survey

A directional survey conducted using a gyroscope for directional control, usually used where magnetic directional control cannot be obtained.

Hole curvature

Refers to changes in inclination and direction of the borehole.

Hydraulic orienting sub

Used in directional holes with inclination greater than 6° to find the low side of the hole. A ball falls to the low side

of the sub and restrict an orifice, causing an increase in the circulating pressure. The position of the tool is known with relation to the low side of the hole.

Hydraulically operated bent sub

A deflection sub that is activated by hydraulic pressure of the drilling fluid.

Inclination angle

The angle of the wellbore from the vertical.

Inclinometer

An instrument that measures an angle of deviation from the vertical.

Jet bit deflection

A method of changing the inclination angle and direction of the wellbore by using the washing action of a jet nozzle at one side of the bit.

Keyseat

A condition wherein the borehole is abraded and extended sideways, and with a diameter smaller than the drill collars and bit; usually caused by the tool joints on the drill pipe.

Kickoff point (kickoff depth)

The position in the well bore where the inclination of the hole is first purposely increased (KOP).

Lead angle

A method of setting the direction of the wellbore in anticipation of the bit walking.

Magnetic declination

Angular difference, east or west, at any geographical location, between true north or grid north and magnetic north.

Magnetic survey

A directional survey in which the direction is determined by a magnetic compass aligning with the earth's magnetic field.

Measured depth

Actual length of the wellbore from its surface location to any specified station.

Mechanical orienting tool

A device to orient deflecting tools without the use of subsurface surveying instruments.

Methods of orientation

Direct method. Magnets embedded in the nonmagnetic drill collar are used to indicate the position of the tool

face with respect to magnetic north. A picture of a needle compass pointing to the magnets is superimposed on the picture of a compass pointing to magnetic north. By knowing the position of the magnets in the tool, the tool can be positioned with respect to north.

Indirect method. A method of orienting deflecting tools in which two survey runs are needed, one showing the direction of the hole and the other showing the position of the tool.

Surface readout. A device on the rig floor to indicate the subsurface position of the tool.

Stoking. Method of orienting a tool using two pipe clamps, a telescope with a hair line, and an aligning bar to determine the orientation at each section of pipe run in the hole.

Monel (K monel)

A nonmagnetic alloy used in making portions of down-hole tools in the bottomhole assembly (BHA), where the magnetic survey tools are placed for obtaining magnetic direction information. Monel refers to a family of nickel-copper alloys.

Mud motor

Usually a positive displacement or turbine-type motor, positioned above the bit to provide (power) torque and rotation to the bit without rotating the drillstring.

Mule shoe

A shaped form used on the bottom of orienting tools to position the tool. The shape resembles a mule shoe or the end of a pipe that has been cut both diagonally and concave. The shaped end forms a wedge to rotate the tool when lowered into a mating seat for the mule shoe.

Multishot survey

A directional survey in which multiple data points are recorded with one trip into the wellbore. Data are usually recorded on rolls of film.

Near-bit stabilizer

A stabilizer placed in the bottomhole assembly just above the bit.

Ouija board (registered trademark of Eastern Whipstock)

An instrument composed of two protractors and a straight scale that is used to determine the positioning for a deflecting tool in a inclined wellbore.

Permissible dogleg

A dogleg through which equipment and/or tubulars can be operated without failure.

Pendulum effect

Refers to the pull of gravity on a body; tendency of a pendulum to return to vertical position.

Pendulum hookup

A bit and drill collar with a stabilizer to attain the maximum effect of the pendulum.

Rat hole

A hole that is drilled ahead of the main wellbore and which is of a smaller diameter than the bit in the main borehole.

Reamer

A tool employed to smooth the wall of a wellbore, enlarge the hole, stabilize the bit and straighten the wellbore where kinks and abrupt doglegs are encountered.

Rebel tool (registered trademark of Eastman Whipstock)

A tool designed to prevent and correct lateral drift (walk) of the bit tool. It consists of two paddles on a common shaft that are designed to push the bit in the desired direction.

Roll off

A correction in the facing of the deflection tool, usually determined by experience, and which must be taken into consideration to give the proper facing to the tool.

Setting off course

A method of setting the direction of the wellbore in anticipation of the bit walking.

Side track

An operation performed to redirect the wellbore by starting a new hole; at a position above the bottom of the original hole.

Slant hole

A nonvertical hole; usually refers to a wellbore purposely inclined in a specific direction; also used to define a wellbore that is nonvertical at the surface.

Slant rig

Drilling rig specifically designed to drill a wellbore that is nonvertical at the surface. The mast is slanted and special pipe-handling equipment is needed.

Spiraled wellbore

A wellbore that has attained a changing configuration such as a helical form.

Spud bit

In directional drilling, a special bit used to change the direction and inclination of the wellbore.

Stabilizer. A tool placed in the drilling assembly to

Change or maintain the inclination angle in a wellbore by controlling the location of the contact point between the hole and drill collars.

Center the drill collars near the bit to improve drilling performance.

Prevent wear and differential sticking of the drill collars.

Surveying frequency

Refers to the number of feet between survey records.

Target area

A defined area, at a prescribed vertical depth, that is planned to be intersected by the wellbore.

Tool azimuth angle

The angle between north and the projection of the tool reference axis onto a horizontal plane.

Tool high-side angle

The angle between the tool reference axis and a line perpendicular to the hole axis and lying the vertical plane.

Total curvature

Implies three-dimensional curvature.

True north

The direction from any geographical location on the earth's surface to the north geometric pole.

True vertical depth (TVD)

The actual vertical depth of an inclined wellbore.

Turbodrill

A downhole motor that utilizes a turbine for power to rotate the bit.

Turn

A change in bearing of the hole; usually spoken of as the right or left turn with the orientation that of an observer who views the well course from the surface site.

Walk (of hole)

The tendency of a wellbore to deviate in the horizontal plane.

Wellbore survey calculation method

Refers to the mathematical method and assumptions used in reconstructing the path of the wellbore and in generating the space curve path of the wellbore from inclination and direction angle measurements taken along the wellbore. These measurements are obtained from gyroscopic or magnetic instruments of either the single-shot or multishot type.

Whipstock

A long wedge and channel-shaped piece of steel with a collar at its top through which the subs and drillstring may pass. The face of the whipstock sets an angle to deflect the bit.

Woodpecker drill collar (indented drill collar)

Round drill collar with a series of indentations on one side to form an eccentrically weighted collar.

4.10.2 Well Positioning

There are several well-positioning and coordinate systems currently utilized in the oilfield industry. Through the years determining a well location has become more critical because of government regulations for surveying accuracy, data interchange between companies, and adjacent wells.

4.10.2.1 Geographic Coordinates

Geographic is the most popular positioning system. It is described by latitude and longitude (see Figure 4.10.1)

- **Latitude:** Parallels run 0° – 90° North (positive) or South (negative) from the Equator.
- **Longitude:** Meridians run 0° – 180° East (positive) or West (negative) from the prime meridian (Greenwich).

There are two different methods to express direction. These are quadrant bearing and Azimuthal bearing (see Figure 4.10.2).

4.10.2.2 Universal Transverse Mercator

Projected coordinate system uses a two-dimensional Cartesian coordinate system to give locations on the surface of the Earth. It is a horizontal position representation, i.e., it is used to identify locations on the Earth independently of vertical position, but differs from the traditional method of latitude and longitude in several respects. The **universal transverse mercator** (UTM) system is not a single map projection. The system instead divides the Earth into 60 zones, each a 6°

FIGURE 4.10.1 Geographic coordinates.
<http://www.earthscienceeducation.org/Db-MapsCartographyRegions/GoogleEarth-GeographicGrid.jpg>.

band of longitude, and uses a secant transverse Mercator projection in each zone (see Figure 4.10.3).

Types of North Reference

- **Magnetic North:** Direction along the earth's surface toward the magnetic north pole. Compasses and other magnetic surveying devices point toward the magnetic north pole.
- **True North (Geodetic North):** Direction along the earth's surface toward the geographic North Pole.
- **Grid North:** Location position with respect to a grid coordinate drawn on a map referenced to true north.

Magnetic Declination Correction

Magnetic declination correction (MDC) is defined as the angular difference between the True North and the Magnetic North. The MDC is positive when magnetic north is east of true north (East Declination), and negative when it is to the west (West Declination). Declination along the Mississippi River in the United States is near zero, and ranges from 15° on the West Coast to -16° on East Coast. Declinations in Mexico, Australia, Eastern Europe, and the Middle East are positive. Declinations in South America, Europe, and Africa are negative (see Figure 4.10.4).

Magnetic field models provide values for MDC. The most common models and their resolution are described in Table 4.10.1.

Quadrant Bearing: Is noted in quadrant position (NE, SE, NW, and SW) and an angle 0°–90°.

Azimuthal Bearing: is noted from 0°–360° clockwise from the North

FIGURE 4.10.5 Earth oblate spheroid. <http://phys.org/news/2012-10-atomic-clocks-good-earth-geoid.html>.

4.10.2.3 Geodetic Coordinate Systems

The earth is an oblate spheroid (Radius at the North Pole is about 13.67 miles shorter than the equator), and its surface has irregular elevations (see Figure 4.10.5), plotting a surface point in a two-dimensional map is unmanageable. Geodesy is used to accurately measure the Earth’s geometric shape, orientation in space, and gravity field providing a technique to represent locations and surveys on well plans.

Geodetic Data define the size and shape of the earth and the origin and orientation of the coordinate systems used to map the earth. Typical data are Canada, USA, and Mexico:

- NAD27 (North American Datum, 1927) and NAD83 (North American Datum, 1983)
- North Sea: ED50 for the GCS (European Datum, 1950)
- WGS84 (World Geodetic System, 1984)

Vertical reference datum is used to measure MD or TVD, generally mean sea level. Other vertical datum references are:

FIGURE 4.10.6 (a). Radius of curvature. <http://www.drillingformulas.com/radius-of-curvature-method/>. Minimum curvature. https://geomag.usgs.gov/downloads/publications/3_geomagnetic.pdf.

- LAT Lowest Annual Tide
- AHD Australian Height Datum
- AGD84 Australian Geodetic Datum 1984
- AGD94 Australian Geodetic Datum 1994
- NAP Nieuw Amsterdamse Peil

Onshore drilling rigs use Rotary Table (or Drill Floor). Sometimes RKB is used, which requires the RKB correction. While Offshore Platforms use Air Gap, and references are corrected by for Heave and Tide.

4.10.3 Well Trajectory

Wellbores are classified as:

- New wells: Exploration and production
- Existing wells: Sidetrack of existing wellbores, and multi-lateral wells from exiting wellbores.

Well Profiles

- Vertical (inclination below 3°)
- Directional wells
 - Build and hold.
 - Build-hold-drop
 - S-wells
- Horizontal wells
 - Build-hold-build-hold
 - Long radius (DLS 2°–6°/100)
 - Medium radius (DLS 6°–35°/100)
 - Short radius (DLS > 35°/100)
 - 3D wells—turnhorizontal wells (nudge-turn, build, and hold)
 - Extended reach wells.—MD is greater than twice the TVD

Survey Calculation Methods

- Tangential
- Balanced tangential method
- Average angle
- Radius of curvature
- Minimum curvature

The tangential, balanced tangential, and average angle methods are based on the trigonometry of a right angle triangle. The radius of curvature and minimum curvature are the most popular and accurate survey calculation methods. Graphical representation is described with Figure 4.1.6a and b.

$$\text{North} = \frac{\text{MD}(\text{Cos}I_1 - \text{Cos}I_2)(\text{Sin}A_2 - \text{Sin}A_1)}{(I_2 - I_1)(A_2 - A_1)} \times \left(\frac{180}{\pi}\right)^2 \quad (4.10.1a)$$

$$\text{North} = \frac{\text{MD}}{2} (\text{Sin}I_1 \times \text{Cos}A_1 + \text{Sin}I_2 \times \text{Cos}A_2) \times \text{RF} \quad (4.10.1b)$$

$$\text{East} = \frac{\text{MD}(\text{Cos}I_1 - \text{Cos}I_2)(\text{Cos}A_1 - \text{Cos}A_2)}{(I_2 - I_1)(A_2 - A_1)} \times \left(\frac{180}{\pi}\right)^2 \quad (4.10.2a)$$

$$\text{East} = \frac{\text{MD}}{2} (\text{Sin}I_1 \times \text{Sin}A_1 + \text{Sin}I_2 \times \text{Sin}A_2) \times \text{RF} \quad (4.10.2b)$$

$$\text{TVD} = \frac{\text{MD}(\text{Sin}I_2 - \text{Sin}I_1)}{I_2 - I_1} \times \left(\frac{180}{\pi}\right) \quad (4.10.3a)$$

$$\text{TVD} = \frac{\text{MD}}{2} (\text{Cos}I_1 + \text{Cos}I_2) \times \text{RF} \quad (4.10.3b)$$

$$\text{RF} = \frac{2}{\text{DL}} \times \text{Tan}\left(\frac{\text{DL}}{2}\right) \quad (4.10.4a)$$

$$\text{DL} = \text{Cos}^{(-1)}[\text{Cos}(I_2 - I_1) - \text{Sin}I_1 \times \text{Sin}I_2 \times (1 - \text{Cos}(A_2 - A_1))] \quad (4.10.5a)$$

$$\text{DLS} = \text{Cos}^{(-1)}[\text{Cos}(I_1) \times \text{Cos}(I_2) + (\text{Sin}I_1 \times \text{Sin}I_2) \times (\text{Cos}(A_2 - A_1))] \times 100/\text{MD} \quad (4.10.6a)$$

$$\text{DLS} = \text{DL} \times \frac{180}{\pi} \times \frac{100}{\text{MD}} \quad (4.10.6b)$$

where;

MD: Measured depth between surveys in ft.	A ₁ : Azimuth direction at upper survey	RF: Ratio factor
I ₁ : Inclination at upper survey in degrees	A ₂ : Azimuth direction at lower survey	DL: is the dog leg angle in
I ₂ : Inclination at lower survey in degrees	DLS: Dogleg severity in degrees/100 ft	Radians

4.10.3.1 Position Uncertainty

The Industry Steering Committee on Wellbore Survey Accuracy (ISCWSA) latest mathematical model describes all error sources for any type of survey. And because the

FIGURE 4.10.7 Ellipsoid of uncertainty (EOU).

wellbore is defined in 3D, the result of this model is a 3D probability distribution of the well location. This 3D volume of uncertainty is called *ellipsoid of uncertainty* (see Figure 4.10.7). The vertical radius of the ellipsoid of uncertainty is the TVD.

The ellipse of uncertainty is the positional uncertainty of the cumulative survey uncertainties at each survey station.

Each survey has an ellipsoid of uncertainty. And the ellipsoids get larger as the depth increases, because it accumulates uncertainty azimuth, inclination, and measured depth, generating a *Cone of Uncertainty*. Errors occur because of both, the tool and the environment.

Depth uncertainty occurs because of drillpipe length measurement, and mechanical and thermal stretch.

Azimuthal and inclination uncertainty accumulates from instrument accuracy, alignment errors in the tool, and tool misalignment, and external magnetic interference affects the azimuth.

4.10.3.2 Survey Management

Because surveys can be used for future operations, it is important to verify the data by quality control measures. Survey management is utilized to eliminate drillstring magnetic interference and local variations of MDCs providing better accuracy for the surveys during drilling operations. Some techniques used for survey quality considerations are:

- *Depth correction*: The depth errors can be as much as 0.2%.
- *Short collar correction*: use the X and Y magnetic readings to calculate the azimuth, correcting for the BHA magnetic interference.
- *Multi-station analysis (MSA)* is used to address the drillstring magnetic interference by comparing the Earth's magnetic field with data magnetic data acquired at multiple survey stations.

- *SAG correction* is an inclination correction for the natural bending of the BHA due to its own weight. It increases with inclination and can be 0.5° or more.
- *Geomagnetic reference*: The selection of the magnetic field reference model is another technique used to improve wellbore position accuracy.

Some of the benefits of survey management are:

- Improves wellbore placement with the use of MSA
- Improves directional control by placing directional sensors closer to bit (Short Collar Correction)
- Detects and corrects for operating conditions outside specifications, often eliminating trips
- Reduces the need for additional surveys as well as additional runs for tool validation
- Mitigates the risks associated with high inclination wells close to magnetic east and west (Sag Correction)
- Measures and corrects for effects of magnetic storms
- Corrects for magnetic influences of metallic particles in the drilling fluid

4.10.3.3 Collision Avoidance

The industry trends contribute to an ever-increasing complexity in the anti-collision process. The traditional separation factor is defined by Equation 4.10.7.

$$SF = \frac{C_2 - C_1}{ER_1 + ER_2} \quad (4.10.7)$$

where:

$C_2 - C_1$ is center to center distance between wellbores at depth of interest.

ER_1 is the distance of the reference ellipsoid in the direction between the wellbores, at 2σ confidence.

ER_2 is the distance of the offset ellipsoid in the direction between the wellbores, at 2σ confidence.

All ellipse dimensions reported are in half-axes or radii and not diameters.

Anti-collision scan calculates the distance from the scanning point of the reference well to the closest point on an offset wellbore (see Figure 4.10.8). It can be displayed in a 3D view as spider view, ladder plot view, separation factor view, traveling cylinder view, or 3D proximity view.

4.10.3.4 Deflection Tool Orientation

Application of a deflecting tool (e.g., downhole motor with a bent sub) requires determining the orientation of the tool so that the hole takes the desired course. There are three effects to consider when setting a deflection tool.

FIGURE 4.10.8 Anti-collision - separation factor.

1. The existing borehole inclination angle
2. The existing borehole direction angle
3. The bent sub angle of the deflection tool itself

These three effects in combination will result in a new dogleg of a wellbore.

The deflection tool orientation parameters can be obtained using the vectorial method of D. Ragland, the Ouija Board, or the three-dimensional mathematical deflecting model.

4.10.3.5 Vectorial Method of D. Ragland

This method is explained by solving two example problems.

Example 4.10.1

Determine the deflection tool-face orientation, tool deflection angle and tool facing change from original course line angle if the data are as follows:

- Existing hole inclination angle: 10°
- Existing hole direction: N300W
- Desired change of azimuth: 25° (to the left)
- Desired hole inclination: 8°

Solution

The solution to this problem is shown in Figure 4.10.9. The following steps are involved in preparing a Ragland diagram.

1. Lay a quadrant N-S-W-E.
2. Select a scale for the angles.

3. With a protractor layoff an angle 30° from N to W.
4. Using the selected angle scale find p. B (10° from p. A).
5. With a protractor layoff an angle 25° to the left of line AB.
6. Find p. C using the angle scale (8° from p. A).
7. Describe a circle about p. B with a radius of $CB = 4.36^\circ$ (read from the diagram). This is the desired overall angle change.
8. Read off required tool-face orientation: S21°W.
9. Read off required tool facing change from original course line: 129° to the left.

Example 4.10.2

The original hole direction and inclination were measured to be S50°W and 6° , respectively. It is desired to obtain a new hole direction of S65°W with an inclination angle of 7° after drilling 90 ft. For this purpose, a whipstock was oriented correctly.

After drilling 90 ft, a checkup measurement was performed that revealed that the hole new direction is S62°W and the new inclination is $6^\circ 30'$. Determine the expected hole curvature delivered by the whipstock, the magnitude of roll-off for this system and the real hole curvature delivered by the whipstock. How should the whipstock be oriented to drill a hole with a direction of S37°W in 90 ft? What should be the inclination of the hole?

Solution

The solution to this problem is shown in Figure 4.10.10. Steps 1 and 2 are the same as in Example 4.10.1

1. Layoff an angle 50° from S to W.
2. Draw a line $00'$.
3. Draw a line OA that will represent the desired new hole (S65°W = 15° to the right of the current direction). Point A is found at a distance of 7° from point O. Radius OA represents the expected overall angle changed of 2.0° .
4. Read off the original whipstock orientation N63°W (67° to the right of the current hole direction).
5. Draw line OB (direction, S62°W, inclination, 6.5°).
6. Describe a circle about p. O' with a radius of OB. Radius $OB = 1.40^\circ$ represents the real overall angle change.
7. The angle $AO'B$ is the roll-off angle. Read off the roll-off angle = 8° to the right.
8. Draw line OC (S37°W). The whipstock orientation should be S68°E, and the final angle is 5.5° . If the roll-off effect is not considered, the whipstock direction is S76°E.

FIGURE 4.10.9 Graphic solution of Example 4.10.1 .

4.10.3.6 Three-Dimensional Deflecting Model

A mathematical model has been presented [5] that enables one to analyze and plan deflection tool runs. The model is a set of equations that relate the original hole inclination angle (α), new hole inclination angle (α_N), overall angle change (β), change of direction ($\Delta\epsilon$), and tool-face rotation from original course direction (γ). These equations are given below:

$$\beta = \cos^{-1} (\cos \alpha \cos \alpha_N + \sin \alpha \sin \alpha_N \cos \Delta\epsilon) \quad (4.10.8)$$

$$\alpha_N = \cos^{-1} (\cos \alpha \cos \beta - \sin \alpha \sin \beta \cos \gamma) \quad (4.10.9)$$

$$\Delta\epsilon = \tan^{-1} \left(\frac{\tan \beta \sin \gamma}{\sin \alpha + \cos \alpha \tan \beta \cos \gamma} \right) \quad (4.10.10)$$

The above equations can be rearranged to the form suitable for a solution of a particular problem. A hand-held calculator may be used to perform required calculations [6].

Practical usefulness of this model is presented below.

Example 4.10.3

Original hole direction and inclination is N20°E and 10°, respectively. It is desired to deviate the borehole so that the new hole inclination is 13° and direction N30°E in 90 ft.

FIGURE 4.10.10 Graphical solution of Example 4.10.2. With a downhole motor, there will be a left-hand reaction torque; therefore, the tool should be turned clockwise from the ideal position.

What is the tool orientation and deflecting angle (dogleg) necessary to achieve this turn and build?

Solution

From Equation 4.10.8, the overall angle change is

$$\beta = \arccos [\cos 10 \times \cos 13 + \sin 10 \times \sin 13 \cos(30 - 20)] = 3.59^\circ$$

The dogleg severity (hole curvature) is

$$C = 100 \frac{\beta}{L} = 100 \frac{3.59}{90} = 3.99^\circ/100 \text{ ft}$$

To obtain the tool orientation we solve Equation 4-267 for γ :

$$\begin{aligned} \cos \gamma &= \arccos \left(\frac{\cos \alpha \cos \beta - \cos \alpha_N}{\sin \alpha \sin \beta} \right) \\ &= \arccos \left(\frac{\cos 10 \times \cos 3.59 - \cos 13}{\sin 10 \times \sin 3.59} \right) = 38.54^\circ \end{aligned}$$

Consequently, the tool-face orientation is 38.54° to the right of the high side of the hole.

Example 4.10.4

Surveying shows that the hole drift angle is 22° and direction S36°W. It is desired to turn the hole of 6° to the right and build angle during next 90ft drilling. For this

purpose a deflection tool that can deliver a hole curvature of $3.333^\circ/100$ ft will be used. What is the expected new hole inclination angle? What is the required tool direction?

Solution

The expected overall angle change in the interval is

$$\beta = 3.333^\circ/100 \text{ ft} \times 90 \text{ ft} = 3^\circ$$

From Equation 4.12.4, we have

$$\cos\beta = \cos\alpha \cos\alpha_N + \sin\alpha \sin\alpha_N \cos\Delta\varepsilon$$

Considering the coefficients $a = \cos\alpha$ and $b = \sin\alpha \cos\Delta\varepsilon$, we obtain

$$\cos\beta = a \cos\alpha_N + b \sin\alpha_N$$

Now consider dividing both sides by $\sqrt{a^2 + b^2}$. We obtain

$$\frac{\cos\beta}{\sqrt{a^2 + b^2}} = \frac{a}{\sqrt{a^2 + b^2}} \cos\alpha_N + \frac{b}{\sqrt{a^2 + b^2}} \sin\alpha_N$$

Making $\cos\phi = \frac{a}{\sqrt{a^2 + b^2}}$ and $\sin\phi = \frac{b}{\sqrt{a^2 + b^2}}$, we have

$$\frac{\cos\beta}{\sqrt{a^2 + b^2}} = \cos\phi \cos\alpha_N + \sin\phi \sin\alpha_N = \cos(\phi - \alpha_N)$$

where $\tan\phi = \frac{b}{a} = \frac{\sin\alpha \cos\Delta\varepsilon}{\cos\alpha}$.
Solving for α_N , we have

$$\begin{aligned} \alpha_N &= \phi - \arccos\left(\frac{\cos\beta}{\sqrt{a^2 + b^2}}\right) \\ &= \arctan\left(\frac{\sin\alpha \cos\Delta\varepsilon}{\cos\alpha}\right) \\ &\quad - \arccos\left(\frac{\cos\beta}{\sqrt{a^2 + b^2}}\right) \end{aligned}$$

Using the expressions for a and b, we obtain

$$\begin{aligned} \alpha_N &= \arctan\left(\frac{\sin\alpha \cos\Delta\varepsilon}{\cos\alpha}\right) \\ &\quad - \arccos\left(\frac{\cos\beta}{\sqrt{\cos^2\alpha + \sin^2\alpha \cos^2\Delta\varepsilon}}\right) \end{aligned}$$

Substituting the data of the problem, we obtain for the new angle

$$\begin{aligned} \alpha_N &= \arctan\left(\frac{\sin 22 \times \cos 6}{\cos 22}\right) \\ &\quad - \arccos\left(\frac{\cos 3}{\sqrt{\cos^2 22 + \sin^2 22 \times \cos^2 6}}\right) \\ &= 23.88^\circ \end{aligned}$$

Using Equation 4.10.9 and solving for γ , we obtain for the tool-face orientation

$$\begin{aligned} \gamma &= \arccos\left(\frac{\cos\alpha \cos\beta - \cos\alpha_N}{\sin\alpha \sin\beta}\right) \\ &= \arccos\left(\frac{\cos 22 \times \cos 3 - \cos 23.88}{\sin 22 \times \sin 3}\right) = 54.02^\circ \end{aligned}$$

Therefore, the tool-face should be oriented at 54.02° to the right of the high side because it is desired to turn the hole to $S42^\circ W$.

4.11 MWD, LWD, AND PWD

Section reviewed by Francisco Sinisterra

Most of the cost in a well is expended during the drilling phase. Any amount of information gathered during drilling can be used to make decisions regarding the efficiency of the process. But the scope and ultimate cost to gather and analyze such information must be offset by a decrease in drilling expenditures, an increase in drilling efficiency and an increase in safety.

As drilling technology moved the pursuit of hydrocarbon resources into higher-cost offshore and hostile environments, intentionally deviated boreholes required information such as azimuth and inclination that could not be derived by surface instruments. Survey instruments, either lowered on a sand line or dropped into the drill pipe for later retrieval, to some degree satisfied the requirements but consumed expensive rig time and sometimes produced questionable results.

For many years researchers looked for a simple, reliable *measurement while drilling* technique, referred to by its abbreviation MWD. As early as 1939, a logging while drilling (LWD) system, using an electric wire, was tested successfully but was not commercialized [1,2]. Mud pulse systems were first proposed in 1963 [3,4]. The first mechanical mud pulse system was marketed in 1964 by Teledrift for transmitting directional information [5]. In the early 1970s, the steering tool, an electric wire operated directional tool, gave the first real-time measurements while the directional buildup was in progress. Finally, the first modern mud pulse data transmission system was commercialized in 1977 by Teleco [6]. State-of-the-art surveys of the technology were made in 1978 [7], in 1988 [7–10], and in 1990 [11].

A problem with the early MWD mud pulse systems was the very slow rate of data transmission. Several minutes were needed to transmit one set of directional data. Anadrill (former subsidiary of Schlumberger) working with a Mobil patent [12] developed in the early 1980s a continuous wave system with a much faster data rate. It became possible to transmit many more drilling data, and also to transmit logging data making LWD possible. Today, as many as 16 parameters can be transmitted in 16 s. The dream of the early pioneers has been more than fulfilled since azimuth, inclination, tool face, downhole weight-on-bit, downhole torque, shocks, caliper, resistivity, gamma ray, neutron, density, Pe, sonic and more can be transmitted in real time to the rig floor and the main office.

4.11.1 MWD Technology

4.11.1.1 Steering Tool

Up until 1970, all directional drilling was conducted using singleshot and multishot data. The normal procedure was

- A. Drill vertically in rotary to the kick-off depth.
- B. Kick-off toward the target using a downhole motor and a bent sub to an inclination of approximately 10°.
- C. Resume rotary drilling with the appropriate bottomhole assembly to build angle, hold, or drop.

The kick-off procedure required numerous single-shot runs to start the deviation in the correct direction. Since, during this phase, the drillpipe was not rotating a steering tool was developed to be lowered on an electric wireline instead of the single shot. The measurements were then made while drilling.

Measurements by electric cable are possible only when the drillstem is not rotating, hence with a turbine or downhole motor. The steering tool is run in the drillstring and is positioned by a mule shoe and key. The process is identical to the one used in the single-shot measurements. The magnetic orientation sensor is of the flux-gate type and measures the three components of the earth's magnetic field vector in the reference space of the logging tool. Three accelerometers measure the three components of the gravity vector still in the same reference space. These digitized values are multiplexed and transmitted by an insulated electric conductor and the cable armor toward the surface. On the surface a minicomputer calculates the azimuth and the drift of the borehole as well as the angle of the tool face permanently during drilling. In the steering tool system, the computer can also determine the azimuth and slant of the downhole motor underneath the bent sub and thus anticipate the direction that the well is going to take. It can also determine the trajectory followed. Figure 4.11.1 shows the steering tool system.

Naturally for operating the tool, the seal must be maintained at the point where the cable enters the drillstring:

- A. At the top of the drillpipes, in which case the logging tool is pulled out every time a new drillpipe length is added on.
- B. Through the drillpipe wall in a special sub placed in the drillstring as near the surface as possible, in which case new lengths are added on without pulling out the logging tool.

Figure 4.11.2 shows the typical operation of a steering tool for orienting the drill bit. The electric wireline goes through a circulating head located on top of the swivel. As mentioned previously, the tool has to be pulled out when adding a single.

Figure 4.11.3 shows the same operation using a side-entry sub. With this sub, the electric wireline crosses over from inside the drill pipe to the outside. Consequently, singles may be added without pulling the steering tool out. On the other hand, there is a risk of damaging the cable if it is crushed between the drillpipe tool joints and the surface casing. The wireline also goes through the rotary table and

FIGURE 4.11.1 Typical steering tool unit with surface panel and driller read-out (courtesy of Institut Francois du Petrole).

FIGURE 4.11.2 Typical operation of a steering tool for orienting the drill bit using a circulating head on the swivel (courtesy of SPE [13]).

FIGURE 4.11.3 Typical operation of a steering tool for orienting the drill bit using a side-entry sub (courtesy of SPE [13]).

special care must be taken not to crush it between the rotary table and the slips. Furthermore, in case of BHA sticking, the steering tool has to be fished out by breaking and grabbing the electric wireline inside the drillpipes.

Figure 4.11.4 shows the arrangement of the sensors used in a steering tool. There flux-gate-type magnetometers and three accelerometers are positioned with their sensitive axis along the principal axis of the tool. O_x is oriented toward the bent sub in the bent sub/tool axis plane. O_y is perpendicular to O_x and the tool axis. O_z is oriented along the tool axis downward.

The arrangement of Figure 4.11.4 is common to all directional tools based on the earth's magnetic field for orientation: MWD tools or wireline logging tools.

The steering tools have practically been abandoned and replaced by MWD systems, mostly because of the electric wireline. However, the high data rate of the electric wireline (20–30 kbits/s) compared to the low data rate of the MWD systems (1–10 bits/s) make the wireline tools still useful for scientific work.

4.11.1.2 Accelerometers

Accelerometers measure the force generated by acceleration according to Newton's law:

$$F = ma \quad (4.11.1)$$

where F = force in lb

m = mass in $(\text{lb} - \text{s}^2)/\text{ft}$ (or slugs)

a = acceleration in ft/sec^2

If the acceleration is variable, as in sinusoidal movement, piezoelectric systems are ideal. In case of a constant acceleration, and hence a force that is also constant, strain gages may be employed. For petroleum applications in boreholes, however, it is better to use servo-controlled accelerometers. Reverse pendular accelerometers and "single-axis" accelerometers are available.

Every accelerometer has a response curve of the type shown schematically in Figure 4.11.5. Instead of having an ideal linear response, a nonlinear response is generally obtained with a "skewed" acceleration for zero current, a scale factor error and a nonlinearity error. In addition, the skew and the errors vary with temperature. If the skew and all the errors are small or compensated in the accelerometer's electronic circuits, the signal read is an ideal response and can be used directly to calculate the borehole inclination. If not, "modeling" must be resorted to, i.e., making a correction with a computer, generally placed at the surface, to find the ideal response. This correction takes account of the skew, all the errors, and their variation with temperature. In this case, the accelerometer temperature must be known. The maximum current feedback defines a measurement range beyond which the accelerometer is saturated. Vibrations must be limited in order not to disturb the accelerometer response.

Assume that the accelerometer has the ideal response shown in Figure 4.11.6, with a measurement range of 2 g ($32.2 \text{ ft}/\text{s}^2$). We want to measure 1 g, but the ambient vibration level is $\pm 3 \text{ g}$. In this case, the accelerometer's indications are shaved and the mean value obtained is not 1 g but 0.5 g. The maximum acceleration due to vibrations which are not filtered mechanically, plus the continuous component to be measured, must be less than the instrument's measurement range.

These instruments serve to measure the earth's gravitational field with a maximum value of 1 g. The typical values of the characteristics are:

- Scale factor, 3 mA/g
- Resolution, 10^{-6} g
- Skew, 10^{-3} g
- Service temperature, -55 to $+150^\circ\text{C}$

For measurement ranges from 0 to 180° , three accelerometers mounted orthogonally must be used as shown in Figure 4.11.7. The x and y accelerometers are

FIGURE 4.11.4 Sketch of the principle of the sensor arrangement in a steering tool and any magnetic directional tool (courtesy of SPE [13]).

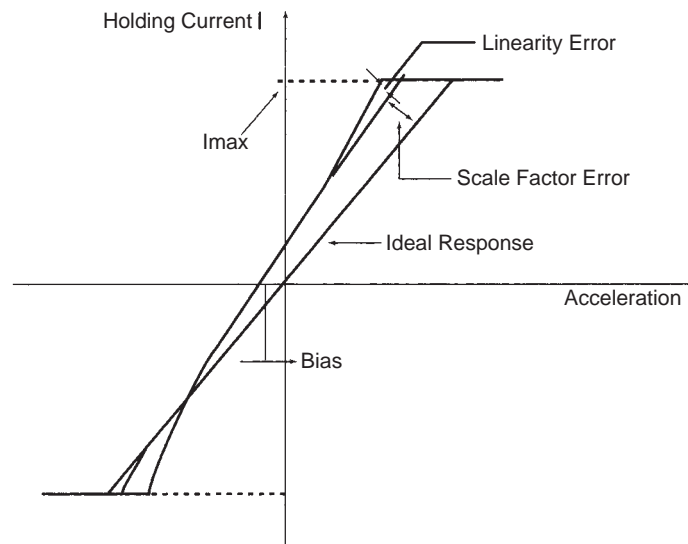

FIGURE 4.11.5 Accelerometer response.

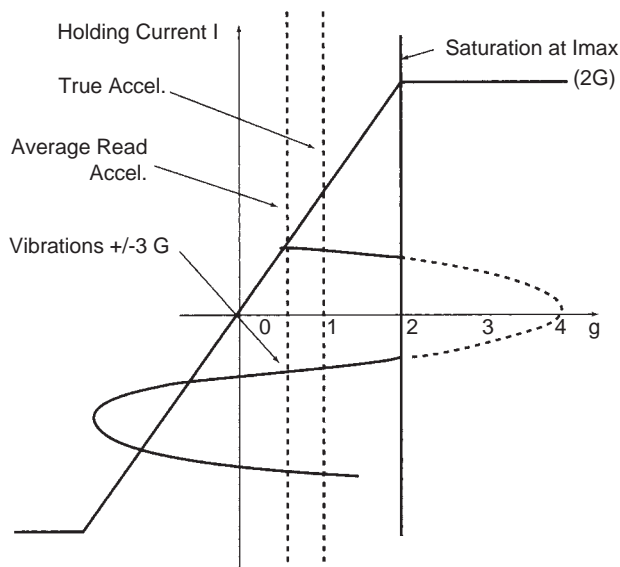

FIGURE 4.11.6 Effect of vibrations on an accelerometer response.

FIGURE 4.11.7 Mechanical drawing of the accelerometer section of a directional tool (courtesy of Sunstrand [14]).

mounted with their sensitive axis perpendicular to the tool axis. The z accelerometer is mounted with its sensitive axis lined up with the tool axis.

Figure 4.11.8 shows the inclination measurement using a triaxial sensor featuring three accelerometers. The three coordinates of earth's gravitational acceleration vector serve to define this vector in the reference frame of the probe. The earth's acceleration is computed as

$$G = \sqrt{G_x^2 + G_y^2 + G_z^2} \quad (4.11.2)$$

It must be equal to the 32.2 ft/s²; otherwise the accelerometers are not working correctly. When the readings are in g units, G must be equal to one.

For the best accuracy, inclination less than 60° is computed with

$$i = \arcsin \frac{\sqrt{G_x^2 + G_y^2}}{G} \quad (4.11.3)$$

and for i greater than 60°

$$i = \arccos \frac{G_z}{G} \quad (4.11.4)$$

The gravity tool face angle, or angle between the plane defined by the borehole axis and the vertical and the plane defined by the borehole axis and the BHA axis below the bent sub, can also be calculated. Figure 4.11.9 shows the gravity tool face angle. It is readily calculated using the equation

FIGURE 4.11.8 Vector diagram of the inclination measurement with three accelerometers.

FIGURE 4.11.9 Solid geometry representing the gravity tool face angle concept.

$$TF = \arctan \frac{-G_y}{G_x} \quad (4.11.5)$$

The gravity tool face angle is used to steer the well to the right, $TF > 0$, or to the left, $TF < 0$.

Typical specifications for a gravity sensor are as follows:

Temperature

- Operating = 0 to 175°C
- Storage = -40 to 175°C
- Scale factor = 0.01 V/°C

Power requirement

- 24 V nominal
- Less than 100 mA

Output impedance

10Ω

Mechanical characteristics

- Length = 60 cm (24 in.)
- Diameter = 3.75 cm (1.5 in.)
- Mass = 2 kg (4 lb)
- Alignment = ±0.4°

Electrical characteristics

- Scale factor = 5 V/g ± 1% (g = 32.2 ft/s²)
- Bias = ±0.005 g @ 25°C
- Linearity = ±0.1% full scale

Environmental characteristics

- Vibrations = 1.5 cm p-p (peak-to-peak), 10 to 50 Hz
50 g, 50 to 2000 Hz
- Shock = 2000 g, 0.5 ms, 0.5 sine

4.11.1.3 Magnetometers

Magnetometers used in the steering tools or MWD tools are of the flux-gate type.

The basic definition of a magnetometer is a device that detects magnetic fields and measures their magnitude and/or direction. One of the simplest types of magnetometers is the magnetic compass. However, due to its damping problems more intricate designs of magnetometers have been developed. The “Hall effect” magnetometer is the least sensitive. The “flux-gate” magnetometer concept is based on the magnetic saturation of an iron alloy core.

If a strip of an iron alloy that is highly “permeable” and has sharp “saturation characteristics” is placed parallel to the earth’s magnetic field, as in Figure 4.11.10, some of the lines of flux of the earth’s field will take a short cut through the alloy strip, since it offers less resistance to their flow than does the air. If we place a coil of wire around the strip, as in Figure 4.11.11 and pass enough electrical current through the coil to “saturate” the strip, the lines of flux due to earth’s field will no longer flow through the strip, since its permeability has been greater reduced.

Therefore, the strip of iron alloy acts as a “flux gate” to the lines of flux of the earth’s magnetic field. When the

FIGURE 4.11.10 Magnetic flux-lines representation in a highly permeable iron alloy core.

FIGURE 4.11.11 Magnetic flux-lines representation in a highly permeable iron alloy core saturated with an auxiliary magnetic field.

strip is not saturated, the gate is open and the lines of flux bunch together and flow through the strip. However, when the strip is saturated by passing an electric current through a coil wound on it, the gate closes and the lines of flux pop out and resume their original paths.

One of the basic laws of electricity, Faraday's law, tells us that when a line of magnetic flux cuts or passes through an electric conductor a voltage is produced in that conductor. If an AC current is applied to the drive winding A-A of Figure 4.11.11 the flux gate will be opening and closing at twice the frequency of the AC current and we will have lines of flux from the earth's field moving in and out of the alloy at a great rate. If these lines of flux can be made to pass through an electrical conductor ("sense winding"), a voltage will be induced each time they pop in or out of the alloy strip. This induced voltage in the sense windings is proportional to the number of lines of flux cutting through it, and thus proportional to the intensity of that component of the earth's magnetic field that lies parallel to the alloy strip.

When the alloy strip is saturated, a lot of other lines of flux are created that are not shown in Figure 4.11.11. The lines of flux must be sorted out from the lines of flux due to the earth's field to enable a meaningful signal to be produced. A toroidal core as shown in Figure 4.11.12 will enable this separation of lines of flux to be accomplished. The material used for the toroidal core is usually mu metal.

Each time the external lines of flux are drawn into the core, they pass through the sense windings B-B to generate a voltage pulse whose amplitude is proportional to the intensity of that component of the external field that is parallel to the centerline of the sense winding. The polarity, or direction of this pulse, will be determined by the polarity of the external field with respect to the sense windings. When the flux lines are expelled from the core they cut the sense windings in the opposite direction and generate

FIGURE 4.11.12 Sketch of principle of a single-axis flux-gate magnetometer.

another voltage pulse of the same amplitude but of opposite polarity or sign. Because of this voltage pulse occurring at twice the driving voltage frequency, the flux gate is sometime known as "second harmonic magnetometer".

The main advantages of the flux gate magnetometers are that they are solid state devices much less sensitive to vibration than compasses, they have uniaxial sensitivity, and sensitivity, and they are very accurate.

Typical specifications are:

Temperature

Operating = 0 to 200°C

Storage = -20 to 200°C

Power requirement, output in impedance, and mechanical characteristics are similar to the accelerometer sensors. Electrical characteristics

Alignment = $\pm 0.5^\circ$

Scale factor = $5 \text{ V/G} \pm 5\%$

Bias = $\pm 0.005 \text{ G} @ 25^\circ\text{C}$

Linearity = $\pm 2\%$ full scale

Note: 1 gauss = 1G = 10^{-4} tesla

Environmental characteristics

Vibrations = 1.5 cm p - p, 2 to 10 Hz

20 g, 10 to 200 Hz

Shock = 1000 g, 0.5 ms, 0.5 sine

Figure 4.11.13 shows the photograph of a Develco high-temperature direction sensor. For all the sensor packages, calibration data taken at 25, 75, 125, 150, 175 and 200°C are provided. Computer modeling coefficients provide sensor accuracy of $\pm 0.001 \text{ G}$ and $\pm 0.1^\circ$ alignment from 0 to 175°C. From 175 to 200 the sensor accuracy is $\pm 0.003 \text{ G}$ and $\pm 0.1^\circ$ alignment.

Example 4.11.1 Steering Tool Measurement-Trajectory Forecast

An interesting problem that can be solved with the steering tool or the MWD measurements is the trajectory forecast when drilling ahead with a given bent sub (constant angle), and a given tool-face angle.

1. After drilling the mud motor length with a given tool face angle and a given bent sub angle, what is the borehole deviation and orientation likely to be at the mud motor depth?

Using the drawing Figure 4.11.14 find the algorithm to compute these angles.

2. If we change the tool face angle to -30° (turning left), what will be the probable borehole deviation and azimuth after drilling another motor length? Use the same computer program.

FIGURE 4.11.13 Photograph of a high-temperature directional sensor with three accelerometers and three magnetometers (courtesy of Develco [15]).

FIGURE 4.11.14 Vector diagram showing the mud motor axis as well as the steering tool axis.

Note: We will assume that the borehole axis is the same as the drill collar axis at the steering tool depth and also that the borehole axis is the same as the mud motor axis at the mud motor depth.

Solution

The same algorithms are used as in Example 3. The vector **Z** (0, 0, 1) is replaced by vector **Z** (sin 2° • cos TF, sin 2° • sin TF, cos 2°), This new vector **Z** should be used to compute the new inclination, using the scalar product between vector **G** and new vector **Z**. The new vector **Z** should also be used to compute the new azimuth.

4.11.1.4 Vibrations and Shocks

Measurements while drilling are made with sensors and downhole electronics that must operate in an environment where vibrations and shocks are sometimes extremely severe. A brief study of vibrations and shocks will be made to understand better the meaning of the specifications mentioned earlier.

The vibration frequencies encountered during drilling are well known. They correspond to the rotation of the drill bit, to the passing of the bit rollers over the same hard spot on the cutting face, and to the impact of the teeth. Figure 4.11.15 gives the order of magnitude for frequencies in hertz (60 rpm = 1 Hz). In each type the lowest frequencies correspond to rotary drilling and the highest ones correspond to turbdrilling. Three vibrational modes are encountered:

1. axis vibrations due to the bouncing of the drill bit on the bottom
2. transverse vibrations generally stemming from axial vibrations by buckling or mechanical resonance
3. angular vibrations due to the momentary catching of the rollers of stabilizers

In vertical rotary drilling, the drillpipes are almost axially and angularly free. Therefore, the highest level of axial

and angular vibration is encountered for this type of drilling. In deviated rotary drilling, the rubbing of the drill string on the well wall reduces axial vibrations, but the stabilizers increase angular vibrations. In drilling with a downhole motor, the rubbing of the bent sub on the well wall reduces the amplitude of all vibrations.

Vibrations are characterized by their peak-to peak amplitude at low frequencies or by their acceleration at high frequencies. Assuming that vibration is sinusoidal, the equation for motion is

$$x = \frac{A}{2} \sin 2\pi f \times t \tag{4.11.6}$$

where x = elongation in m

A = peak-to-peak amplitude in m

f = frequency in Hz

t = time in s

By deriving twice, acceleration becomes

$$a = -\frac{A}{2} (2\pi f)^2 \sin 2\pi f \times t \tag{4.11.7}$$

Maximum acceleration is thus $a_m = 2A\pi^2 f^2$. For example, peak-to-peak 12 mm at 10 Hz corresponds to $a_m = 11.8 \text{ m/s}^2 = 1.2 \text{ g}$. Acceleration of gravity is expressed as g.

Figure 4.11.16 can be proposed to measure vibration in vertical rotary drilling. The lower limits correspond to soft sandy formations and the upper limits to heterogeneous formations with hard zones. Table 4.11.1 gives the specifications that the manufacturers propose for several tools.

The shocks that measuring devices are subjected to are generally characterized by an acceleration (or deceleration) and a time span. For example, a device is said to withstand 500 g (5,000 m/s²) for 10 ms. This refers to a “half-sine.” Shock testing machines produce a deceleration impulse having the form shown in Figure 4.11.17.

Measuring devices run inside the drillstring are mainly subject to axial impacts. These shocks come from sudden

FIGURE 4.11.15 Main vibration frequencies encountered while drilling.

FIGURE 4.11.16 Order of magnitude of the vibration amplitudes encountered during drilling.

TABLE 4.11.1 Resistance of Some Directional Tools or Components to Vibrations

Tool	Low Frequencies	High Frequencies
Azintac (1)	1 mm cm ³ (5-50 Hz)	10 g (50-500 Hz)
Drill-director (2)	2 g (5-45 Hz)	5 g (45-400 Hz)
Q-Flex accelerometer		25 g
Develco accelerometer	12.7 mm cm ³ (20-40 Hz)	40 g (40-2000 Hz)
4-Gimbal gyroscope	2 g (10-200 Hz)	
2-Axis gyroscope	5 g (10-300 Hz)	
On-shore military specifications		14 g (50-2000 Hz)

 (2) Humphery Inc. Trademark
 (The acceleration values correspond to maximum amplitudes)

FIGURE 4.11.17 Theoretical deceleration variation during a shock or impact.

halts in the mule shoe or from an obstruction in the string. The measuring devices used while drilling are generally subjected to axial and angular impacts caused by the bouncing of the bit on the bottom and by the catching of the rollers and stabilizers on the borehole walls.

Table 4.11.2 gives the specifications compiled by manufacturers for several measuring devices. It can thus be seen that such devices must be equipped with an axial braking system capable of having a stroke of 10 and even 20 cm.

4.11.1.5 Teledrift and Teleorienter

The first transmission of data during drilling using mud pulses was commercialized by B.J. Hughes Inc. in 1965 under the name of *teledrift* and *teleorienter*. Both tools are purely mechanical. A general sketch of principle is given in Figure 4.11.18. The tool is now operated by Teledrift Inc.

TABLE 4.11.2 Resistance of Some Directional Tools or Components to Axial Shocks or Impacts

Tool	Deceleration	Time (ms)	Braking	Initial Velocity
	(g, G)		Distance (m)	(m/s)
Azintac	60	11	0.024	4.35
Drill-director	700	10	0.23	46.2
Q-Flex accelerometer	250	11	0.10	18.15
Develco accelerometer	400	1	0.0013	2.64
4-Gimbal accelerometer	50	10	0.016	3.3
2-Axis gyroscope	100	10	0.033	6.6
Military specifications	30 to 100	10		

**FIGURE 4.11.18** Sketch of principle of the telelift tool or teleorienter tool attached to the drillstring (courtesy of Teledrift, Inc. [16]).

The tool generates at bottom positive pulses by restricting momentarily the flow of mud each time that the mud flow (pumps) is started. The pulses are detected at the surface on the stand pipe and recorded as a function of time.

Figure 4.11.19 shows the sketch of principle of the telelift unit which is measuring inclination.

A pendulum hangs in a conical grooved bore. A spring tends to move the pendulum and the poppet valve upwards when the circulation stops. If the tool is inclined, the pendulum catches the grooves at different levels according to the inclination and stops there. For example, for minimum inclination (Figure 4.11.19B) it stops the poppet valve past the first restriction. In Figure 4.11.19D the poppet valve stops past the seventh restriction due to the high inclination.

When the circulation is started, the poppet valve travels slowly down, generating one pressure pulse when passing each restriction. The measurement range in the standard tool is of 2.5° (also 7° ranges, 1° increments, max. 17°).

Table 4.11.3 gives the inclination angles corresponding to one to seven pulses with three cones. Fifteen cones are available. The maximum measurable angle is 10° . The range must be selected before lowering the drillstring.

The cone can be replaced by a mechanism that senses the angular position rather than the inclination of the drillstring.

The tool is then sensitive to the tool face and is called the *teleorienter*.

Figure 4.11.20 shows the read-out display of the driller in a zero tool-face position. Four mud pressure pulses will be recorded each time the pumps are started. In Figure 4.11.21a, a tool-face value of 20° is indicated by three pulses, turning to the right. In Figure 4.11.21b, a tool-face value of -20° is indicated by five pulses, and the borehole is turning left.

These tools have been widely used in the past by the cost conscious operators. The tool could be rented and operated

FIGURE 4.11.19 Teledrift mechanism in various coding positions (courtesy of Teledrift, Inc. [16]).

Angle Range	Deviation Angle in Degrees						
	1 signal	2 signals	3 signals	4 signals	5 signals	6 signals	7 signals
0.5–3.0	0.5	1.0	1.5	2.0	2.5	3.0	3+
1.0–3.5	1.0	1.5	2.0	2.5	3.0	3.5	3.5+
7.5–10.0	7.5	8.0	8.5	9.0	9.5	10.0	10.0+

by the rig floor personnel. However, the inclination ranges are limited, only one tool, teledrift or teleorienter, can be used during a trip, and only the tool-face angle is read by the teleorienter, not the azimuth.

These tools are still available but tend to be replaced by the MWD systems.

4.11.1.6 Mud Pressure, EM and Wired-Drillpipe Telemetry

Three methods are currently used to transmit data from downhole to surface: mud pressure telemetry, electromagnetic earth transmission, and wired-drillpipe telemetry.

FIGURE 4.11.20 Drill read-out display of the teleorienter in a zero tool face angle “go straight, build angle” position (courtesy of Teledrift, Inc. [16]).

Mud pulse telemetry is the most common real-time data transmission. The three main mud pulse telemetry systems are:

1. positive pulses obtained by a momentaneous partial restriction of the downhole mud current;
2. negative pulses obtained by creating a partial and momentaneous communication between the drill string internal mud stream and the annular space at the level of the drill collars;
3. phase changes of a low-frequency oscillation of the drilling mud pressure induced downhole in the drill-string.

Figure 4.11.22 shows sketches of the three systems.

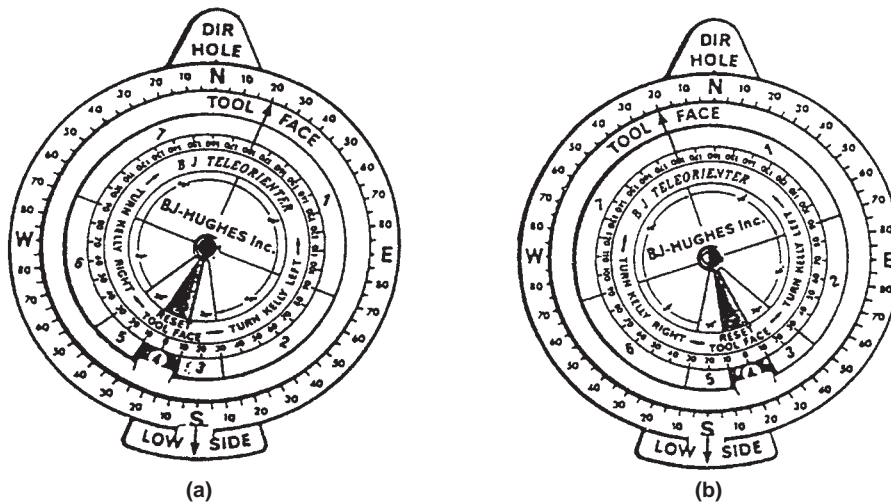

FIGURE 4.11.21 Driller read-out display of the teleorienter: (a) +20° tool-face angle, turning right position; (b) -20° tool-face angle, turning left position (courtesy Teledrift, Inc. [16]).

Transmission by Positive Pulses

This system is by far the most common. It is placed in a nonmagnetic drill collar containing sensors of the flux-gate type for measuring the direction of the earth’s magnetic field and accelerometers for measuring the gravity vector. An electromagnetic and electronic unit, every time rotation is halted, calculates and memorizes the azimuth, drift and tool face angles. Bottomhole electric power is supplied by an AC generator coupled with a turbine situated on the mud stream in the drill collar, or by batteries.

Flow sensors, or vibration sensors can be used to trigger the measurement mode. These sensors can be programmed for either flow on or flow off surveys modes. Figure 4.11.23, gives a schematic diagram of a 2 positive pulse generator.

The coding principle is given in Figure 4.11.24. Each angular value of azimuth, drift and tool face is represented by ten bits. The practical “positive pulse” system is slightly different. The “1” bits correspond to incomplete strokes of the poppet valve as shown in Figure 4.11.25, making the system a slow phase-shift keying system. Transmission rates of 0.2 or 0.4 bit/s are commonly used.

The calculation of the amplitude of pressure variation at bottom can be done assuming that the restriction behaves as a choke. The pressure loss can be estimated using the relations

$$\Delta P = \frac{Q^2 \cdot \gamma \cdot 144}{2 \cdot g_c \cdot c^2 \cdot A_0^2} \quad (4.11.8)$$

where ΔP = pressure loss in psi

Q = flowrate in ft^3/s

γ = fluid specific weight in lb/ft^3

c = coefficient assumed to be one

A_0 = cross-sectional area of the restriction in in.^2

g_c = acceleration of gravity ($32.2 \text{ ft}/\text{s}^2$)

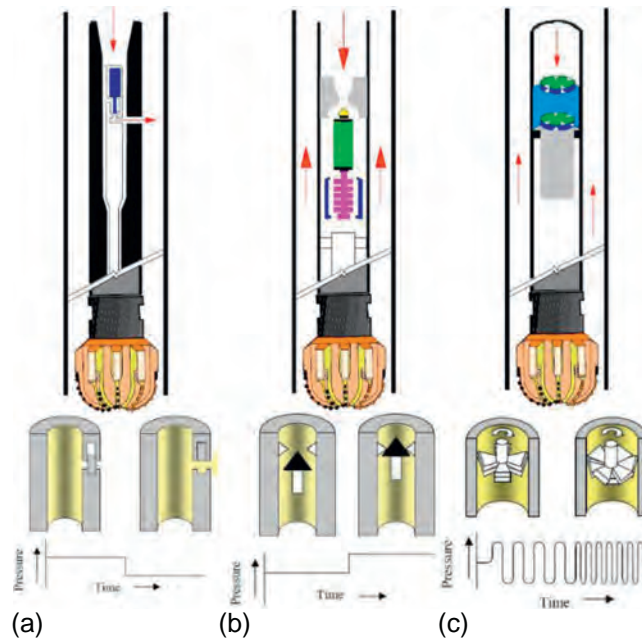

FIGURE 4.11.22 Telemetry systems using mud pressure waves: (a) negative pulse system; (b) positive pulse system; (c) continuous wave system.

When using a mud motor, the ΔP due to the restriction must be added to the ΔP due to the motor and the bit nozzles. The mud motor pressure loss is given by

$$\Delta P = \frac{1714 \cdot W}{\eta \cdot Q} \quad (4.11.9)$$

where ΔP = pressure loss in psi
 W = motor power in HP
 η = motor efficiency
 Q = mud flowrate in gal/min

Formula 4.11.8 will apply to the bit nozzle pressure loss.

Transmission by Negative Pulses

Drilling with a nozzle bit or with a downhole motor introduces a differential pressure between the inside and the outside of drill collars. This differential pressure can be changed by opening a valve and creating a communication between the inside of the drill string and the annular space. In this way, negative pulses are created that can be used to transmit digital data in the same way as positive pulses. Halliburton and other companies are marketing devices using this transmission principle.

Equation 4.11.8 can be used to calculate the pressure change inside the drill collars by changing the cross-sectional area A_0 from bit nozzles only to bit nozzles plus the pulser nozzle.

Continuous-Wave Transmission

Anadrill markets a tool which produces a 12-Hz sinusoidal wave downhole. Ten-bit words representing data are trans-

mitted by changing or maintaining the phase of the wave at regular intervals (0.66 s). A 180° phase change represents a 1, and phase maintenance represents a 0.

Figure 4.11.26 shows a sketch of principle of the system and of the phase-shift keying technique. Frames of data are transmitted in a sequence. Each frame contains 16 words, and each word has 10 bits. Some important parameters may be repeated in the same frame, for example, in Figure 4.11.27 the torque T_p , the resistivity R and the gamma ray GR , are repeated four times. The weight on bit WOB is repeated twice, and the alternator voltage V_{alt} one time. Note that a synchronization pulse train starts the frame.

The early system was transmitting 1.5 bits/s (4 sine wave to identify one bit). Later systems went to 3 bits/s. Now with a 24-Hz carrier frequency, 6 bits/s can be transmitted.

Then, with data compression techniques (sending only changes for most of the words in the frame and rotating the data), an effective transmission rate of 10 bits/s can be achieved.

The continuous wave technique has a definite advantage over the other techniques: a very narrow band of frequencies is needed to transmit the information. The pulse techniques, on the contrary, use a large band of frequencies, and the various noises, pump noises in particular, are more difficult to eliminate.

In principle, several channels of information could be transmitted simultaneously with the continuous wave technique. In particular, a downward channel to control the tool modes and an upward channel to bring up the information. However, continuous wave transmission requires well maintained pumps and rig circulation system.

FIGURE 4.11.23 Schematic diagram of the positive pulse system (courtesy of Inteq-Teleco [17]).

Surface Detection of the Mud Pressure Signals

The pulse or wave amplitude varies largely according to depth, frequency, mud type and pulse generator device. A typical mud surface pulse amplitude is 1 bar (14.5 psi). In a sine wave transmission the surface amplitude may go as low as 0.1 bar (1.5 psi) rms. The pump noise must be low-

ered to minimum by the use of properly adjusted dampeners and triplex instead of duplex pumps, the pulse amplitude being about twice as large for the duplex pumps. The pump noise amplitude varies from 0.1 to 10 or more bars (1.5 to 145 psi) with dominant frequencies ranging from 2 to 10 Hz. The rotation speed of the pumps may have to be changed so the noise frequency does not interfere with the measurements. The pressure sensors are generally of the AC-type, which sense only the pressure variations. A common sensor is of the piezoelectric type with a crystal transducer. Generally a built-in constant current follower amplifier converts the signal to a low impedance voltage. A typical sensitivity is 5 V per 1,000 psi (70 bars) with a maximum constant pressure of 10,000 psi (700 bars). The filtering can be done with digital filters or Fourier transform analyzers. For Fourier transform processing, the signal must be properly analog-filtered and then digitized. Two pressure transducers can be used at different locations on the standpipe, as shown in Figure 4.11.28, to take advantage of the phase shift that is opposite for pump noise and downhole signal. Sophisticated digital cross correlation techniques can then be used.

Downhole Recording

Most MWD service companies offer the possibility of recording the data versus time downhole. The memories available may reach several megabytes, allowing the recording of many parameter values during many hours. This information is particularly valuable when the mud pulse link breaks down. The data can be dumped in a computer, during the following drillpipe.

Retrievable Tools

Retrievable MWD tools similar to the steering tools are available from several service companies. They are generally battery powered and generate coded positive pressure mud pulses or continuous pressure waves the lower part of the tool has a mule shoe that engages in a sub for orientation. Currently tools are available for measuring directional parameters and gamma rays. A typical retrievable tool is shown in Figure 4.11.29.

FIGURE 4.11.24 Principle of the coding of the positive pulse system (courtesy of Inteq-Teleco [17]).

FIGURE 4.11.25 Pressure waves used in the practical application of the positive pulse system (courtesy of Inteq-Teleco [17]).

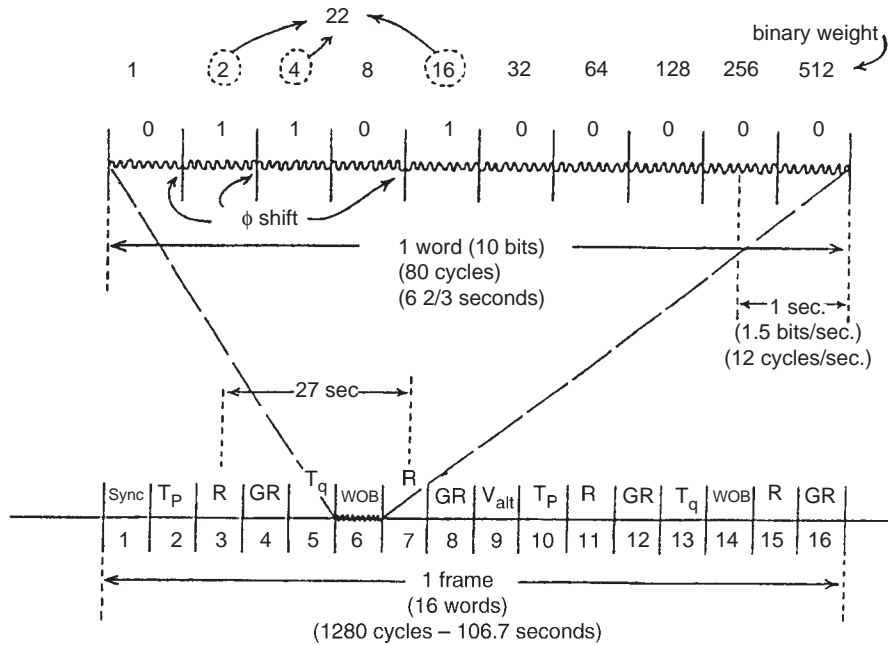

FIGURE 4.11.27 Example of a frame of data transmitted by the continuous wave system (Courtesy of Anadrill [18]).

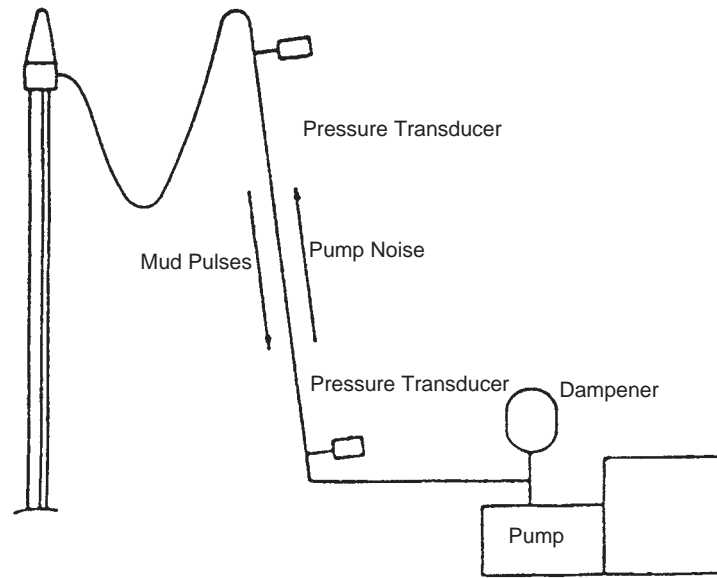

FIGURE 4.11.28 Surface pressure transducers location for pump noise elimination.

The benefits of such a tool are apparent in the following instances:

- kickoffs and sidetracks
- correction runs
- high stuck-pipe risk
- high temperature
- slim hole
- low-budget drilling. Replacing a faulted MWD tool

Velocity and Attenuation of the Pressure Waves

The velocity and attenuation of the mud pulses or waves have been studied theoretically and experimentally. The velocity depends on the mud weight, mud compressibility, and on the drillpipe characteristics, and varies from 4920 ft/s for a light water-base mud to 3,940 ft/s for a heavy water-base mud. An oil-base mud velocity will vary from 3,940 ft/s for a light mud to 3,280 ft/s for a heavy mud.

The propagation velocity can be calculated using the equation

$$V = \sqrt{\frac{g_c \cdot 144 \cdot B \cdot M}{\gamma (B + M)}} \quad (4.11.10)$$

and

$$M = E \frac{(a^2 - b^2)}{4 \cdot b^2 \left(\frac{5}{4} - \lambda\right) + 2(1 + \lambda)(a^2 + b^2)} \quad (4.11.11)$$

where V = pressure wave velocity in ft/s

g_c = acceleration due to gravity: 32.17 ft/s²

B = mud bulk modulus in psi (inverse of compressibility)

E = steel Young modulus of elasticity in psi

a = OD of the pipe in in.

b = ID of the pipe in in.

λ = steel Poisson ratio

γ = mud specific weight in lb/ft³

Figure 4.11.30a and b gives the pressure wave amplitude versus the distance for various typical muds.

Electromagnetic Transmission Systems

One system uses a low-frequency antenna built in the drill collars. This system is a two-way electromagnetic arrangement allowing communication from bottom to surface for data transmission and from surface to bottom to activate or modify the tool mode. At any time the sequence of the transmitted parameters, as well as the transmission rate, can be modified. The tool is battery powered and can work without mud circulation. The receiver is connected between the pipe string and an electrode away from the rig for the bottom to surface mode. This system can be used on-or offshore in theory. Two tools are available: the directional tool, which transmits inclination, azimuth, gravity tool face or magnetic tool face, magnetic field inclination and intensity, and the formation evaluation tool, which measures gamma ray and resistivity. The formation evaluation data are stored downhole in a memory that can be interrogated from the surface or transferred to a computer when pulling out.

FIGURE 4.11.29 Retrievable MWD tool (courtesy of Anadrill [18]).

Figure 4.11.31a gives the attenuation per kilometer as a function of frequency for an average formation resistivity of 10 and 1 $\Omega \bullet m$.

With the downhole power available and the signal detection threshold at surface, Figure 4.11.31b gives the maximum depth that can be reached by the technique as a function of frequency. Assuming that phase-shift keying is used with two cycles per bit, in a 10 $\Omega \bullet m$ area (such as the Rocky mountains) depth of 2 km (6,000 ft) could be reached while transmitting 7 bits/s.

Coding and Decoding

Ten-bit binary codes are used to transmit the information in most techniques. In one technique, the maximum reading to be transmitted is divided ten times. In a word, each bit has the value corresponding to its rank.

Demonstration

Transmit a range of values between 0 and 90°.

Bit 1 1 1 1 1 1 1 1 1 1

Value 45 22.5 11.25 5.62 2.81 1.40 0.70 0.35 0.17 0.08789

Word 111111111 = 89.91°

Word 1011011001 = 64.06°

Word 0001100111 = 9.04°

In another technique, each bit represents a power of two in a given word. The highest number that can be transmitted is

$$2^9 + 2^8 + 2^7 + 2^6 + 2^5 + 2^4 + 2^3 + 2^2 + 2^1 + 2^0 = 1023$$

as well as zero.

The smallest value that can be transmitted for a full scale of 90° is

$$90/1024 = 0.08789^\circ$$

Each bit has the following numerical value:

Bit	2 ⁹	2 ⁸	2 ⁷	2 ⁶	2 ⁵	2 ⁴	2 ³	2 ²	2 ¹	2 ⁰
Value	512	256	128	64	32	16	8	4	2	1

For example, to transmit 64.06°, the numerical value is

$$64.06/0.08789 = 729$$

- We will have one “2⁹” bit: 729 – 512 = 217
- one “2⁷” bit: 217 – 128 = 89
- one “2⁶” bit: 89 – 64 = 25
- one “2⁴” bit: 25 – 16 = 9
- one “2³” bit: 9 – 8 = 1
- one “2⁰” bit: 1 – 1 = 0

The word would be 1011011001 = 729. This is the same binary word as found previously. In each technique the accuracy is 0.08789° for a range of 0 to 90°. The rounding must be done the same way when coding and decoding.

Pressure variation with depth is shown in Figure 4.11.32.

4.11.1.7 Directional Drilling Parameters

With the modern accelerometers and solid-state magnetometers, a complete set of data is available for inclination, tool face and azimuth calculation. Magnetic corrections can be done. Inclination can be calculated with Equations 4.11.3 and 4.11.4. The gravity tool face angle can be calculated with Equation 4.11.5.

Azimuth calculation can be done by using vector analysis. In Figure 4.11.33, the vector **Z** represents the borehole axis, vector **H** the earth magnetic field and vector **G** the vertical or gravity vector. The azimuth is the angle between the vertical planes V_H and V_Z counted clockwise starting at V_H. This angle is the same as the angle between vectors

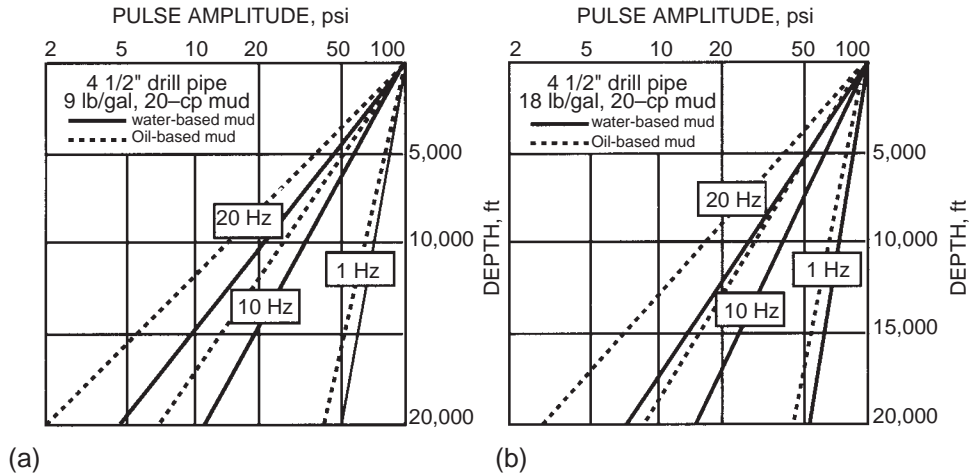

FIGURE 4.11.30 Wave amplitude variation as a function of distance in water base mud and in oil-base mud: (a) mud weight, 9 lb/gal; (b) mud weight, 17.9 ft/gal (courtesy of Petroleum Engineer International [20]).

FIGURE 4.11.31 Attenuation of electromagnetic signals for 1 and 10 $\Omega \cdot m$ average earth resistivity: (a) attenuation as a function of frequency; (b) maximum depth reached versus frequency (courtesy of Geoservices [21]).

A and **B**, respectively, perpendicular to V_H and V_z . We know that

$$\begin{aligned} \mathbf{A} &= \mathbf{G} \times \mathbf{H} \text{ (vector product)} & (4.11.12) \\ \mathbf{B} &= \mathbf{G} \times \mathbf{Z} \end{aligned}$$

The components of **H** and **G** measured in the referential of the MWD tool, and **z** is the vector (0,0,1) in the same referential. Now the azimuth α of the borehole can be computed with the scalar product $\mathbf{B} \cdot \mathbf{A}$; thus

$$\alpha = \arccos \left(\frac{\mathbf{A} \cdot \mathbf{B}}{|\mathbf{A}| \cdot |\mathbf{B}|} \right) \quad (4.11.13)$$

Some precautions must be taken to be sure that the correct angle is computed since $\cos(\alpha) = \cos(-\alpha)$.

The MWD sensors are located in a nonmagnetic part of the drill collars. The magnetic collars located several feet away still have an effect by creating a perturbation

in the direction of the borehole axis. This introduces an error that is empirically corrected with the single-shot instruments. Since the three components of **H** are measured, the magnitude of the error vector can be calculated if the module of the nonperturbed earth magnetic vector is known. The corrected dip angle vector can also be computed and compared to the non-perturbed dip angle. The computation should match; if it does not, then a nonaxial perturbation is present. This perturbation may be due to “hot spots,” points in the nonmagnetic drill collar that have developed some magnetism, or to external factors such as a casing in the vicinity. Correction techniques have been introduced for the hot spots.

External magnetism due to casing or steel in the well vicinity is used in passive ranging tools for blowout well detection from a relief well.

The accuracy of MWD directional measurements is generally much better than the single- or multishot-type

FIGURE 4.11.32 Pressure variation with depth: grid with the solution.

measurements since the sensors are more advanced and the measurements more numerous. The azimuth measurement is made with the three components of the earth magnetic field vector and only with the horizontal component in the case of the single shot or multishot. The accelerometer measurements of the inclination are also more accurate whatever the value of the inclination. The average error in the horizontal position varies from 6 ft per 3,000 ft drilled at no deviation to 24 ft per 3,000 ft drilled at 55° of deviation. The reference position is given by the inertial Ferranti platform FINDS [23]. A large dispersion is noted on the 102 wells surveyed.

When the borehole is vertical and a kickoff must be done, a mud motor and bent sub are generally used. To orient the bent sub in the target direction, the gravity toolface is undetermined according to Equation 4.11.5. Up to about 5° or 6° of deviation the *magnetic tool face* is used. The

magnetic tool face is the angle between the north vertical plane and the plane defined by the borehole (vertical) and the mud motor or lower part of the bent sub if the bent sub is located below the mud motor. After reaching 5° or 6° of inclination the surface computer is switched to the gravity tool face mode.

Drilling Parameters

The main drilling parameters measured downhole are

- weight-on-bit
- torque
- bending moment
- mud pressure
- mud temperature

Strain gages are usually used for the first four measurements.

FIGURE 4.11.33 Solid geometry sketch of the planes defining the azimuth angle.

Strain Gages

Strain gages are used to measure the strain or elongation caused by the stress on a material. They are usually made of a thin foil grid laid on a plastic support as shown in Figure 4.11.34. They are the size of a small postal stamp and are glued to the structure to be stressed.

The sensitive axis is along the straight part of the conducting foil. When elongated, this conducting foil increases in resistance. The change in resistance is very low. Two gages are usually used and mounted in a Wheatstone bridge. Two more gages not submitted to the strain are also used to compensate for temperature variation.

Weight-on-Bit

Weight-on-bit is usually measured with strain gages attached to a sub subjected to axial load. The axial load is composed of three parts:

1. weight on bit proper
2. end effect due to the differential internal pressure in the drill collar
3. hydrostatic pressure effects

Hydraulic lift must also be taken into account when using diamond bits and PDC bits. The weight-on-bit varies

between 0 and 100,000 lb or 0 and 50 ton-force. The end effect is due to the differential pressure between the drill collar internal pressure and the external hydrostatic pressure. This differential pressure acts on the sub internal cross-sectional area.

Torque

The torque is measured by placing two strain gages at 45° on the sub as shown in Figure 4.11.35.

Using two gages in opposite legs of the bridge will double the sensitivity.

The axial load (compression) gives a uniform stress and strain in the absence of a bending moment. If a bending moment exists, then one side is extended while the other is compressed.

During the rotation an alternative signal for the axial load is superimposed on the DC signal. By filtering, both the axial load and the bending moment can be measured. In practice, the strain gages are placed in holes drilled in the measuring sub as shown in Figure 4.11.36.

Mud Pressure

Internal and external mud pressures are usually measured with strain gages mounted on a steel diaphragm. Figure 4.11.37 shows a sketch of principle.

FIGURE 4.11.34 Sketch of principle of glued foil strain gage transducers.

One steel diaphragm is exposed to the internal pressure, the other is exposed to the external pressure. Four gages are normally used. Two of them are sensitive to pressure and temperature, and two are sensitive to the temperature. A Wheatstone bridge is used for detection of the pressure.

Downhole Shocks Measurements

An accelerometer in the MWD telemetry tool measures transverse accelerations, or shocks, that may be damaging for the bottomhole assemblies. When acceleration exceeds a certain threshold, the event is signaled to the surface as being a shock. These events versus time or depth are displayed as shock count. This information is used as a warning against excessive downhole vibrations and to alert the driller to change the rpm or weight on the bit [18].

A simple circuit has been designed to count the number of shocks that the tool experiences above a preset "g" level. The transverse shocks are measured in the range of 2 to 1,000 Hz in excess of the preset level. The level is adjustable and defaults at 25 g's (when no preset level is specified).

Downhole shock measurements are used to

- send alarms of excessive downhole vibration in real-time so that action can be taken to reduce damage to the MWD tools, drill bits, and bottomhole assemblies;
- reduce costly trips to replace damaged equipments;
- improve drilling rate by eliminating counter-productive BHA vibration motion.

Downhole Flowrate Measurement

Anadrill's basic MWD tool can be set up to monitor the alternator voltage being produced by the mud flowing across the MWD turbine downhole. By comparing this voltage to the standpipe pressure and the pump stroke rate, the surface system shows that a washout in the drill string is occurring much quicker than with conventional methods [18].

The downhole flowrate monitoring and washout detection system is used to

- avoid potential twist-offs from extensive drill string washouts;
- determine if the washout is above or below the MWD tool, thus saving rig time when searching for the failure.

Downhole pressure subs may achieve the same result as most pressure tools supply internal as well as annular pressure while circulating.

Bottomhole Gas Detection

Many techniques could be used for bottomhole gas detection:

- mud acoustic velocity (Figure 4.11.38)
- mud acoustic attenuation
- mud specific weight
- mud resistivity
- mud temperature
- annulus noise-level
- annular pressure changes (Figure 4.11.39)

FIGURE 4.11.35 Sketch of theoretical strain gage position in a sub to read WOB, torque, and bending moment.

Mud Resistivity

The mud resistivity can be measured only with the water-base muds. It is measured easily with a small microlog-type sensor embedded in the outer wall of the drill collar. Assuming the free gas is dispersed in small bubbles in the mud, the resistivity of the gas cut mud is

$$R_{gcm} = \frac{R_m}{(1 - f_g)^2} \quad (4.11.14)$$

where R_{gcm} = gas cut mud resistivity in $\Omega \bullet m$
 R_m = gas free mud resistivity in $\Omega \bullet m$
 f_g = volumetric gas content (fraction)

The variation is independent of the mud weight, pressure, or temperature, but is sensitive to fluids other than gas, such as oil or saltwater. Figure 4.11.40 shows the resistivity variations for a 1- $\Omega \bullet m$ mud. If we assume that a change of 10% can be detected, then the alarm could be given again for a free gas or oil volumetric concentration of 2 to 5%.

FIGURE 4.11.36 Practical design of a drilling parameter sub (courtesy of Anadrill [18]).

FIGURE 4.11.37 Sketch of principle of downhole pressure measurements.

Mud Temperature

One can attempt to calculate the variation of the temperature of the mud when it mixes with a gas stream cooled by expansion.

Calculations were made with a 500-gal/min mud flowrate, an expansion from 10,500 to 10,000 psi with an 18-lb/gal mud and also an expansion from 5,500 to 5,000 psi with a 9-lb/gal mud. The temperature decrease of the mud was a few °F up to 50% gas by volume in the mud.

Temperature measurements do not seem to be good gas indicators.

FIGURE 4.11.38 Acoustic velocity in the annulus as a function of the gas content in the mud (courtesy of *Petroleum Engineer International* [8]).

FIGURE 4.11.40 Bottomhole mud resistivity in the annulus as a function of the gas content of the mud (courtesy of *Petroleum Engineer International* [20]).

FIGURE 4.11.39 Bottomhole mud density in the annulus as a function of the gas content of the mud (courtesy of *Petroleum Engineer International* [8]).

Mud acoustic attenuation and annulus noise level are being investigated. It is expected that attenuation would be very sensitive to free gas concentration.

Example 4.11.2 Drilling Parameters — Drill Collar Pressure Drop

The following data characterize a well during drilling:

- depth: 10,000 ft
- 4½-in. drillpipes (ID = 3.64 in.)
- mud specific weight: 12 lb/gal

- flowrate: 500 gal/min
- three-bit nozzles: 16/32-in. diameter
- mud viscosity: 12 cp
- nozzle factor: C = 1.0
- hole diameter: 8.5 in.

1. Assuming no cutting in the annulus, compute the pressure recorded inside the drill collars downhole and the pressure in the standpipe at surface using the formula given hereafter.
2. A leak develops in the pipe string. The standpipe pressure reading drops to 1,896 psi with the same mud flowrate and the downhole drill collar inside pressure drops to 6,700 psi. What is the flowrate of the leak? What is the area of the leaking hole assuming it is located at 3,000 or 5,000 or 7,000 ft? (Assume that ΔP annulus does not change.)

Equations

1. Hydrostatic pressure is

$$P_H = 0.052 \cdot \gamma \cdot z \quad (4.11.15)$$

where P_H = hydrostatic pressure in psi
 γ = mud specific weight in lb/gal
 z = depth in ft

2. Turbulent flow pressure loss in pipe is

$$\Delta P = \frac{\Delta L \cdot \gamma^{0.75} \cdot v^{1.75} \cdot \mu^{0.25}}{1800 \cdot d^{1.25}} \quad (4.11.16)$$

where ΔP = pressure loss in psi
 ΔL = pipe length in ft
 γ = fluid specific weight in lb/gal
 v = average fluid velocity in ft/s
 m = fluid viscosity in cp
 d = pipe ID in in.

with

$$v = Q / (2.448 \times d^2)$$

where Q = flowrate in gal/min
 d = pipe ID in in.

3. Turbulent flow pressure loss in annulus is

$$\Delta P = \frac{\Delta L \cdot \gamma^{0.75} \cdot v^{1.75} \cdot \mu^{0.25}}{1396 (d_2 - d_1)^{1.25}} \quad (4.11.17)$$

where (notations same as above)
 d_2 = borehole or casing diameter in in.
 d_1 = pipe OD in in.

4. Flowrate through a choke, or nozzle, or leak is

$$Q = C \cdot A \cdot \sqrt{\frac{2 \cdot g_c \cdot \Delta P}{144 \cdot \gamma}} \quad (4.11.18)$$

where Q = flowrate in ft³/s
 C = coefficient (0.95 to 1.0)
 g_c = acceleration of gravity (32.17ft/s²)
 ΔP = pressure loss in psi
 γ = fluid specific weight in lb/ft³
 A = area in ft²

Solution

- ΔP drillpipes: 1,590 psi
 ΔP bit nozzles: 718 psi
 ΔP annulus: 74 psi
 Hydrostatic pressure: 6,240 psi
 P inside DC: 7,032 psi
 P standpipe: 2,382 psi
- Total DP in pipe (friction plus lead): 1,436 psi
 Pressure drop in DC due to leak: 332 psi
 New ΔP across nozzles: 386 psi
 Q through nozzles: 366.5 gal/min
 Q through drillpipes below leak: 366.5 gal/min
 Q through leak: 133.5 gal/min

If leak at 3000 ft:

Pipe ΔP above leak: 477 psi
 Pipe ΔP below leak: 646.5 psi
 ΔP across leak: 312.5 psi
 Leak cross-section: 0.24 in.²

If leak at 5000 ft:

Pipe ΔP above leak: 745 psi
 Pipe ΔP below leak: 462 psi
 ΔP across leak: 229 psi

Leak cross-section: 0.28 in.²

If leak at 7,000 ft:

Pipe ΔP above leak: 1,272 psi
 Pipe ΔP below leak: 277 psi
 Sum is more than total ΔP
 The leak must be above 7,000 ft

4.11.2 LWD Technology

Logging while drilling has been attempted as early as 1939. The first commercial logs were run in the early 1980s. First gamma ray logs were recorded downhole and transmitted to the surface by mud pulses. Then came the resistivity logs of various types that were also recorded downhole and/or transmitted to the surface. Now, neutron-density and Pe logs are also available. Sonic logs are offered commercially by Schlumberger, Halliburton-Baker Hughes, and Weatherford. Newest technologies now include formation pressure (D.S.T. Equivalent) monitoring.

4.11.2.1 Gamma Ray Logs

Gamma rays of various energy are emitted by potassium-40, thorium, uranium, and the daughter products of these two last elements contained in the earth formations surrounding the borehole. These elements occur primarily in shales. The gamma rays reaching the borehole form a spectrum typical of each formation extending from a few keV to several MeV.

The gamma rays are detected today with sodium iodide crystals scintillation counters. The counters, 6 to 112 in. long (15 to 30 cm) are shock mounted and housed in the drill collars. Several types of measurements can be made: total gamma rays, direction-focused gamma rays, spectral gamma rays.

Total Gamma Rays

Total gamma ray logs have been run on electric wireline since 1940. The sondes are rather small in diameter (1.5 to 4 in. or 37 to 100 mm). The steel housing rarely exceeds 0.5 in. (12 mm) and a calibration is done in terms of API units, arbitrary units defined in a standard calibration pit located at the University of Houston.

While early MWD total gamma ray tools could not be calibrated in the standard pit since they are too large, newer smaller tools can. Their calibration in API units was difficult because it varies with the spectral content of the radiation. By spectral matching the MWD logs we made to closely resemble the wireline logs. The logs which were recorded by the MWD companies in counts per second (cps) were then recorded in API units.

Another difference between the wireline logs and the MWD logs is the logging speed. With a wireline, the sonde is pulled out at a speed of 500 to 2,000 ft/min (150 to 600 m/min). The time constant used to optimize the effect of the statistical variations of the radioactivity emission, varied

FIGURE 4.11.41 Example of good similarity displayed between the MWD gamma ray log and the wireline log.

from 2 to 6 s. Consequently, the log values are somewhat distorted and inaccurate.

In MWD, the recording speed is the rate of penetration which rarely exceeds 120 to 150 ft/hr or 2 to 2.5 ft/min, two orders of magnitude less than the logging speed. Counters can be made shorter and time constant longer (up to 30 s or more). This results in a better accuracy and a better bed definition. Figure 4.11.41 shows an example of comparison between MWD gamma ray log and the wireline log ran later.

To summarize, the total gamma ray measurements are used for real-time correlation, lithology identification, depth marker, and kick-off point selection.

Direction-Focused Gamma Rays

It is important to keep the trajectory of horizontal or nearly horizontal wells in the pay zone. By focusing the probe-

nance of the gamma rays it is possible to determine if a shale boundary is approached from above or from below.

The tool shown in Figure 4.11.42 has its scintillation detector inserted in a beryllium-copper housing, fairly transparent to gamma rays. A tungsten sleeve surrounds the beryllium-copper housing, with a 90° slot or window running from top to bottom. Figure 4.11.42 is a sketch of the tool cross-section. The center of the window is keyed to the reference axis of the directional sensor. Consequently the directional sensor indicates if the window is pointing up or down.

By rotating the tool, one can differentiate between the level of gamma rays entering from the top and the lower part of the borehole. A sinusoidal response is recorded which depends on the following:

- distance from the bed boundary.
- gamma ray intensity of the bed in which the tool is in.

FIGURE 4.11.42 Cross-section of an MWD focused gamma ray tool (courtesy of SPWLA [24]).

- the contrast of radioactivity at the boundary.
- the shielding efficiency of the tungsten sleeve.

An example of the log ran is a horizontal borehole as shown in Figure 4.11.43. The depths on the log are along the hole depths. Vertical depths are shown in the higher part of the log with a representation of the true radioactivity of each bed. The following observations can be made:

- Approaching formation bed boundaries are detected by concurrent separation and displacement of the high and low gamma counts. These are shown in Figure 4.11.43 at measured depth intervals (7970–7980 ft) and (8010–8020 ft).
- Radioactive events occur in the measured depth interval (8,100–8,200 ft) with no displacement of the low/high side gamma ray logs. The radioactive events must be perpendicular to the gamma detector and could be indications of vertical natural fractures in the formation.

The disadvantage of relying on such tools is due to the shallow depth of investigation. Gamma detectors rely on statistical measurements by definition.

Spectral Gamma Ray Log

This log makes use of a very efficient tool that records the individual response to the different radioactive minerals. These minerals include potassium-40 and the elements in

the uranium family as well as those in the thorium family. The GR spectrum emitted by each element is made up of easily identifiable lines. As the result of Compton effect, the counter records a continuous spectrum. The presence of potassium, uranium and thorium can be quantitatively evaluated only with the help of a computer that calculates in real time the amounts present. The counter consists of a crystal optically coupled to a photomultiplier. The radiation level is measured in several energy windows.

Figure 4.11.44 shows an example of a MWD spectral GR log. On the left track, SGR is the total GR count, and CGR is this total minus the uranium count. On the right side of Figure 4.11.44 the wireline spectral gamma ray in the same interval is displayed. The curves are similar but some differences occur in the amplitude of the three curves.

The main field applications of this log are

1. Clay content evaluation: Some formations may contain nonclayey radioactive materials. Then the curve GR-U or GR-K may give a better clay content estimate.
2. Clay type identification: A plot of thorium versus potassium will indicate what type of clay is present. The thorium/potassium ratio can also be used.
3. Source rock potential of shale: A relation exists between the uranium-to-potassium ratio and the organic carbon content. The source rock potential of shale can thus be evaluated.

FIGURE 4.11.43 MWD focused gamma ray composite log in a horizontal borehole (courtesy of SPWLA [24]).

4.11.2.2 Resistivity Logs

Four types of resistivity logs are currently run while drilling:

1. Short normal resistivity
2. Focused current resistivity
3. Electromagnetic resistivity
4. Toroidal system resistivity

Short Normal Resistivity (after Anadrill)

The short normal (SN) resistivity sub provides a real-time measurement of formation resistivity using a 16-in. electrode device suitable for formations drilled with water-base muds having a moderate salinity. A total gamma ray measurement is included with the resistivity measurement; an annular bottomhole mud temperature sensor is optional. The short normal resistivity sub schematically shown in

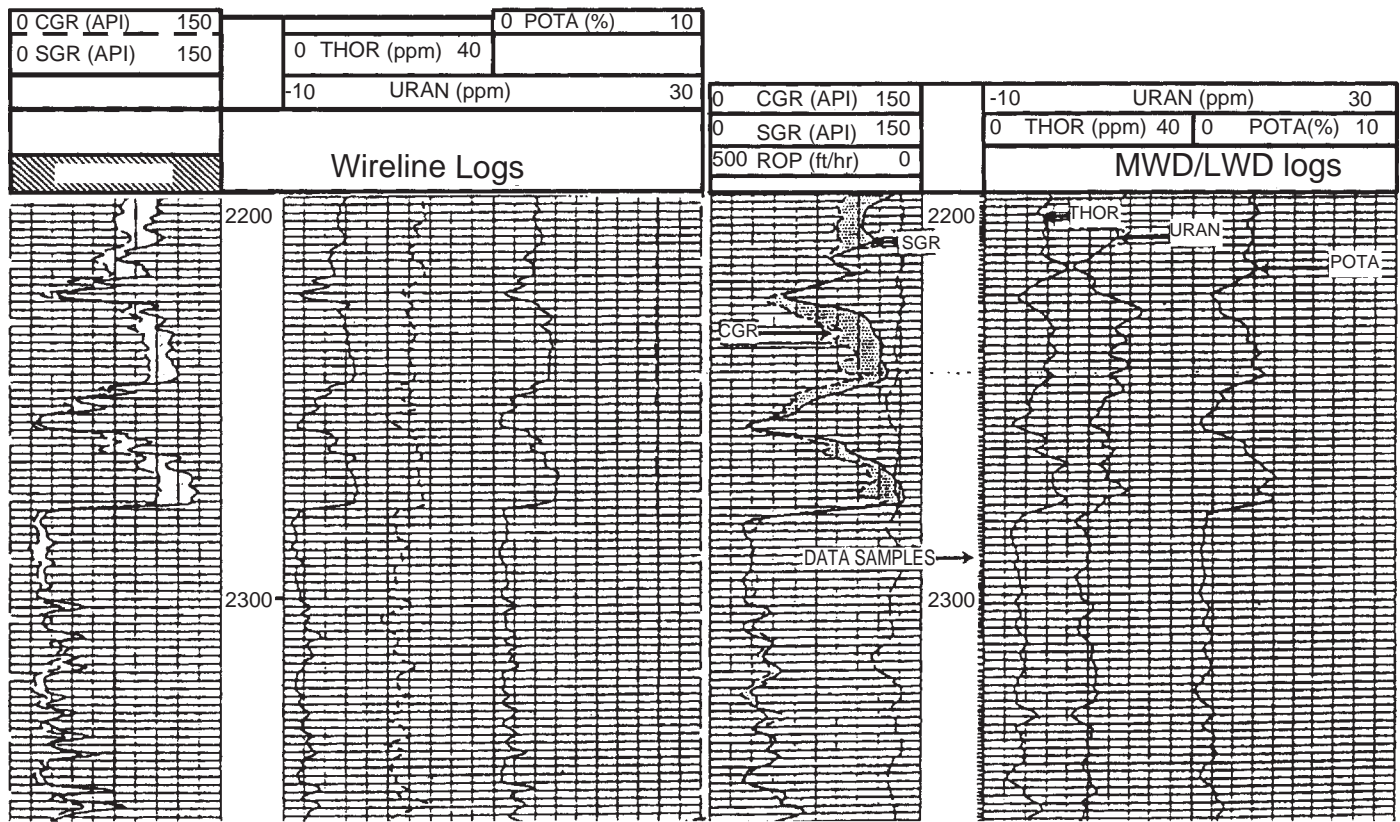

Figure 4.11.44 Example of natural gamma ray spectral logs recorded while drilling and with a wireline.

FIGURE 4.11.45 Short normal resistivity sub (courtesy Anadrill[25]).

Figure 4.11.45 must be attached to the MWD telemetry tools and operate in the same conditions as the other sensors.

Due to the small invasion and the large diameter of the sonde body, a resistivity near the true resistivity of the formation is generally measured. This is particularly true in shale where no invasion takes place. The main applications are:

- real-time correlation and hydrocarbon identification
- lithology identification for casing point and kick-off point selection
- real-time pore pressure analysis based on resistivity trend in shales
- resistivity range: 0.2 to 100 $\Omega \bullet m$

Focused Current Resistivity

Focused resistivity devices are particularly suited for wells where highly conductive drilling muds are used, where relatively high formation resistivities are encountered and where large resistivity contrasts are expected.

The focused current system employs the guarded electrode design shown in Figure 4.11.46.

The system is similar to the laterolog 3 used in wireline logging. A constant 1-kHz AC voltage is maintained for all

FIGURE 4.11.46 Focused current resistivity tool (adapted from SPE [26] and oilfield review slb [43]).

electrodes. The current flowing through the center electrode is measured.

The resistivity range is 0.1 to 1000 $\Omega \bullet m$. Beds as thin as 6 in. (15 cm) can be adequately delineated.

Electromagnetic Resistivity

The measurement in electromagnetic resistivity systems is similar to the wireline induction sonde resistivity. The frequency used is 2 MHz instead of 20 kHz. This is due to the drill collars steel that would completely destroy a 20-kHz signal. Early systems had one transmitter coil and two receiver coils. Systems presently in use have two to four transmitters allowing the recording of many curves with different depths of investigation. Figure 4.11.47a shows the CDR, compensated dual resistivity tool of Anadrill.

Figure 4.11.47b is a schematic of the operating principle. Two signals are measured: the wave amplitude reduction and the wave phase shift.

Two values of the resistivity can be calculated. The wave amplitude resistivity (R_{ad}) appears to have a deep investigation radius: 35 to 65 in. according to the formation resistivity. The phase shift resistivity (R_{ps}) appears to have a shallow investigation radius: 20 to 45 in. An example of tool response is given in Figure 4.11.48.

The deep penetration curve reads a value close to the noninvaded zone resistivity and the shallow penetration curve reads a value much lower than the invaded zone resistivity. The resistivity ranges for an acceptable accuracy are 0.15 to 50 $\Omega \cdot m$ for the deep investigation radius (R_{ad}) and 0.15 to 200 $\Omega \cdot m$ for the shallow investigation radius (R_{ps}). The vertical resolution is 6 in. (15 cm).

Toroidal System Resistivity (after Gearhart-Halliburton)

The system uses one toroidal transmitter operating at 1 kHz and a pair of toroidal receiver coils mounted on the drill collars. Figure 4.11.49 shows a sketch of a toroid.

The winding of the toroid acts as a transformer primary and the drill collar as the secondary. The current lines induced by the drill collar are shown in Figure 4.11.50.

The drill collar acts as a series of elongated electrodes in a way similar to the laterolog 3 wireline sonde. The lower electrode, which is the drill bit, is used to get the “forward” resistivity curve. A lateral resistivity measurement is made between the two toroid receivers. An example of toroid logs is shown in Figure 4.11.51.

The readings of both toroid curves seem to follow closely the ILd and ILm curves.

Example 4.11.3 Gamma Ray and Resistivity Interpretation

A typical set of logs recorded while drilling is shown in Figure 4.11.52. The wireline caliper is shown in the gamma ray track. Displayed on this attachment are gamma ray, R_{wa} curve, P_e curve, neutron and density curve. The delta-rho curve is the quality curve check for the density log.

1. Draw a lithology description in the depth column.
2. Is the clean formation permeable? Why?

3. Does the porous zone contain hydrocarbons? What type? Give the boundaries.
4. Determine R_w .
5. Compute the hydrocarbon saturation at 8400 ft assuming $a = 1$ and $m = 2$.

Solution

1. 8,450 to 8,434 ft dolomite
8,434 to 8,430 ft shale
8,430 to 8,426 ft dolomite
8,426 to 8,423 ft shale
8,423 to 8,374 ft dolomite
8,374 to 8,350 ft shale
Rock nature is read on the P_e log.
2. Yes, a mud cake is seen on the caliper log.
3. Yes, the R_{wa} curve increases sharply in the main zone at 8425 ft. Oil from 8425 to 8400 ft. Gas above 8,400 ft. Gas is indicated by a density porous larger than the neutron porosity.
4. $R_w = 0.05 \Omega \cdot m$; read on R_{wa} curve in the lower porous zone.
5. At 8400 ft, porosity = 20%, $R_{wa} = 0.45$, $F = 25$, $R_t = 11.25 \Omega \cdot m$

$$S_w = \sqrt{\frac{25 \cdot 0.05}{11.25}} = 0.33 = 33\% \quad (4.11.19)$$

$$S_{hc} = 67\%$$

4.11.2.3 Neutron-Density Logs

The physics of the measurements made by the MWD neutron-density tools are similar to those of corresponding wireline sondes. A sketch of principle of the Anadrill tool is shown in Figure 4.11.52.

For the neutron porosity measurement, fast neutrons are emitted from a 7.5-curie (Ci) americium-beryllium (Am-Be) source. The quantities of hydrogen in the formation, in the form of water or oil-filled porosity as well as crystallization water in the rock if any, primarily control the rate at which the neutrons slow down to epithermal and thermal energies. Neutrons are detected in near- and far-spacing detectors, located laterally above the source. Ratio processing is used for borehole compensation.

The energy of the detected neutrons has an epithermal component because a high percentage of the incoming thermal neutron flux is absorbed as it passes through 1 in. of drill collar steel. Furthermore, a wrap of cadmium under the detector banks shields them from the thermal neutron arriving from the inner mud channel. This mainly epithermal detection practically eliminates adverse effects caused by thermal neutron absorbers in the borehole or in the formation, such as boron.

Figure 4.11.53 shows a typical comparison of wireline and MWD gamma ray and neutron logs in a borehole in

FIGURE 4.11.47 Compensated dual-resistivity tool: (a) sub design; (b) operating principle (courtesy of Anadrill [25]).

FIGURE 4.11.48 Comparison of the compensated dual-resistivity log resistivities run while drilling to the invaded and noninvaded resistivities calculated with wireline phasor induction data. The spurt loss is the ratio R_{ps}/R_{ad} (courtesy of Anadrill [25]).

FIGURE 4.11.49 Toroid mounted on a drill collar (courtesy of SPWLA [27]).

excellent hole conditions. The MWD/LWD log matches the wireline log almost perfectly.

The density section of the tool, also seen in Figure 4.11.52, uses a 1.7 curie (Ci) of 137-cesium (Ce) gamma ray source in conjunction with two gain-stabilized scintillation detectors to provide a high-quality, borehole compensated density measurement.

The tool also measures the photoelectric effect Pe for lithology identification. The density source and detectors are positioned close to the borehole wall in the fin of a full-gage clamp-on stabilizer as seen in Figure 4.11.52. This geometry excludes mud from the path of the gamma rays,

greatly reducing borehole effect. In deviated and horizontal wells, the stabilizer may be run under gage for directional drilling purposes. Rotational processing provides a correction in oval holes and yields a differential caliper. Figure 4.11.54 shows a schematic of the tool positions in a borehole.

In the top part of Figure 4.11.54 the stand-off is constant during the rotation. In the oval borehole represented in the lower part of the figure, the stand-off is excessive when the density system is oriented up and the normal $\Delta\rho$ correction is not enough.

Statistical methods are used to measure the density variation as the tool rotates, the stand-off can be estimated and the density corrected. A density caliper can be computed that works for cavings of 2 in. (5 cm) or less when the tool rotates at a speed ranging from 6 to 150 rpm.

Figure 4.11.55 shows a typical MWD density log compared to a wireline density log. The calipers are also shown. At 1620 ft, the wireline caliper detects a much larger casing because it was run several days later.

Photoelectric (Pe) Curve

The Compton effect (change in gamma ray energy by interaction with the formation electrons) is used for measuring the density of the formation. The energy range is 200 to 450 keV. The photoelectric effect (absorption of a low-energy gamma due to ejection of a low orbital electron from its orbit) is seen for gamma in an energy range of 35 to 100 keV.

FIGURE 4.11.50 Computed current pattern in a homogeneous formation for the MWD toroid system (courtesy of SPWLA [27]).

FIGURE 4.11.51 LWD logs recorded while drilling [25].

By counting the gamma of low energy reaching the first counter a Pe curve sensitive to the nature of the formation can be recorded. A special counter protection fairly transparent to low-energy gamma ray (beryllium) is used. Table 4.11.4 shows the value of Pe for various lithologies.

Two systems are presently used by the MWD service companies concerning the radioactive source installation. One way is to lock the sources in holes in the drill collars.

Thus, if the BHA is lost, the sources are left in the formation.

Another way (Anadrill) is to use removable sources. Figure 4.11.56 shows the sources being installed in the tool at surface. The two sources, neutrons and gammas, are mounted on the same flexible shaft. They are moved from the shield to the sub without being exposed. Furthermore, if the BHA becomes stuck, they can be fished out with an overshot that connects to the fishing head on top of the

FIGURE 4.11.52 Neutron-density sub (courtesy of Anadrill [25]).

neutron source possibly lost higher in the BHA, should the wireline operation have difficulties.

Example 4.11.4 Neutron-Density Logs Interpretation

The set of logs in Figure 4.11.57 have all been recorded while drilling in a Gulf Coast sand-shale sequence.

1. Give the boundaries of the clean sand. Are some zones shaly?
2. Give the probable hydrocarbon/water contact. Give the probable nature of the hydrocarbons and the gas/oil contact.
3. Compute the gas saturation at 9692 ft.

4. Can the oil saturation be computed at 9720 ft using the basic formula given in this chapter?

Solution

1. Shaly sand. Cleanest parts: 9679 to 9696 and 9803 to 9808 ft.
2. Hydrocarbon/water contact at 9750 ft with R_{wa} curve. Oil to 9696 ft. Gas above with neutron density.
3. At 9692 ft, $\Phi = 30\%$, $R_t = 8 \Omega \bullet m$, $R_w = 0.1 \Omega \bullet m$, $S_w = 3.3\%$, $S_g = 6.7\%$.
4. No, shaly sand formula must be used.

Example 4.11.5 Neutron-Density Logs Interpretation

The Gulf Coast logs shown in Figure 4.11.57 have been run in the same interval with MWD/LWD sondes and wireline sondes.

1. Draw the lithology description in the depth column.
2. Looking at the R_{wa} curve, where is the hydrocarbon/water contact?
3. Do we have enough information to know if we have oil or gas?
4. What is the invasion diameter at 8397 ft using the wireline logs? What is the invasion diameter using the MWD/LWD logs?
5. What is needed to compute the hydrocarbon saturation?

Solution

1. Shale-sand sequence:
Top to 8,374 ft shale
8,374 to 8,425 ft sand
8,425 to 8,429 ft shale break
8,429 to bottom sand
2. Hydrocarbon/water contact: 8,413 ft.
3. No, we need the neutron and density curves.
4. According to chart in Figure 4.11.76, $d_i = 40$ in. with the wireline logs. The d_i cannot be calculated with the MWD/LWD logs since we have only two resistivity curves.
5. We need the porosity. R_w is given by R_{wa} in the lower sand. We also need R_t .

Ultrasonic Caliper and Sonic Log while Drilling

In the ultrasonic caliper sub, 3 ultrasonic sensors are mounted 120° apart (pathfinder), or two ultrasonic sensors are mounted 180° apart on stabilizer blades as shown in Figure 4.11.58.

The sensors function in a pulse-echo mode that allows the direct measurement of stand-off, from short and long axes of the borehole diameter are computed. The vertical resolution is 1 in. (25 mm) and accuracy of the diameter measurement is ± 0.1 in (2.5 mm).

Figure 4.11.53 Comparison of wireline and LWD gamma ray and neutron logs in a borehole in good conditions.

FIGURE 4.11.54 Schematic of the density tool position in a borehole (courtesy of Anadrill [30]).

The caliper is used to correct the density and neutron porosity measurements for borehole effects and also can be used as a borehole stability indicator. Figure 4.11.59 shows an example of comparison between the MWD ultrasonic caliper and the four-arm wireline caliper run five days later.

The MWD caliper sub can also be used for downhole detection of free gas in the annulus (gas bubbles, not dissolved gas) through a combination of formation and “faceplate” echo signals. In Figure 4.11.58b a schematic of the system is represented. The faceplate is the interface between the window and the mud. The faceplate echo signal is the echo due to the impedance mismatch between the window and the mud. This echo is affected by the gas content of the mud, with echo amplitude increasing with the gas content. It can be seen in Figure 4.11.58b that concurrently the formation echo decreases.

The smallest amount of gas detectable is about 3% of free gas in volume. Real-time transmission of this information can shorten the time needed to detect gas influxes while drilling. It can help and simplify the kill operations.

Figure 4.11.60 shows an example of drilling in underbalance conditions. Gas influxes are very well outlined.

MWD Sonic

A LWD tool developed by Anadrill provides sonic compressional Δt measurements in real time and recorded modes. The tool operates on the same general principles as modern wireline sonic tools. As the drilling operation progresses, the transmitter is actuated and acoustic waves propagating through the mud and formation are detected by the receiver array. Using a downhole processing algorithm, the compressional Δt of the formation is extracted from the waveforms

FIGURE 4.11.55 Density comparison in a deviated well (courtesy of Anadrill [25]).

TABLE 4.11.4 Pe and Rock Matrix Densities for Various Lithologies

Lithologies	Pe	Rock Density (g/cm ³)
Sandstone	1.81	2.65
Limestone	5.08	2.71
Dolomite	3.14	2.85
Illite	3.45	2.45–2.65
Kaolinite	1.83	2.35–2.50
Smectite	2.04	2.05–2.30

FIGURE 4.11.56 Radioactive sources being installed in the neutron-density sub (courtesy of Andrill [25]).

and transmitted uphole in real time via mud telemetry. The compressional Δt and porosity logs are generated, providing an input for lithology identification and overpressure determination.

A successful sonic-while-drilling tool must overcome four major problems:

- suppressing collar arrivals
- transmitter and receiver mounting on drill collars
- interference of drilling noise
- processing sonic waveforms downhole

A diagram of the tool is shown in Figure 4.11.61. The array length and the use of four receivers give a good compromise for compatibility with wireline measurements and spatial aliasing properties. The choice of four receivers also minimizes memory and power requirements, which are both proportional to the number of receivers. The separation between transmitter and receivers is a compromise between a long distance for good signal amplitude and minimum tool cost. This distance is also similar to that used in wireline array tools. The receivers are small, wideband piezoceramic stacks, which have responses similar to wireline receivers.

The battery-powered electronics acquire and store sonic waveforms. Under the control of a downhole microprocessor, the transmitter is fired, and four receiver waveforms are simultaneously digitized at 12 bits and added to a signal stack. The transmitter firing is done in bursts at the rate of 10 Hz, which allows minimum movement while stacking.

The data acquisition rate is generally set so that the sample spacing of the sonic log (the distance between two acquired data points) ranges from 6 in. to 1 ft based on the anticipated drilling rate of penetration (ROP).

For LWD/wireline sonic log comparison, we highlight the zone from 600 to 1000 ft in Figure 4.11.62. However, the two sonic measurements in the 840–860 ft interval show

FIGURE 4.11.57 Wireline and LWD logs showing the effect of invasion (courtesy of Anadrill [25]).

a major disagreement. This disagreement probably results from the deteriorated hole condition (two large washouts shown on the caliper logs) when the wireline logs were acquired (10 days after drilling).

Of particular interest in Figure 4.11.62 is the shaly sandstone in the 690–720-ft interval. In this zone, the LWD sonic measurements are consistently faster than the wireline measurements. Since the wireline logs were acquired 10 days after drilling, it is likely that shale swelling in the shaly sandstone has taken place. The phenomenon, known as formation alteration, causes the wireline sonic measurements to be slower. In this type of zone, LWD sonic yields a more correct Δt , which will better match surface seismic sections.

4.11.2.4 Measuring While Tripping: Wiper Logs

When the MWD systems are battery powered and have a downhole recording capability or use an electromagnetic telemetry, logging measurements can be repeated each time the bit is pulled out to run into the borehole. This new

capability provides a way to map the progression of the filtrate front in the permeable formations. On replace wireline in highly deviated holes after drilling.

Downhole Recording

When the logging measurements are battery powered the logging parameters can be recorded versus time while tripping the drill string. If the depth is simultaneously recorded versus time, the data can be plotted versus depth. Common memory capabilities are of the order of 2 to 10 megabytes. The recording rate is adjusted to obtain about two data sets per foot.

Electromagnetic Telemetry

The electromagnetic telemetry is usually powered downhole with batteries. Parameters such as gamma ray, resistivity and temperature, can be transmitted while tripping up or down. Since a two-way communication is possible, the system can be switched to a “logging only” mode to transmit only the logging information.

FIGURE 4.11.58 MWD ultrasonic caliper: (a) sensor in the stabilizer blades; (b) schematic of the echoes (courtesy of Anadrill [25]).

Invasion Diameter Versus Time

Many parameters determine the invasion diameter:

- formation porosity
- formation permeability
- mudcake permeability
- mudcake thickness
- differential pressure
- mud filtrate and formation fluid viscosity

Figure 4.11.63 shows two typical cases for a 1- μ d, 0.25-in. (6 mm) mudcake, 500 psi (3450 kPa) differential pressure, 20% porosity (a), and 30% porosity (b).

The factor permeability is important only for the low permeabilities, below 1 md. The invasion diameter increases rapidly in the first few days, making the measurements during tripping particularly significant.

Example 4.11.6 Wiper Logs

Figure 4.11.64 shows a set of resistivity logs run in a sand-shale sequence of Gulf Coast. We have one wireline dual induction log, one MWD resistivity log, a wiper-MWD resistivity log and one gamma ray log:

1. Describe the lithology of this zone.
2. How do we know that the cleaner zones marked A and B are permeable?
3. Compare the invasion for the various logs.
4. What is the true resistivity of Zone A and Zone B?

Solution

1. Laminated shaly zone; two fairly clean intervals marked A and B.

2. Invasion causes curve separation for wiper and wireline logs.

3. No invasion in the MWD/LWD log. In the wireline log, using the chart in Figure 4.11.75.

Sand A: $d_1 = 32$ in.

Sand B: $d_1 = 30$ in.

Using the wiper log, we have invasion but it can not be determined quantitatively.

4. In the wireline log (R_{fd}),

Sand A: $R_t = 3.0 \Omega \bullet m$

Sand B: $R_t = 1.8 \Omega \bullet m$

Using the wiper log (R_{att})

Sand A: $R_t = 3.0 \Omega \bullet m$

Sand B: $R_t = 1.5 \Omega \bullet m$

Example 4.11.7 Wiper Logs

Figure 4.11.65 shows a set of MWD/LWD logs recorded in a Gulf Coast well.

1. What are the boundaries of the main sand? What curve is used for lithology?
2. Is there a hydrocarbon/water contact? Where? Which curve(s) will tell us?
3. Is the upper part gas or oil saturated?
4. Determine the porosity at 400 ft.
5. Determine the hydrocarbon saturation at 400 ft.

Solution

1. Top of sand at 383 ft. Bottom of sand at 486 ft.
2. Gamma ray indicates shales and clean formations.

FIGURE 4.11.59 Comparison of MWD ultrasonic caliper logs with the 4-arm wireline caliper logs run five days later (courtesy of Anadrill [25]).

FIGURE 4.11.60 MWD ultrasonic caliper and gas influx log (courtesy of Anadrill [25]).

FIGURE 4.11.63 Invasion diameter versus invasion time for various formation permeabilities. (a) Filtrate invaded porosity: 20%; mudcake permeability: $1\mu\text{d}$; mudcake thickness: 0.25"; differential pressure: 500 psi. (b) Filtrate invaded porosity: 30%; mudcake permeability: $1\mu\text{d}$; mudcake thickness: 0.25"; differential pressure: 500 psi (courtesy of Louisiana State University [11]).

FIGURE 4.11.64 Comparison of compensated dual-resistivity logs run while drilling and in a wiper pass with the wireline induction logs (courtesy of Anadrill [25]).

FIGURE 4.11.65 LWD resistivity logs recorded during a wiper pass (courtesy of Anadrill [25]).

3. Yes, hydrocarbon/water contact at 410 ft. Resistivity and R_{wa} .
4. With chart in Figure 4.11.74, $\Phi = 28\%$. Slightly above sandstone line, probably gas.
5. Saturations: $R_{wa} = 0.01$; $R_t = 6 \Omega \cdot m$; $\Phi = 28\%$; $S_w = 12\%$; $S_g = 88\%$.

4.11.2.5 Measurement at the Bit and Imaging Measurement

Real-time bit inclination and imaging technology (i.e. gamma ray, resistivity, neutron density, and Pe) is used in

geosteering to optimize well placement. Figure 4.11.66a shows a LWD tool that combines both technologies (Near bit inclination and imaging gamma-ray). This tool consists of two separate subs, lower transmitter (LXM) located directly above the bit, which acquires the data, that is electromagnetic communicated to the upper transmitter (LXM) located above the drilling motor. The LXM is connected to the MWD system to transmit this data to the surface. Figure 4.11.66b shows a typical imaging log obtained with this tool.

Well placement uses the imaging data in the shapes of smiles and frowns to determine bit corrections to ensure that

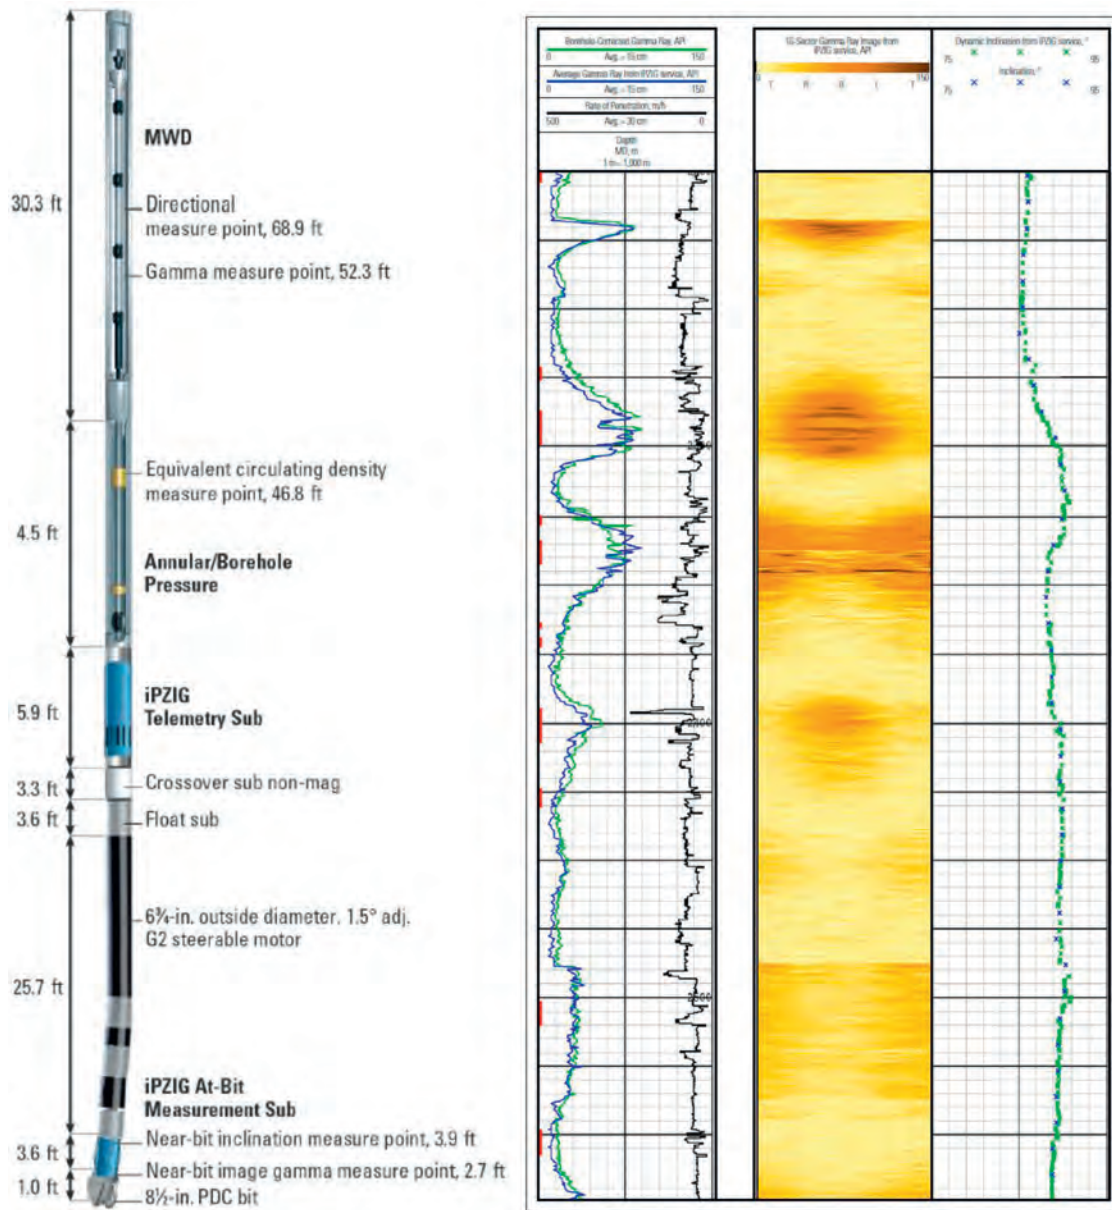

FIGURE 4.11.66 i-PZIG at-bit inclination and natural gamma ray image measuring Tool and Log (Courtesy of Schlumberger). (a) was obtained from Reference [45, Figure 2]; and (b) was obtained from Reference [46, Figure 3].

the wellbore remains in the target zone. When a wellbore crosses a bed plane, an azimuthal logging tool indicates if the wellbore is exiting an ascending or descending geologic layer. Figures 4.11.67a and 4.11.67b show the frown and smile created when the well is intersecting an ascending or descending layer respectively.

The time elapsed between drilling and recording the data at a given depth can be read in Table 4.11.5 for various rates of penetration.

To meet the challenges posed by horizontal drilling in particular, systems have been developed to make the measurements at or near the bit and transmit them to the

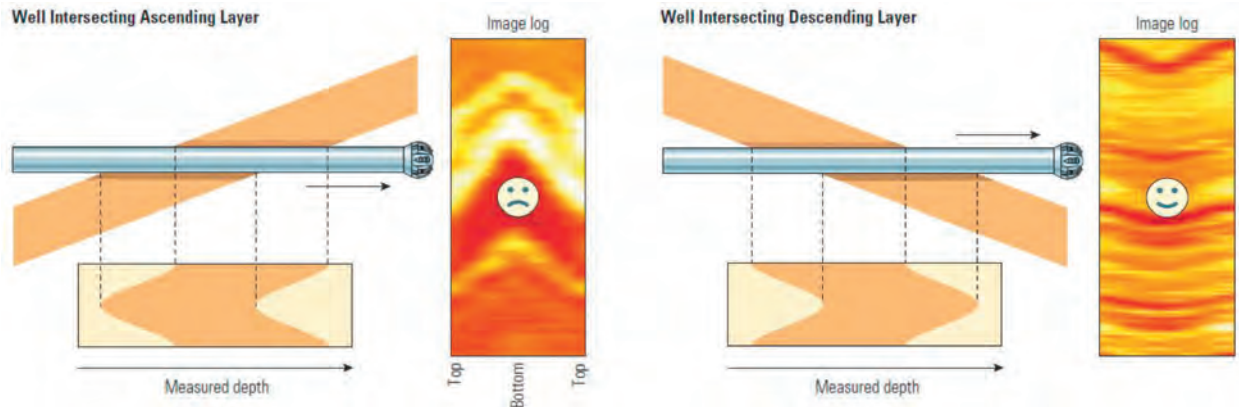

FIGURE 4.11.67 Imaging data interpretation of layer intersection (Courtesy of Schlumberger). (a) and (b) are from Reference 47.

TABLE 4.11.5 “Time Since Drilling” for Various MWD/LWD Logs with Typical Spacings

mud telemetry section of the MWD bottomhole assembly. The resistivity at the bit tool is similar to the toroidal resistivity tool described in the section titled “Resistivity Logs.” As shown in Figure 4.11.68, the Anadrill geosteering package includes below the Power Pak mud motor:

- a surface adjustable bent housing
- a sub for measurement of the bit resistivity, azimuthal gamma ray, inclination, and bit rpm (the same sub contains an electromagnetic transmission system that sends the data to the mud telemetry above the mud motor)
- a $\frac{3}{4}^\circ$ fixed bent-housing section equipped with the bit resistivity toroid and the azimuthal resistivity button
- a stabilizer and bearing section, just above the drill bit

Figure 4.11.69a shows the sketch of principle of the resistivity measurement in water-based mud.

The drill bit resistivity is measured below toroid T_2 . An average resistivity is measured between toroid T_1 and T_2 . The azimuthal resistivity is measured with button R. In normal buildup drilling, the azimuthal resistivity measures the high side of the borehole and the gamma ray window sees the low side of the borehole. Measurements in other orientations are made by rotating the bottom-hole assembly. In the geosteering configuration, the resolution of resistivity at the bit is 6 ft (1.8 m). When drilling in rotary, the resistivity at the bit (RAB) is also measured with a similar toroidal system as shown in Figure 4.11.69b. The RAB tool has three button electrodes spaced to give azimuthal resistivities with three depths of investigation: 3, 6 and 9

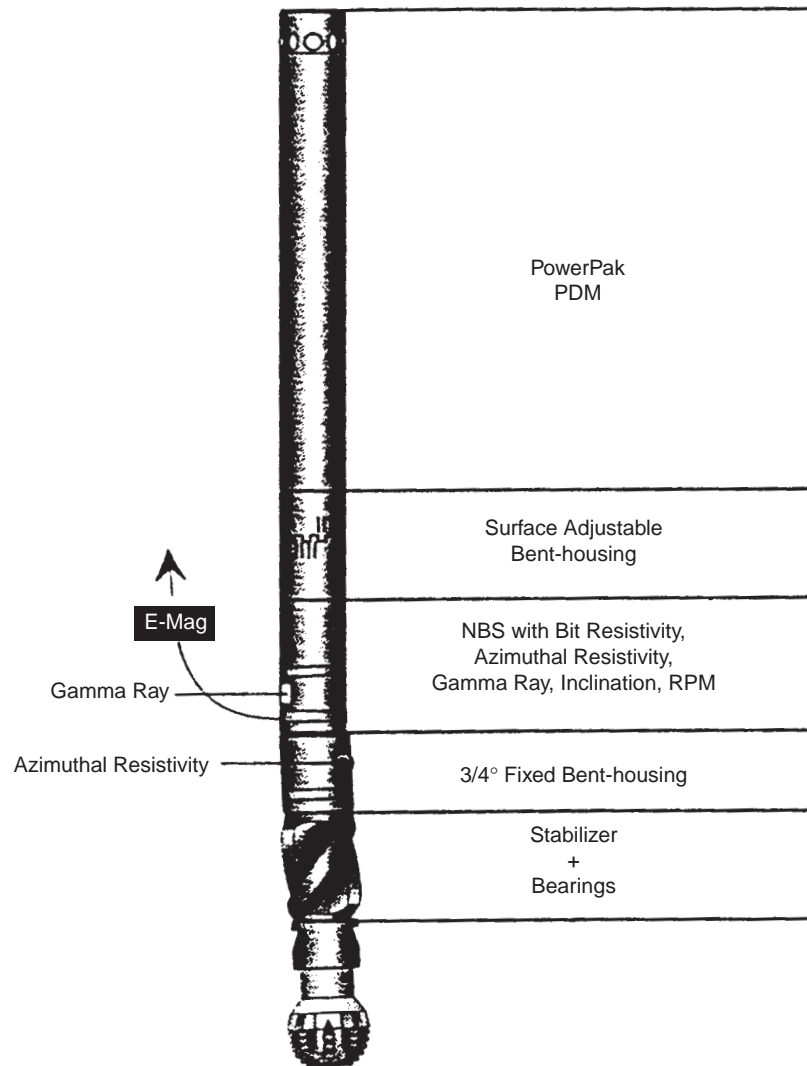

FIGURE 4.11.68 Anadrill geosteering tool (courtesy of Anadrill [25]).

in. (7.6, 15 and 23 cm). A ring electrode is also provided to yield an axial focused resistivity 5 ft above the drill bit. Focusing is improved by a near-bit transmitter. The radius of investigation of the ring electrode is about 12 in. (30 cm) and the vertical resolution about 2 in. (5 cm). Figure 4.11.70 is a sketch of the ring electrode measurement. The button electrode measurement is similar with a button instead of the ring.

Both rotary and mud motor systems use an electromagnetic wireline telemetry to relay the data from the near-bit sub to the mud telemetry sub.

4.11.2.6 Basic Log Interpretation

The log interpretation using logging while drilling logs is very similar to the interpretation made with wireline logs.

FIGURE 4.11.69 Measurement at the drill bit (from Anadrill [25] and Oilfield Review [43]).

FIGURE 4.11.70 Principle of the ring resistivity-at-the-bit tool (Oilfield Review [43]).

One major difference is that the invasion is usually less important due to the short time elapsed between drilling and logging.

Lithology

Gamma ray is used to differentiate between shales and clean formations. Pe is used to determine the nature of the clean formations: sandstone, limestone or dolomite.

Porosity

Two porosity logs are run today (1994); neutron and density. Soon the sonic will also be available.

With the lithology matching the log scale, and assuming the formation fully invaded by mud filtrate, a neutron porosity and a density porosity can be determined.

- If the two porosities match, the formation is saturated with a liquid, water or oil, and the porosities are true porosities.
- If the neutron porosity is low and the density porosity is high, the formation contains gas and the true porosity can be determined with charts.

Saturation

Resistivity logs are used for saturation estimates. One, two or more resistivity logs with different investigation depths are usually available. The true resistivity of the formation can be estimated. If a water sand has been drilled near the interval of interest, the formation water R_w can be determined by

$$R_w = \frac{R_0}{F} \quad (4.11.20)$$

where R_0 = true resistivity of the water sand

F = formation factor

and

$$F = \frac{1}{\Phi^2} \quad (4.11.21)$$

or

$$F = \frac{0.62}{\Phi^{2.15}} \quad (4.11.22)$$

where Φ = porosity in fraction

Equation 4.11.21 is used in carbonates (limestone and dolomite) and Equation 4.11.22 is used in unconsolidated to medium consolidated sandstones. A third Equation 4.11.23 can be used in highly consolidated sandstones. This is

$$F = \frac{0.81}{\Phi^2} \quad (4.11.23)$$

If no water sand exists, then an estimate of R_w must be made based on regional knowledge.

Since the true porosity has been determined, formation water saturation can be determined by

$$S_w = \sqrt{\frac{F \bullet R_w}{R_t}} \quad (4.11.24)$$

where

S_w = formation water saturation

F = formation factor

R_w = formation water resistivity

R_t = true resistivity of the formation

The oil or gas saturation is

$$S_{hc} = 1 - S_w \quad (4.11.25)$$

where

S_{hc} = hydrocarbon saturation

The volume of hydrocarbons in place at reservoir conditions is

$$Q_{IP} = 775 \bullet \Phi \bullet S_{hc} \bullet h \quad (4.11.26)$$

where

Q_{IP} = volume of hydrocarbons in bbl/acre

Φ = porosity in fraction

S_{hc} = hydrocarbon saturation in fraction

h = formation thickness in ft.

Apparent Water Resistivity R_{wa}

Some MWD/LWD log sets display a curve labeled R_{wa} . R_{wa} is computed using Equation 4.11.24 assuming that $S_w = 1$ (100%). Consequently we have

$$R_w = R_{wa} = \frac{R_t}{F} \quad (4.11.27)$$

Since

$$F = \frac{a}{\Phi^m} \quad (4.11.28)$$

where

F = formation factor

a = constant depending on the formation, generally

1 or 0.81 or 0.62

m = cementation factor, generally 2 or 2.15

Finally,

$$R_{wa} = \frac{R_t \Phi^m}{a} \quad (4.11.29)$$

The true porosity Φ is determined with the neutron-density Pe logs. R_t is generally given by the deep investigation resistivity curve. R_{wa} equals R_w in the water formations. It increases rapidly in hydrocarbon saturated formations.

Permeability

Permeable zones can be identified with the resistivity measurements made with different radius of investigation. A departure between the curves of deep and shallow investigation is a qualitative indication of permeability.

The charts mentioned in the section titled “Measuring While Tripping: Wiper Logs” can be used to estimate quantitatively the permeability if several measurements during tripping are made with resistivity devices that can give the invasion diameter.

Surface measurements on the mud can be used to estimate the mudcake characteristics. If the formation pressure is known, the differential pressure can be calculated, and a chart similar to Figures 4.11.64a and b can be plotted.

The invasion diameters at various times should follow one of the permeability curves. Note that the permeability effect is seen only for formations with 1 md or less permeability. Above 1 md, the invasion diameter is dependent mostly on porosity.

Log Samples

Figure 4.11.71 shows samples of gamma ray and spectral gamma ray logs. The boundaries of the clean (not shaly) zone can be seen very clearly:

- 2,256–2,274 ft shale
- 2,274–2,356 ft clean zone
- 2,356–2,388 ft shale

Shale streaks are visible in most of the lower part of the clean section.

A high radioactivity peak can be seen at 2388 ft. Looking at the spectral log it can be seen that this peak is due to a high uranium content. Other radioactive elements’ concentration is normal.

Figure 4.11.72 shows sample neutron-density Pe log over the same interval. Figure 4.11.73 shows sample MWD resistivity (left) and wireline dual induction (right) for the same interval.

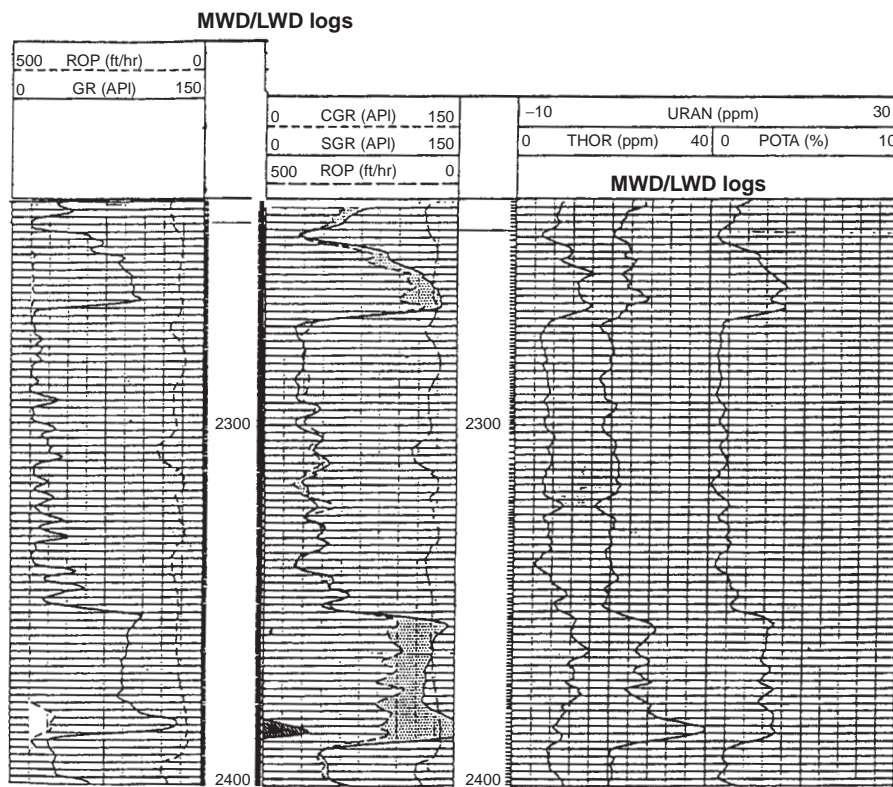

FIGURE 4.11.71 Sample of MWD/LWD logs.

FIGURE 4.11.72 Sample of MWD/LWD logs.

Porosity and Lithology Determination from
Litho-Density* Log and CNL* Compensated Neutron Log
Liquid-Filled Holes $\rho_f = 1.000 \text{ g/cc}$, $C_f = 0 \text{ ppm}$

FIGURE 4.11.74 Porosity and lithology determination from the Litho-Density* logs and the CNL* Compensated neutron log (courtesy of Schlumberger). (*Trade mark of Schlumberger).

A high neutron porosity and low density porosity occur in the shale zones: 2256–2274 and 2356–2388 ft. In the clean zone, around 2280–2290 ft, the cleanest part reads $\Phi_n = 18\%$ and $\Phi_d = 13\%$. Plotting the point in the CNL chart of Figure 4.11.74, the rock matrix appears to be a dolomitized limestone and the true porosity is 17%.

Since the deep and shallow curve of the MWD log and the deep, shallow and guard (laterolog) of the wireline log shows a departure, the zone 2274–2356 ft is invaded, consequently permeable. Using the dual induction chart of Figure 4.11.75, we can plot the point at 2290 ft:

$$R_{IM}/R_{ID} = 1.2/1 = 1.2$$

$$R_{LL}/R_{ID} = 7/1 = 7$$

The invasion diameter is 36 in.

Where

$$R_{x0}/R_{ID} = 11$$

$$R_t/R_{ID} = 0.98$$

Consequently:

$$R_t = 0.98 \Omega \bullet m \cong 1 \Omega \bullet m$$

$$R_{x0} = 11 \Omega \bullet m$$

The formation factor is

$$F = 1/\Phi^2 = 1/0.172 = 34.6$$

FIGURE 4.11.75 Resistivities and invasion determination with the Dual Induction log (DIL*) and the laterolog-8 (courtesy of Schlumberger). (*Trade mark of Schlumberger.).

If we assume a 100% water saturation, the water resistivity is

$$R_w = R_t/F = 0.029 \Omega \bullet m$$

If an oil or gas zone is present above this water sand, R_t should be computed the same way and S_w calculated.

4.12 DOWNHOLE MOTORS AND ROTARY STEERABLE SYSTEMS (RSS)

Section reviewed by Francisco Sinisterra

4.12.1 Background

In 1873, an American, C. G. Cross, was issued the first patent related to a downhole turbine motor for rotating the drill bit at the bottom of a drillstring with hydraulic power [1]. This drilling concept was conceived nearly 30 years before rotary drilling was introduced in oil well drilling. Thus the concept of using a downhole motor to rotate or otherwise drive a drill bit at the bottom of a fluid conveying conduit in a deep borehole is not new.

The first practical applications of the downhole motor concept came in 1924 when engineers in the United States and the Soviet Union began to design, fabricate and field test both single-stage and multistage downhole turbine motors [2]. Efforts continued in the United States, the Soviet Union and elsewhere in Europe to develop an industrially reliable downhole turbine motor that would operate on drilling mud. But during the decade to follow, all efforts proved unsuccessful.

In 1934 in the Soviet Union a renewed effort was initiated to develop a multistage downhole turbine motor [2–5]. This new effort was successful. This development effort marked the beginning of industrial use of the downhole turbine motor. The Soviet Union continued the development of the downhole turbine motor and utilized the technology to drill the majority of its oil and gas wells. By the 1950s the Soviet Union was drilling nearly 80% of their wells with the downhole turbine motors using surface pumped drilling mud or freshwater as the activating hydraulic power.

In the late 1950s, with the growing need in the United States and elsewhere in the world for directional drilling capabilities, the drilling industry in the United States and elsewhere began to reconsider the downhole turbine motor technology. There are presently three service companies that offer downhole turbine motors for drilling of oil and gas wells. These motors are now used extensively throughout the world for directional drilling operations and for some straight-hole drilling operations.

The downhole turbine motors that are hydraulically operated have some fundamental limitations. One of these is high rotary speed of the motor and drill bit. The high rotary speeds limit the use of downhole turbine motors when drilling with roller rock bits. The high speed of these direct drive motors shortens the life of the roller rock bit.

In the 1980s in the United States an effort was initiated to develop a downhole turbine motor that was activated by compressed air. This motor was provided with a gear reducer transmission. This downhole pneumatic turbine has been successfully field tested [6,7].

The development of positive displacement downhole motors began in the late 1950s. The initial development was the result of a United States patent filed by W. Clark in 1957. This downhole motor was based on the original work of a French engineer, René Monineau, and is classified as a helimotor. The motor is actuated by drilling mud pumped from the surface. There are two other types of positive displacement motors that have been used, or are at present in use today: the vane motor and the reciprocating motor. However, by far the most widely used positive displacement motor is the helimotor [2].

The initial work in the United States led to the highly successful single-lobe helimotor. From the late 1950s until the late 1980s there have been a number of other versions of the helimotor developed and fielded. In general, most of the recent development work in helimotors has centered around multilobe motors. The higher the lobe system, the lower the speed of these direct drive motors and the higher the operating torque.

There have been some efforts over the past three decades to develop positive displacement vane motors and reciprocating motors for operation with drilling mud as the actuating fluid. These efforts have not been successful.

In the early 1960s efforts were made in the United States to operate vane motors and reciprocating motors with compressed air. The vane motors experienced some limited test success but were not competitive in the market of that day [7]. Out of these development efforts evolved the reciprocating (compressed) air hammers that have been quite successful and are operated extensively in the mining industry and have some limited application in the oil and gas industry [8]. The air hammer is not a motor in the true sense of rotating equipment. The reciprocating action of the air hammer provides a percussion effect on the drill bit, the rotation of the bit to new rock face location is carried out by the conventional rotation of the drill string.

In this section the design and the operational characteristics and procedures of the most frequently used downhole motors will be discussed. These are the downhole turbine motor and the downhole positive displacement motor.

4.12.2 Turbine Motors

Figure 4.12.1 shows the typical rotor and stator configuration for a single stage of a multistage downhole turbine motor section. The activating drilling mud or freshwater is pumped at high velocity through the motor section, which, because of the vane angle of each rotor and stator (which is a stage), causes the rotor to rotate the shaft of the motor. The kinetic energy of the flowing drilling mud is converted through these rotor and stator stages into mechanical rotational energy.

FIGURE 4.12.1 Basic turbine motor design principle (Courtesy of Smith International, Inc).

4.12.2.1 Design

The rotational energy provided by the flowing fluid is used to rotate and provide torque to the drill bit. Figure 4.12.2 shows the typical complete downhole turbine motor actuated with an incompressible drilling fluid.

In general, the downhole turbine motor is composed of two sections: (1) the turbine motor section and (2) the thrust-bearing and radial support bearing. These sections are shown in Figure 4.12.2. Sometimes a special section is used at the top of the motor to provide a filter to clean up the drilling mud flow before it enters the motor, or to provide a by-pass valve.

The turbine motor section has multistages of rotors and stators, from as few as 25 to as many as 300. For a basic motor geometry with a given flowrate, an increase in the number of stages in the motor will result in an increase in torque capability and an increase in the peak horsepower. This performance improvement, however, is accompanied by an increase in the differential pressure through the motor section (Table 4.12.1). The turbine motor section usually has bearing groups at the upper and lower ends of the rotating shaft (on which are attached the rotors). The bearing groups have only radial load capabilities.

The lower end of the rotating shaft of the turbine motor section is attached to the upper end of the main shaft. The drilling fluid after passing through the turbine motor section is channeled into the center of the shaft through large openings in the main shaft. The drill bit is attached to the lower end of the main shaft. The weight on the bit is transferred to the downhole turbine motor housing via the thrust-bearing section. This bearing section provides

for rotation while transferring the weight on the bit to the downhole turbine motor housing.

In the thrust-bearing section is a radial support bearing section that provides a radial load-carrying group of bearings that ensures that the main shaft rotates about center even when a side force on the bit is present during directional drilling operations.

There are of course variations on the downhole turbine motor design, but the basic sections discussed above will be common to all designs.

TABLE 4.12.1 Turbine Motor, 6³/₄-in. Outside Diameter, Circulation Rate 400 gpm, Mud Weight 10 lb/gal

318	2118	807	1924	326	30

*At optimum speed.
Courtesy of Eastman-Christensen.

The main advantages of the downhole turbine motor are:

1. Hard to extremely hard competent rock formations can be drilled with turbine motors using diamond or the new polycrystalline diamond bits.
2. Rather high rates of penetration can be achieved since bit rotation speeds are high.
3. Will allow circulation of the borehole regardless of motor horsepower or torque being produced by the motor. Circulation can even take place when the motor is installed.

The main disadvantages of the downhole turbine motor are:

1. Motor speeds and, therefore, bit speeds are high, which limits the use of roller rock bits.
2. The required flowrate through the downhole turbine motor and the resulting pressure drop through the motor require large surface pump systems, significantly larger pump systems than are normally available for most land and for some offshore drilling operations.

3. Unless a measure while drilling instrument is used, there is no way to ascertain whether the turbine motor is operating efficiently since rotation speed and/or torque cannot be measured using normal surface data (i.e., standpipe pressure, weight on bit).
4. Because of the necessity to use many stages in the turbine motor to obtain the needed power to drill, the downhole turbine motor is often quite long. Thus the ability to use these motors for high-angle course corrections can be limited.
5. Downhole turbine motors are sensitive to fouling agents in the mud; therefore, when running a turbine motor steps must be taken to provide particle-free drilling mud.
6. Downhole turbine motors can only be operated with drilling mud.

4.12.2.2 Operations

Figure 4.12.3 gives the typical performance characteristics of a turbine motor. The example in this figure is a 6³/₄-in. outside diameter turbine motor having 212 stages and activated by a 10-lb/gal mud flowrate of 400 gal/min.

FIGURE 4.12.3 Turbine motor, 6³/₄-in. outside diameter, two motor sections, 212 stages, 400 gal/min, 10-lb/gal mud weight (Courtesy of Baker Hughes Co.).

For this example, the stall torque of the motor is 2,824 ft-lb. The runaway speed is 1,614 rpm and coincides with zero torque. The motor produces its maximum horsepower of 217 at a speed of 807 rpm. The torque at the peak horsepower is 1,412 ft-lb, or one-half of the stall torque.

A turbine device has the unique characteristic that it will allow circulation independent of what torque or horsepower the motor is producing. In the example where the turbine motor has a 10-lb/gal mud circulating at 400 gal/min, the pressure drop through the motor is about 1,324 psi. This pressure drop is approximately constant through the entire speed range of the motor.

If the turbine motor is lifted off the bottom of the borehole and circulation continues, the motor will speed up to the runaway speed of 1,614 rpm. In this situation the motor produces no drilling torque or horsepower.

As the turbine motor is lowered and weight is placed on the motor and thus the bit, the motor begins to slow its speed and produce torque and horsepower. When sufficient weight has been placed on the turbine motor, the example motor will produce its maximum possible horsepower of 217. This will be at a speed of 807 rpm. The torque produced by the motor at this speed will be 1,412 ft-lb.

If more weight is added to the turbine motor and the bit, the motor speed and horsepower output will continue to decrease. The torque, however, will continue to increase.

When sufficient weight has been placed on the turbine motor and bit, the motor will cease to rotate and the motor is described as being stalled. At this condition, the turbine motor produces its maximum possible torque. Even when the motor is stalled, the drilling mud is still circulating and the pressure drop is approximately 1,324 psi.

The stall torque M_s (ft-lb) for any turbine motor can be determined from [9].

$$M_s = 1.38386 \times 10^{-5} \frac{\eta_h \eta_m n_s \bar{\gamma}_m q^2 \tan \beta}{h} \quad (4.12.1)$$

where η_h = hydraulic efficiency

η_m = mechanical efficiency

n_s = number of stages

$\bar{\gamma}_m$ = specific weight of mud in lb/gal

q = circulation flowrate in gal/min

β = exit blade angle in degrees

h = radial width of the blades in in.

Figure 4.12.2 is the side view of a single-turbine stage and describes the geometry of the motor and stator.

The runaway speed N_r (rpm) for any turbine motor can be determined from

$$N_r = 5.85 \frac{\eta_v q \tan \beta}{r_m^2 h} \quad (4.12.2)$$

where η_v = volumetric efficiency

r_m = mean blade radius in in.

The turbine motor instantaneous torque M (ft-lb) for any speed N (rpm) is

$$M = M_s \left(1 - \frac{N}{N_r} \right) \quad (4.12.3)$$

The turbine motor horsepower HP (hp) for any speed is

$$HP = \frac{2\pi M_s N}{33,000} \left(1 - \frac{N}{N_r} \right) \quad (4.12.4)$$

The maximum turbine motor horsepower is at the optimum speed, N_o , which is one-half of the runaway speed. This is

$$N_o = \frac{N_r}{2} \quad (4.12.5)$$

Thus, the maximum horsepower HP_{max} is

$$HP_{max} = \frac{\pi M_s N_r}{2 (33,000)} \quad (4.12.6)$$

The torque at the optimum speed M_o is one-half the stall torque. Thus

$$M_o = \frac{M_s}{2} \quad (4.12.7)$$

The pressure drop Δp (psi) through a given turbine motor design is usually obtained empirically. Once this value is known for a circulation flowrate and mud weight, the pressure drop for other circulation flowrates and mud weights can be estimated.

If the above performance parameters for a turbine motor design are known for a given circulation flowrate and mud weight (denoted as 1), the performance parameters for the new circulation flowrate and mud weight (denoted as 2) can be found by the following relationships:

Torque

$$M_2 = \left(\frac{q_2}{q_1} \right)^2 M_1 \quad (4.12.8)$$

$$M_2 = \left(\frac{\bar{\gamma}_2}{\bar{\gamma}_1} \right) M_1 \quad (4.12.9)$$

Speed

$$N_2 = \left(\frac{q_2}{q_1} \right) N_1 \quad (4.12.10)$$

Power

$$HP_2 = \left(\frac{q_2}{q_1}\right)^3 HP_1 \quad (4.12.11)$$

$$HP_2 = \left(\frac{\bar{\gamma}_2}{\bar{\gamma}_1}\right) HP_1 \quad (4.12.12)$$

Pressure drop

$$\Delta p_2 = \left(\frac{q_2}{q_1}\right)^2 \Delta p_1 \quad (4.12.13)$$

$$\Delta p_2 = \left(\frac{\bar{\gamma}_2}{\bar{\gamma}_1}\right) \Delta p_1 \quad (4.12.14)$$

Table 4.12.2 gives the performance characteristics for various circulation flowrates for the 212 stage, 6³/₄-in. outside diameter turbine motor described briefly in Table 4.12.3 and shown graphically in Figure 4.12.3.

Table 4.12.3 gives the performance characteristics for various circulation flowrates for the 318-stage, 6³/₄-in. outside diameter turbine motor described briefly in Table 4.12.1. Figure 4.12.4 shows the performance of the 318-stage turbine motor at a circulation flowrate of 400 gal/min and mud weight of 10 lb/gal.

The turbine motor whose performance characteristics are given in Table 4.12.2 is made up of two motor sections with 106 stages in each section. The turbine motor whose performance characteristics are given in Table 4.12.3 is made up of three motor sections.

The major reason most turbine motors are designed with various add-on motor sections is to allow flexibility when applying turbine motors to operational situations.

For straight hole drilling the turbine motor with the highest possible torque and the lowest possible speed is of most use. Thus the turbine motor is selected such that the motor produces the maximum amount of power for the lowest possible circulation flowrate (i.e., lowest

speed). The high power increase rate of penetration and the lower speed increase bit life particularly if roller rock bits are used.

For deviation control drilling the turbine motor with a lower torque and the shortest overall length is needed.

Example 4.12.1

Using the basic performance data given in Table 4.12.2 for the 6 3/4-in. outside diameter turbine motor with 212 stages, determine the stall torque, maximum horsepower and pressure drop for this motor if only one motor section with 106 stages were to be used for a deviation control operation. Assume the same circulation flow rate of 400 gal/min, but a mud weight of 14 lb/gal is to be used.

Stall Torque

From Table 4.12.2 the stall torque for the turbine motor with 212 stages will be twice the torque value at optimum speed. Thus the stall torque for 10 lb/gal mud weight flow is

$$M_s = 2(1421) = 2,842 \text{ ft-lb} \quad (4.12.15)$$

From Equation 4.12.1, it is seen that stall torque is proportional to the number of stages used. Thus the stall torque for a turbine motor with 106 stages will be (for the

circulation flowrate of 400 gal/min and mud weight of 10 lb/gal)

$$M_s = 2,842 \left(\frac{106}{212} \right) = 1,421 \text{ ft-lb} \quad (4.12.16)$$

and from Equation 4.12.9 for the 14-lb/gal mud weight

$$M_s = 1,421 \left(\frac{14}{10} \right) = 1,989 \text{ ft-lb} \quad (4.12.17)$$

Maximum Horsepower

From Table 4.12.2 the maximum horsepower for the turbine motor with 212 stages is 217. From Equation 4.12.6, it can be seen that the maximum power is proportional to the stall torque and the runaway speed. Since the circulation flow rate is the same, the runaway speed is the same for this case. Thus, the maximum horsepower will be proportional to the stall torque. The maximum power will be (for the circulation flowrate of 400 gal/min and mud weight of 10 lb/gal)

$$HP_{max} = 217 \left(\frac{1421}{2842} \right) = 108.5 \quad (4.12.18)$$

and from Equation 4.12.12 for the 14-lb/gal mud weight

$$\begin{aligned} \text{HP}_{\max} &= 108.5 \left(\frac{14}{10} \right) \\ &= 152 \end{aligned} \quad (4.12.19)$$

Pressure Drop

Table 4.12.2 shows that the 212-stage turbine motor has a pressure drop of 1,324 psi for the circulation flowrate of 400 gal/min and a mud weight of 10 lb/gal. The pressure drop for the 106 stage turbine motor should be roughly proportional to the length of the motor section (assuming the motor sections are nearly the same in design). Thus the pressure drop in the 106-stage turbine motor should be proportional to the number of stage. Therefore, the pressure drop should be

$$\begin{aligned} \Delta p &= 1,324 \left(\frac{106}{212} \right) \\ &= 662 \text{ psi} \end{aligned} \quad (4.12.20)$$

and from Equation 4.12.14 for the 14-lb/gal mud weight

$$\begin{aligned} \Delta p &= 662 \left(\frac{14}{10} \right) \\ &= 927 \text{ psi} \end{aligned} \quad (4.12.21)$$

The last column the Tables 4.12.2 and 4.12.3 show the thrust load associated with each circulation flowrate (i.e., pressure drop). This thrust load is the result of the pressure drop across the turbine motor rotor and stator blades. The magnitude of this pressure drop depends on the individual internal design details of the turbine motor (i.e., blade angle, number of stages, axial height of blades and the radial width of the blades) and the operating conditions. The additional pressure drop results in thrust, T (lb), which is

$$T = \pi r_m^2 \Delta p \quad (4.12.22)$$

Example 4.12.2

A $6\frac{3}{4}$ -in outside diameter turbine motor (whose performance data are given in Tables 4.12.2 and 4.12.3) is to be used for a deviation control direction drilling operation. The motor will use a new $8\frac{1}{2}$ -in. diameter diamond bit for the drilling operation. The directional run is to take place at a depth of 17,552 ft (measured depth). The rock formation to be drilled is classified as extremely hard, and it is anticipated that 10 ft/hr will be the maximum possible drilling rate. The mud weight is to be 16.2 lb/gal. The drilling rig has a National Supply Company, triplex mud pump Model 10-P-130 available. The details of this pump are given in

TABLE 4.12.4 Triplex Mud Pump, Model 10-P-13, National Supply Company, Example 4.12.2

Input Horsepower, 1300; Maximum Strokes per Minute, 140; Length of Stroke, 10 Inches

	Liner Size (inches)				
	$5\frac{1}{4}$	$5\frac{1}{2}$	$5\frac{3}{4}$	6	$6\frac{1}{4}$
Output per Stroke (gals)	2.81	3.08	3.37	3.67	3.98
Maximum Pressure (psi)	5095	4645	4250	3900	3595

Table 4.12.4 (also see the section titled “Mud Pumps” for more details). Because this is a deviation control run, the shorter two motor section turbine motor will be used.

Determine the appropriate circulation flowrate to be used for the diamond bit, turbine motor combination and the appropriate liner size to be used in the triplex pump. Also, prepare the turbine motor performance graph for the chosen circulation flowrate. Determine the total flow area for the diamond bit.

Bit Pressure Loss

To obtain the optimum circulation flowrate for the diamond bit, turbine motor combination, it will be necessary to consider the bit and the turbine motor performance at various circulation flowrates: 200, 300, 400 and 500 gal/min.

Since the rock formation to be drilled is classified as extremely hard, 1.5 hydraulic horsepower per square inch of bit area will be used as bit cleaning and cooling requirement [10]. The projected bottomhole area of the bit A_b (in.²) is

$$\begin{aligned} A_b &= \frac{\pi}{4} (8.5)^2 \\ &= 56.7 \text{ in.}^2 \end{aligned} \quad (4.12.23)$$

For a circulation flowrate of 200 gal/min, the hydraulic horsepower for the bit HP_b (hp) is

$$\begin{aligned} \text{HP}_b &= 1.5 (56.7) \\ &= 85.05 \end{aligned} \quad (4.12.24)$$

The pressure drop across the bit Δp_b (psi) to produce this hydraulic horsepower at a circulation flowrate of 200 gal/min is

$$\begin{aligned} \Delta p_b &= \frac{85.05(1,714)}{200} \\ &= 729 \text{ psi} \end{aligned} \quad (4.12.25)$$

Similarly, the pressure drop across the bit to produce the above hydraulic horsepower at a circulation flowrate of 300 gal/min is

$$\begin{aligned}\Delta p_b &= \frac{85.05(1,714)}{300} \\ &= 486 \text{ psi}\end{aligned}\quad (4.12.26)$$

The pressure drop across the bit at a circulation flowrate of 400 lb/gal is

$$\Delta p_b = 364 \text{ psi} \quad (4.12.27)$$

The pressure drop across the bit at a circulation flowrate of 500 gal/min

$$\Delta p_b = 292 \text{ psi} \quad (4.12.28)$$

Total Pressure Loss

Using Table 4.12.2 and Equations 4.12.3 and 4.12.14, the pressure loss across the turbine motor can be determined for the various circulation flowrates and the mud weight of 16.2 lb/gal. These data together with the above bit pressure loss data are presented in Table 4.12.5. Also presented in Table 4.12.5 are the component pressure losses of the system for the various circulation flowrates considered. The total pressure loss tabulated in the lower row represents the surface standpipe pressure when operating at the various circulation flowrates.

Pump Limitations

Table 4.12.4 shows there are five possible liner sizes that can be used on the Model 10-P-130 mud pump. Each liner size must be considered to obtain the optimum circulation flowrate and appropriate liner size. The maximum pressure available for each liner size will be reduced by a safety

factor of 0.90.* The maximum volumetric flowrate available for each liner size will also be reduced by a volumetric efficiency factor of 0.80 and an additional safety factor of 0.90.** Thus, from Table 4.12.4, the allowable maximum pressure and allowable maximum volume, metric flowrates will be those shown in Figures 4.12.5 through 4.12.9, which are the liner sizes $5\frac{1}{4}$, $5\frac{1}{2}$, $5\frac{3}{4}$, 6 and $6\frac{1}{4}$ in., respectively. Plotted on each of these figures are the total pressure losses for the various circulation flowrates considered. The horizontal straight line on each figure is the allowable maximum pressure for the particular liner size. The vertical straight line is the allowable maximum volumetric flowrate for the particular liner size. Only circulation flowrates that are in the lower left quadrant of the figures are practical. The highest circulation flowrate (which produces the highest turbine motor horsepower) is found in Figure 4.12.7, the $5\frac{3}{4}$ in. liner. This optimal circulation flowrate is 340 gal/min.

Turbine Motor Performance

Using the turbine motor performance data in Table 4.12.2 and the scaling relationships in Equations 4.12.8 through 4.12.14, the performance graph for the turbine motor operating with a circulation flowrate of 340 gal/min and mud weight of 16.2 lb/gal can be prepared. This is given in Figure 4.12.10.

Total Flow Area for Bit

Knowing the optimal circulation flowrate, the actual pressure loss across the bit can be found as before in the above. This is

$$\begin{aligned}\Delta p_b &= \frac{85.05(1,714)}{340} \\ &= 429 \text{ psi}\end{aligned}\quad (4.12.29)$$

With the flowrate and pressure loss across the bit, the total flow area of the diamond bit A_{tf} (in.²) can be found using [88]

$$\Delta p_b = \frac{q^2 \bar{\gamma}_m}{8795 \left(A_{tf} e^{-0.832 \frac{ROP}{N_b}} \right)^2} \quad (4.12.30)$$

where ROP = rate of penetration in ft/hr

N_b = bit speed in rpm

The bit speed will be the optimum speed of the turbine motor, 685 rpm. The total flow area A_{tf} for the diamond bit is

$$\begin{aligned}A_{tf} &= \left[\frac{(340)^2 16.2}{8795 (429)} \right]^{1/2} \frac{1}{0.9879} \\ &= 0.713 \text{ in.}^2\end{aligned}\quad (4.12.31)$$

TABLE 4.12.5 Drill String Pressure Losses at Various Circulation Flowrates for Example 4.12.2

Components	Pressure (psi)			
	200 gpm	300 gpm	400 gpm	500 gpm
Surface Equipment	4	11	19	31
Drill Pipe Bore	460	878	1401	2021
Drill Collar Bore	60	117	118	272
Turbine Motor	536	1207	2145	3352
Drill Bit	729	486	364	292
Drill Collar Annulus	48	91	144	207
Drill Pipe Annulus	133	248	391	561
Total Pressure Loss	1970	3038	4652	6736

*This safety factor is not necessary for new, well-maintained equipment.

**The volumetric efficiency factor is about 0.95 for precharged pumps.

4.12.3 Positive Displacement Motor

Figure 4.12.11 shows the typical rigid rotor and flexible elastomer stator configuration for a single chamber of a multichambered downhole positive displacement motor section. All the positive displacement motors presently in commercial use are of Moineau type, which uses a stator made of an elastomer. The rotor is made of rigid material such as steel, covered with hard industrial chrome or tungsten carbide and is fabricated in a helical shape. The activating drilling mud, freshwater, aerated mud, foam or misted air is pumped at rather high velocity through the motor section, which, because of the eccentricity of the rotor and stator configuration, and the flexibility of the stator, allows the hydraulic pressure of the flowing fluid to impart a torque to the rotor. As the rotor rotates the fluid is passes from chamber to chamber (a chamber is a lengthwise repeat of the motor). These chambers are separate entities and as one

opens up to accept fluid from the preceding, the preceding closes up. This is the concept of the positive displacement motor.

4.12.3.1 Design

The rotational energy of the positive displacement motor is provided by the flowing fluid, which rotates and imparts torque to the drill bit. Figure 4.12.12 shows the typical complete downhole positive displacement motor.

In general, the downhole positive displacement motor constructed on the Moineau principle is composed of four sections: (1) the dump sub or top sub section, (2) the power section, (3) the bend housing section, and (4) the thrust and radial-bearing section. These sections are shown in Figure 4.12.12. Usually the positive displacement motor has multichambers, however, the number of chambers in a positive displacement motor is much less than the number

FIGURE 4.12.6 A 5½-in. liner, total pressure loss versus flowrate, Example 4.12.2 (Courtesy of Baker Hughes Co.).

of stages in a turbine motor. A typical positive displacement motor has from two to seven chambers.

The dump valve is used above the motor to allow the drill string to fill when tripping into the hole and drain when tripping out of hole. Top Sub is a crossover, used instead of a Dump Sub, to provide a catch shoulder for the rotor catch. This is a fail-safe mechanism to enable the retrieval of the motor assembly should a failure of the upper stator connection occur. Top Subs may be bored on their upper ends to accept float valves.

The power section is composed of only two continuous parts, the rotor and the stator. Although they are continuous parts, they usually constitute several chambers. In general, the longer the motor section, the more chambers. The stator is an elastomer tube formed to be the inside surface of a rigid cylinder. This elastomer tube stator is of a special material and shape. The material resists abrasion and damage from drilling muds containing cuttings and hydrocarbons.

The inside surface of the stator is of an oblong, helical shape. The rotor is a rigid steel rod shaped as a helix. The rotor, when assembled into the stator and its outside rigid housing, provides continuous seal at contact points between the outside surface of the rotor and the inside surface of stator (see Figure 4.12.11). The rotor or driving shaft is made up of n_r lodes. The stator is made up of n_s lodes, which is equal to one lobe more than the rotor. Typical cross-sections of positive displacement motor lobe profiles are shown in Figure 4.12.13. As drilling fluid is pumped through the cavities in each chamber that lies open between the stator and rotor, the pressure of the flowing fluid causes the rotor to rotate within the stator. There are several chambers in a positive displacement motor because the chambers leak fluid. If the first chamber did not leak when operating, there would be no need for additional chambers.

In general, the larger lobe profile number ratios of a positive displacement motor, the higher the torque output and

FIGURE 4.12.7 A 5 $\frac{3}{4}$ -in. liner, total pressure loss versus flowrate, Example 4.12.2 (Courtesy of Baker Hughes Co.).

the lower the speed (assuming all other design limitations remain the same).

The rotors are eccentric in their rotation at the bottom of the motor section. Thus, the connecting rod section provides a flexible coupling between the rotor and the main drive shaft located in the thrust and radial bearing section. The main drive shaft has the drill bit connected to its bottom end.

The thrust and radial-bearing section contains the thrust bearings that transfer the weight-on-bit to the outside wall of the positive displacement motor. The radial support bearings, usually located above the thrust bearings, ensure that the main drive shaft rotates about a fixed center. As in most turbine motor designs, the bearings are cooled by the drilling fluid. There are some positive displacement motor designs that use grease-packed, sealed bearing assemblies. There is usually a smaller upper thrust bearing that allows rotation of the motor while pulling out of the hole. This

upper thrust bearing is usually at the upper end of thrust and radial bearing section.

There are, of course, variations on the downhole positive displacement motor design, but the basic sections discussed above will be common to all designs.

The main advantages of the downhole positive displacements motor are:

1. Soft, medium and hard rock formations can be drilled with a positive displacement motor using nearly any type of rock bit.
2. Rather moderate flow rates and pressures are required to operate the positive displacement motor. Thus, most surface pump systems can be used to operate these downhole motors.
3. Rotary speed of the positive displacement motor is directly proportional to flowrate. Torque is directly proportional to pressure. Thus, normal surface instruments

FIGURE 4.12.8 A 6-in. liner, total pressure loss versus flowrate, Example 4.12.2 (Courtesy of Baker Hughes Co.).

can be used to monitor the operation of the motor downhole.

4. High torques and low speeds are obtainable with certain positive displacement motor designs, particularly, the higher lobe profiles (see Figure 4.12.13).
5. Positive displacement motors can be operated with aerated muds, foam and air mist.

The main disadvantages of the downhole positive displacement motors are

1. When the rotor shaft of the positive displacement motor is not rotating, the surface pump pressure will rise sharply and little fluid will pass through the motor.
2. The elastomer of the stator can be damaged by high temperatures and some hydrocarbons.

4.12.3.2 Operations

Figure 4.12.14 gives the typical performance characteristics of a positive displacement motor. The example in this figure is a $6\frac{3}{4}$ in. outside diameter positive displacement motor having five chambers activated by a 400-lb/gal flowrate of drilling mud.

For this example, a pressure of about 100 psi is required to start the rotor shaft against the internal friction of the rotor moving in the elastomer stator (and the bearings). With constant flowrate, the positive displacement motor will run at or near constant speed. Thus, this 1:2 lobe profile example motor has an motor speed of 408 rpm. The torque and the horsepower of the positive displacement motor are both linear with the pressure drop across the motor. Therefore, as more weight is placed on the drill bit (via the motor), the greater is the resisting torque of the rock. The mud pumps

FIGURE 4.12.9 A 6 $\frac{1}{4}$ -in. liner, total pressure loss versus flowrate, Example 4.12.2 (Courtesy of Baker Hughes Co.).

can compensate for this increased torque by increasing the pressure on the constant flowrate through the motor. In this example the limit in pressure drop across the motor is about 580 psi. Beyond this limit there will be either extensive leakage or damage to the motor, or both.

If the positive displacement motor is lifted off the bottom of the borehole and circulation continues, the motor will simply continue to rotate at 408 rpm. The differential pressure, however, will drop to the value necessary to overcome internal friction and rotate, about 100 psi. In this situation the motor produces no drilling torque or horsepower.

As the positive displacement motor is lowered and weight is placed on the motor and thus the bit, the motor speed continues but the differential pressure increases, resulting in an increase in torque and horsepower. As more weight is added to the positive displacement motor and bit, the torque and horsepower will continue to increase with increasing differentiated pressure (i.e., standpipe pressure).

The amount of torque and power can be determined by the pressure change at the standpipe at the surface between the unloaded condition and the loaded condition. If too much weight is placed on the motor, the differential pressure limit for the motor will be reached and there will be leakage or a mechanical failure in the motor.

The rotor of the Moineau-type positive displacement motor has a helical design. The axial wave number of the rotor is one less than the axial wave number for the stator for a given chamber. This allows the formation of a series of fluid cavities as the rotor rotates. The number of stator wave lengths n_s and the number of rotor wave length n_r per chamber are related by [2,9].

$$n_s = n_r + 1 \quad (4.12.32)$$

The rotor is designed much like a screw thread. The rotor pitch is equivalent to the wavelength of the rotor. The

FIGURE 4.12.10 Turbine motor, 6³/₄-in. outside diameter, two motor sections, 212 stages, 340 gal/min, 16.2-lb/gal mud weight, Example 4.12.2 (Courtesy of Baker Hughes Co.).

FIGURE 4.12.11 Basic positive displacement motor design principle (Courtesy of Smith International, Inc.).

rotor lead is the axial distance that a wave advances during one full revolution of the rotor. The rotor pitch and the stator pitch are equal. The rotor lead and stator lead are proportional to their respective number of waves. Thus, the relationship between rotor pitch t_r (in.) and stator pitch, t_s (in.) is [9]

$$t_r = t_s \quad (4.12.33)$$

The rotor lead L_r (in.) is

$$L_r = n_r t_r \quad (4.12.34)$$

The stator lead L_s (in.) is

$$L_s = n_s t_s \quad (4.12.35)$$
