The VSD also protects the downhole motor from poor-quality electricity power. The VSD is relatively insensitive to incoming power balance and regulation while providing closely regulated and balanced output. The VSD will not put transients out to the downhole motor but it can be shut down or damaged by such transients. Given the choice, most operators prefer to repair surface installation equipment rather than pull and run downhole equipment. Within limits, the VSD upgrades poor quality electric power by “rebuilding.” The VSD takes a given frequency and voltage AC input, converts the AC to DC, and then rebuilds the DC to an AC waveform.

The soft-start capability of a VSD provides two major benefits. First, it reduces the startup drain on the power system. Second, the strain on the pump shaft (and its associated components) is significantly reduced when compared with that of a standard start. This capability is valuable in gassy or sandy wells. In some cases, slowly ramping a pump up to operating speed may avoid pump damage.

Pressure-Sensing Instrument

The pressure-sensing instrument provides the operator with precise downhole pressure and temperature data. This instrument has two components: the downhole transducer/sending unit, and a surface readout unit. The downhole transducer/sending unit connects electrically and bolts to the base of the motor. Both pressure and temperature are transmitted from the transducers/sending unit to the surface readout through the motor windings and the power cable on a DC carrier signal. The transducer receives operating power from the motor’s neutral winding. This allows the operation of the pressure-sensing instrument even when the motor is not running.

The main function of the pressure-sensing instrument unit is to determine the producing potential of a well. This is accomplished by determining both static and dynamic

reservoir pressures. By correlating the change in pressure with a given producing rate, a well’s inflow performance can be accurately quantified. This in turn will allow equipment selection that optimizes well production.

6.4.5.2.6 Surface and Subsurface Power Cable

Electric power is supplied to the downhole motor by a special submersible three-phase cable. There are two cable configurations: flat (or parallel) and round. Round construction is used except where casing clearance requires the lower profile of flat construction. The standard range of conductor sizes is 1/0 to 6 AWG (American wire gauge). This range meets virtually all motor’s amperage requirements. Almost all conductors are copper.

Mechanical protection is provided by armor made from galvanized steel or, in extremely corrosive environments, Monel. Unarmored cable is used in low-temperature (less than 180°F) wells with a static BHP of less than 1500 psi.

Cable is constructed with three individual conductors, one for each power phase. Each conductor is enclosed by insulation and sheathing material. The thickness and composition of the insulation and sheathing determines the conductor’s resistance to current leakage, its maximum temperature capability, and its resistance to permeation by well fluid and gas.

Motor Flat Cable

The *motor flat cable* is the lowest section of the power cable string. The motor flat cable has a lower profile than standard flat power cable so that it can run the length of the pump, seal, and intake sections in limited clearance situations. The motor flat cable is manufactured with a special terminal, designed to allow entry of electric power into the motor while sealing the well fluid entry.

6.4.5.2.7 Casing Wellhead

The ESP wellhead or tubing support is used as a limited pressure seal. The wellhead provides a pressure tight pack-off around the tubing and power cable. High-pressure wellheads, up to 5000 psi, use an electrical power feed to prevent gas migration through the cable. Wellheads are manufactured to fit standard casing sizes from $4\frac{1}{2}$ to $10\frac{3}{4}$ in.

6.4.5.3 Surface Control Panel

6.4.5.3.1 Surface Junction Box

A *junction box* connects the power cable from the switchboard to the well’s power cable. The junction box is necessary to vent to the atmosphere of any gas that may migrate up the power cable from the well. This prevents accumulation of gas in the switchboard that can result in an explosive and unsafe operating condition. *A junction box is required on all ESP installations.*

6.4.5.3.2 Surface Transformer

The ESP system involves three different transformer configurations: three single-phase transformers, three-phase standard transformers, or three-phase autotransformers. Transformers generally are required because primary line voltage does not meet the downhole motor voltage requirement. Oil-immersed self-cooled (OISC) transformers are used in land-based applications. Dry type transformers are sometimes used in offshore applications that exclude oil-filled transformers.

6.4.5.4 Introduction ESP System Design

The sizing of an ESP system, as with any other artificial lift method, is not an exact and universal procedure due to the different application conditions where the method is to be used. Designing an efficient ESP is not a complicated task, but reliable and accurate information must be handled for the calculation process in order to guarantee the appropriate selection of components.

The data requirements for selection of an ESP are categorized as mechanical data, production data, fluid data, and power supply. The following is a brief description of each:

Mechanical Data

1. Casing size and weight
2. Tubing size, weight, and thread
3. Well depth (both measured and true vertical)
4. Perforation depth (both measured and true vertical)
5. Unusual conditions such as tight spots, doglegs, and deviation from true vertical at desired setting depth

Production Data

1. Current and desired production rate
2. Oil production rate
3. Water production rate
4. GOR, free gas, solution gas, and gas bubble point
5. Static BHP and fluid level
6. Producing BHP and stabilized fluid level
7. Bottomhole temperature
8. System backpressure from, flowlines, separator, and wellhead choke

Fluid Data

1. Oil API gravity, viscosity, pour point, paraffin content, sand, and emulsion tendency
2. Water specific gravity, chemical content, corrosion potential, and scale-forming tendency
3. Gas specific gravity, chemical content, and corrosion potential
4. Reservoir FVF, bubble point pressure, and viscosity/temperature curve

Power Supply

1. Voltage available and frequency
2. Capacity of the service
3. Quality of service (spikes, sags, etc.)

6.4.5.4.1 Determining Reservoir Inflow Capacity (Productivity Index)

The reservoir inflow capacity will be governed by the inflow performance relationship (IPR) curve. This curve shows the flow rate associated with each bottomhole flowing pressure for a specific reservoir condition. Depending on how stable the reservoir static pressure (P_{ws}) is, this information could be considered for a long period of time (if PI is high) or only for current well condition (if PI is low).

There are several methodologies to calculate this IPR curve: the straight line method being the most used (if flowing pressure, P_{wf} , is higher than the bubble point pressure, P_b) and the Vogel method (if P_{wf} is lower than P_b).

1. If the bottomhole flowing pressure (P_{wf}) is higher than or equals to the bubble point pressure (P_b), no free gas is present at the reservoir so compressibility of the liquid is insignificant. Under this assumption, a straight line (or constant PI) behavior could be considered for the relation between P_{wf} and flow rate (Q):

$$PI = \frac{Q}{P_{ws} - P_{wf}} \quad (6.4.92)$$

2. If P_{wf} is lower than P_b , free gas will be liberated from the solution. This means that PI will decrease while the pressure decreases. Under these conditions, the method of Vogel is one of the most appropriate procedures to establish the relationship between P_{wf} and Q . Following, the equation:

$$\frac{Q}{Q_{max}} = 1 - 0.2 \cdot \left(\frac{P_{wf}}{P_{ws}} \right) - 0.8 \cdot \left(\frac{P_{wf}}{P_{ws}} \right)^2 \quad (6.4.93)$$

Q_{max} will be the maximum flow rate that reservoir can produce when P_{wf} is equal to zero (maximum drawdown).

6.4.5.4.2 Determining Fluid Properties at Pump Intake Condition

Pressure and temperature conditions along the wellbore change depending on specific production conditions and the mechanical configuration of the well. Due to these changes, produced fluid properties also change affecting not only their physical characteristics but also their relative volumes. The relationship between pressure, volume, and temperature is known as PVT properties of fluids. The best way to attain these properties is with laboratory analysis. Another, perhaps the common way, is with PVT correlation such as Standing, Vasquez & Beggs, Lasater, Lee, Baker & Swerdloff, Dodson & Standing, etc.

Determining fluid properties as fluid specific gravity and viscosity at pump intake conditions is very important because they have a strong influence on the pump performance curve. Fluid specific gravity will affect both the

head capacity and the horsepower requirement of the pump, typically reduced for fluids lighter than water (specific gravity less than 1.00). Viscosity has a different effect on the pump, increasing the horsepower requirement (up to 2.5 times) and reducing displacement (up to 40%) and head capacities (up to 30%), as it increases. Therefore, knowledge of these two parameters is extremely important to select the appropriate pump.

PVT properties will also help to determine the equivalent volumes of oil, gas, and water produced by the well at pump intake conditions. Following is a detailed calculation procedure to determine such volumes.

Oil Volume at Pump Intake

First, gas solubility, R_s , should be calculated using following relation:

$$R_s = \gamma_g \left[\frac{PIP + 14.7}{18 \times 10^{(0.0009 - (T+460) - 0.0125 \text{ API})}} \right]^{1.204} \quad (6.4.94)$$

Then, the oil volumetric factor, B_o , using:

$$B_o = 0.972 + 0.000147 \times \left(R_s \cdot \left(\frac{\gamma_g}{\gamma_o} \right)^{0.5} + 1.25T \right)^{1.175} \quad (6.4.95)$$

$$\text{with } \gamma_o = \frac{141.5}{131.5 + \text{API}} \quad (6.4.96)$$

Finally, calculation of oil volume at intake, V_o , is made using:

$$V_o = Q_o \times B_o \quad (6.4.97)$$

Water Volume at Pump Intake

Volume of water at pump intake conditions (V_w) can be assumed as equal to the water flow rate at stock conditions (Q_w) because of its relative insignificant compressibility.

Free Gas Volume at Pump Intake

First, gas compressibility factor, z , is calculated using the following relation:

$$z = A + B \cdot Pr + (1 - A) \cdot e^{-C} - H \cdot \left(\frac{Pr}{10} \right)^4 \quad (6.4.98)$$

where : $Tr = (T + 460)/(175 + 307\gamma_g)$

$$Pr = Pa/(701 - 47\gamma_g)$$

$$A = -0.101 - 0.36Tr + 1.3868 \cdot (Tr - 0.919)^{0.5}$$

$$B = 0.021 + 0.0425/(Tr - 0.65)$$

$$C = Pr(D + E \cdot Pr + F \cdot Pr^4)$$

$$D = 0.6222 - 0.224Tr$$

$$E = 0.0657/(Tr - 0.86) - 0.037$$

$$F = 0.32e^{(-19.53(Tr-1))}$$

$$H = 0.122e^{(-11.3(Tr-1))}$$

Second, gas volumetric factor, B_g , is calculated as:

$$B_g = \frac{0.0283 \cdot z \cdot (T + 460)}{PIP + 14.7} \quad (6.4.99)$$

Then, free gas volume at intake, V_g , is obtained using:

$$V_g = 0.17811 \cdot Q_o \cdot (GOR - R_s) \cdot B_g \quad (6.4.100)$$

Once the oil, water, and gas volumes at pump intake are calculated, the total fluid volume, V_t , to be handled by the pump should be calculated as:

$$V_t = V_o + V_w + V_g \quad (6.4.101)$$

The fraction of free gas content, F_g , will be:

$$F_g = \frac{V_g}{V_t} \quad (6.4.102)$$

If F_g is higher than 10% with radial-flow impeller pumps or 15% with mixed-flow impeller pumps, the use of a gas separator is recommended in order to minimize gas interference at the pump and an eventual premature failure of the pump.

6.4.5.4.3 Determining Total Dynamic Head

The Total Dynamic Head (TDH) could be defined as the differential pressure (or energy) that the pump must supply to get the desired flow rate at the tank. This differential pressure is defined by the pump discharge pressure (function of surface pressure, flow losses through tubing string, and weight of liquid column inside the tubing) and the pump intake pressure (function of the reservoir inflow performance). The best way to estimate the discharge pressure is by using multiphase flow correlations that consider elevation, acceleration, and friction forces as Duns and Ros, Orkizewski, Beggs and Brill, Ansari, etc. The intake pressure could be calculated as a static column above the perforations, using as a reference the bottomhole flowing pressure corresponding to a specific flow rate.

The following is a simplified calculation procedure that assumes a single-phase flow pattern into the tubing string. This single-phase fluid will be a liquid; properties are equal to the average properties of current produced fluids (water, oil, and gas).

1. Calculation of fluid specific gravity, γ_f .

$$\gamma_f = \frac{(\gamma_o \cdot V_o) + (\gamma_w \cdot V_w) + (\gamma_g \cdot V_g)}{V_t} \quad (6.4.103)$$

2. Calculation of net suction head, H_s (in feet):

$$H_s = \frac{PIP}{(0.433 \cdot \gamma_f)} \quad (6.4.104)$$

3. Calculation of equivalent vertical head, H_d (in feet):

$$H_d = H_{sd} - H_s$$

4. Calculation of surface back-head, P_d (in feet):

$$P_d = \frac{P_{\text{surface}}}{(0.433 \cdot \gamma_f)} \quad (6.4.105)$$

5. The friction losses in the tubing string (F_t) could be estimated using the Hazen-Williams correlation, which is shown graphically on [Table 6.4.13](#) (formula is also shown).

6. Calculation of Total Dynamic Head, TDH (in ft.):

$$TDH = H_d + P_d + F_t \quad (6.4.106)$$

Selection of Pump, Motor, and Seal Section

Selection of a specific pump involves identifying a pump of the largest possible diameter that can be run in the well. The pump should have the target capacity (V_t) within its recommended operating range and close to its Best Efficient Point (BEP). The initial pump capacity selection can be made using as reference the [Table 6.4.14](#). Use the recommended operating range as a guide.

The individual pump curve should then be reviewed to determine the optimal producing range and the proximity of the design-producing rate to the pump's BEP (see [Table 6.4.15](#) as a reference). It is very important to choose a producing rate that is in the recommended capacity range of the specific pump. When a pump operates outside this range, premature failure can result.

Once the pump is chosen, the number of stages (N_{stages}) required can be calculated using the head per stage (H_{stage}) reading from the pump performance curve, as follows:

$$N_{\text{stages}} = \frac{TDH}{H_{\text{stage}}} \quad (6.4.107)$$

The horsepower required by the pump design can then be calculated. To accomplish this, the horsepower required per stage is read from the specific pump performance curve. The required motor horsepower (BHP_{motor}) is determined by multiplying the horsepower required per stage (BHP_{stage}) by the number of design stages (N_{stages}). The performance curve horsepower data apply only to specific gravity 1.0 fluids. For other fluids (other specific gravities), the water horsepower also must be multiplied by the specific gravity of the fluid pumped (γ_f). Thus, the following equation for the motor horsepower calculation:

$$BHP_{\text{motor}} = BHP_{\text{stage}} \cdot N_{\text{stages}} \cdot \gamma_f \quad (6.4.109)$$

Once the design motor horsepower is determined, specific motor selection is based on setting depth, casing size, and motor voltage. Although the cost of the motor is generally unrelated to voltage, overall ESP system cost may be reduced by, using higher-voltage motors in deep applications. This lower cost can sometimes occur because a higher voltage can lower the cable conductor size required. A smaller conductor size, lower-cost cable can more than offset the increased cost of a higher-voltage switchboard. Setting depth is a major variable in motor selection because of starting and voltage drop losses that are a function of the motor amperage and cable conductor size.

The seal section selection variables are pump and motor series (sizes), motor horsepower, and well temperature. Normally the seal section is the same series as the pump and motor. Large horsepower motors (150 HP and larger) may require a larger oil capacity, so a positive seal double-bag model or a tandem labyrinth model is used. Temperature will limit the type of elastomer used in positive seal types (single- or double-bag) as 250°F for HSN elastomers, 300°F for Viton, and 350°F for Aflas. Higher temperatures could be handled by labyrinth type seal sections.

Finally, in order to ensure the appropriate selection of pump and motor, the following precautions must be taken:

1. *Pump, Motor, and Seal Section Sizes:* Check for outside diameter of these elements and confirm that they can be run into the specific casing size. This information is typically provided by manufacturers.
2. *Pump Housing Limit:* Pumps are provided with two different types of housing material. Maximum pressure to be supported by the housing will be at the start-up of the equipment, which means, at zero flow rate. To calculate this value, read the pump head at 0 BPD from the pump performance curve (when the pump head curve crosses the left-vertical axis) and multiply it by the number of stages. Then, find the equivalent pressure to this maximum head and check the limit of each type of housing provided for that specific pump model. Manufacturers typically provide this information.
3. *Pump, Motor and Seal Shaft Limit:* Check for horsepower limits of pump, motor and seal section shafts in order to determine if a standard or high strength material must be used. Manufacturers typically provide this information.
4. *Seal Thrust Bearing Capacity:* Check for maximum axial load that thrust bearing can support by multiplying the differential pressure through the pump by the shaft cross-sectional area, axial load on the shaft is obtained. Information provided by manufacturers.
5. *Fluid Passing the Motor:* To guarantee enough fluid cooling capacity, the recommended minimum fluid velocity passing the motor must be 1 ft/sec. Knowing the flow rate, casing size and motor series (size) such velocity could be estimated using [Table 6.4.16](#).

TABLE 6.4.13 Friction Losses as Hazen-Williams correlation

Based on Hazen William Formula:

$$F = \frac{2.083 \left(\frac{100}{C}\right)^{1.85} \left(\frac{Q}{34.3}\right)^{1.85}}{ID^{4.8655}} \quad (6.4.108)$$

Where:

- F: Friction Losses (feet/1000 feet)
- C: Pipe Coefficient (Old = 100, New = 120)
- Q: Flow Rate (BFPD)
- ID: Tubing Inside Diameter (inches)

6.4.5.4.4 Selection of Downhole Power Cable

Selection of proper type and size of downhole power cable will depend on several well conditions: bottomhole ambient temperature, motor load current, casing and tubing sizes, pump setting depth, well fluid and environment (presence of H₂S, CO₂, free gas, additives, etc.), and power cost considerations.

The cable type must be selected in order to match environmental conditions where ambient temperature and fluid composition are the main parameters to be considered. Table 6.4.17 shows a summary of different cable specifications as well as a guide for their application ranges.

Once the type of cable is selected, Table 6.4.18 must be used to determine the voltage drop. Using motor nom-

TABLE 6.4.14 Pump Recommended Operating Range

Model	Housing OD (inches)	BEP @ 60 Hz (Bls/day)	Maximum HP (HP)	Recommended Operating Range @ 60 Hz (Bls/day)	
				Minimum	Maximum
400-365	4.00	365	94	200	500
400-450	4.00	450	94	200	650
400-675	4.00	675	94	400	1000
400-850	4.00	850	94	600	1300
400-1200	4.00	1200	94	800	1500
400-1600	4.00	1600	94	1100	2100
400-1800	4.00	1800	94	1100	2100
400-2050	4.00	2050	94	1200	2400
400-2600	4.00	2600	256	1500	3750
400-3750	4.00	3750	256	2000	5800

400-5500	4.00	5500	256	3500	7500
400-5600	4.00	5600	256	3600	7600
513-1600	5.13	1600	375	1100	2200
513-1750	5.13	1750	375	1100	2250
513-2500	5.13	2500	375	1700	3900
513-3400	5.13	3400	375	2200	5000
513-3600	5.13	3600	375	2200	5000
513-5700	5.13	5700	375	3500	8000
513-8000	5.13	8000	637	5500	10000
513-9500	5.13	9500	637	6000	13000
538-4700	5.38	4700	375	3500	7000
538-7000	5.38	7000	375	5000	10500
538-8500	5.38	8500	375	5000	11000
538-11000	5.38	11000	637	8000	16000

inal current as the maximum, the voltage drop per 1000 ft. can be read per each size of cable. In order to get a reasonable leakage, a maximum of 30 V/1000 ft. is accepted. If voltage drop is higher than such limit, a bigger size cable must be selected. Note that [Table 6.4.18](#) works with conductor temperature and not with ambient temperature.

Also, note that [Table 6.4.19](#) has been built at 77°F of conductor temperature. To correct such temperature to the ambient bottomhole condition, the read value in [Table](#)

[6.4.18](#) must be multiplied by the correction factor read on [Table 6.4.19](#). Again, results cannot exceed 30 V/1000 ft.

Finally, verify that voltage at the motor during start-up conditions is not too low. Divide the total cable voltage drop by the surface voltage required (motor nominal voltage plus cable voltage drop). Enter the result in horizontal axis of [Table 6.4.20](#) and meet the red line. Read the corresponding value on vertical axis and, if result is higher than 40%, the motor rating is OK. If not, use a motor with lower nameplate voltage.

TABLE 6.4.15 Typical Pump Performance Curves, Fixed Speed

6.4.5.4.5 Selection of Switchboard

All applications, except where VSDs are used, will require a surface switchboard or control panel. Selection of such switchboard will depend on voltage and amperage requirements. The surface voltage will be the result of adding motor nameplate voltage plus cable voltage losses. Amperage will be equal to motor nameplate current.

In 60-Hz frequency applications, switchboards are available in 600, 1500, 2500, 3600, and 4800 V with different amperage capacities. Use of motor controller (as vortex or eliminator) must be determined in order to finalize the switchboard selection process.

6.4.5.4.6 Selection of Transformers

Distribution of service transformers is electrically rated by input/output voltage and KVA (KVA is the abbreviation for Kilo-Volts-Amperes or thousand of Volts-Amperes that is a measure of apparent power). The minimum required total transformer KVA rating can be found using the following formula for three phase operation:

$$KVA = \frac{V_{surface} \cdot I_{mn} \cdot \sqrt{3}}{1000} \tag{6.4.110}$$

When using a single auto-transformer or three-phase transformer, the calculated KVA value must not exceed the transformer’s rating. Three single-phase transformers have a total KVA rating of three times their individual rating.

Transformer sizing for normal installations is relatively simple; however, special cases do arise which will require transformer derating. One such case where derating would be necessary is where only two single-phase transformers must be used. (Note however that using only two single-phase transformers is not recommended). An open Wye-Wye or open Wye-Delta connection requires that transformers total rating be decreased to 86.6%. For example, another derating case would be where the primary voltage is 12,470 V, and the three, transformer primary ratings are 14,400/24,940 Y.

TABLE 6.4.16 Fluid Velocity Passing the Motor

TABLE 6.4.17 Downhole Power Cable Information for Manufacturer A.

Model	Shape	Insulation	Jacket	Armor	Temperature Rating	Application
DW205 R	Round	Polypropilene	Nitrile	Galvanized or Armor	205°F	Maximum operating downhole temperatures of 170°F. Good for mild environments. Low cost cable. Flat configuration allows downhole equipment to fit in smaller casing.
DW205 FL	Flat	Polypropilene	Nitrile	Galvanized or Armor	205°F	
DW300 R	Round	EPDM	Nitrile	Galvanized or Armor	300°F	Maximum operating downhole temperatures of 265°F. Good for moderate (Nitrile Jacket) to harsh (EPDM Jacket) environments. Most popular cable in the industry.
DW300 RE	Round	EPDM	EPDM	Galvanized or Armor	300°F	
DW400 R	Round	EPDM	EPDM	Galvanized or Armor	400°F	Maximum operating downhole temperatures of 365°F. Good for harsh environments.
DW450 FL	Flat	EPDM	EPDM w/ Lead Sheath	Galvanized or Armor	450°F

TABLE 6.4.19 Cable Voltage Drop Correction Factor

6.4.5.4.7 Design with VSD

The following important considerations must be taken when applying a VSD to an ESP system:

Pump Performance

When applying a VSD to a submersible pump installation, it is first necessary to understand the effects of varying the pump speed. Pump performance is affected by changes in rotational speed (known as centrifugal pump’s affinity laws).

When the speed (N) is changed, the flow (Q) varies directly as the speed:

$$\frac{Q_1}{Q_2} = \frac{N_1}{N_2} \tag{6.4.111}$$

When the speed is changed, the head (H) varies directly as the square of the speed:

$$\frac{H_1}{H_2} = \left(\frac{N_1}{N_2}\right)^2 \tag{6.4.112}$$

When the speed is changed, the brake horsepower required by the pump (BHP) varies directly as the cube of the speed:

$$\frac{BHP_1}{BHP_2} = \left(\frac{N_1}{N_2}\right)^3 \tag{6.4.113}$$

Motor Performance

The rotational speed of an AC motor varies directly with the change in frequency or cycles per second. A normal 60 cycles input to a two-pole electric motor produces a rotational synchronous speed of 3500 rpm. Any other frequency (F) will produce a proportional change in rotational speed; i.e., 30 cycles equals approximately 1750 rpm, 90 cycles equal approximately 5250 rpm. This statement can be simplified with the formula:

$$\frac{F_1}{F_2} = \frac{N_1}{N_2} \tag{6.4.114}$$

When the frequency (F) is changed, the motor output brake horsepower (BHP_{motor}) varies directly as the frequency; provided a constant voltage (V)-to-frequency ratio is maintained:

$$\frac{BHP_{motor1}}{BHP_{motor2}} = \frac{F_1}{F_2} \text{ provided } \frac{F_1}{F_2} = \frac{V_1}{V_2} \tag{6.4.115}$$

Assuming the voltage-to-frequency ratio is constant, the motor full current load (I) will remain approximately constant:

$$I_1 = I_2 \text{ provided } \frac{F_1}{F_2} = \frac{V_1}{V_2} \tag{6.4.116}$$

TABLE 6.4.20 Cable Voltage at Start-Up

It is important to note that variable speed drives generally maintain a constant voltage-to-frequency ratio over a limited frequency range. Therefore, the transformer located between the drive and the motor may require a change to the transformer ratio to maintain the required constant voltage of frequency ratio (maintain constant flux density). Be sure to consult the VSD manufacturer to obtain the equipment limitations and select a transformer that is capable of operating within the required range.

Operating Range:

Because the pump will operate at a head/capacity that intersects, the system required head/capacity, definite speed limitations (both high and low) need to be established to prevent premature failures. Be sure the speed range allows the pump to perform within the recommended pump operating range.

1. A speed that is too low may result in an insufficient flow past the motor to maintain adequate cooling (a minimum of 1 ft./s is recommended).

2. A speed that is too low may also result in the unit operating at shut-in (zero flow). Operating in this condition will result in an unit failure within a very short period of time. In addition to the motor having insufficient flow past it for cooling, the pump is adding energy to the fluid in the form of heat that compounds the problem. Operating in this condition also results in extreme hydraulic down thrust, which will reduce the life of the thrust washers, thus reducing the unit run life.
3. A speed that is too high can result in a motor overload condition. Since the pump brake horsepower varies as the cube of the speed, extreme care must be taken when selecting the required motor horsepower rating (the motor must be sized for the largest anticipated load).

Table 6.4.21 shows a typical variable speed curve for an ESP.

6.4.6 Progressing Cavity Pumping Systems

6.4.6.1 Introduction

In the late 1920s, Rene Moineau developed the concept for a series of helical gear pumps. One of these pumps took the form of what is now known as the progressing cavity (PC) pump, screw pump, or Moineau pump. The PC pump has been utilized in many industries in a wide variety of applications since its licensing. It has been used as a pump in just about every industry: chemical, coal, food, metal working, mining, paper textile, tobacco, water, waste treatment, and petroleum. Since the first serious efforts to apply them as a method of artificial lift in the early 1980s, PC pumping systems have experienced a gradual emergence in the petroleum industry. As of 2002, from Alaska to South

America, from Russia to Australia, from the interior of Africa to secluded mountain spas in Japan, it is estimated that there are approximately 50,000 wells worldwide operating on-shore and off-shore with these systems.

PC pumping systems possess unique characteristics that can make them preferable over other artificial lift systems. Their most important characteristic is high overall system efficiency. PC pumping systems typically exhibit overall efficiencies of 50% to 70%, which is higher than any of the other major artificial lift types. Some additional advantages of PC pumping systems include:

- The ability to produce high viscosity fluids, large solids concentrations, and moderate percentages of free gas
- Low internal shear rates, which limit fluid emulsification by agitation
- No valves or reciprocating parts to clog, gas lock, or wear
- Low capital and power costs
- Simple installation and operation as well as low maintenance
- Low profile and low noise surface equipment.

PC pumping systems also have some disadvantages compared with other forms of artificial lift. The most prominent of these are limitations with respect to pump capacity, lift, and elastomer compatibility. The list below summarizes the current application limitations and major operational difficulties associated with PC pumping systems:

- Limited production rates: maximum = 800 m³/d (5000 bbls/d)
- Limited lift: maximum = 3000 m (9800 ft.)
- Limited temperature capability: maximum = 170°C (330°F)
- Sensitivity to fluid environment: elastomer may swell or deteriorate upon exposure to certain fluids
- Tendency of pump stator to sustain permanent damage if pumped dry even for short periods
- Lack of user experience with system design, installation and operation

These limitations are rapidly being overcome with the development of new products and improvements in materials and equipment design. In many applications, PC pumping systems can provide the most economic (and in some cases the only) means of artificial lift when configured and operated properly.

6.4.6.1.1 Major Applications

Presently the major applications for PC pumping systems include:

Heavy Oil

- <18 API gravity
- 500 to 15,000 cps viscosity
- 300 to 800 m (1000–2500 ft.)
- Up to 70 m³/d (440 bbls)
- Sand cuts up to 85%
- Water cuts up to 100%
- Low aromatics, GOR
- H₂S and CO₂ possible

Medium Oil — 18 to 30 API Gravity

- <500 cps viscosity
- 600 to 1400 m (2000–4500 ft.)
- Up to 500 m³/d (3100 bbls)
- <2% Sand cuts
- Water cuts up to 100%
- Greater possibilities of aromatics, higher GORs, H₂S, and CO₂

Light Oil 30 API Gravity

- <20 cps viscosity
- >1000 m (3200 ft.)
- up to 500 m³/d (3100 bbls)
- Trace sand
- Water cuts up to 100%

- High possibility of aromatics, high GORs, H₂S, and CO₂

Water

- Water source wells
- Gas water separation
- Coalbed methane extraction
- 800 m³/d (5000 bbls)
- Depth 900 m (3000 ft.)
- Abrasive cuts up to 70%
- Low aromatics
- High GORs, H₂S, and CO₂ possible
- Mature steam drive operations

6.4.6.1.2 Pumping Principles

PC pumps are positive displacement pumps, which consist of two primary parts, a *rotor* and a *stator*. The geometry of the assembly is such that it constitutes two or more series of lenticular, spiral, separate cavities. When the rotor rotates inside the stator, the cavities move spirally from one end of the stator to the other, from inlet to outlet, creating the pumping action. As each cavity progresses from the inlet to the outlet, the pressure increases from the inlet pressure to the outlet pressure, ideally in a linear fashion.

Most PC pumping systems are rod-driven with the stator run into the well on the bottom of the production tubing, and the rotor connected to the bottom of the rod string. To turn the rotor downhole, the rod string is rotated at surface by means of a hydraulic or direct drive power transmission.

6.4.6.1.3 Pump Geometry

The pump geometry is governed by four parameters:

1. Lobe ratio
2. Offset or eccentricity
3. Stator pitch
4. Rotor diameter

Lobe Ratio: The stator will always have one more lobe than the rotor. Most PC pumps are of the 1:2 geometry. The 1 represents the number of lobes on the rotor; 2 represents the number of lobes on the stator. Most multilobe pumps will be of a 2:3 geometry (Figure 6.4.70).

Cavity Formation: At any cross-section, the number of cavities is equal to the number of lobes on the stator, i.e., 1:2 geometry there are 2 cavities 180° apart. Cavities are one stator pitch in length. One cavity starts where the other ends. The pitch of the rotor is one-half that of the stator.

Rotor Movement: Rotor rotates about its own axis in a clockwise direction at the pump speed. Rotor rotates eccentrically about the stator axis in a counter-clockwise direction at the pump speed times the number of lobes on the rotor.

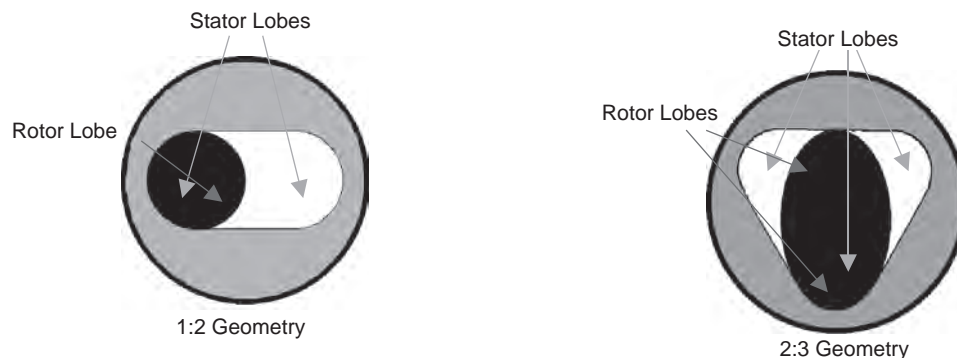

FIGURE 6.4.70 Lobe ratio.

Offset or Eccentricity: *Eccentricity* is the radius of the circle the rotor head traces about the stator centreline. For a 1:2 geometry pump, the eccentricity is the difference between the rotor head centreline and rotor centre.

Cavity Area: The cavity area for a 1:2 geometry pump is equal to the rotor diameter multiplied by the stator pitch and four times the eccentricity.

$$\text{Cavity Area} = D \times 4e \times \text{stator pitch}$$

Pump Displacement: The *pump displacement* is a product of the rotor minor diameter, pump eccentricity, and stator pitch multiplied through by a constant.

$$V = Cedp$$

where : $V = \text{m}^3/\text{d}/\text{rpm}$

$C = 5.7 \text{ e-}6$

$d = \text{rotor minor diameter (mm)}$

$e = \text{eccentricity (mm)}$

$p = \text{stator pitch (mm)}$

Figure 6.4.71 shows a typical progressing cavity pumping system configuration.

6.4.6.2 How Progressing Cavity Pumps Develop Pressure

The combination of the maximum pressure that can be developed in a single cavity and the number of cavities in a PC pump defines its pressure capability. The pressure that can be supported by each cavity is a function of the interference fit between the rotor and stator and the properties of the produced fluid. In general, as the rotor/stator interference fit and fluid viscosity increases the pressure capability of each cavity increases. Differential pressure between the cavities causes fluid to leak across the rotor/stator seal lines from the high-pressure cavity to the low-pressure cavity. Fluid slip is directly related to the amount of differential across

Typical Progressing Cavity Pumping System Configuration

FIGURE 6.4.71 Typical progressing cavity pumping system configuration.

the pump and is independent of speed. With conventional sizing, each cavity can support approximately 35 psi (240 kPa) of pressure differential.

The example in Figure 6.4.72a illustrates that if the rotor/stator interference fit is the same for two pumps, by

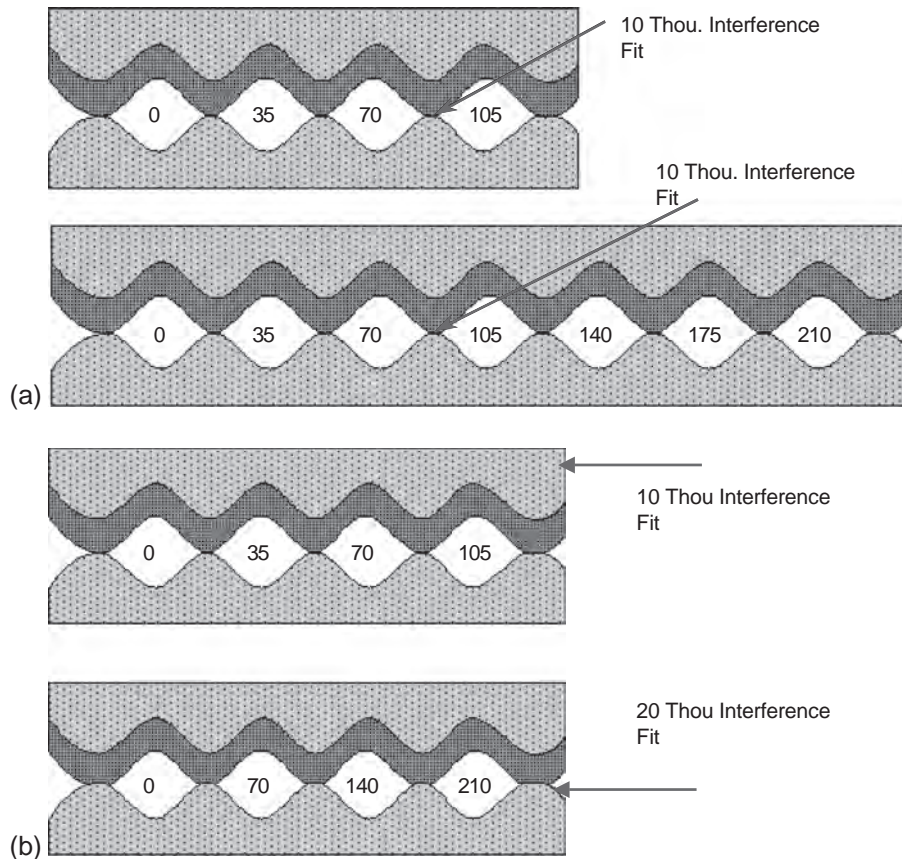

FIGURE 6.4.72 Rotor/stator interference fit in a PC pump.

adding more cavities we increase the pressure capability of that pump.

The example in Figure 6.4.72b illustrates that if the two pumps have the same number of cavities, by increasing the rotor/stator interference fit the pressure differential those cavities can support increases.

6.4.6.2.1 Pump Efficiency or “Slip”

The most common method to measure pump performance is by volumetric efficiency. Volumetric efficiency can be defined as the benchmark flow rate @ 0 head minus the “Slip” @ rated head. It is represented as a percentage.

The following example is an illustration of a typical PC pump performance curve (Figure 6.4.73). The curve is for a PC pump model 10–1200 where:

10 = pump displacement in $\text{m}^3/\text{d}/100 \text{ rpm}$

1200 = pump rates lift in meters of head based on fresh water. To convert this to a pressure, multiply the meters of lift by the fresh water gradient.

(i.e., $1200\text{m} \times 9.81\text{kPa}/\text{m} = 11,788\text{kPa}$).

If the pressure differential across the pump continues to increase, it will eventually exceed the rotor/stator interference fit. When this occurs, a percentage of fluid from the low-pressure cavity will not be produced into the high-pressure cavity resulting in a reduction of flow. With no pressure differential across the pump, the rotor/interference fit is not compromised, and 100% of the fluid is produced from the low- pressure cavity to the high-pressure cavity (i.e., 100% volumetric efficiency at 0 head). In this example it can be seen that at the rated lift of the pump there is 20% slip (80% volumetric efficiency). If the differential pressure continues to increase, a pressure will eventually be reached at which no flow occurs. At this point the slip is 100% and, in the following example, occurs when the pump has a pressure differential of 1800 m of head across it. This is also the maximum pressure the progressing cavity pump can develop under this particular set of test conditions (Figure 6.4.74).

The following example illustrates that if pump 1 and pump 2 have the same rotor/stator interference fit, by adding more cavities, the pump efficiency will be greater because there is less pressure differential between the cavities (Figure 6.4.75a).

FIGURE 6.4.73 Development of pressure in a PC pump.

FIGURE 6.4.74 Differential pressure (meters of lift) 10–1200 HNBR @ 100 rpm 10–1200 @ 100 rpm.

To optimize pump life, we try to find a balance between the lift capacity of the pump versus rotor/stator interference fit to achieve a desired pump efficiency for a specific set of well parameters. To extend pump life, we want to add seal lines so the pump is less loaded. By reducing the pressure differential across the pump, we no longer need to have as tight of a rotor/stator interference fit to achieve the desired pump efficiency. This is illustrated below by the two graphical examples (Figure 6.4.75b).

6.4.6.2.2 Slip as a Function of Pump Volumetric Efficiency

Slip is directly affected by the pressure differential across the pump. The more pressure differential across a pump for a given set of condition, the higher the slip will be. Therefore, it is safe to say as the pressure differential across the pump increases, the volumetric efficiency will decrease for a given set of conditions.

Even though slip remains constant for a given differential pressure, the pump volumetric efficiency can be significantly impacted depending on what the pump rota-

tional speed is. The effect of the pump rotational speed on volumetric efficiency is illustrated in the following example.

Example

- PCP Model: **10-1200**
- Test Speed: **300 rpm**
- Pump Efficiency: **70%**

Theoretical production at 100% efficiency

$$= 30 \text{ m}^3/\text{d} \text{ (} 10 \text{ m}^3/\text{d}/100 \text{ rpm} \times 300 \text{ rpm} \times 100\%)$$

- Fluid rate at measured efficiency = $21 \text{ m}^3/\text{d}$ ($30 \text{ m}^3/\text{d} \times 70\%$)

$$\text{Slip} = 9 \text{ m}^3/\text{d} \text{ at rated lift or 1200 m of head (} 30 \text{ m}^3/\text{d} - 21 \text{ m}^3/\text{d})$$

Now if the pump speed is reduced to 150 rpm, but the pressure differential across the pump remains the same the theoretical rate is:

Pump Lift Capacity Effect on Slip

FIGURE 6.4.75 Pump lift capacity effect on slip (1200 and 1800 m).

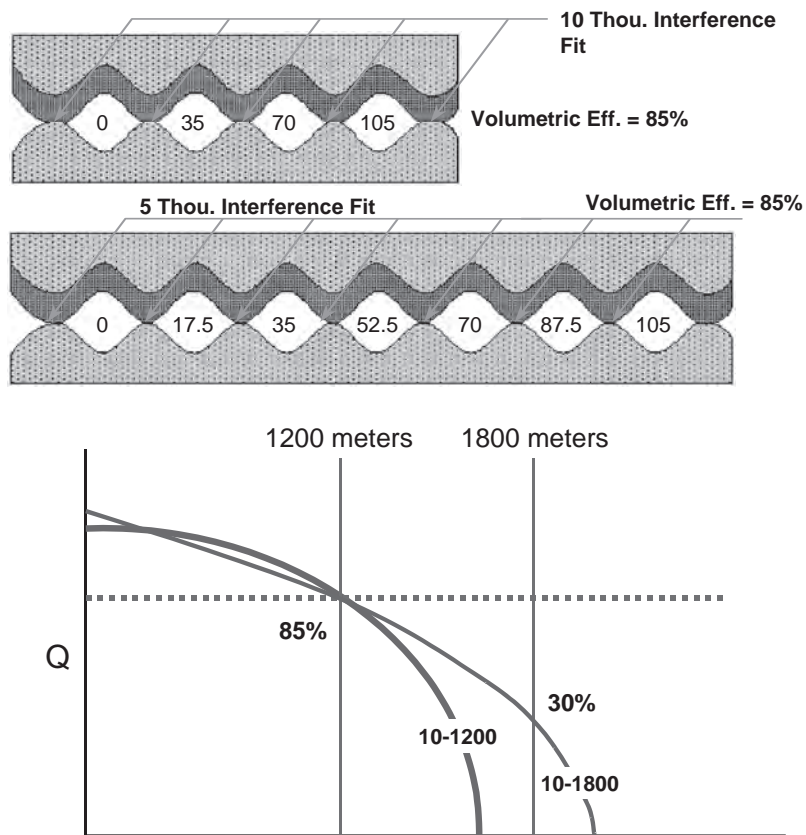

FIGURE 6.4.75, Cont'd.

- $10 \text{ m}^3/\text{d}/100 \text{ rpm} \times 150 \text{ rpm} = 15 \text{ m}^3/\text{d}$; however, because since the pressure differential is still the same, the slip remains constant at $9 \text{ m}^3/\text{d}$. Therefore, the new pump efficiency is:

$$(15 \text{ m}^3/\text{d} - 9 \text{ m}^3/\text{d})/15 \text{ m}^3/\text{d} = 40\% @ 150 \text{ rpm}$$

Now if the pump speed is increased to 400 rpm but the pressure differential across the pump remains the same the theoretical rate is:

- $10 \text{ m}^3/\text{d}/100 \text{ rpm} \times 400 \text{ rpm} = 40 \text{ m}^3/\text{d}$; however, because since the pressure differential is still the same, the slip remains constant at $9 \text{ m}^3/\text{d}$. Therefore, the new pump efficiency is:

$$(40 \text{ m}^3/\text{d} - 9 \text{ m}^3/\text{d})/40 \text{ m}^3/\text{d} = 78\% @ 400 \text{ rpm}$$

6.4.6.2.3 Pressure Stage

Although not commonly used anymore, some operators still refer to stages when defining the pressure rating of a PC pump. The problem with this terminology is that not all manufacturers define a pump stage by the same set of parameters.

As previously discussed, a pump cavity can support approximately 35 psi (240 kPa) pressure differential with

a standard rotor/stator interference fit. Each stator pitch has two cavities 180° out of phase. Therefore, by definition one stator pitch would have a differential pressure rating of 70 psi (480 kPa). However, most manufacturers have defined a pump stage as three cavities or $1\frac{1}{2}$ stator pitches. Therefore, by this standard a pump stage would be equal to approximately 100 psi (690 kPa). By this definition if you had an 18-stage pump, the pump would be rated for 1800 psi (12,400 kPa) of pressure differential.

6.4.6.3 Elastomers

The weakest link in progressing cavity pumping systems is the elastomer. Elastomer failures often occur as a result of the chemical or physical breakdown that is induced by the downhole environment and produced fluid properties.

Elastomer performance is dependent on its chemical and mechanical properties. The most commonly referenced mechanical properties are:

- *Hardness (Shore A)*: very important as it is used to characterize the relationship between the rotor/stator interference fit and the resulting sealing force
- *Tear Strength*: the next most important property as it is used to measure the resistance to tearing and is directly related to fatigue and abrasion resistance

- *Tensile Strength*
- *Abrasion Resistance*
- *Resilience*

Although not classed as a mechanical property, equally important is an elastomer's resistance to liquid, gas swell, and temperature degradation. Elastomers are very sensitive to temperature, and in most cases, the mechanical properties will deteriorate significantly with increasing temperature. The rate of fluid swell will also increase with higher temperatures. Chemical resistance is normally evaluated through compatibility testing with the produced fluid.

In PC pumping systems, there are basically three types of elastomers. The formula for an elastomer is generally proprietary, and as a result, there is no naming standard. However, there are certain generic names common to the manufacturers, but the properties of the elastomers can vary significantly. For example, there are approximately 20 different ingredients such as fillers, plasticizers, curatives, and carbon black. Of each of these ingredients, there are a number of different types, which can lead to an infinite number of formulations. Almost all of the PC pump elastomers use some variation of a synthetic nitrile rubber.

Nitrile (NBR)—Trade Name Buna The majority of elastomers are classified as a conventional nitrile rubber (NBR). The base polymer is an emulsion copolymerisation of butadiene with acrylonitrile. NBR elastomers are typically classed as a medium nitrile (Buna) or high nitrile.

Medium Nitrile (Buna): The medium nitrile has ACN content between 30% and 40%. It is sulphur or peroxide cured at elevated temperatures. For these reasons it is not recommended for applications that contain high levels of H₂S or temperatures that exceed 100°C (212°F), due to the advanced vulcanization and surface hardening that occurs.

Medium nitrile elastomers typically have the best mechanical properties, are the easiest to mold, and generally are the most economical.

High Nitrile: High-nitrile elastomers have ACN content between 40% and 50%. Increasing the ACN content increases the polarity, which improves the elastomers resistance to nonpolar oils and solvents such as *benzene, toluene, and xylene*. However, increasing the ACN content generally results in a decline in certain mechanical properties.

Saturated Nitrile (HNBR) NBRs often contain a large degree of unsaturation in the form of double and triple bonds. Unlike a single bond, which is more stable, the unsaturated bonds are more susceptible to chemical attack and/or additional cross-linking. The unsaturation is why temperature, H₂S, and some chemicals limit NBRs. To decrease the amount of unsaturated bonds, the nitrile polymer is put through a hydrogenation process, which makes it more stable. The resulting elastomer is *commonly referred to as a saturated nitrile or hydrogenated nitrile (HNBR)*. Mechanical properties are similar to a NBR, but the big advantage is in the increased heat resistance, 125°C (257°F), and improved tolerance to chemicals and H₂S. HNBR elastomers are difficult to mold and typically cost four times as much for an equivalent volume of NBR.

Fluoroelastomers (FKM)—Trade Name VITON Fluorine is used to saturate the carbon bond. The carbon fluorine bond is extremely strong, which gives it superior heat and chemical resistance to NBR elastomers. FKM elastomers contain low level of fillers and additives but a high amount of fluoro-polymer. The low level of fillers and additives results in extremely poor mechanical properties.

FKM elastomers (VITON) have minimal fluid swell with most oilfield fluids, including aromatics, and have the potential to be used in temperatures up to 200°C (400°F). They have been somewhat successful in light oil applications as long as the pump is not subjected to excessive mechanical loading. FKM is extremely hard to mold, and the costs can be several hundred times that compared to that of NBR, making it uneconomical in most applications (Table 6.4.22).

TABLE 6.4.22 General Elastomer Selection Guide

Characteristics	Elastomer Type			
	Buna	High Nitrile	Hydrogenated	Viton
Mechanical Properties	<i>Excellent</i>	<i>Good</i>	<i>Good</i>	<i>Poor</i>
Abrasive Resistance	<i>Very Good</i>	<i>Good</i>	<i>Good</i>	<i>Poor</i>
Aromatic Resistance	<i>Good</i>	<i>Very Good</i>	<i>Good</i>	<i>Excellent</i>
H ₂ S Resistance	<i>Good</i>	<i>Good</i>	<i>Excellent</i>	<i>Excellent</i>
Water Resistance	<i>Very Good</i>	<i>Good</i>	<i>Excellent</i>	<i>Excellent</i>
Temperature Limit**	95C (203°F)	95C (203°F)	135°C (275°F)	150°C (302°F)

**The internal operating temperature of the pump due to the friction heat generated by the rotor/stator interference fit can be significantly higher than the reservoir fluid temperature.

6.4.6.3.1 Produced Fluid and Wellbore Effects on Elastomers

All most all fluids produced through the pump to some degree will impact the pump performance and mechanical properties. Elevated temperatures and exposure to some chemicals, such as amine-based corrosion inhibitors, also impact the elastomer.

The most common effects that we see occur to elastomers when exposed to the above environments are:

- Swelling
- Softening
- Shrinkage
- Hardening
- Blistering

Fluid and Gas Swell

The elastomer is a permeable membrane and is therefore susceptible to absorption of fluid and gas by a diffusion process that results in overall increase in mass and volume. Fluid absorption will continue until equilibrium between the produced fluid and elastomer is achieved. Depending on the fluid properties and wellbore conditions, this can occur in weeks to years. In some cases the absorption rate is so slow that equilibrium may not be reached within the pump's life. Fluid swell typically results in the deterioration of the elastomers mechanical and chemical properties.

Oilfield fluids that commonly cause swell are:

- Higher API gravity oils that contain single-ring aromatics (i.e., benzene, toluene, xylene).
- Water
- Gas
- Chemicals (i.e., amine-based corrosion inhibitors)

Elastomers that have high compatibility with a fluid will swell more than a fluid that is not compatible. Fluid compatibility varies depending on the type of elastomer. For example nonpolar fluids such as aromatics will swell lower in polar elastomers such as high nitrile NBR and swell higher in lower polar elastomers such as conventional NBR (Buna) elastomers.

Swelling can cause an excessively tight rotor/stator interference fit. A certain amount of torque is required to overcome the rotor/stator interference fit. In some cases, because of swelling, it is not uncommon to have the fit become so tight that the torque required to overcome the fit exceeds what is available with the surface drive configuration. A tight pump can cause accelerated hysteresis that may eventually result in a premature pump failure. Badly swollen stators can generally not be reused. However, if swelling is minor the stator can sometime be sized with a smaller rotor and reused. The internal operating temperature of the pump due to the friction heat generated by the rotor/stator interference fit can be significantly higher than the reservoir fluid temperature.

The amount of swell or expansion can be expressed as a percentage of the elastomer thickness with the thicker elastomer sections swelling comparatively more to thinner sections. Therefore the amount of change is dependent on the cross-sectional profile of the stator elastomer and since this profile is nonuniform the resultant swell or expansion is also non-uniform. The altered stator geometry will result in lower pump volumetric efficiencies, [Figure 6.4.76a](#). [Figure 6.4.76b](#) is an example of a uniform-thickness pump. Having a uniform elastomer thickness means the elastomer also swells or expands in a uniform fashion. Properly sizing the rotor for aggressive applications is therefore much simpler.

Softening

Certain fluids that attack the chemical make-up of the elastomer will breakdown some of the mechanical properties, which results in softening of the elastomer. Amine-based corrosion inhibitors are a good example of a chemical that will cause severe softening of an elastomer.

Hardening

Heat, pressure, time, and curatives such as sulphur are used in the manufacturing vulcanization process of the elastomer. As an oilfield wellbore can typically have all of the above, it is not uncommon to see the elastomer hardness increase over time in any particular application. However, wells that contain a high mole% of H_2S may aggressively advance vulcanize the elastomer. As the elastomer hardens, it becomes more prone to fatigue and flex cracking—type

FIGURE 6.4.76a Altered stator geometry.

FIGURE 6.4.76b Wellbore effects on elastomers — softening & hardening.

failures due to the deterioration of these particular mechanical properties. HNBR elastomers have been formulated to reduce the effects of H₂S.

Shrinkage

Lower-molecular-weight paraffin (C₃–C₃₀) can extract plasticizers from NBR elastomers, which will cause an overall reduction in elastomer volume. Shrinkage will reduce the rotor/stator interference, resulting in a reduction in pump volumetric efficiency. Wells that generally exhibit waxing problems correlate with elastomer shrinkage. Extraction of the plasticizers results in a deterioration of the elastomer's mechanical properties.

Thermal Swell

Heat causes overall expansion. Operating at elevated temperatures will result in advanced vulcanization and the deterioration of the elastomer's mechanical properties such as *tear strength*.

Gas Swell

The amount of gas that can enter the elastomer is dependent on the permeation rate, diffusion process, and solubility of the gas in the elastomer. The diffusion process is governed by temperature, pressure differential, and elastomer thickness. The higher the diffusivity rate, the easier it is for gas to move in and out of the elastomer. The permeation rate is determined mainly by the gas size, shape, and polarity. Solubility determines the quantity of gas that will absorb into the elastomer. Gas solubility increases as the molecular weight of the gas increases; i.e., CO₂ and H₂S have higher molecular weight than methane and therefore are more soluble.

Explosive Decompression

When an elastomeric compound is exposed to high pressure for a period sufficient for gas molecules to diffuse into the compound, a subsequent rapid reduction in pressure can cause internal fracturing of the rubber. Internal fracturing may be in the form of cracks or blisters. This phenomenon is known as *explosive decompression (ED)*.

ED is the result of a three-stage process:

- *Stage One*, gas diffusion into the elastomer.

- *Stage Two*, the migration of gas molecules, immediately after decompression, to *areas of flow energy state (LES)* within the elastomer.
- *Stage Three*, is crack growth and subsequent blister formation in the *areas of LES*.

For blister growth the *critical pressure* inside the gas bubble must be at or above the *fracture or tearing strength* of the elastomer. The critical pressure required for crack growth or blistering increases with the square root of the elastic modulus and critical tear strength of the material.

As the distance below the surface of the elastomer increases, the critical pressure required to initiate crack or blister growth increases. This would mean that you would expect to see less damage toward the center of the material than at the surface; however, the opposite is the normal. Observations of failed pieces often show that ED damage is generally greater in the thicker sections. This is explained by the ability of the gas molecules to easily diffuse out of thin sections of elastomer or the surface layer as opposed to migrating out from thicker sections.

6.4.6.3.2 Other Effects on Elastomers

Gas Temperature

At higher temperatures gas solubility and diffusion coefficients change to increase the rate at which gas can escape from the elastomer. However there is a counterbalancing effect offset by the decrease in the elastomer *tear strength* with increasing temperature. Depending on the elastomer the net effect of ED in higher temperature applications could be less.

Gas Pressure

Gas pressure correlates directly to the pressure within the *areas of LES*. Therefore the higher the operating pressures of the PC pump the greater the gas pressure within the *areas of LES*. Higher gas pressure will create more energy for crack and blister growth.

Effects of CO₂

When exposed to a gas, most PC pump elastomers will become saturated with that gas resulting in a volumetric increase in the elastomer. The solubility of gas in the elastomer increases with the molecular weight of the gas,

temperature, polarity, and differential pressure. The diffusion rate is influenced by its size, shape, and polarity. The more complex the size and shape the lower the diffusion rate will be.

As the temperature and pressure of an application increases the time required for a gas to reach equilibrium within the elastomer decreases.

If we compare CO₂ to methane (CH₄) and CO₂ molecule has a greater molecular weight and polarity as well as a more complex molecular size and shape. Therefore, CO₂ will have a lower diffusion rate but will be more soluble than methane. The result of this is that CO₂ will take longer to diffuse into the elastomer; however, the solubility will be greater, resulting in higher volumetric swell. The impact of this is that when a rapid pressure drop occurs across the pump (*i.e., due to pump stoppage resulting in a fluid dump scenario or when the pump is retrieved to surface*), it will take longer for the CO₂ to diffuse out of the elastomer than methane. This is supported by observations on dissected pumps, with similar well conditions, in which the observed ED damage to the elastomer was more catastrophic when the gas mixture contained CO₂.

The resulting rapid reduction in pressure causes the gas trapped inside the elastomer to expand at a tremendous rate, which results in severe swelling, cracking and blistering. A small decrease in pressure results in a significant increase in gas volume. This does not mean that the gas within the elastomer will occupy this volume. Factors such as the elastomer thickness and mechanical properties work as a closed vessel to restrict the expansion of gas. As noted previously in order for crack or blister growth to occur the *critical pressure* within the *areas of LES* must exceed the *fracture or tear strength* of the elastomer.

Minimizing the Effects of Explosive Decompression

The degree of damage sustained to an elastomer as a result of ED is governed by several conditions:

1. Pressure drop across the elastomer face
2. Free gas production through the pump
3. Time take for the reduction in pressure to occur
4. Concentration of gas within the elastomer
5. Tear energy of the elastomer
6. Mechanical properties of the elastomer

A PC pumping system designed to address the effect of CO₂ on the elastomer has the potential to significantly reduce the impact of ED. Design criteria that should be considered, as they pertain to the aforementioned conditions, for CO₂ applications are:

6.4.6.4 Drive Heads

Progressing cavity pumping systems are extremely flexible in terms of their ability to work in diverse range of applications. However, their success in a particular application

requires that the pumping equipment be properly matched to the well conditions and operating environment. Because PC pumping systems function in an integrated manner, it is also important that the individual pieces of equipment are configured so that they operate together effectively as a system.

When purchasing a PC pumping unit, the design considerations play an important role in the safe operations of the unit. The application designer must establish the maximum surface loading and ensure the equipment being purchased will operate within its maximum limit. To choose the best drive for the application the following should be considered:

- Depth of well
- Fluid level
- Pump size
- Size of sucker and polished rod
- Operating torque
- Speed range
- Prime mover (electric or gas driven motor or engine)

The loading or work done by a PC pumping system is primarily determined by the following:

- Pump take pressure
- Pump discharge pressure
- Rod string/tubing friction
- Internal pump friction

Several other factors influence these parameters and they usually change throughout the life of an oil well.

Other factors may include:

- Fluid contaminants
- Pressure, volume, temperature properties the production medium, reservoir characteristics, tubing roughness
- Side wall stress as a result of tubing/rod contact
- Tubing and casing pressure fluctuations
- Interference pump fit between rotor/stator

Computer aided software tools are available to help determine these factors. Calculations must be made before purchasing a unit. When predicting load limits, a safety factor of at least 10% should be considered to account for error associated with the reliability of assumptions or the accuracy of mathematical correlations.

Operating loads may change through the operating cycle life.

After the initial start up, actual operating loads should be confirmed to verify design expectations. If the system loading exceeds the design, changes to operating parameters or equipment are necessary. Control devices that will protect the unsupervised system and provide the operator with an indication of equipment condition are equally important. The PC drive systems could include instrumentation to monitor and control the following: braking mechanism tem-

perature, backspin speed, operating torque, and hydraulic fluid levels.

The following items are recommended best practices outlined to reduce hazards while working around PC pumping equipment. Production personnel should consider:

- All new installations require a design input data sheet be filled out, ensuring that a qualified person within the producing company has reviewed the design of the unit being installed.
- A file should be maintained for each PC pump system in the field. The file should include the following information:

1. Equipment Specifications

Equipment specifications should include the maximum allowable: forward speed, backspin speed, drive head fluid temperature, hydraulic fluid levels, pressures, braking mechanism temperature, horsepower/torque, thrust loading, and motor fan speed. It should also include the power factor and motor efficiency, nameplate volt/amps, and motor speed.

2. Sheave and Belt Information

Sheave dimensions, belt types and sizes, maximum-rated sheave rpm.

3. Sizing Data

Normal operating horsepower at the motor, start-up horsepower requirements and torque, normal operating torques and operating speed, production volumes, bottomhole flowing pressure, static reservoir pressure, maximum tubing head pressure, and thrust loading.

4. Commissioning/Start-up Measurements

Start-up values at design speed such as: starting volts/amps, running volt/amps, calculated starting and running horsepower and torque, forward and backspin rpm hydraulic fluid level, braking mechanism temperature, production volumes, annular fluid level data, and polished rod stock up amount.

5. Limit Set Points-Control Devices (if applicable)

Shut down settings for the following: hydraulic drive head fluid levels, maximum braking temperature, backspin speed, forward speed, running torque, start-up torque, and low torque shutdown.

6. Equipment/Operating Changes

A list of any changes to operating parameters or equipment. After changes are made, the operator must ensure the system is still operating within the design parameters.

- The operator must ensure that the equipment is operating within its design after every PC work over.
- The production operator should review the design predictives to ensure the equipment will operate within the calculated parameters.

- The operator must be familiar with the limit shutdowns for the equipment. The operator can refer to the operator's manual for those maximum limit values.
- The actual loads should be checked at least every 6 months to ensure the operating loads fall within the design parameters.
- For right angle drive assemblies, the drive assembly should be installed perpendicular to the control panel to ensure that in the event of a sheave failure, debris would be deflected away from personnel standing at the control panel. Caution must also be used in the placement of other equipment on the lease, to ensure that a sheave failure would not adversely effect other equipment or personnel.

6.4.6.5 Hydraulic Drives and Power Units

Progressing cavity pumps are often driven by hydraulic drive systems. Hydraulic drives and power units are particularly used when variable speed is required. Also, with gas engine as the prime mover, electrical power is not required on site. All hydraulic power units featured automatic torque control and recoil as standard features.

The hydraulic power unit, or ‘skid’ powers the hydraulic drive head. The skid has a prime mover, which drives a hydraulic pump. Fluid flows from the pump then drives the hydraulic motor on the drive head, which in turn drives the rod string.

When a well is shut down, the rods release torsional energy stored in them, and fluid may drain through the pump, turning the rods in reverse. There is potential for the rods to spin back at a high rate of speed, causing a safety hazard if spinning parts (sheaves, for example) should fail. The backspin may also cause damage to the hydraulic motor.

A backspin retarder is generally built into every hydraulic power unit system. A check valve is in the hydraulic lines on the pressure side of the motor. When the drive is turning in the forward direction, the check valve is forced open by the fluid flowing into the motor. When the drive spins in reverse, the check valve is forced closed and drains the fluid at a slow controlled rate of speed. In order to ensure that there is no loss of suction in the motor, the backspin speed is very slow (Figure 6.4.77).

6.4.6.5.1 Right-Angle Drive

Right-angle drives typically will have an internal gear reduction system. Although not limited to them, the most common internal gear ratios are 2:1 and 5:1. This allows the drive to operate at lower speeds. The limitation with this style of drive is typically in the amount of torque that can be

HYDRAULIC DRIVE HEAD and POWER UNIT (GAS PRIME MOVER)

FIGURE 6.4.77 Drive heads.

transmitted through the pinion gears and as such the drive is generally delegated to lower horsepower applications.

By design, the right-angle drive can be driven by a gas engine and therefore is a popular option for applications in which the well site is not electrified motor.

6.4.6.5.2 Direct Drive

Direct drives generally do not incorporate any type of internal gear reduction. Power transmission and speed control is accomplished directly through a set of belts and sheaves connected to the motor.

6.4.6.5.3 Recoil Control

Rod string backspin occurs whenever a surface driven PC pumping system shuts down due to either routine operator intervention or automatic power cut-off in overload cases in which the pump seizes or sands up. When the power supply to the drive is lost or interrupted, the torsional strain and fluid energy that is stored in the production system during pumping is released. The release of this energy will cause the surface equipment and drive string to accelerate in the direction opposite to its normal operating mode. If not suitably restrained by the surface drive braking equipment, backspin speeds can increase to the point where severe equipment damage results. The most serious type of incident (due to its potential to cause personnel injury) is the fragmentation and subsequent “explosion” radially outward of drive head sheaves.

Backspin events can be divided into two different types: (1) routine shutdown of the pumping system (i.e., normal shutdown), and (2) when the pump rotor seizes within the stator (i.e., seized pump scenario). In a normal shutdown, the fluids in the production tubing drains back to the well through the pump causing both the pump and drive system to rotate backward. This continues until the fluid column in the annulus and the pump friction balance the fluid energy in the tubing. This can take anywhere from several minutes to hours depending on the circumstances. Although the recoil event resulting from a normal shutdown can result in equipment damage due to excessive energy input, there is usually limited potential for a catastrophic failure as long as the brake is initially functional. More likely to produce a catastrophic failure is the seized pump scenario. In the instance, shutdown occurs with the drive string is usually loaded to an extremely high torque. Strain energy (twists) stored in the drive string tends to be released rapidly resulting in a short but high-speed recoil.

There are five major types of recoil devices used in progressing cavity pumping systems.

1. Disc brake
2. Fixed orifice
3. Centrifugal

4. Vane
5. Hydro-dynamic

Disc Brake

Features a hydraulic braking system like on vehicle, which consists of a pump, manifold and a disk brake. The self-powered braking system engages when the rod string begins to run in the reverse direction. A belt connects the main shaft (rod string) with the hydraulic pump, which produces pressure that activates the caliper or brake pads. The pressure of the system proportionately varies with the speed of the main shaft therefore adjusting the braking force (Figure 6.4.78).

Fixed Orifice

In hydraulic systems, the hydraulic motor at the wellhead will force the hydraulic fluid backwards through the system when the rods recoil. A check valve is in the hydraulic lines on the pressure side of the motor. When the drive is turning in the forward direction, the check valve is forced open by fluid flowing into the motor. When the drive spins in reverse, the check valve is forced closed and drains the fluid at a slow rate of speed (Figure 6.4.79).

Centrifugal

The technology used is similar to that of a drum brake except that centrifugal force, created during backspin, assisted by the mechanical design of a clutch is used to throw brake shoes against a stationary housing. Because the braking system relies on centrifugal force the braking mechanism will not activate until the polished rod speed reaches a specified speed. An example of this is the Weatherford MG drive head, and once an approximate speed of 250 rpm is reached, centrifugal force overcomes the spring tension and braking is activated. In turn, once the speed of the brake is reduced to a speed of under the approximated 250 rpm, the spring tension retracts the brake shoes and the drive is allowed to spin with out a brake unless the speed returns to approximately 250 rpm (Figure 6.4.80).

Vane

Drive head braking resistance is developed using a vane style hydraulic pump that is activated in the recoil or shutdown mode through a normally overrunning clutch. Clutch engagement occurs during backspin as a result of rollers in the outer portion of the clutch locking onto an inner clutch hub that is located on the drive head shaft. Engagement of the clutch causes the vane pump rotor within the drive head to rotate with in its housing. Rotation of the rotor produces braking torque by forcing the drive head lubricant oil through a restriction. Baking torque generated in the vane style pump is transferred from the rotor through the clutch and into the drive shaft and polished rod.

The brake torque generated is proportional to the pumping speed (i.e., recoil speed) and changes as a function of the lubricating oil viscosity and the nature of the restriction. The restriction occurs between the upper and lower sealing

FIGURE 6.4.78 Disc brake.

FIGURE 6.4.79 Fixed orifice.

surfaces on the rotating vane pump rotor and the stationary bottom rotor housing and upper thrust plate (Figure 6.4.81).

Hydrodynamic

Much like the torque converter in a vehicle, braking is accomplished by forcing vanes to rotate within a viscous fluid.

Safe Operation of Wellhead Drives

When undergoing a controlled or uncontrolled shut down of a progressing cavity pumping system, it is critical to understand the recoil speed, if left unrestricted, can exceed the surface drive component (brake/belts/sheaves) ratings and cause that component to fail. The worst type of failure from a personal safety standpoint is to exceed the rim speed of the sheaves causing the sheave to explode.

FIGURE 6.4.80 Centrifugal.

Remember that the recoil control unit of any surface drive should be considered as a safety device to control the release of torque from the rod string during shut down, but it is not the only means of safe operation. For improved overall safety in operation and shut down of progressing cavity surface drive systems, the following steps should be considered.

Properly designed surface equipment

- Do not exceed manufacturers recommended specifications for torque and speed ratings
- Design the belts and sheaves for the prime mover horsepower using correct safety factors.
- Use sheaves that are in new condition only.
- Use a straight polished rod with minimum stick up.
- Use PC pump polished rod clamps only (not conventional clamps).

Improved stability of the surface drive in higher torque/speed applications.

- Flange mount drives.

Limit the input torque to the polished rod.

- Maximum torque should not exceed the surface drive ratings.
- Maximum torque generated by an electric motor can be as high as 250% of the rated torque so a high amp shut down must be properly set.

- Maximum torque should not exceed the torque rating of the sucker rod string.

History shows that throughout the industry most of the serious incidents with any PC pump drive heads have occurred when the pump is seized downhole and PC pumping system has been torqued up in an attempt to free the pump. In a direct electric application, this input torque is typically limited only by the maximum horsepower the motor can deliver and the rod strings ability to transmit torque down to the pump. Unknown to most operators is the fact that all electric motors have the ability to deliver over 250% of the full load nameplate horsepower. This potential applied torque can far exceed the published structural and braking limits of the drive head.

In new installations, the best way to limit the maximum torque input is to restrict the motor size and sheave ratio in order to limit the maximum torque that can potentially be applied. Under certain circumstances, the potential exists for a recoil event to occur where the stored energy in the rod string and the fluid column may be greater than the drive head is designed to control.

This potential is based on the sheave ratio and the connected horsepower in direct electric motor applications and ability of the drive head recoil control device to safely handle the recoil.

6.4.6.6 Belt and Sheave Selection Considerations

A variety of sizes, styles and lengths of belts and sheaves are available. Due to the numerous alternatives and complexity of selecting the correct belts and sheaves it is recommended that the procedure in a power transmission products manual be followed. The following is a simplistic example of the steps necessary to select the right belt and sheave combination for your application:

6.4.6.6.1 Determine the Size and Speed of Electric Motor

- Estimate the desired polished rod speed and maximum torque the system will operate under. Example — Desired speed of 200 rpm and a maximum torque of 900 ft.lbs.
- From Table 6.0.1 — Torque/Horsepower/Speed Relationships, select the electric motor that best meets the desired speed and torque.
- According to the table, a 40-hp, 1200-rpm, 460-V, 60-hz, three-phase motor produces 175 ft.lbs of torque at full load ratings. To develop a polished rod speed of 200 rpm a 6:1 sheave ratio is required (1200/200). This assumes a 1:1 drive ratio drive. With a 6:1 sheave ratio; 1050 ft.lbs (175 × 6) of torque can be applied to the polished rod (assuming the belts and sheave will transfer it). Torque will vary with changes to line voltage, line current, and

FIGURE 6.4.81 Vane.

line frequency. With the addition of a variable frequency drive (VFD), motor speeds can be increased 50%, and then the maximum polished rod speed becomes 300 rpm in this example. Note that motor torque decreases as motor frequency increases above rated speed.

6.4.6.6.2 Sheave Selection

- Sheaves are made with either cast iron or ductile iron. Cast iron has a maximum sheave rim velocity of 65,000 ft./min. Depending on the situation; recoil speeds in excess of this can be reached. A spoked wheel ductile iron sheave is rated for a maximum speed of 10,000 ft./min and a solid wheel ductile sheave for 15,000 ft./min.

6.4.6.6.3 Belt Selection

- There are various styles and sizes of V belts available for PC pumping systems. These include:

- classical, sizes “A,” “B,” “C,” and “D”
- narrow, sizes “3V,” “5V,” and “8V”
- joint or banded
- wrapped
- cogged

In this example, with a small driver sheave of “the amount of” “rubber on the sheave” is limited and a cogged belt with transfer more power than the other styles.

- Using a Power Transmission Products Manual the horsepower each belt transfers can be determined; and knowing the Horsepower requirements, calculating the number of belts is simple. Ensure that the combined horsepower rating of all the V belts exceeds the design horsepower of the system.
- If the amount of power transferred by V belts is a concern than a high torque drive (HTD) belt and corresponding sprockets are recommended. This combination provides a positive slip-proof engagement when the belt teeth mesh with the sprocket grooves.

6.4.6.7 Installation Procedures

The procedures listed below are intended to form a basic framework for a typical installation of a progressing cavity pumping systems. Special applications or equipment may necessitate changes in these procedures. In these cases, a technical representative can provide assistance in formulating modified installation procedures.

6.4.6.7.1 Preinstallation Procedures

1. Clean out the well, removing any solid (e.g., sand, coal fines) build-up in the bottom of the wellbore. It is recommended that a minimum of 2 or 3 m below the pump be clear. Solids build-up should also be at least 2m below the bottom of the perforations.
2. Ensure all proper crossovers and changeovers are on location to attach the stator to the tubing string and the rotor to the rod string. It is recommended that swages be avoided due to their restricted drift and potential for thread failure.
3. Ensure that various lengths of the appropriate size pony rods are available to allow proper space out of the rotor and polish rod.
4. If a pump seating nipple (PSN) is going to be used, verify clearance against the major diameter of the rotor. Information for *Weatherford pumps* provided in Table 7.1.1 (Recommended Pup-Joint and Pony rod Connection) can assist with this.
5. The rotor and stator are matched for optimum pump efficiency in a particular application. Ensure the rotor serial number located on the rotor head (top) corresponds with the last set of numbers on the stator.
6. Measure the distance between the top of the tag bar pin and the bottom of the elastomer. This is required for the space out procedures described in “Space-out Guidelines.”

6.4.6.7.2 Stator Installation Procedures

1. Attach any accessories (i.e., gas anchor, no-turn tool, tail joint) to bottom of the stator.
2. Attach stator to first tubing joint with appropriate fittings. Depending on the pump model being used, it may be convenient to attach a pup joint directly on top of the stator to reduce the assembly length and simplify handling. If the production tubing is of smaller diameter than the pump stator, run larger diameter tubing above the pump and then use a crossover to down size. It is recommended that any down size in tubing be done at least 1.2 m (4 ft.) above the stator. Failure to do this may restrict the eccentric rotor movement and produce fatigue failures in the rod string directly above the pump.
3. Run in the production tubing keeping an accurate tally including the stator and fittings. Ensure that all connections are cleaned, inspected, doped and torqued to

optimum levels according the guidelines in API RP5C1 (“Recommended Practice for Care and Use of Casing, Tubing and Drill Pipe”). Recommended tubing make-up torque is included for common sizes and grades of tubing in Table 6.4.23 — Suggested Torque Make-up for Tubing. The stator should be considered as equivalent to Grade J55 tubing. Proper makeup is critical because the rotor normally rotates clockwise in the stator, which tends to loosen improperly tightened tubing connections. Make sure the backup wrench is on the tubing below the collar.

4. Positioning of the pump intake is critical to ensure optimal pump performance and life. The most suitable pump location is dependent on the nature of the application. In most cases, the pump should be positioned with its intake near or below the bottom the perforations to facilitate natural separation of the gas from the produced fluid. However, in wells producing significant quantities of sand, it may be preferable to locate the pump above the perforations to limit problems with sanding equipment in. For unique applications, a technical representative can provide detailed pump landing recommendations on an individual application basis. Note that except in special circumstances, the use of extended length tail joints is not recommended.

6.4.6.7.3 Rotor Installation Procedures

1. Count out the number of rods required to equal the total tubing tally plus one extra rod to ensure sufficient length of rod string. Be sure to include the length of the rotor. Check all rods for evidence of damage, wear, and corrosion. It is recommended that rods that are permanently deformed (i.e., yielded) due to excessive torque not be used in applications with high loads or fluctuating loads. Use API RP11BR Section 6 (“Recommended Practice for Care and Handling of Sucker Rods”) as a guide to grade the rod. Replace all suspect or substandard rods.
2. Care should be taken while handling the rotor on surface to avoid damaging the pin threads or the finished surface. The rotor should be supported in a manner as to prevent excessive bending that may cause permanent damage.
3. Liberally apply grease over the full length of the rotor to provide initial lubrication. Attach the rotor to the first sucker rod. A transition coupling may be required if the rotor pin and sucker rod threads are not the same size. It is recommended that one standard rod without guides (i.e., 7.6 m (25 ft.)) be placed above the pump rotor before any pony rods are added to the string. This is because the positioning of large centralizers or guides a short distance above the pump may restrict the orbital motion of the rotor causing damage to the pump. *If pony rods are required directly above the rotor they should be limited to a 0.3 m (1 ft.) machined pony rod.*

TABLE 6.4.23 Suggested Make-up Torque For Tubing

Size		Weight		Grade	Makeup Torque	
SI	Imperial	SI	Imperial		SI	Imperial
60.3 mm	2375 in	7.0 kg/m	4.7 lbs/ft	H40	1340 N·m	990 ft·lbs

114.3 mm	4500 in	19.0 kg/m	12.8 lbs/ft	L80	5340 N·m	3940 ft·lbs
114.3 mm	4500 in	19.0 kg/m	12.8 lbs/ft	N80	5450 N·m	4020 ft·lbs
114.3 mm	4500 in	19.0 kg/m	12.8 lbs/ft	C90	5870 N·m	4330 ft·lbs

4. Run in all but the last few sucker rods making them up as outlined in API RP 11BR Section 5 (“Recommended Practice for Care and Handling of Sucker Rods”). Note that it is essential that each connection is made up to its recommended torque during installation because tightening under loading damages the connection and may result in a premature failure. It is recommended that if significant sand production is anticipated, a shear be installed at least two full sucker rod lengths above the rotor to facilitate rod string removal in the event of a sanded pump. It is also good practice to record details of the rod string configuration, especially when different types of rod centralizers and rod guides are being used.
8. Remove enough of the sucker rods to make room for the polish rod. The difference between the sucker rod removed versus the length of polish rod added must be made up with pony rods. It is recommended that the polish rod be long enough to allow the rotor to be pulled totally out of the stator without removing the surface equipment. Not only is this important to allow a proper flush-by procedure, but it is also a safety consideration in well servicing operations.

6.4.6.8 Space Out Guidelines

1. Record the weight of the rod string before to running the last few sucker rods.
2. Continue to run the remaining sucker rods taking care to lower them very slowly to avoid damaging the stator elastomer. The rod string will normally rotate as the rotor enters the stator.
3. Continue to lower the rod string until the rotor comes to rest on the tag bar at the bottom of the stator. This bottoming out will be indicated by a reduction in rod weight to near zero. Pull up and lower the rotor again to reconfirm that it is positioned on the tag bar.
4. With the rotor landed on the tag bar, pull up slowly on the rod string until full rod weight (measured in step 1 above) is restored. At this point all slack is taken out of the rod string and the rotor is slightly above the tag bar.
5. Lift the rod string the distance from the tag bar to the bottom of the stator rubber. This tag bar distance was measured in step 6 under “Stator Installation Procedures.”

The space-out procedures also need to compensate for rod stretch due to pump loading. This distance can be obtained from the manufacturer.

To accommodate for rod stretch during operation the rods should be lifted up by the amount determined above. Note that in some cases it may be necessary to space-out an incremental amount to account for thermal expansion of the rod string.

6. The rotor is now correctly landed in the stator and the length of the sucker rods in the hole must be adjusted to allow for the polish rod. The rotor should now be in the operating position. Do not lift the rotor from this position. Landing with least amount of rotor sticking out of the stator minimizes downhole vibration.
7. Measure the height of the drive head and add the length of the drive assembly to the operating position. This becomes the clamping point. Allow an additional 6 in. to 12 in. for polish rod stick up above the clamping point.

9. Attach the polish rod to the top pony rod using a polish rod coupling. To ensure proper sealing of the stuffing box, it is critical that the polish rod is straight and does not have significant wear or corrosion. It is recommended that the polish rod not be used to move or lift the drive head because of the potential to cause permanent bending of the polish rod. DO NOT leave wrench marks on the polish rod.
10. Confirm the pump space-out (steps 3 to 7 above) with the modified string configuration. The *target* mark should be within 15 cm (6 in.) of the top of the polish rod. If it is not, make the necessary adjustments to the pony rod lengths. When properly positioned, install a clamp on the polish rod adjacent to the top of the flow tee. It is also recommended that any pony rods be buried at least two full sucker rod lengths down the rod string to prevent surface vibration problems.

6.4.6.9 Safety Warning

Polished rod stick-up of more than 46 cm (18 in.) above the top of the drive clamp can cause severe damage during recoil.

6.5 STIMULATION AND REMEDIAL OPERATIONS

Section reviewed by Carl Montgomery and Michael B. Smith

Reservoir stimulation deals with well productivity, and a successful stimulation treatment requires the accurate identification of the parameters controlling the well production. As a result, causes of impaired production must be identified. Furthermore, it must be determined whether or not a particular treatment can improve production. This is the very first step of the stimulation job design.

Darcy's law in its simplest form is adequate to study the issue. For oil, a familiar expression (for steady-state and in a radial reservoir) is written as

$$q = \frac{kh(p_e - p_{wf})}{141.2 B\mu(\ln r_e/r_w + s)} \quad (6.5.1)$$

- where q = well flowrate (STB/d)
 k = reservoir permeability in md
 h = reservoir thickness in ft.
 p_e = outer boundary reservoir pressure in psi
 p_{wf} = flowing bottomhole pressure in psi
 B = formation volume factor in resbbl/STB
 μ = fluid viscosity in cp

- r_e = equivalent drainage radius in ft.
 r_w = well radius in ft.
 s = skin effect

Each of the variables on the right-hand side of Equation 6.5.1 affects well productivity, and certain actions may favorably change its impact. Of particular interest to the stimulation engineer are the permeability and the skin effect. Both of these variables may be obtained from a pretreatment pressure transient test. Ignorance of these two variables would result in an inappropriate or less than optimum stimulation treatment; in addition, a posttreatment analysis and job evaluation would be impossible.

As can be easily seen from Equation 6.5.1, a low value of the permeability (tight reservoir) or a high value of the skin effect (damaged or badly completed well) would result in low well productivity. There is virtually nothing practical that can be done to the permeability, although certain investigators have erroneously suggested that hydraulic fracturing increases the effective reservoir permeability. A hydraulic fracture is a superimposed structure on a reservoir that remains largely undisturbed outside of the fracture. The fracture, however, can greatly improve the well productivity by creating a large contact surface between the well and the reservoir. The production improvement results from effectively increasing the wellbore radius.

Prats [72] proposed the idea of an “equivalent wellbore radius.” That is, there would be some artificial (equivalent) wellbore radius, r'_w , that would produce the same production as the fractured well.

As a first approximation to r'_w , one can simply equate the inflow surface areas.

$$\text{Wellbore Inflow Area} = 2\pi r_w h$$

$$\text{Fracture Inflow Area} = (2x_f)2h$$

$$\rightarrow r'_w = \frac{2}{\pi} x_f \approx 0.6x_f$$

However, simply equating inflow areas implies that the flowing pressure at the tip of the fracture is the same as at the wellbore, i.e., infinite conductivity. For finite conductivity, a relation between C_{FD} and r'_w is seen in Figure 6.5.1 [54].

Matrix stimulation is generally intended to reduce a large skin effect resulting from permeability damage around the wellbore during completion or production. Often, there is confusion in distinguishing matrix acidizing (a form of matrix stimulation) from acid fracturing. The latter requires that the treatment is done at formation fracturing pressure, and it relies on a residual *etched* width of the created fracture. The two methods of stimulation are applicable to entirely different types of formations: matrix acidizing is applied to high-permeability reservoirs, whereas acid fracturing is appropriate for low-permeability, acid-soluble reservoirs such as carbonates.

FIGURE 6.5.1 Equivalent wellbore radius, r'_w [54].

All stimulation practices adjust the skin effect, either by improving a negative component (fracturing) or by reducing a positive value caused by damage (matrix stimulation) [1].

6.5.1 Fracturing

Hydraulic fracturing of petroleum reservoirs was first introduced into the industry in 1947. The body of knowledge of fracturing as a reservoir stimulation treatment is a very active process with over 16,000 papers published on the subject.

A classic concept introduced in 1957 [2] concluded that fractures are “approximately perpendicular to the axis of least stress.” The stress field can be decomposed into three principal axes: a vertical and two horizontal, which are unequal. For most reservoirs the minimum stress is horizontal, resulting in vertical hydraulic fractures.

6.5.1.1 Stress Distribution

In a sedimentary environment, the vertical stress σ_v is equal to the weight of the overburden and can be calculated from

$$\sigma_v = \frac{1}{144} \int_0^H \rho \, dH \quad (6.5.2)$$

where ρ = density of each layer in lb/ft^3
 H = thickness of overburden in ft.

Equation 6.5.2 can be evaluated using a density log. In its absence, a value of 1.1 psi/ft . can be used as a reasonable approximation.

A porous medium, containing fluid, is subjected to an *effective* stress, rather than the absolute stress given by

Equation 6.5.2. The effective stress σ' is related to the pore pressure p by

$$\sigma' = \sigma - \alpha p \quad (6.5.3)$$

where α is Biot’s “poroelastic” constant and varies from 0 to 1. For most petroleum reservoirs, it is equal to 0.7. It is important that the concept of the effective stress is understood. An implication is that in a propped hydraulic fracture, the effective stress on the proppant is greatest during production ($p = p_{wf}$) and must be considered in the proppant selection.

Although the absolute and effective overburden stress can be computed via Equations 6.5.3 and 6.5.4, the two principal horizontal stresses are more complicated and their determination requires either field or laboratory measurements.

In a tectonically inactive formation, the elastic properties of the rock (Poisson ratio) may be used to relate the effective vertical stress with the effective minimum horizontal stress

$$\sigma'_{H,\min} = \frac{\nu}{1 - \nu} \sigma'_v \quad (6.5.4)$$

where ν = Poisson ratio.

For sandstone formations, the Poisson ratio is approximately equal to 0.25, leading to a value of $\sigma'_{H,\min}$ approximately equal to $\frac{1}{3} \sigma'_v$. For most shales the Poisson ratio is larger, leading to abrupt changes in the horizontal stress profile. This variation, which can envelope a sandstone reservoir because of overlaying and underlying shales, is the single most important reason for fracture height containment.

The horizontal in situ stresses can generally be written as

$$\sigma_H = K(\sigma_V - \beta p) + \beta p \pm T \quad (6.5.5)$$

with the stress due to a gravity component plus any added (subtracted) tectonic forces and cooling (subtracted) temperature effects [57]. Normally, the gravity component is the largest part of the in situ stress, and this is driven by three parts:

- **K**—This is a rock property ($\gamma =$ Poisson ratio) which may be approximately determined from calibrated shear wave sonic logs. For porous, permeable formations, it is typically about 1/3 but can be as high as 2/3 for elastic shales and as low as 1/3 for very stiff limestones.
- **OB**—This is the weight of the overburden which (suitably corrected for water depth) seldom varies too much from 1.0 to 1.05 psi/ft (0.022 to 0.023 MPa/m).
- **p**—This is reservoir pressure, and thus, this becomes the first BIG unknown in fracturing. It is the largest unknown in terms of closure pressure, along with affecting many other factors such as fluid selection, fluid loss, post-frac clean-up considerations, etc.

6.5.1.2 Vertical versus Horizontal Fractures

Consider Figure 6.5.1. Graphed are the three principal stresses, σ_V , $\sigma_{H,\min}$, $\sigma_{H,\max}$. The first is given by Equation

6.5.2, whereas $\sigma_{H,\min}$ can be extracted from Equation 6.5.4. The maximum horizontal stress $\sigma_{H,\max}$ can be considered as equal to $\sigma_{H,\min}$ plus some tectonic component σ_{tec} . If the original ground surface remains in place, then $\sigma_{H,\min}$ is less than σ_V , leading always to a vertical fracture which would be perpendicular to $\sigma_{H,\min}$. However, if the present ground surface has been the result of massive glaciation and erosion, as depicted in Figure 6.5.2, the overburden is reduced. Because the horizontal stresses are “locked” in place, there exists a critical depth, shallower of which the minimum horizontal stress is no longer the minimum stress. In such a case, a horizontal fracture will be created in the reservoir. This has been observed in a number of shallow reservoirs.

The definition of *principal* stress direction implies that all shear stresses vanish. Thus, when a vertical well is drilled, usually it coincides with a principal stress direction. This is not the case when a deviated or horizontal well is drilled (unless, in the latter case, the well is drilled in the direction of one of the principal horizontal stresses). However, for the mass of deviated wells that are drilled from platforms or drilling pads, their direction implies a nonvanishing shear stress [3]. The implications for fracturing are substantial. A deviated well requires a higher fracture initiation pressure. Furthermore, the production performance of a fractured deviated well is impaired. This point will be addressed in a later subsection.

FIGURE 6.5.2 Stress profiles (vertical and two horizontal stresses). Glaciation and erosion reduced the overburden, enabling a critical depth above which horizontal fractures may be generated. Below, only vertical fractures, normal to the minimum horizontal stress, are generated.

FIGURE 6.5.3 Wellbore “tension” for cases with σ_H -Max \gg σ_H -min.

The creation of a wellbore disturbs the in situ stresses and creates stress concentrations in the near wellbore region resulting in circumferential or hoop stress around the wellbore. Differential stress drives the wellbore into tension as shown in Figure 6.5.3. Fracture initiation occurs when the hoop stress equals the tensile strength of the rock and the fracture initiates parallel to the borehole and will orient to the far field stress field approximately 2.5 borehole radii away from the borehole [56,59].

6.5.1.3 Pressure Related to Fracturing

The pressure signature created during the pumping of a fracturing treatment, and the associated pressure decline after injection, contains a significant amount of information relating to the fracture itself as well as the reservoir where the fracture has been placed. Applying specialized analysis of pressure during the various stages of the fracturing process provides a powerful technique for developing a comprehensive understanding about this process. Analysis during pumping provides a qualitative indicator of fracture growth, as well as estimates of several primary fracture parameters. The analysis of pressure decline after pumping can be broken into two distinct periods, with the early period being dominated by pressure falloff that is related

FIGURE 6.5.4 Expected pressure response during a hydraulic fracture treatment [6].

to the fracture closing, whereas late time is governed by the transient pressure response of the reservoir. Figure 6.5.4 shows the pressure response during the three stages of fracture evolution: growth, closure, and afterclosure reservoir response.

Pressure measured during pumping provides an indication of the fracture growth process. The primary diagnostic tool for this period is the slope of the log-log plot of net pressure (i.e., the fracturing pressure above the reference closure pressure) versus pumping time. Figure 6.5.5 demonstrates how the slope of the log-log plot is used to characterize the fracture geometry.

The pressure response during fracture closure is governed largely by the rate of fluid loss. The analysis of pressure during this period estimates the fluid efficiency and the leakoff coefficient. These parameters are determined from a plot of the pressure decline versus a specialized function of time, commonly referred to as the *G*-plot. This specialized plot provides the fracturing analog to the Horner plot for well testing.

FIGURE 6.5.5 Interpretation of log-log plot fracture pressure slopes.

Interpretation of log-log plot fracture pressure slopes		
Propagation Type	Log-Log Slope	Interpretation
Ia	$-\frac{1}{2}$ to $-\frac{1}{3}$	Frac Height growing faster than length; KGD
Ib	$-\frac{1}{2}$ to $-\frac{1}{3}$	Frac Height growing faster than length; Radial
II	$\frac{1}{2}$ to $\frac{1}{4}$	Confined Frac Height. Length growing faster than height; PKN
III	Reduced from II	Controlled height growth Stress-sensitive fissure
IV	0	Height growth through pinch point Fissure dilation T-shaped fracture
V	≥ 1	Restricted extension
VI	Negative following IV	Uncontrolled height growth

Note: $n = 0.5$

The final fracturing pressure analysis pertains to the evaluation of pressure after fracture closure. The pressure response during this period loses its dependency on the mechanical response of an open fracture and is governed by the transient pressure response within the reservoir. This transient results from fluid loss during fracturing and can exhibit either linear flow or a long-term radial response. Each of these flow patterns can be addressed in a manner analogous to conventional well test analysis for a fixed-length conductive fracture. The afterclosure period characterizes the reservoir's production potential [67,68].

6.5.1.4 Breakdown Pressure (Fracture Initiation Pressure)

The fracture initiation pressure is estimated via Terzaghi's criterion [4], giving an upper bound for the value of the breakdown pressure p_b , such that

$$p_b = 3\sigma_{H,\min} - \sigma_{H,\max} + T_0 - p \quad (6.5.6)$$

where T_0 = tensile strength of the formation (psi)

Hence, hydraulic fracturing describes the tensile failure of the rock and Equation 6.5.6 can be used during a fracture calibration treatment to calculate the horizontal stress components.

6.5.1.5 Determination of Closure Pressure

Closure pressure is defined as the pressure when the fracture width becomes zero. In a homogenous reservoir and where $\sigma_{H,\min}$ is the smallest stress, the closure pressure is approximately equal to this value. Nolte [5, 6] pioneered the analysis of the pressure response during fracture calibration treatments and the calculation of important fracture variables.

The pressurization/pressure decline stages shown in Figure 6.5.4 can be refined and used in accordance with Nolte's analysis to calculate the closure pressure and, as will be shown in the next subsection, the leakoff coefficient and fracturing fluid efficiency. The closure pressure is not exactly the minimum horizontal stress. With very little fluid leakoff (i.e., not upsetting the pore pressure in Equation 6.5.3) and with a contained fracture height, the closure pressure is very near the minimum horizontal stress. Otherwise, the closure pressure is a bulk variable taking into account fluid leakoff and especially horizontal stress heterogeneities along the fracture area. If the injected fluid is minimized, then with both leakoff and fracture height migration also minimized, the closure pressure is approximately equal to the effective minimum horizontal stress.

The pump-in/flowback test, which can be done as the first peak in Figure 6.5.4, has been devised to allow for the estimation of the closure pressure. The test involves injecting fluid, normally treated water, at rates (e.g., 5 to

10 bpm) and volumes (e.g., 30 to 50 bbl) sufficient to create a fracture.

Of particular importance is the flowback period. This must be done at rates between $\frac{1}{3}$ and $\frac{1}{4}$ of the injection rate. The flowback rate must be held constant via a regulating valve exactly to prevent any flowrate transients to mask the pressure response. During this flowback period, the interpretation is qualitative and based on a deduction of the ongoing closure process and should have two distinctly different periods:

- while the fracture is closing
- after the fracture is closed

The pressure profile would then have two regions reflecting the two different phenomena. These two regions would be separated by a clear change in slope, and the pressure corresponding to this inflection point is the *fracture closure pressure*.

Another method for determining fracture closure pressure is called the "equilibrium test". This is an injection test similar to the conventional pump-in/shut-in/decline, with one exception: instead of shutting in the well, the fluid continues to be injected at a small rate, as illustrated in Fig. 6.5.6. The treating pressure will initially decline as in the conventional shut-in decline because the new injection rate will approach or even be less than the leak-off rate. The fracture volume and the pressure will decrease with time as more fluid leaks off than is injected. This will result in the fracture volume being sufficiently reduced, and therefore, the fracture length will recede as the fracture approaches closure. The leak-off rate will decrease with time, and eventually, the leak-off rate and the injection rate q become equal. At that time, the fracture volume will stop decreasing, and the wellbore pressure will flatten out and start increasing. The minimum pressure when rate equilibrium is reached will be called the *equilibrium pressure*.

FIGURE 6.5.6 Equilibrium test.

The equilibrium pressure P_{eq} is an upper bound of the closure pressure P_c . By subtracting the instantaneous pressure change at the final shut-in, ΔP_{si} , any remaining pressure relating to friction or tortuosity is removed. The corrected equilibrium pressure, $P_{eq} - \Delta P_{si}$, differs from closure pressure only by the net pressure in the fracture, which should be relatively small because the rate q is small and therefore provides a direct approximation of closure pressure.

For very soft, high-permeability formations that have high leakoff the use of a “pulse or rebound test” is used. Post-closure pulse testing requires that a moderate size data-fracture (usually 100 bbl) be pumped into the formation before pulse testing is attempted. Consequently, the smaller-volume pulse is pumped into a pre-existing fracture of greater dimensions than the pulse volume would normally generate on its own. Because the pulse fluid travels along the pre-existing fracture, this scenario is equivalent to creating a fracture in which, at the pulse’s tip, the rock toughness (K_{Ic}) and tensile strength (T_o) are both equal to zero. Thus, the fracture resistance at the pulse’s tip is negligible, and its small fluid volume can disperse down the pre-existing fracture length more rapidly than would otherwise be possible. This results in the fracture width being minimized, which, in combination with a low plane-strain modulus (E') of the rock, results in a negligible P_{net} . [73]. In this test a volume to low-viscosity fluid is injected at sufficient rates to inflate and propagate the fracture created during the data-frac. The pressure is then allowed to decline. Periodically the pressure is brought up again by injecting a small volume of fluid and allowed to rebound back to the pressure decline. If the fracture is open then the pressure will drop to the original decline curve and continue to decline as shown on the left side of Figure 6.5.7. If the fracture is closed then the pressure will drop back to the closure pressure and then return to the decline. In the example shown in Figure 6.5.7 the closure pressure is 600 psi surface pressure. To

determine closure the hydrostatic head must be added to this value.

6.5.1.6 Fracturing Pressure Decline Analysis

Castillo [8] extended Nolte’s techniques for pressure decline analysis. He introduced a time function $G(\Delta t_D)$, which, graphed against pressure during the closing period of the fracture calibration treatment, forms a straight line.

Figure 6.5.8 is a graphical depiction after Castillo [8]. First, the necessity of an independent determination of the closure pressure (e.g., through a pump-in/flowback test) becomes obvious. The closure pressure would mark the end of the straight line, an important point of concern when dealing with real field data. Castillo’s time function is given by

$$G(\Delta t_D) = \frac{16}{3\pi} \left[(1 + \Delta t_D)^{3/2} - \Delta t_D^{3/2} - 1 \right] \text{ (upper bound)} \tag{6.5.7}$$

A second expression, for lower bound, is given in Castillo [8]. The dimensionless time Δt_D is simply the ratio of the closing time Δt and the injection time t_p .

The slope of the straight line in Figure 6.5.8, m_p , is

$$m_p = \frac{\pi C_L r_p \sqrt{t_p}}{2c_f} \tag{6.5.8}$$

where C_L = leakoff coefficient in $\text{ft./min}^{1/2}$

r_p = ratio of the leakoff height (h_p) to the fracture height (h_f)

t_p = pumping time in min

c_f = fracture compliance in ft./psi

The fracture compliance is model dependent. The Perkins and Kern (PKN) model is given by

$$c_f = \frac{\pi \beta h_f}{2E'} \tag{6.5.9}$$

FIGURE 6.5.7 Example of a pulse test to determine closure.

FIGURE 6.5.8 Pressure decline analysis [8].

where

$$\beta = \frac{2n' + 2}{2n' + 3 + a} \quad (6.5.10)$$

and

$$E' = \frac{E}{1 - \nu^2} \quad (6.5.11)$$

(Fracturing models will be described later.)

In Equations 6.5.10 and 6.5.11

- n' = fluid power law exponent
- a = viscosity degradation coefficient (0, linear degradation; 1, zero viscosity at the tip)
- E = Young's modulus in psi
- ν = Poisson ratio

Nolte [6] contains all pertinent equations for fracturing pressure decline analysis.

Barree and Mukherjee (53) extended the techniques described above by utilizing a G-function derivative analysis to identify a leakoff type and provide a definitive indication of fracture-closure. The graphical technique requires

a graph of the bottomhole pressure, and the derivative of pressure (dp/dG) and the superposition derivative (Gdp/dG) versus the G-function. Craig et al. (55) provided a graphical representation which can be used to identify four common leakoff types. Figure 6.5.9 identifies the four types as normal, pressure-dependent leakoff (PDL), fracture-height recession and fracture-tip extension during shut-in.

Another important variable that can be extracted from pressure decline analysis is the fluid efficiency. The independently determined closure pressure identifies not only the end of the straight line in Figure 6.5.8 but also the fracture closure time, corresponding to Δt_{cD} . This dimensionless closure time can then be used with Figure 6.5.10 to estimate the fluid efficiency. This is a particularly important variable and allows the determination of the total fluid requirements and the ratio of "pad" volume to the proppant carrying fluid.

Recently Mayerhofer, Economides, and Nolte [9, 10] investigated the stress sensitivity of crosslinked polymer filtercakes in an effort to decouple the components of fracturing pressure decline. Fracturing fluid leakoff can be regarded as a linear flow from the fracture into the reservoir.

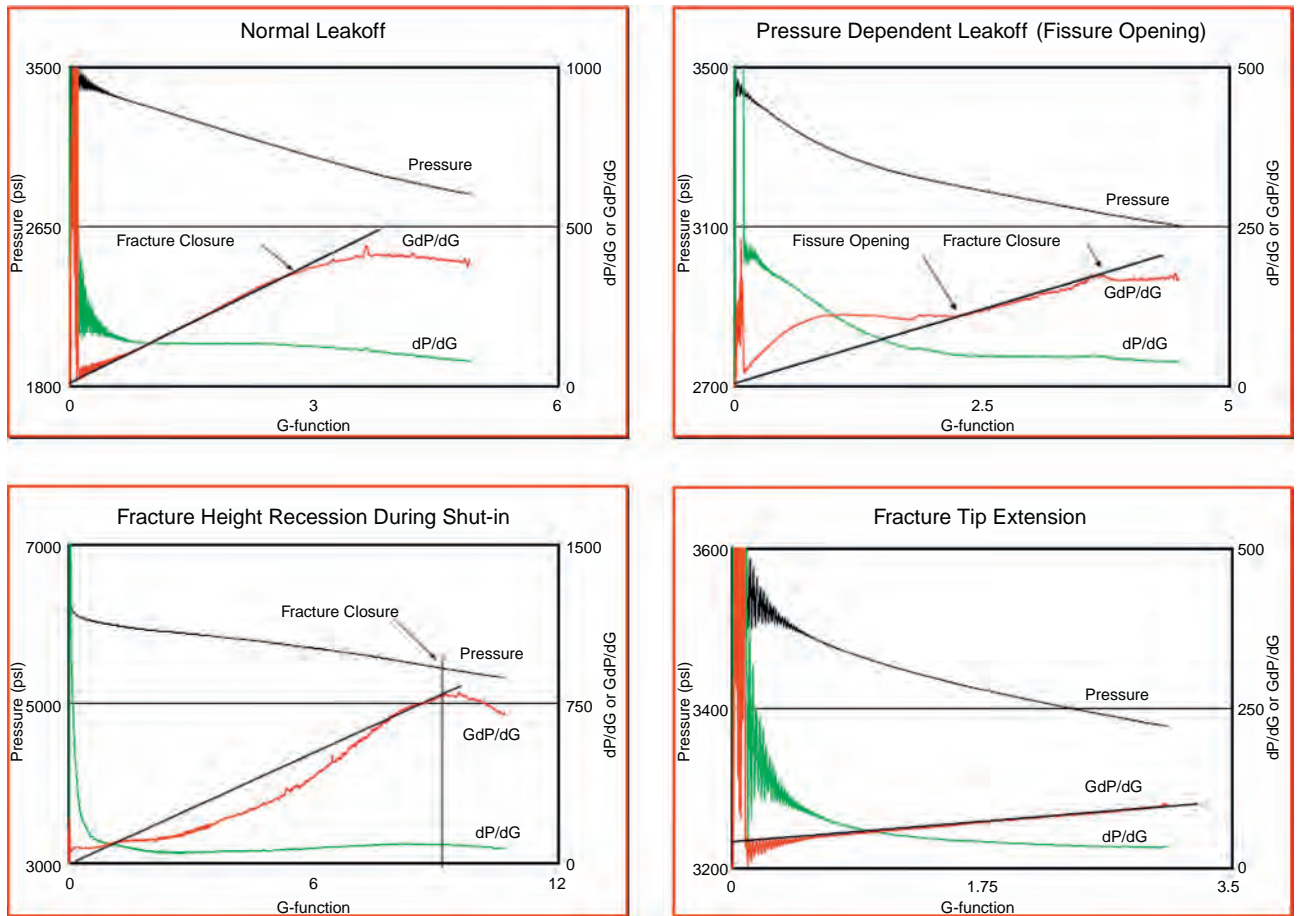

FIGURE 6.5.9 G-function derivative analysis graph showing four common leakoff types.

FIGURE 6.5.10 Fracturing fluid efficiency correlation. The dimensionless closure time Δt_{cD} is the ratio of the closure time to the pumping time [6].

Therefore, a new approach to analyze the pressure decline of a fracturing treatment is visualized.

The concept of individual pressure drops in series, constituting the overall pressure drop between the fracture and the reservoir, can be used and is given by

$$\Delta p_{\text{total}} = \Delta p_{\text{cake}} + \Delta p_{\text{iz}} + \Delta p_{\text{res}} \quad (6.5.12)$$

where Δp_{total} = pressure drop across the filtercake

Δp_{iz} = pressure drop within the polymer invaded zone

Δp_{res} = pressure drop in the reservoir

Figure 6.5.11 is a conceptual diagram of the individual zones and the corresponding pressure drops.

The effects of stress-sensitive filtercake leakoff were described by the hydraulic filtercake resistance, which is defined (with Darcy's law) as [9, 11]

$$R = \frac{l_c}{k_c} = \frac{\Delta p_{\text{cake}} A}{\mu q} \quad (6.5.13)$$

The dimensionless resistance was also introduced:

$$R_D = \frac{\Delta p q_{\text{ref}}}{q \Delta p_{\text{ref}}} \quad (6.5.14)$$

which is a rate-normalized pressure at any time with respect to a reference value.

It was found [9, 10] that polymer filtercakes behave as viscoelastic bodies. The Kelvin or Voight model, which is a mechanical analog commonly used in linear viscoelastic theory, was found to be an appropriate model for analyzing the relation between differential pressure across the filtercake and the dimensionless resistance:

$$R_D(t) = \frac{1}{\mu} \int_0^t \sigma(t - \tau) e^{-\tau/\lambda} d\tau \quad (6.5.15)$$

where $\sigma(t - \tau)$ = change of the differential pressure

λ = retardation time

μ = viscosity

The viscoelastic filtercake relaxation, which was described by Equation 6.5.15, and the additional cake increase are the essential features during closure [9, 10]. Figure 6.5.12 shows, in a plot of R_D versus Δp , the dominance of the stress-sensitive relaxation of the filtercake deposited and compressed during pumping over the additional cake increase.

The stress-sensitive filtercake resistance is equivalent to a skin-effect and can therefore be incorporated as a component of the linear flow from the fracture into the reservoir.

6.5.1.7 Pressure Interpretation After Fracture Closure

Another application of pressure evaluation pertains to the pressure response after fracture closure. The pressure during this period reflects the transient reservoir response to fracturing and is independent of the mechanisms governing fracture propagation. Its character is determined entirely by the response of a reservoir disturbed by the fluid-leakoff process. During this period, the reservoir may initially exhibit formation linear flow, followed by transitional behavior and finally long-term pseudoradial flow.

The afterclosure response is similar to the behavior observed during a conventional well test of a propped fracture. It therefore supports an evaluation methodology analogous to the established principles of pressure transient evaluation. The afterclosure period provides information that is traditionally determined by a standard well test (i.e., transmissibility and reservoir pressure). It completes a chain of fracture pressure analysis that provides a continuum of increasing data for developing a unique characterization of the fracturing process. Nolte et al. [70] and Mayerhofer et al.

FIGURE 6.5.11 Hydraulic fracture with filtercake and invaded zone.

FIGURE 6.5.12 Stress-sensitive dimensionless resistance [9].

[62] provide a straight-line technique for determining reservoir permeability and fracture-face resistance by visually determining whether the transient response is dominated by flow in the reservoir or at the fracture face.

6.5.1.8 Properties of Fracturing Fluids

The expected functions of the fracturing fluid are to initiate and propagate the fracture and to transport the proppant with minimum leakoff and minimum treating pressure.

Fluid viscosity is thus critical. An ideal fracturing fluid should have relatively low viscosity in the tubing (sufficient to carry proppant through the surface equipment but low enough to avoid unnecessary friction pressure losses), and high viscosity within the fracture where a large value can provide bigger fracture width and transport the proppant efficiently down the fracture. However, what a high-viscosity fracturing fluid does, inadvertently, is to plug the high permeability of the propped fracture, creating a highly unfavourable mobility. A mechanism to reduce the viscosity after the job to a very low value is then necessary. How are these apparently contradictory demands accomplished?

A typical, water-base fracturing fluid consists of water and a thickening polymer such as guar or one of the guar derivatives such as hydroxypropyl guar (HPG) or carboxymethylhydroxypropyl guar (CMHPG). The polymer concentrations could vary from 15 to 80 lb/1000 gal, depending on the required viscosity.

Such polymer solutions produce viscous fluids at ambient temperatures. At reservoir conditions these solutions thin substantially. To overcome this limitation, crosslinking agents are used to significantly increase the effective

molecular weight of the polymer, thereby increasing the viscosity of the solution. Several different metal ions can be used as crosslinkers with borate compounds and transition metal complexes such as titanium (Ti[IV]), zirconium (Zr[IV]), and aluminum (Al[III]) being the most common. The reaction of these crosslinkers is often delayed so that the substantial increase in viscosity takes place near the perforations. This delay reduces tubing friction pressure and improves the long-term stability of the viscous fluid.

Recently polymer-free, water-base fracturing fluids have been developed using viscoelastic surfactants (VESs). Surfactants, when added to water, will associate into structures called micelles. The surfactants used to create VES fluids form rodlike micelles that will associate with one another at a sufficient concentration, and the resulting hindered movement causes the fluid to become both viscous and elastic.

In addition to water-based fluids, there are other types of fracturing fluids. Oil-based fluids were the first fluids to be used. They can be thickened via an associative mechanism using an aluminum-phosphate ester polymer chain. However, oil-based fluids are expensive to use and dangerous to handle due to their flammability. Hence, they are applied to formations that are perceived to be particularly water sensitive. Multiphase fluids such as emulsions (oil and water) and foams (gas and water) have been used widely.

The most common emulsion is composed of 67% hydrocarbon (internal) phase and 33% water (external) viscosified phase. Emulsions are very viscous fluids, providing good proppant transport but resulting in high friction pressures and high fluid costs. They also thin significantly, and thus, they cannot be used in hot wells.

Foams (a mixture of liquid and gas stabilized with a surfactant) are particularly popular as fracturing fluids because the contained gas provides a very rapid cleanup following the treatment. The gas phase of foam is generally pumped at a concentration ranging from 52% up to 95%. Stable dispersions of gas in liquid can be prepared with qualities less than 52%, but they can be used effectively as energized fluids even though they do not meet the true definition of a foam. Viscosifying the liquid phase with a polymer is an effective method for increasing the stability and viscosity of foams. Both nitrogen and CO₂ are commonly used as the gas phase. Nitrogen is pumped as a gas and is readily available throughout the oilfield. Nitrogen is considered completely nondamaging, as it is an inert gas and is not very soluble in liquids. CO₂ is pumped as a liquid and therefore creates a denser foam that aids in lowering surface treating pressures because of the increased hydrostatic head in the wellbore. CO₂ is also much more soluble in water or oil, requiring more gas to saturate the liquid and create the foam. The solubility of the CO₂ can aid in cleanup although the CO₂ saturated fluid will naturally have a lower surface tension. Economically, nitrogen will show benefits in shallow wells, whereas CO₂ will become the gas of choice at deeper depths.

For all fracturing fluids, the viscous properties of the fluid must be reduced or “broken” after the treatment. Unfortunately, the polymer chains concentrate throughout the treatment as the base liquid leaks off to the formation. The concentrated polymer is very difficult to completely break down, even in the presence of breakers. Different combinations of crosslinkers and polymers can be more resistant than others, leading to only partial decomposition, which can result in significant residue and therefore damage to the proppant pack. This phenomenon can lead to substantial proppant pack permeability damage with devastating effects on the fractured well performance.

For polymer fluids, breakers such as oxidative compounds (e.g., peroxydisulfates) or enzymes (e.g., hemicellulase) are used to reduce the length of the polymer chains and their molecular weight. These same breakers will also be added to emulsions and foams to degrade the polymer stabilizers in the water phase. VES fluids are broken by simply destabilizing the rodlike micelle structure. This may be accomplished by simply producing well fluids, either hydrocarbons or formation water, and mixing these fluids with the treating fluid. External breakers may also be added to the VES fluids to accelerate the viscosity degradation and facilitate cleanup immediately after the treatment.

The effects of the type of breaker, its quantity, and the mode of application are shown in Figure 6.5.13. Encapsulated breakers are desirable because they become active only when the fracturing treatment is over. Early breaker polymer reaction is detrimental because it degrades the needed viscous properties of the fluid, whereas minimizing or eliminating the breaker is particularly problematic because it may lead to permanent proppant-pack permeability impairment. Encapsulated breakers allow very high breaker concentrations to be run that can minimize fluid damage, while preventing premature viscosity degradation [13].

Foams, emulsions, and VES fluids are generally considered to be less damaging to the proppant pack than conventional polymer-based fluids. Foams and emulsions use significantly less polymer due to the addition of the gas or hydrocarbon phase. With less polymer present, the potential for damage is minimized. VES fluids contain no solids, so once the viscosity is reduced, there will virtually no permeability reduction to the proppant pack.

The selection of what type of fluid is based on the evaluation of numerous fluid performance parameters, including viscosity and stability at temperature, fluid efficiency or the ability to control fluid loss to the formation, minimal

FIGURE 6.5.13 Viscosity degradation of fracturing fluids with and without encapsulated breakers [13].

friction pressure losses during dumping, fluid damage to the proppant pack, compatibility with the formation rock and the formation fluids, environmental friendliness, and cost. Each of these performance parameters must be weighed against the others in order to select the optimum fracturing for any given reservoir. Each of these parameters can be economically evaluated against the others during the design process using net present value simulations as described in a subsequent section.

6.5.1.9 Proppants

During the execution of the fracture treatment, the imposed hydraulic pressure holds the fracture open. However, when the pumping stops, it is up to the injected particulates to hold open or prop the fracture. The propped fracture width and thus the amount of proppant required will be addressed in the design subsection. However, two other variables are important in the determination of the proppant pack permeability: the proppant strength and the grain size. For a given stress under which the proppant pack will be subjected, the maximum value of fracture permeability can be estimated. Figure 6.5.14 shows a set of proppant conductivities as a function of fracture closure pressure. Bauxite, a high strength proppant, and ISP (Intermediate Strength Proppant, a synthetic material) maintain a large portion of

their permeability at high stresses. Sand, however, experiences more than a magnitude permeability reduction when the stress increases from 4000 to 8000 psi. Resin coatings can be applied to sand to increase the crush resistance and therefore the associated permeability. Understanding proppant permeability at a given stress is important in the selection of a proppant because, although sands are less costly, they crush readily, and therefore higher-strength, but more costly, proppants are more suitable at higher stresses. At lower stresses the permeability provided by sand may be sufficient.

Proppant size is also important. Larger grain sizes result in larger fracture permeability. However, larger sizes are more susceptible to crushing as stresses increases, and the relative reduction in the pack permeability is much larger in the larger-size proppants. Reference [14] contains a number of correlations for size and size distribution effects on proppant pack permeability.

These permeabilities are maximum values. As mentioned earlier, fracture permeability damage is caused by unbroken polymer residue, which is by far the biggest culprit. Thus, although proppant strength and size selection can be done using formation strength criteria, damage due to fracturing fluid residue must be controlled. Otherwise, additional damage factors, as high as 80% to 90%, can be

FIGURE 6.5.14 ISO standard conductivity vs. fracture closure pressure for various proppants.

experienced after the stress-induced permeability impairment is accounted for.

It is also important to ensure that the proppant remains trapped inside the fracture during clean up and production. This can be a major problem in high flow-rate wells and where fluid drag forces dislodge and carry proppant out of the fracture. This can also be exacerbated in wide fractures (6 or more proppant grains) where a stable bridging arch is difficult to maintain regardless of closure stress. In most cases, proppant flowback does not reduce well production, but the proppant that does flowback can have a detrimental wear effect on the production equipment and may require the use of separators in the production line.

Several techniques have been used to control proppant flowback: forced closure, resin flush, the use of curable-resin-coated proppants, and fiber technology. *Forced closure* is a procedure in which fluid flowback begins immediately at the end of pumping. The theorized benefits of forced closure are that a “reverse” screenout takes place at the perforations (i.e., the fracture width closes to below that required for a stable arch) and that the fracture closes before the proppant has a chance to settle in the fracture.

The *resin flush technique* involves pumping a curable resin into the fracture at the end of the job. The resin coats the proppant in the fracture near the wellbore and forms a bond that glues the individual proppant grains together while still maintaining most of the permeability.

A curable resin coating may also be applied to sand or other types of proppants to prevent the flowback of proppants near the wellbore. The curable-resin-coated proppants are mixed and pumped in the later stages of the treatment, and the well is shut in for a period of time to allow the resin to bind the proppant particles together. Under sufficient closure stress, shut-in time, and temperature, the resin-coated proppant cures into a consolidated, but permeable, proppant pack that resists flowback.

Fiber technology holds the proppant in the fracture during production without the use of chemical curing

reactions. Providing a physical mechanism of random fiber reinforcement prevents proppant flowback while allowing more flexibility in the flowback design.

6.5.1.10 Propped Fracture Design

The previous information was intended to serve as background information for propped fracture design. Montgomery and Smith [66] provide a comprehensive work flow for designing a hydraulic fracture. This work flow, which is described in detail in the book, is provided as [Figure 6.5.15](#). Meng and Brown [15] and Balen *et al.* [16] presented the concept and applications of the net present value (NPV) as a systematic approach to fracture design. Others have also outlined similar schemes. The complexity of the various design components and their interrelationships invariably require an economic criterion for meaningful comparisons of design options and fracture sizes.

[Figure 6.5.16](#) contains the steps and components for optimizing fracture design. First, a fracture half-length x_f is selected. This is done incrementally, with each new fracture half-length longer than the previous (e.g., by 100 ft).

At first, let’s follow the lower branch on [Figure 6.5.10](#). For a given formation, the lithology, temperature, and reservoir fluids would dictate the choice of the fracturing fluid while the state of stress and the desired fractured performance would point toward the proppant selection. A fracture propagation simulator may then describe the fracture geometry. There are several types of simulators including fully three-dimensional (3D), planar 3D (PL3D), pseudo 3D (P3D) (coupled 3D fracture and two dimension [2D] fluid flow), and the classic analytical 2D models. The latter include the PKN model (Perkins and Kern [17]; Nordgren [18]) and the KGD model (Khristianovich and Zheltov [19]; Geertsma and de Klerk [20]).

The higher the complexity of the simulation, the higher the demand for appropriate data and the longer the simulation time. For the purpose of this exercise, the elegant, analytical PKN and KGD models will be used.

FIGURE 6.5.15 Work flow for designing a hydraulic fracture.

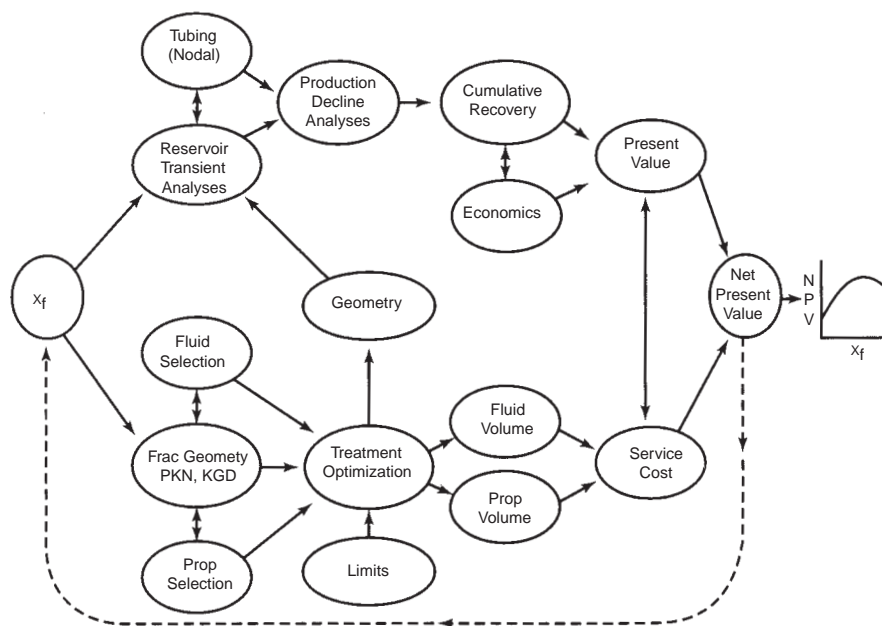

FIGURE 6.5.16 The components of the fracture net present value (NPV) calculation [15].

A depiction of the PKN geometry is given in Figure 6.5.17. For this simulation two limits are necessary: the fracture height, h_f , and the maximum allowable or available treating pressure.

Thus the fracture geometry can be determined and, with the imposed limits, a treatment optimization may be done. The average width of a fracture of half-length x_f can be obtained from

$$\bar{w} = 0.3 \left[\frac{q_i \mu (1 - \nu) x_f^2}{G} \right]^{1/4} \left(\frac{\pi}{4} \gamma \right) \quad (6.5.16)$$

- where q_i = injection rate in bpm
- μ = fracturing fluid viscosity in cp
- G = elastic shear modulus in psi
- γ = geometric factor = 0.75

The bracketed expression on the right hand side of Equation 6.5.17 gives the maximum width value (at the wellbore), whereas the multiplier in the parentheses provides a geometrically averaged width.

For the KGD model, depicted in Figure 6.5.18, the analogous expression is

$$\bar{w} = 0.29 \left[\frac{q_i \mu (1 - \nu) x_f^2}{G h_f} \right]^{1/4} \left(\frac{\pi}{4} \right) \quad (6.5.17)$$

In both Equations 6.5.17 and 6.5.18, the relationship between viscosity or injection rate and the fracture width is quarter root, indicating that to double the width a 16-fold increase in either of these two variables is needed.

The calculation of fracture width, the assumed fracture height and half-length, and the fluid leakoff lead toward a simple material balance

$$q_i t_i = \frac{\bar{w} A_f}{2} + \frac{(K_L C_L A_f r_p) \sqrt{t_i}}{2} \quad (6.5.18)$$

where the lefthand side is equal to the fluid volume injected, the first term on the righthand side is the volume of the fracture created, and the second term represents the fluid leakoff. The latter is a square root of time relationship.

The area A_f is total fracture area and is equal to $4x_f h_f$. All other variables in Equation 6.5.18 have been described earlier except K_L , which is a multiplier to the leakoff coefficient and is applicable during pumping. Nolte [5] has shown that

$$K_L = \frac{8}{3} \eta + \pi(1 - \eta) \quad (6.5.19)$$

where η = fluid efficiency

is a good approximation.

Equation 6.5.18 is a quadratic relationship for the square root of the injection time t_i , and can be solved readily. Thus, the product $q_i t_i$ can be calculated, representing the total amount of fluid V_i required to generate a fracture of the calculated geometric and leakoff features.

The pad volume has been related to the total volume injected, V_i , in Reference [6], such that

FIGURE 6.5.17 The geometry of the Perkins and Kern [17] and Nordgren [18] model (PKN).

$$\text{Pad volume} = V_i \frac{(1 - \eta)}{(1 - \eta)} \quad (6.5.20)$$

The next item is to calculate the proppant volume and its injection schedule. The latter is given by

$$c_p(t) = c_f \left(\frac{t - t_{\text{pad}}}{t_i - t_{\text{pad}}} \right) \quad (6.5.21)$$

- where $c_p(t)$ = slurry concentration (lb/gal added) as a function of time
- c_f = desired slurry concentration at the end of the job (lb/gal absolute)
- t_{pad} = time for pad injection

The continuous proppant addition described by Equation 6.5.21 (and shown schematically in Figure 6.5.19, opposed to the classic “stairstep” proppant addition) from t_{pad} to t_i can provide the total amount of proppant injected. This amount, divided by the fracture area, can provide the proppant concentration within the fracture C_p given in lb/ft.³ The propped width may then be calculated from

$$w = \frac{12C_p}{(1 - \phi_p)\rho_p} \quad (6.5.22)$$

- where ϕ_p = proppant pack porosity in fraction
- ρ_p = proppant density in lb/ft.³

FIGURE 6.5.18 The geometry of the Khristianovich and Zheltov [19] and Geertsma and de Klerk [20] model (KGD).

FIGURE 6.5.19 Continuous vs. “stairstep” proppant addition. The continuous pressure addition is superior and is described by Equation 6.5.21.

Finally, the net fracturing pressure to generate a half length equal to x_f may be calculated for the PKN model (for a Newtonian fluid)

$$\Delta p_f = 0.0254 \left[\frac{G^3 q_i \mu x_f}{(1 - \nu)^3 h_f^4} \right]^{1/4} \quad (6.5.23)$$

and for the KGD model

$$\Delta p_f = 0.050 \left[\frac{G^3 q_i \mu}{(1 - \nu)^3 h_f x_f^2} \right]^{1/4} \quad (6.5.24)$$

The treatment pressure is then simply

$$p_f = \sigma_{H,\min} + \Delta p_f \quad (6.5.25)$$

Equations 6.5.23 and 6.5.24 show the classic pressure patterns that may reveal during execution the type of fracture that is generated. For the PKN model and for a constant fracture height (Equation 6.5.23), there is an increasing pressure profile for increasing fracture length, whereas for the KGD model (Equation 6.5.24), there is a decreasing pressure profile for a propagating fracture.

Assuming also that the treating pressure must be kept below a certain level to avoid migration, then a PKN-type fracture can be propagated at constant net pressure. This can be accomplished by decreasing the fluid viscosity or the injection rate as can be concluded from Equation 6.5.23. Given the choice, treatment optimization has shown that reduction in viscosity is more desirable than a reduction in injection rate.

The calculation of the fluid volume (Equation 6.5.17) and proppant mass requirements (Equation 6.5.21), injection rates, and treatment pressures (Equation 6.5.25) lead to the calculation of the cost to create the fracture.

The second branch in Figure 6.5.16 may now be addressed. The calculated propped fracture width w (Equation 6.5.22), the fracture half-length x_f , the proppant pack permeability (stress- and damage-adjusted proppant) k_f , and the known reservoir permeability lead to the dimensionless fracture conductivity

$$F_{CD} = \frac{k_f w}{k x_f} \quad (6.5.26)$$

Cinco-Ley *et al.* [21] presented the solution for the performance of finite-conductivity fractures, as shown in Figure 6.5.1. Their type curves are in the standard form of a log-log graph of dimensionless pressure p_D against

dimensionless time t_{Dxf} for a range F_{CD} s. Hence, any real time corresponds to a dimensionless time, and the dimensionless pressure value is related to the real flowrate and real pressure drop. Thus, the expected performance can be calculated. No-flow boundary conditions for various reservoir geometries have been given in Reference [15]. The flowrate decline curve can then be coupled with the tubing performance resulting in wellhead rates.

It is very easy step to integrate these rates into the cumulative production. The incremental cumulative production (above the one the unstimulated well could deliver) multiplied by the unit price of the hydrocarbons (oil or gas) and discounted to time zero is the present value of the incremental revenue.

If the cost to perform the job, calculated from the first branch in Figure 6.5.16, is subtracted from the present value of the incremental revenue, it results in the NPV.

A plot of the construction is given in Figure 6.5.20. The fracture half-length is graphed against the NPV. Optimum fracture design corresponds to the maximum NPV. Two case studies are graphed: case A, which provides a positive NPV, and case B, in which the incremental revenue does not recover the stimulation cost. In this case hydraulic fracturing should not be done.

Potentially, one of the most powerful applications of the NPV approach is to perform parametric studies. If a variable (e.g., permeability or slurry concentration) is not known or determined, then a sensitivity analysis can be done to assess the impact of its variation on the optimum design. Large spread in the maximum NPV could be considered as the “cost of ignorance.” In that case, measurement of the unknown variable via some type of testing is warranted. An

FIGURE 6.5.20 Case studies of the NPV design procedure. Case A is positive, Case B is negative.

FIGURE 6.5.21 NPV fracture design parametric study of reservoir permeability.

example parametric study with the reservoir permeability is shown in Figure 6.5.21.

6.5.1.11 Fracture Propagation Modeling

Common to all descriptions of fracture propagation are (1) a material balance equation relating volume change to flow across the boundaries, (2) an elasticity relationship between fracture aperture and net pressure, (3) a fluid-flow equation relating the flowrate with the pressure gradient in the fracture, and (4) a tip propagation criterion.

6.5.1.11.1 Width Equations

The theory of linear elasticity provides solutions to idealized problems. One of them, the pressurized crack problem, deals with a crack (a straight line) of length $2b$ that is in an infinite plane. The stress σ acting far from the crack and normal to its direction is compressive, trying to close it. On the other hand, a pressure p is acting against the stress, trying to open the crack from the inside. If the net pressure, $\Delta p = p - \sigma$, is positive, the crack will be open and its shape will be elliptic. The maximum width is given by

$$w_{\max} = \frac{(1 - \nu)}{G} (2b) \Delta p \quad (6.5.27)$$

(The equations, unless otherwise stated, are written in a coherent system of units in this section.) Several models originating from Perkins and Kern [17] figure the hydraulically induced fracture as a constant height channel obeying Equation 6.5.27 in every vertical cross-section, with $2b$ replaced by h_f . In such a channel of elliptical shape (with a width significantly less than the height), a

Newtonian fluid having constant flowrate q is driven by the pressure drop

$$\frac{dp}{dx} = -\frac{64\mu q}{\pi w^3 h_f} \quad (6.5.28)$$

The elasticity relation [6.5.27] and the fluid-flow equation [6.5.28] are combined to establish a relation between width at the wellbore and fracture length. To obtain a closed form solution, the fluid leakoff is neglected at this stage of the model development. In addition, zero width (zero net pressure) is assumed at the tip. With these assumptions the created width profiles are similar, and hence, a constant multiplier can be used to transform the wellbore width into the average width.

Historically, the KGD model [19,20] preceded the PKN model. It is also based on the pressurized crack solution but applied in the horizontal direction. There are additional differences, that is, the pressure drop equation is written for a channel with rectangular cross section and the existence of a nonwetted (nonpressurized) zone is assumed near the tip.

The two widely used width equations were presented earlier as Equations 6.5.16 and 6.5.17. The PKN equation has been considered as a suitable approximation for long fractures (compared to height), whereas the KGD has been suggested as more appropriate for fractures with significant height compared to length.

A width equation such as Equation 6.5.16 or 6.5.17 leaves only one degree of freedom for the geometry of the fracture. If we give (directly or indirectly) the fracture volume, the shape is determined. The additional information on the fracture volume is provided through the material balance.

6.5.1.11.2 Material Balance

Material balance suggests that the injected fluid either generates fracture volume or leaks off. In describing leakoff, Carter [22] applied two important assumptions. In his formulation the following was presented:

$$\frac{V_L}{A_L} = 2C_L\sqrt{t} + S_p \quad (6.5.29)$$

where V_L = volume of the fluid leaked off
 A_L = area available for leakoff
 C_L = leakoff coefficient
 S_p = spurt loss coefficient

The first term represents decreasing intensity of the fluid leakoff with time elapsed, and the second term is an additional volume that is lost at the very moment of opening (the spurt loss). In addition, Carter assumed that *from the point of view of the material balance*, the fracture geometry can be well approximated by a constant rectangular cross-section, with the only dimension changing with time being the length. He wrote the material balance for a unit time interval in the form

$$q_i = 4 \int_0^t \frac{C_L}{\sqrt{t-\tau}} h_f \frac{dx_f}{d\tau} d\tau + 2h_f w \frac{dx_f}{d\tau} \quad (6.5.30)$$

where q_i = opening time

The solution of the above integral equation is

$$x_f(t) = \frac{q_i w}{8\pi h_f C_L^2} \left[\exp(\alpha^2) \operatorname{erf} c(\alpha) + \frac{2\alpha}{\sqrt{\pi}} - 1 \right] \quad (6.5.31)$$

where

$$\alpha = \frac{2C_L\sqrt{\pi t}}{w} \quad (6.5.32)$$

(Note that x_f is the length of one wing, and q_i is the injection rate for two wings.) The complementary error function $\operatorname{erf} c(x)$ is available in the form of tables or computer algorithms.

If we want to apply the above equation, we have to decide how to estimate the constant width in this relation. It is the sum of the average width and the spurt width,

$$w = \bar{w} + 2S_p \quad (6.5.33)$$

where, strictly speaking, the averaging should be done not only in space but also in time.

The combination of Equation 6.5.31 with one of the width equations results in a system that is completely determined if either the length or the injection time is given. For the solution, simple iterative methods can be applied.

The use of Equation 6.5.31 is somewhat complicated. The material balance would take a simple form if the volume leaked off could be determined. Unfortunately, it

depends on the opening time *distribution*, which in turn reflects the history of the fracture growth process. A simple version of the material balance is derived assuming some plausible bounds on the distribution of the opening time. Then the fluid lost during pumping (in the two wings) $2V_L$ is bounded by [5]

$$\pi > \frac{2V_L}{2C_L x_f h_f \sqrt{t}} > \frac{8}{3} \quad (6.5.34)$$

The upper bound corresponds to low fluid efficiency and the lower bound to high fluid efficiency. At any medium efficiency, we can use a linear interpolation between these two bounds. Therefore, Equation 6.5.31 can be replaced by

$$x_f = \frac{(1-\eta)q_i t}{\left[\frac{8}{3}\eta + \pi(1-\eta) \right] 2h_f C_L \sqrt{t}} \quad (6.5.35)$$

where the fluid efficiency is computed from

$$\eta = \frac{2x_f h_f \bar{w}}{q_i t} \quad (6.5.36)$$

The combination of Equation 6.5.35 with one of the width equations is another short-cut 2D model. Essentially the same concept was used in the design section (see Equations 6.5.18 and 6.5.19).

6.5.1.11.3 Detailed Models

Clearly, the short-cut 2D models are based on several approximations, some of those being contradictory. For example, the geometric picture behind the Carter equation (and behind the upper and lower bounds) would require a fracture propagating with a constant width. The PKN or KGD width equations, on the other hand, give width changing in time as well.

Nordgren [18] presented a constant-height model in the form of a partial differential equation that contains coherent assumptions on the geometry. Kemp [23] showed the correct tip boundary condition for Nordgren's equation. Interestingly, the numerical solution does not differ much from the one of the PKN models. The main reason is that in both the detailed Nordgren model and the PKN versions, the fracture tip propagation rate is controlled by the linear velocity of the fluid at the tip. In other words, in these models there is no mechanism to hamper the opening of the fracture faces once the fluid arrives there. This latter statement is valid also for the different KGD variations.

Appearance of irregular pressure profiles and posttreatment observation of fracture height growth initiated a departure from the ideal geometry assumptions. This generated higher dimensional models and prompted the introduction of improved calculation procedures. The two most important concepts are the vertical distribution of the (minimum horizontal) stress and the fracture toughness.

Most of the researchers agree that stress distribution is the major factor controlling the height growth of hydraulically induced fractures [24]. Building this concept into a PL3D or P3D model, a more realistic fracture shape can be computed. The fracture is contained in the pay layer if the minimum principal stress is significantly higher in the neighboring layers. On the other hand, if the stress in the neighboring layers is only moderately higher than in the pay layer, then a limited height growth is predicted. The PL3D and P3D models differ in how detailed the computation of the height is and to what degree it is coupled with the fluid flow equation [25]). Although the significance of the vertical distribution of the stress is well understood, the usefulness of this concept is somewhat limited by the fact that the necessary data are often lacking. (In fact, even the value of the minimum horizontal stress in the pay layer might be uncertain within a range of several hundred psi.)

There is less consensus in the usefulness of the concept of fracture toughness. This material property is defined as the critical value of the stress intensity factor necessary to initiate the rupture. The stress intensity factor is a quantity having the dimension pressure (i.e., stress) multiplied by the square root of length. Its value increases with both the net pressure and the size of the fracture. Several investigators have arrived at the conclusion that within the physically realistic range of the fracture toughness, its influence on fracture propagation is not significant.

P3D models are used routinely nowadays for the design of fracturing treatments, in real time during the actual treatment, and for postjob evaluation. There are two broad categories of P3D models: cell-based and lumped:

- *Lumped* models assume that the fracture consists of two half-ellipses of variable half-heights, joined along a horizontal line in the fracture length direction. At each time step, the fracture length tip and top and bottom tips are calculated as part of the solution.
- *Cell-based* models assume that the fracture is divided into a number of PKN cells along the fracture length direction. At each time step, the fracture length and height of each cell is computed as part of the solution.

Regardless of the numerical scheme employed, P3D models are more powerful than the simpler PKN-type models because they allow limited height growth as part of the solution, thereby expanding the range of treatments that can be designed and monitored.

A major drawback of the P3D models is that these solutions are all based on the concept of averaging reservoir properties over the fracture height, thereby limiting the range of treatments that can be designed. PL3D models remove this restriction because they employ a 2D mesh to describe the fracture footprint, that is, a mesh that allows variations in fluid pressure and fracture width along the fracture length and height directions. PL3D models are

much more powerful and can model complicated geometric configurations, including runaway height growth situations, pinch points, concave sections on the fracture perimeter, and indirect vertical fracturing. However, they are computationally very expensive compared with P3D models and are currently only used in a limited number of treatment designs that involve more complex fracturing behavior.

There are two classes of PL3D models available:

- models based on a *moving* mesh (usually constructed with triangular elements)
- models based on a *fixed* mesh (usually constructed with rectangular elements)

The moving-mesh models are desirable because they provide good resolution at both early and late times during the injection and consume a relatively small number of elements, making them computationally fairly efficient. However, remeshing is required as the fracture footprint changes its shape, resulting in accumulative interpolation errors. These errors can become significant, especially in situations involving layered reservoirs. The fixed-mesh models suffer from poor resolution at early times and can become computationally expensive at later times once many elements become activated. However, they do not suffer from errors in mass balance, unless the mesh is coarsened at later times to reduce the number of active elements and improve Computer Processing Unit (CPU) times.

There are also a limited number of noncommercial “truly” 3D models available that allow nonplanar fracture growth (i.e., limited twisting and turning of the fracture). However, these models are currently prohibitively expensive to exercise, even for research purposes, and do not generally address transverse or longitudinal shear failure that will naturally arise as soon as nonplanar fracture growth is allowed.

Many fracturing treatments are performed in reservoirs that exhibit highly nonlinear or plastic-like material behavior, such as in the Gulf of Mexico. The current linear elastic models (whether P3D, PL3D, PKN, KGD, or radial) need to be adapted to cope with these plastic deformations. Fracturing treatments performed in such soft formations are expected to generate more fracture width and different pressure responses compared with fractures injected in competent rock. Possible remedies include the implementation of a fracture growth criterion in current models that are based on continuum damage mechanics theory [27] or the theory of plasticity [28].

6.5.1.11.4 Evaluation of Fracture Design

Successful stimulation is when the optimum design treatment is performed and the posttreatment flowrate coincides with the one forecasted. Figure 6.5.22 shows a posttreatment well performance showing a good agreement with the predicted flowrate from the designed fracture length. If the

FIGURE 6.5.22 Posttreatment fractured well performance and comparison with predicted flowrate.

two deviate and especially if posttreatment performance is far below expectations, then an evaluation procedure should be implemented.

Primarily, two items should be examined:

- Fracture height migration—this can be done via a post-treatment temperature or radioactive log.
- Fracture permeability reduction—this could be the result of proppant pack damage or a choke (overdisplacement or other reasons that reduce the contact between well and fracture). Assessment of the geometric and conductivity characteristics of the fracture can be done via a posttreatment pressure transient test using the model outlined in Reference [21].

6.5.1.12 Acid Fracturing

Acid fracturing is a stimulation process in which acid, usually hydrochloric acid (HCl), is injected into a limestone (CaCO_3) or dolomite (CaMgCO_3) formation at a pressure sufficient to fracture the formation. As the acid flows along the fracture, portions of the fracture face are dissolved. The flowing acid tends to etch in a nonuniform manner, creating conductive channels that will remain after the fracture closes and ultimately will provide the necessary fracture conductivity. The length of the etched fracture is determined by the acid type, strength, volume, leakoff parameters, reaction rate, and spending rate.

There are certain comparative advantages and disadvantages of acid fractures (versus propped fractures) in carbonate reservoirs.

- **Acid fractures have placement advantages in highly fissured reservoirs** in which proppant placement is

difficult and often leads to screenouts due to the high leakoff of fracturing fluid to the associated fissures.

- In very low permeability formations in which long fracture lengths are required, propped fractures will be preferred. In acid fracturing, the acid-based fracturing fluid is continually spending and therefore is consumed as the fracture penetrates deeper into the reservoir. This results in fracture half-lengths that may be limited to a few hundred feet, especially as the temperature of the reservoir increases [30].
- Operationally, acid fracturing has several advantages over propped fracturing, including 1) the addition of proppant is eliminated, thereby greatly simplifying the pumping execution process; 2) problems related to screenouts are eliminated; 3) proppant cleanout from the wellbore after the treatment is not necessary; and 4) no proppant production problems are encountered when production begins.

The biggest uncertainty for acid fracturing is what the final post-frac flow capacity or conductivity that will be created due to the acid dissolving the rock. The final conductivity is affected by the crack width under closure stress. This depends on the character of the surface asperities that were created during the acidizing process and what the mechanical strength of the asperities are. This is controlled by the acid contact and leakoff time coupled with the rock lithology/heterogeneity and mechanical properties. There is no accurate mathematical model to predict etched acid fracture conductivity so it is predicted using empirical correlations have been developed that use the dissolved-rock equivalent conductivity as a function of rock strength and formation

closure. Because the methods used to predict conductivity are empirical they should not be expected to be very accurate. Typically the conductivity values are calibrated under field conditions by measuring the effective conductivity with a pressure transient test.

The maximum fracture conductivity k_{fw} for an acid fracture is given by

$$k_{fw}(\text{md/in.}) = 9.39 \times 10^{13}(w^3/12) \quad (6.5.37)$$

However, this value is affected by two variables: the effective stress (σ') and the rock embedment strength S_{rock} . Nierode and Kruk [31] proposed fracture conductivity correlations based on experimental data.

$$k_{fw} = C_1 e - c_2 \sigma' \quad (6.5.38)$$

where

$$C_1 = 1.77 \times 10^8 w^{2.47} \quad (6.5.39)$$

and

$$C_2 = (13.9 - 1.3 \ln S_{\text{rock}}) \times 10^{-3} \quad (6.5.40)$$

for

$$S_{\text{rock}} < 20,000 \text{ psi} \quad (6.5.41)$$

and

$$C_2 = (3.8 - 0.28 \ln S_{\text{rock}}) \times 10^{-3} \quad (6.5.42)$$

for

$$S_{\text{rock}} > 20,000 \text{ psi} \quad (6.5.43)$$

Ben-Naceur and Economides [32] have presented acid fracture performance type curves for a range of effective stresses (3,000 to 9,000) and rock embedment strengths (30,000 to 200,000).

The main limitation of the Nierode/Kruk correlation is that it uses an ideal width which puts the emphasis on the volume of rock removed and does not account for rock

heterogeneity and surface roughness. Gangi [58] proposed modeling the asperities in the fracture as a “bed of nails” which would depict the fracture as a bunch of rods of the same diameter but different heights projecting from the face of the fracture (Figure 6.5.23). The model accounts for the variation of conductivity along the fracture via the equation:

$$k_{fw} = (k_{fw})_0 \left[1 - \left(\frac{\sigma}{\sigma_e} \right)^m \right]^3 \quad (6.5.44)$$

where:

$(k_{fw})_0$: Conductivity under zero closure stress

σ : Closure stress

σ_e : Effective modulus of asperities $\sigma_e = E\alpha_c$

α_c : Contact ratio $\alpha_c = \frac{A_c}{A}$

where A_c is the contact area of the asperities and A is the area of the fracture

m : Constant ($1 < m < 1$) that characterizes the

distribution function of asperity heights.

Ming et al. [64] extended these ideas by developing a model which (1) correlates the surface roughness to acidizing conditions, (2) relates the contact area and fracture opening to asperity distributions, and then (3) calculates the fracture conductivity to the fracture aperture under stress. The correlation is potentially better than the Nierode-Kruk method, in that it is based on more thorough physics. Figure 6.5.24, which is taken from Gong’s paper, shows a set of lab experiments on five Indiana Limestone cores along with a comparison of the prediction given by Nierode-Kruk’s to the Gong correlation for that rock. The main limitation of the Gong correlation is that it requires lab testing of the rock to determine conductivity under zero stress conditions.

6.5.1.13 Acid Systems and Placement Techniques

The effective length of an acid fracture is limited by the distance live acid travels along the fracture before becoming

Assume the asperities in the fracture as a “bed of nails” with the height distribution a power-law variation.

$$k_{fw} = (k_{fw})_0 \left[1 - \left(\frac{\sigma}{\sigma_e} \right)^m \right]^3$$

- $(k_{fw})_0$: Conductivity under zero closure stress
- σ : Closure stress
- σ_e : Effective modulus of asperities
- α_c : Contact ratio

FIGURE 6.5.23 Gangi’s “Bed of Nails” Model [58].

FIGURE 6.5.24 Comparison of Nierofd-Kruk and Gong's correlation to actual data (Indiana Limestone).

spent or lost to the matrix to fluid loss. Controlling fluid loss is a difficult challenge because the acid is continuously reacting with the fracture face and increasing the fracture face permeability. Flow channels, called wormholes, will develop, which will greatly increase the effective area where leakoff can take place.

Wormholes form due to heterogeneity within the rock. At a spot of higher porosity and/or higher permeability, acid begins to preferentially leak off into the formation. This increases the pore and pore throat size at that point, accelerating acid flow into the formation. This becomes an unstable process with the wormhole eventually taking 100% of the fluid loss. Modeling of the wormholing process is empirical and uses a model termed the "Volumetric Model" [52, 61]. The model is based on the assumption that a constant fraction of rock volume is dissolved in the area penetrated by wormholes. The model takes the form:

$$L_{wh}(t) = \frac{V(t)}{A\phi PV_{bt}} \quad (6.5.45)$$

where:

$L_{wh}(t)$ = Length of the wormhole at a designated time

$V(t)$ = volume of acid injected into one face of the fracture at the designated time

A = Fracture Area at the designated time

ϕ = Formation porosity

PV_{bt} = Pore volume to breakthrough

The key parameter in this model is PV_{bt} which is a laboratory measured value of the number of pore volumes injected at wormhole breakthrough for a linear core flood [65]. The PV_{bt} can vary from slightly lower than 1 to as high as 50. A value of <1 indicates that the wormhole is propagating faster than the general acid invasion front,

and that wormholes will dominate fluid loss. This is the optimum rate in limestone. A value $\gg 1$ (maybe 50) indicates that wormholing process is not efficient and the wormhole penetration is far behind the spent acid invasion front. The wormhole would have minimal effect on fluid loss which is a common behavior for dolomite and chalk. A value of 1 indicates that wormholes are increasing formation permeability the full length of the acid leakoff zone, bypassing this zone so far as fluid loss control is concerned. Figure 6.5.25 shows the effect of different rock types on the penetration rate of the wormhole.

Controlling leakoff becomes a challenge due to the acid continually reacting with the fracture face and removing any filtercake that is laid down, plus the formation of wormholes. To overcome this problem, many acid fracture treatments are design to pump alternating stages of nonreactive viscous pad fluid and acid. The initial viscous pad promotes viscous fingering of the acid that follows. The selective acid flow increases penetration and tends to create etched flow channels that provide good conductivity. Subsequent stages of the viscous fluid will reestablish any filtercake removed by the acid and also flow into and plug off the excessive leakoff associated with wormholes. Crosslinked acid systems have also shown to be very effective at controlling excessive leakoff. These systems are designed to crosslink upon acid spending, which limits the creation of wormholes [33].

Acid and oil emulsion fluids have been designed for use in high temperature wells to reduce the acid reaction rate, which aids in getting live acid to the tip of the fracture. These emulsions are generally oil-external-phase and provide the retarding properties because the oil phase physically separates the acid from the reactive carbonate surface [34].

As shown in Figure 6.5.26, Metcalf [63] provides a fracture acidizing decision tree that can be used to determine the treatment keys to success.

FIGURE 6.5.25 Impact of reaction rate and fluid loss on acid penetration patterns.

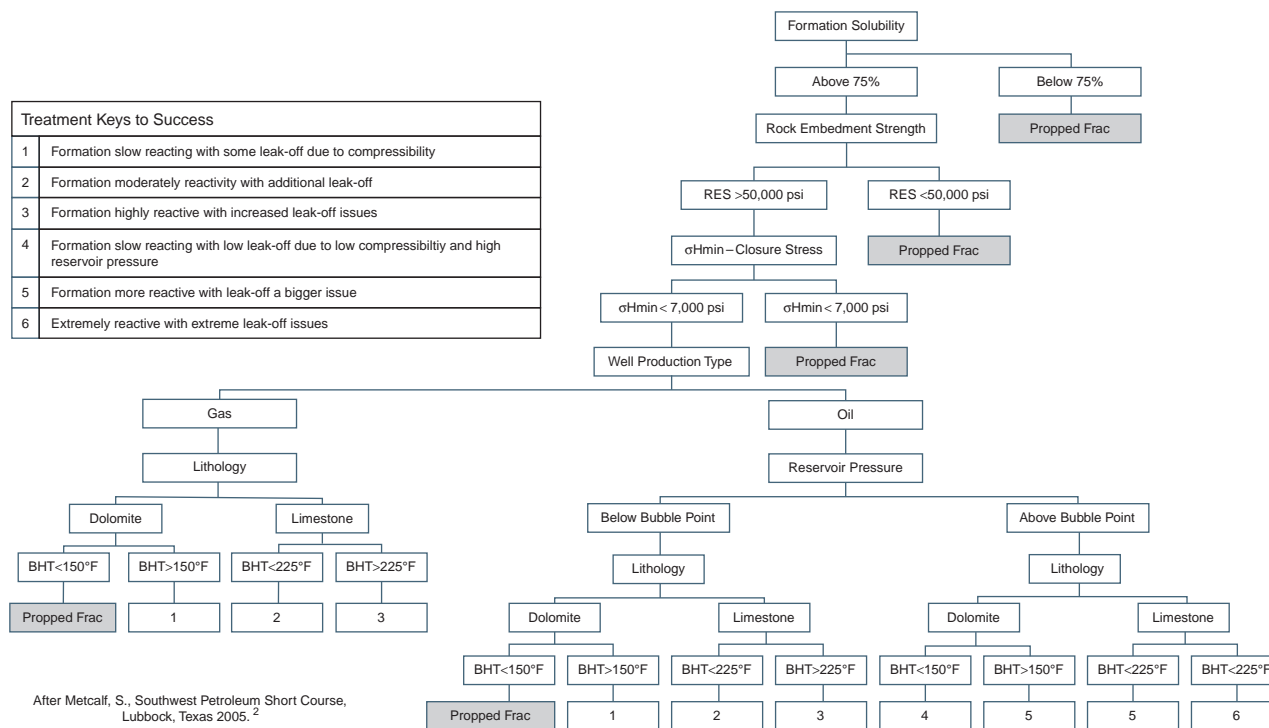

FIGURE 6.5.26 Fracture acidizing decision tree.

6.5.1.14 Fracturing of Deviated and Horizontal Wells

Horizontal wells are rapidly emerging as a major type of well completions. There are three meaningful comparisons of performance between a vertical and a horizontal well in the same reservoir:

- Open-hole or fully perforated completions (i.e., no well configuration skin effects) in the vertical and horizontal cases.
- A vertical well with a vertical hydraulic fracture and a fully completed horizontal well.

- A vertical well with a vertical hydraulic fracture and a horizontal well with one or more vertical hydraulic fractures.

Only the second and third comparisons are of interest to the fracturing engineer. For a reservoir with permeability isotropy in the horizontal plane ($k_x = k_y$), but accounting for permeability anisotropy in the vertical plane, the relationship for equal productivity indexes is [35]:

$$r'_{wD} x_f = \frac{2r_{ev}/L}{\left(a + \sqrt{a^2 - (L/2)^2}\right) \left(\frac{\beta h}{(\beta+1)r_w}\right)^{\beta h/L}} \quad (6.5.46)$$

where P is the vertical-to-horizontal permeability anisotropy ratio and is defined as

$$\beta = \sqrt{k_H/k_v} = \sqrt{(k_x k_y)^{0.5}/k_v} \quad (6.5.47)$$

Also, the large axis of the drainage ellipse a is given by

$$a = \frac{L}{2} \left\{ 0.5 + \left[0.25 + \left(\frac{r_{eH}}{L/2} \right)^4 \right]^{0.5} \right\} \quad (6.5.48)$$

Equation 6.5.46 is for a fully producing along its length, undamaged, horizontal well. It is also valid for reservoirs in which the horizontal permeability is the same in all directions. However, in highly anisotropic formation, while the direction of the *hydraulic* fracture is likely to be normal to the smallest permeability [36], the horizontal well can be drilled normal to the maximum permeability. In such a case, the situation will be considerably different from the one for a horizontally isotropic reservoir.

Equation 6.5.46 can be used for a comparison of the performance of an unfractured horizontal well of length L with a fractured vertical well with a fracture half-length x_f .

Figure 6.5.27 is such a comparison for five permeabilities and $\beta h = 150$ ft. The optimum fracture lengths are also marked. This graph shows the required horizontal well lengths to deliver the same productivity index. Clearly, although detailed economic calculations on the costs versus benefits of all options may be undertaken, it is evident that in reservoirs where vertical wells are usually fracture stimulated ($k < 1$ md), horizontal wells without fracture stimulation are not viable alternatives. The required horizontal well lengths would be far more expensive than the cost of a vertical well with a hydraulic fracture at the indicated optimum fracture half-length. For higher permeability reservoirs, the required horizontal well lengths are more attractive. However, in all cases, these horizontal wells must be fully stimulated to remove damage and allow flow contributions from the entire well length. Production logging often indicates that less than one-half of the wellbore length contributes to production. A well with this type of limited producing interval would require

FIGURE 6.5.27 Fracture half-length in vertical well and required horizontal well length for equal productivity index ($\beta h = 150$ ft.).

the horizontal well lengths to be more than doubled from those reported above.

However, reservoirs with $\beta h \leq 25$ ft are normally naturally fractured. Although the theoretically optimum fracture half-lengths may require certain equivalent horizontal well lengths, actual fracture executions may not deliver the desired fracture lengths. Screenouts because of excessive leakoff or the opening of fissures normal to the hydraulic fracture trajectory may prevent the creation of these lengths. Thus, horizontal wells may be good alternatives to vertical wells with propped fractures in cases in which fracture length will be limited.

Finally, *horizontal* permeability anisotropy is exceptionally important. In moderately to highly anisotropic formations, horizontal wells can be good substitutes for fractured vertical wells.

Of particular importance is the third comparison, which allows the possibility to drill the horizontal well either in the direction that would result in transverse fractures or in the direction that would result in largely longitudinal (parallel) fractures. A comprehensive review of the issue has been presented by McLennan *et al.* [37].

The drilling of a highly deviated or horizontal well (that does not coincide with a principal stress axis) results in a nonvanishing shear stress component. This was addressed in an earlier subsection, and it frequently implies additional pressure requirements for fracture initiation. The fracturing pressure of horizontal wells is affected by the stress concentrations near the well given by [38].

$$\begin{matrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{zz} \\ \tau_{yz} \\ \tau_{xz} \\ \tau_{xy} \end{matrix} = \begin{vmatrix} 1 & 0 & 0 \\ 0 & \sin^2 a & \sin^2 a \\ 0 & \cos^2 a & \cos^2 a \\ 0 & -\sin a \cos a & -\sin a \cos a \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{vmatrix} \begin{matrix} \sigma_v \\ \sigma_{H,min} \\ \sigma_{H,min} \end{matrix} \tag{6.5.49}$$

and at the borehole wall by

$$\sigma_{rr} = p_w \tag{6.5.50}$$

$$\begin{aligned} \sigma_{\theta\theta} &= (\sigma_{xx} + \sigma_{yy} - p_w) - 2(\sigma_{xx} - \sigma_{yy}) \cos(2\theta) \\ &\quad - 4\tau_{xy} \sin(2\theta) \end{aligned} \tag{6.5.51}$$

$$\begin{aligned} \sigma_{zz} &= \sigma_{zz} - 2\nu(\sigma_{zz} - \sigma_{yy}) \cos(2\theta) \\ &\quad - 4\nu\tau_{xy} \sin(2\theta) \end{aligned} \tag{6.5.52}$$

$$\begin{aligned} \tau_{r\theta} &= \tau_{rz} = 0 \\ \tau_{\theta z} &= 2(-\tau_{xz} \sin \theta + \tau_{yz} \cos \theta) \end{aligned} \tag{6.5.53}$$

Figure 6.5.28 presents the theoretical fracturing pressure of horizontal wells at different deviation angles from the fracture direction in a reservoir. Also, six actual wells

with multiple (in certain cases, more than ten) fracturing treatments are indicated. The agreement between predicted and observed values is excellent.

Because in highly deviated wells the direction of fracture initiation is likely to differ from the ultimate direction of propagation, this turning of the fracture direction can have major implications during fracture execution (screenouts as a result of inadequate width “around a bend”) and a choked fracture for the production after the treatment.

A most attractive element is the option to drill a horizontal well in the direction of minimum horizontal stress (i.e., transverse fractures will be initiated) or in the direction of maximum horizontal stress (i.e., a longitudinal fracture will be initiated). In Reference [37], guidelines are given to decide on either of these two options.

The base case is a vertical well with a vertical fracture. If $FCD > 10$, then a horizontal well with transverse orthogonal fractures is indicated. If $FCD < 2$, a horizontal well with a colinear, longitudinal, fracture is indicated. For FCD values between 2 and 10, a more detailed calculation is needed. This is a gain outlined in Reference [37].

In all cases the decision to drill a horizontal well instead of a vertical well must be done on the basis of NPV calculations. The incremental performance, if any, must cover the incremental cost of drilling the horizontal well.

For transverse fractures, each individual fracture is penalized by a skin effect describing the inefficient contact between well and fracture [35]. Then the sum of the individual NPVs is optimized. Each fracture is assessed a

FIGURE 6.5.28 Fracturing pressure of six arbitrarily oriented horizontal wells [38].

share of the drainage area and a portion of the incremental drilling costs.

6.5.2 Matrix Stimulation

Matrix stimulation is the process of injecting a fluid, either an acid or a solvent, into a well at a pressure below the fracturing pressure. For sandstone reservoirs this type of treatment will simply attempt to remove the damage and restore the natural permeability, whereas in carbonates, the damage is not only removed but may also be bypassed by creating new highly conductive channels called wormholes.

Any damage around the near wellbore region may severely reduce the production or injection rate of a well. This damage, which may have a variety of origins, may also be of different type and nature and can be characterized as either natural or induced. Natural damages include fines migration, swelling clays, water-formed scales, and organic deposits, such as paraffins or asphaltenes. Induced damages form after the injection or leakoff of a fluid and include plugging from solids or polymers, wettability changes, water blocks, emulsions, and bacterial growth.

Flow impairment around the wellbore has been described by a positive skin effect as has been introduced in Equation 6.5.1. A common representation of the skin effect due to damage is given by Hawkins' formula:

$$S = \left(\frac{k}{k_s} - 1 \right) \ln \frac{r_s}{r_w} \tag{6.5.54}$$

where k_s = permeability of damage zone in md
 r_s = extent of damage zone in ft.

The skin effect, influencing the well performance (and the one obtained from a pressure transient test), is a multi-

component variable including mechanical effects, phase, and rate-dependent effects, along with the near-wellbore damage. Thus, the total skin effect s_t is

$$s_t = s_d + s_{c+\theta} + s_p + \sum ps \tag{6.5.55}$$

where

s_d = skin due to damage

$s_{c+\theta}$ = skin effect due to partial penetration and slant [39]

s_p = skin effect due to perforations [40]

$\sum ps$ = rate and phase-dependent pseudoskin factors.

The $s_{c+\theta}$ and s_p can be calculated as outlined in References [39] and [40], respectively, whereas $\sum ps$ can be usually quantified by variations (and correlation) of the producing pressure and rate. This exercise is necessary for every well in order to isolate the damage-induced skin effect, which is the only one that can be removed via matrix treatments. The other components of the skin effect can be large, and their quantification is necessary in the design and evaluation of matrix stimulation treatments, but they will not be removed or reduced due to the stimulation treatment. The type of fluid used in a treatment often depends on the damage being addressed. Acids can be used when plugging is a problem, but solvents are used for organic deposits. In sandstone reservoirs, knowing the damage mechanism is especially important, because the damage must be removed to regain matrix permeability. In carbonate rocks, damage identification is less critical because of the new flow channels created to bypass the damage.

Because not all damage is acid-removable, an identification of the different types of damage and their treatments are shown in Figure 6.5.29 from Reference [41]. Only damage

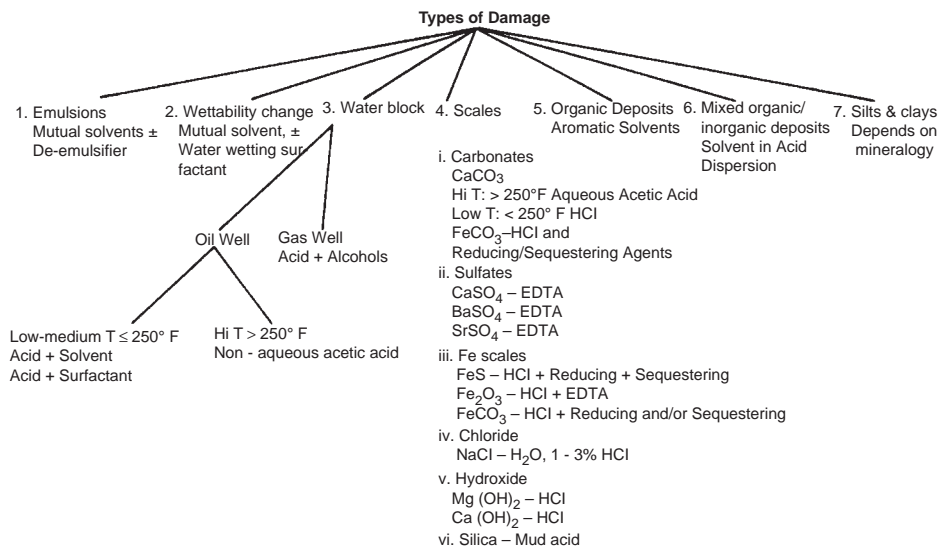

FIGURE 6.5.29 Types of damage and suggested matrix treatments.

caused by scales or silts and clays (under headings number 4 and 7) can be removed by acid.

Sandstone acidizing and the appropriate fluid selection depends on mineralogy, temperature and nature of damage. HCl or organic acid can effectively remove carbonate, iron, and hydroxide scales while chelating agents such as EDTA will be required to dissolve most sulfates. If the damage can be characterized as relating to silts and clays, a blend of HCl and hydrofluoric acid will be required. This acid blend is commonly referred to as *mud acid* and can be run at varying ratios using different concentrations where the hydrofluoric acid will range from 0.5% to 3% and the HCl will have a concentration of 3% to 13.5%. Figure 6.5.20 from Reference 42 outlines a treatment selection guide for damage removal in sandstone reservoirs.

Fluid selection guidelines for preflush fluids			
Mineralogy	Permeability		
	> 100 md	20 to 100 md	< 20 md
< 10% silt and < 10% clay	15% HCl	10% HCl	7.5% HCl
> 10% silt and > 10% clay	10% HCl	7.5% HCl	5% HCl
> 10% silt and < 10% clay	10% HCl	7.5% HCl	5% HCl
< 10% silt and > 10% clay	10% HCl	7.5% HCl	5% HCl

Note: Selection guidelines for all temperatures
Guidelines when clay content contains chlorite/glaucanite
 For 4% to 6% chlorite/glaucanite, use < 20-md guidelines with 5% acetic acid.
 For > 6% to 8% chlorite/glaucanite, do not use HCl; use 10% acetic acid preflush to mud acid plus 5% acetic acid.
 For > 8% chlorite/glaucanite, do not use HCl; use 10% acetic acid and organic mud acid.

Guidelines when clay content contains zeolites
 For < 2% zeolite, use 5% acetic acid in all fluids containing HCl and preflush with 10% acetic acid.
 For > 2% to 5% zeolite, do not use HCl preflush; use 10% acetic acid preflush and overflush to mud acid containing 10% acetic acid.
 For > 5% zeolite, do not use HCl in any system; use 10% acetic acid preflush and overflush to organic acid prepared from 10% citric acid/HF.

6.5.2.1 Matrix Acidizing Design

Reference 43 lists the major steps necessary for a matrix acidizing design:

1. Ensure that the well is damaged and that a high skin effect is not mechanically induced.
2. Establish the nature of damage.

Fluid selection guidelines for mud acid fluids			
Mineralogy	Permeability		
	> 100 md	20 to 100 md	< 20 md
< 10% silt and < 10% clay	12% HCl-3% HF	8% HCl-2% HF	6% HCl-1.5% HF
> 10% silt and > 10% clay	13.5% HCl-1.5% HF	9% HCl-1% HF	4.5% HCl-0.5% HF
> 10% silt and < 10% clay	12% HCl-2% HF	9% HCl-1.5% HF	6% HCl-1% HF
< 10% silt and > 10% clay	12% HCl-2% HF	9% HCl-1.5% HF	6% HCl-1% HF

Note: Selection guidelines for all temperatures
Guidelines when clay content contains chlorite/glaucanite
 For 4% to 6% chlorite/glaucanite, use < 20-md guidelines with 5% acetic acid.
 For >6% to 8% chlorite/glaucanite, do not use HCl; use 10% acetic acid preflush to mud acid plus 5% acetic acid.
 For >8% chlorite/glaucanite, do not use HCl; use 10% acetic acid and organic mud acid.

Guidelines when clay content contains zeolites
 For <2% zeolite, use 5% acetic acid in all fluids containing HCl and preflush with 10% acetic acid.
 For >2% to 5% zeolite, do not use HCl preflush; use 10% acetic acid preflush and overflush to mud acid containing 10% acetic acid.
 For >5% zeolite, do not use HCl in any system; use 10% acetic acid preflush and overflush to organic acid prepared from 10% citric acid/HF.

3. Determine the appropriate fluid for the treatment (see Figure 6.5.29 for general fluid selection and Table 6.5.1 for acidizing treatments).
4. Calculate maximum rate and pressure to avoid unintentional formation fracturing.
5. Determine volume requirements for treatment.
6. If the formation is multilayered or if it presents a substantial vertical permeability anisotropy, determine a placement technique (diversion).
7. Evaluate treatment for its success (or failure) and consider these findings in future, similar treatments.

Of the above, items 4, 5, 6, and 7 will be outlined.

6.5.2.1.1 Rate and Pressure Limits for Matrix Treatments

A major step in designing a matrix stimulation job is to determine the conditions for the matrix flow regime. To avoid fracturing the formation, the bottomhole injection pressure must not exceed the fracturing pressure. The maximum allowable injection rate that does not fracture the formation is derived from Darcy's radial flow equations. Equation 6.5.56 is a simplified inflow performance

TABLE 6.5.1 Conventional Sandstone Matrix Acid Use Guidelines [60]

Formation character	Recommended acid	
	Preflush	Main acid stage
HCl solubility > 15%	Avoid the use of HCl acid	
Calcite or dolomite	5% NH ₄ Cl	15% HCl only ^a
High iron carbonate ^b	5% NH ₄ Cl + 3% Acetic Acid	15% HCl + Iron Control
High permeability (>100 mD) ^c		
High quartz (>80%) Low clay	15% HCl	12% HCl/3% HF
Moderate clay (<5%-8%), low feldspar (<10%)	10% HCl	7.5% HCl/1.5% HF
High clay (>10%)	5%–10% HCl	6.5% HCl/1% HF
High feldspar (>15%)	15% HCl	13.5% HCl/1.5% HF
High feldspar (>15%) and clay (>10%)	10% HCl	9% HCl/1% HF
High iron chlorite clay (>8%)	5% HCl	3% HCl/0.5% HF
	10% acetic acid + 5% NH ₄ Cl	10% Acetic Acid/0.5% HF
Medium permeability (10–100 mD) ^c		
High clay (>5–7%)	10% HCl	6% HCl/1.5% HF
Low clay (<5%–7%)	10% HCl	9% HCl/1% HF
High feldspar (>10%–15%)	10%–15% HCl	12% HCl/1.5% HF
High feldspar (10–15%) and clay (>10%)	10% HCl	9% HCl/1% HF
High iron chlorite clay (>8%)	5% HCl	3% HCl/0.5% HF
	10% Acetic Acid + 5% NH ₄ Cl	10% Acetic Acid/0.5% HF
High iron carbonate (>5%–7%)	10% HCl	9% HCl/1% HF
	10% HCl	5% HCl/0.5% HF ^d
Low permeability (1–10 mD) ^c	Consider hydraulic fracturing ^e	
Low clay (<5%) and HCl solubility <10%	5% HCl	6% HCl/1.5% HF
High clay (>8%–10%)	5% HCl	3% HCl/0.5% HF
High iron chlorite clay (>5%)	10% acetic acid + 5% NH ₄ Cl	10% acetic acid/0.5% HF
High feldspar (>10%)	10% HCl	9% HCl/1% HF
Very low permeability (<1 mD)	Avoid use of HF; if near wellbore damage is indicated use a non-HF matrix stimulation. Hydraulic fracturing is preferred	

^aThe location of carbonate in the matrix is important. It may be possible to include HF acid in naturally fractured formation with high carbonate content.

^bAnkerite or siderite.

^cIf zeolites (analcime) are present (>3%) replace the HCl with organic acids.

^d $k < 25$ mD.

^eAlthough fracturing may be preferable, low-permeability, low-clay sands may respond favorable to acidizing with HF which is contrary to conventional wisdom.

relationship that can be used as a guideline for treatment design [44].

$$q_{\max} = \frac{4.917 \times 10^{-6} kh(p_{fg} \times d) - \Delta p_s - p_r}{\mu B \left(\ln \frac{r_s}{r_w} + s \right)} \quad (6.5.56)$$

where q_{\max} = maximum injection rate (bbl/min)

k = undamaged permeability (md)

h = net height of the formation (ft)

p_{fg} = fracture gradient (psi/ft)

d = TVD to mid-perforations (ft)

p_s = safety margin (typically 200 to 500 psi) (psi)

p_r = average reservoir pressure (psi)

m = viscosity of injection fluid (cp)

B = formation volume factor (res bbl/STB)

r_s = drainage radius (ft)

r_w = wellbore radius (ft)

s = skin value (dimensionless)

The maximum allowable surface pressure can be determined using Equation 6.5.57.

$$p_s = p_{fg} \times d - p_h + p_f \quad (6.5.57)$$

where p_s = maximum surface pressure (psi).

p_{fg} = fracture gradient (psi/ft.)

d = TVD to mid-perforations (ft.)

p_h = hydrostatic pressure (psi).

p_f = pipe friction pressure (psi).

Friction pressure can be determined through Reynolds number calculations, by applying values from friction pressure charts, or by measuring at the wellsite with pretreatment injection tests; however, friction is nearly negligible for many matrix treatments due to the low pumping rates of the treatment.

6.5.2.1.2 Fluid Volume Requirements

For sandstones, a matrix acidizing treatment usually consists of a preflush, an acid, and an overflush volume. The preflush provides a separation between conate water and hydrofluoric acid to help prevent the formation of damaging sodium and potassium fluosilicates and reacts with carbonate minerals to prevent their reaction with the mud acid. The reaction of mud acid with carbonate minerals will not only create a calcium fluoride precipitate that is potentially damaging, but it also spends the mud acid, limiting the strength and effectiveness of the acid when contacting the silts and fines that are damaging the well. Depending on the carbonate and clay contents of the formation and its permeability, 5% to 15% HCl or 5% to 10% acetic acid is used. The volume of the preflush needs to be large enough to completely dissolve the carbonate minerals to a depth into the reservoir that ensures the mud acid will not contact these minerals. The volume of required mud acid can be estimated by using a derivation of the Hawkins equation that accounts

for both damage and stimulation [45].

$$s = \frac{k}{k_s} \ln \frac{r_s}{r_i} + \frac{k}{k_i} \ln \frac{r_i}{r_w} - \ln \frac{r_s}{r_w} \quad (6.5.58)$$

where s = skin value (dimensionless)

k = undamaged permeability (md)

k_s = damaged permeability (md)

k_i = stimulated or improved permeability (md)

r_w = wellbore radius (ft)

r_s = damage radius (ft)

r_i = stimulated radius (ft)

Experience has shown that mud acid volumes of 125 to 200 gal/ft. of formation will generally provide acceptable results [36].

The overflush volume, ranging from 50 gal/ft. to one to five times the volume of the acid formulation, is usually either 3% to 10% HCl, NH_4Cl , or a light hydrocarbon, such as diesel. For a gas well, nitrogen may be used.

For carbonate reservoirs, the flow and reaction of acid within the formation is significantly more complicated. Viscous fingering, but particularly special instabilities called *wormholes*, are generated. The quantification of the wormholing phenomenon as it pertains to the skin effect reduction was presented by Daccord *et al.* [46]:

$$- \frac{1}{d} \ln \left(1 + \text{Ac} N_{\text{Pe}}^{1/3} \frac{bV}{\pi \text{th} \phi r_w^d} \right) \quad (6.5.59)$$

where d = fractal dimension (= 1.6 for mass-transfer-limited kinetics and = 2 for surface-reaction kinetics)

Ac = acid capacity number [46]

N_{Pe} = Peclet number

V = volume of acid injected.

6.5.2.1.3 Diversion In Matrix Acidizing

The placement of treating fluids into all zones of interest, especially those that are damaged, is a significant challenge. Successful matrix treatments depend on the uniform vertical distribution of the treatment fluid over the entire production (or injection) interval. When acid is pumped into a well, it naturally tends to flow into the highest permeability or zone with the least amount of damage (or both) and through the open perforations. Improper placement of acid between regions of different injectivities can be avoided by using diversion techniques.

The earliest diverting techniques relied on mechanical means to restrict flow and included inflatable packers and ball sealers. Chemical diverters became popular not only because they could be pumped concurrently with the matrix stimulation fluid, but because they were also designed to clean up once the well went to production. Chemical diverters such as sized rock salt (water soluble) and benzoic acid flakes (highly hydrocarbon soluble and slowly water soluble at high temperatures) effectively divert fluid

stages by temporarily bridging and plugging the perforation tunnels. Hydrocarbon resins (hydrocarbon soluble) can be made into particulates of various sizes and can effectively provide diversion by creating a filtercake on the formation. Selection of the correct particle size is based on the permeability and therefore the associated pore throat size, of the formation. Resin diverters injected preferably just prior to the acid injection or with the acid itself are deposited on the sandface, creating a diverter cake of a resistance R_{cake} and thus a temporary skin factor s_{cake} [11]:

$$s_{\text{cake}} = \frac{2\pi kh}{A} R_{\text{cake}} \quad (6.5.60)$$

where A is the area of flow and R_{cake} is experimentally determined. The amount of diverter deposited on the sandface increases as long as the layer takes a disproportionate amount of fluid. Cake deposition ends when the flowrate is distributed to another zone. Figure 6.5.30 is a depiction of matrix stimulation injection without and with a diverter.

More recently foams and fluids made from VESs have shown to be effective diverting agents. These systems enter into the matrix porosity of the reservoir, where they form a viscous structure that inhibits further flow into the zone. Viscoelastic diverting fluids are increasingly popular because of improved stability, being operationally simple, and not requiring specialized pumping equipment compared with foams. Both of these systems provide the benefit of helping the acid to selectively treat the appropriate zone. They are inherently less stable in hydrocarbon bearing zones (thus allowing acid penetration) and they are very stable in water zones (thus diverting acid away from these zones and minimizing the stimulation effects) [47].

6.5.2.1.4 Matrix Stimulation in Horizontal Wells

To evaluate a proper matrix stimulation treatment in horizontal wells, a description of the damage profile along and normal to the horizontal well trajectory is necessary. Frick and Economides [48] have shown that the distribution of formation damage surrounding a horizontal well is neither radial nor is it evenly distributed along the wellbore.

During drilling and well completion, mud filtrate and completion fluids penetrate the pay zone. Because the exposure time of the formation to drilling and completion fluids is longer at the horizontal section nearer the vertical section, the shape of damage distribution along the wellbore will be a truncated cone, with the larger base near the vertical section of the well. This profile of damage is evident also during production, because the pressure gradient normal to the well nearer the vertical section is (usually) the largest.

Permeability anisotropy, represented by β , generates an elliptical shape of damage distribution normal to the well. The geometrical shape of a truncated elliptical cone results in an expression for the skin effect around a horizontal well [48]:

$$s'_{\text{eq}} = \left(\frac{k}{k_s} - 1 \right) \ln \left[\frac{1}{(\beta) + 1} \sqrt{\frac{4}{3} \left(\frac{a_{H,\text{max}}^2}{r_w^2} + \frac{a_{H,\text{max}}}{r_w} + 1 \right)} \right] \quad (6.5.61)$$

where $a_{H,\text{max}}$ is the horizontal half-axis of the larger base of the elliptical cone of damage, as shown in Figure 6.5.31 along with cross-sections of damage for various β . This

FIGURE 6.5.30 Fluid distribution for matrix stimulation injection in a multi-layered reservoir. On the left, without diverters; on the right, with diverters.

expression is analogous to Hawkins' formulation for vertical wells and can be used in the usual manner, implying a steady-state pressure drop.

Stimulation Considerations.

Horizontal wells have such long exposed intervals that stimulation fluid volumes per unit length used in vertical wells are not practical. While pumping as much as 150 gal/ft. is routine in vertical wells, such coverage implies 300,000 gal of acid in a 2000-ft. horizontal well. Pumping at 1 bpm, these volumes would require 120 hours of pumping.

A further constraint is proper placing of acid (diversion): acid has a tendency to extend existing flow paths. Thus, acid thief zones are either natural or created, and there is therefore a need for substantial optimization of matrix stimulation in terms of technical and economic considerations.

When planning for a partial removal of the damage, the distribution of the stimulation fluid is a crucial issue. A simple calculation of posttreatment skin effect determines that the distribution of the stimulation fluid should mimic the shape of damage. Deliberate blanking of horizontal well segments and complete damage removal in the perforated sections offer another potential for significant optimization of the stimulation treatment.

The previous considerations require a methodology of acid placement. Bull-heading the fluids into the horizontal portion is not recommended. Such treatments stimulate only a minor portion of the horizontal well, usually near the heel. Coiled tubing is a proper tool for the distribution of stimulation fluids. After the coiled tubing is run to the toe of the well, the stimulation fluid can be pumped as the coiled tubing is concurrently withdrawn. The rate of coiled tubing withdrawal can be calculated and depends on the injection rate and volumetric coverage. In addition, new jetting tools placed on the end of the coiled tubing have proven to be very effective at ensuring acid coverage over long intervals [49].

6.5.2.2 Evaluation of Matrix Acidizing Treatments

Paccaloni [50] was the first to use instantaneous pressure and rate values to compute the changing skin effect at any time during the treatment and thus evaluate the progress of the job. He used a steady-state pressure response and defined a "damage ratio" DR:

$$DR = \frac{\ln(r_e/r_w) + s}{\ln(r_e/r_w)} \tag{6.5.62}$$

FIGURE 6.5.31 Shape of damage along and normal to a horizontal well [48].

The method allows the estimation of both the original (damage) skin effect as well as its evolution.

A new technique, which does not use a steady-state assumption, was introduced by Prouvost and Economides [51]. The method uses reservoir transients during acid injection to simulate pressure response and compares it with measured values. The difference between these values is attributed to the changing skin effect, namely,

$$\Delta s = \frac{kh\Delta p_{\text{departure}}}{141.2qB\mu} \quad (6.5.63)$$

where: $\Delta p_{\text{departure}}$ = difference between simulated pressure (with a constant nonremovable skin effect) and the measured value. The technique is illustrated on Figure 6.5.32.

The simulated pressure requires a knowledge of reservoir and well parameters, namely the permeability k , and the skin effect that cannot be removed by acid. If the latter is not known, then zero can be used. The two pressure curves would then be apart at the end of the job by a constant value proportional to the nonremovable skin effect.

A graph of the evolving skin can then be drawn as shown in Figure 6.5.33.

FIGURE 6.5.32 Simulated and measured pressure response during a matrix acidizing treatment [51].

FIGURE 6.5.33 Evolution of skin effect [51].

6.6 OIL AND GAS PRODUCTION PROCESSING SYSTEMS

Section reviewed by Michael C. Jackson

6.6.1 Surface Production/Separation Facility

The purpose of the surface production facility (Figures 6.6.1 and 6.6.2) is:

- To separate the wellstream into its three fundamental components—gases, liquids, and solid impurities
- To remove water from the liquid phase
- To treat crude oil to capture gas vapors
- To condition gas

This section is a discussion of the design, use, function, operation, and maintenance of common facility types. In this section facilities will be referred to as the following:

- Oil production facilities as *batteries*
- Primary gas production facilities as *gas units*
- Water handling/disposal as *brine stations*

Identification of the service of each facility and associated equipment is also required. Is the service natural gas, crude oil, produced water, multiphase? Is it sweet (little to no H₂S) or sour (H₂S present)? H₂S or sour service is ambiguous at best without the following:

- National Association of Corrosion Engineers (NACE) MR-01-75 addresses material selection to avoid sulfide stress cracking. Threshold concentrations for application are in the Scope section of this document. In general, MR-01-75 applies to wet production steams (where free water is present) when operating pressure exceeds 50 psig and H₂S. The Minerals Management Service (MMS) cautions that even though materials listed may be resistant to sulfide stress corrosion environments, they may not be suitable for use in chloride stress cracking environments [1].
- Where H₂S concentration exceeds 100 ppm, The Texas Railroad Commission Rule 36 [2] and New Mexico

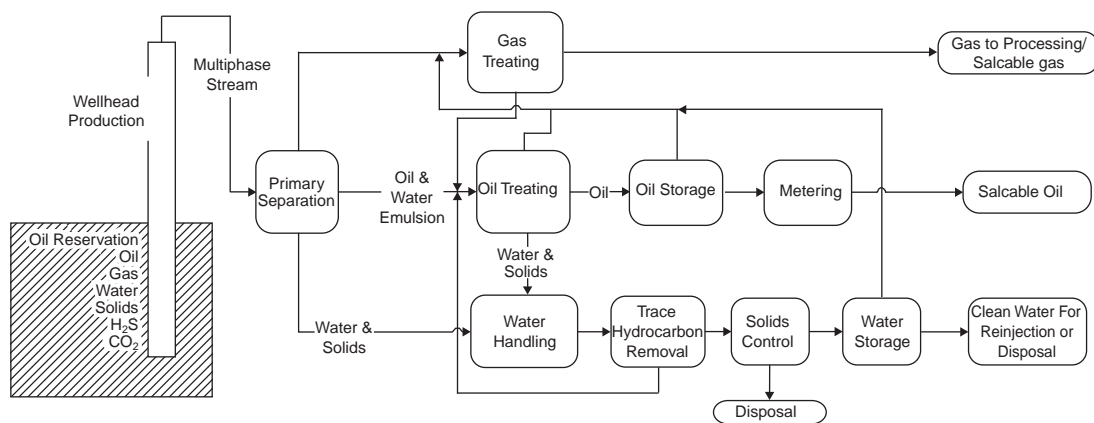

FIGURE 6.6.1 Typical oil production process system.

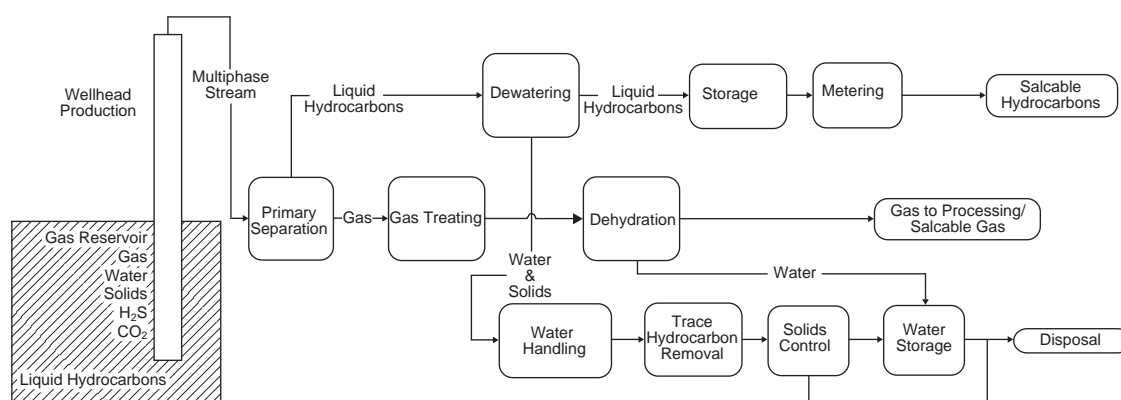

FIGURE 6.6.2 Typical gas production process system.

OCD Rule 118 [3] apply. Both these rules address public safety. Other states have similar rules.

- Many oil and gas companies also have recommended standards for various levels of H_2S concentration, so be aware that these may also need to be taken into account.

Before anything is designed, construction codes need to be reviewed as well. Some of the most referenced codes are:

- American National Standards Institute (ANSI) B31.8 “Gas Transmission and Distribution Piping Systems” is used for general oil field construction. ANSI B31.8 dictates that the qualification of welders and the quality of fit-up, taking, welding, and radiographic inspection for noncritical service should conform to API Standard 1104 “Standard for Field Welding of Pipelines, otherwise, welders should be qualified to ASME Boiler and Pressure Vessel Code”.
- ANSI B31.3 “Chemical Plant and Petroleum Piping” applies to all process piping in gas plants and compressor station installation with pressures over 750 psig.
- Title 49 of the Code of Federal Regulations (CFR) covers Department of Transportation (DOT) regulations in parts 191, 192, and 195 [4–6].

- As always, be aware that various other state and federal requirements may apply. Refer to Table 6.9.1 for a partial listing of applicable federal and state regulatory agencies.

Figure 6.6.3 is an example process flow diagram of surface production equipment more commonly referred to as a *battery*.

From a technical point of view, production equipment can be divided into four major groups:

- pressure vessels
- storage tanks
- prime movers (pumps and compressors)
- piping

6.6.1.1 Nomenclature of Separating Pressure Vessels

Pressure vessels in the oilfield are used for separating well fluids produced from oil and gas wells into the gaseous and liquid components. Vessels are separated into two groups

- *Slug Catcher*—A separator, which is designed to absorb sustained inflow of large liquid volumes at irregular intervals. Usually found on gas-gathering systems or other two-phase pipeline systems. A slug catcher may be a single large vessel or a manifold system of pipes. Typically, these are high-pressure vessels.
- *Flash Tank (Chamber, Trap, or Vessel)*—A conventional oil and gas separator operated at low pressure, with the liquid from a higher-pressure separator being “flushed” into it. This flash chamber is quite often the second or third stage of separation, with the liquid being discharged from the flash chamber to storage.
- *Expansion Vessel*—A first-stage separator on a low-temperature or cold-separation unit. This vessel may be equipped with a heating core to melt hydrates, or a hydrate-preventative liquid (such as glycol or methanol) may be injected into the well fluid just before expansion into this vessel.
- *Desanders*—A high-pressure vessel that is installed on some gas wells to “catch” any sand that is produced along with the gas. This sand may be from a frac job, or it may be from the formation. The pressure drop at the desander allows the majority of this sand to drop out at a controlled location rather than in the lines, at measurement points, or in production equipment.

All new pressure vessels should be designed and constructed per ASME Boiler and Pressure Vessel Code, Section VIII. It is up to the purchaser if the vessel is to be certified and registered by the National Board of Boiler and Pressure Vessel Inspectors [8]; in critical service, this may be worth the extra time and expense to obtain a National Board Number and the associated paperwork. It is imperative that all the construction drawings, steel mill reports, and the U1A form that is provided by the ASME Code Shop/Fabricator be filed in a Central Filing System. Those records are required to be maintained and accessible as part of the Code requirements. Any subsequent repair or alterations made to the vessel are to be documented and filed as well. It is suggested that a unique company number be assigned to each vessel and cold stamped into a vessel leg or skirt, as nameplates can be damaged or removed over time, especially if equipment is moved from one location to another. This unique number allows for maintaining the records from cradle to grave for each vessel.

Utilizing used equipment is a matter of timing and economics. The cost of new versus used needs to be taken into account on all projects. The cost of used equipment needs to include inspection, repair, and certification costs as well as the cost of the vessel itself.

All equipment should be upgraded and tested to a level that meets regulations and industry standards (i.e., API) for operability and safety. Used pressure vessels should conform to API 510 standards [9].

The design and operation of various vessels are discussed later in this section.

6.6.2 Pressure Vessel Relief Systems

All pressure vessels are to be equipped with a pressure relief valve set to open at a pressure no greater than the maximum allowable working pressure (MAWP) of that vessel and sized to prevent pressure from rising more than 10% or 3 psi, whichever is greater, above the MAWP at full open flow. For vessels with multiple relief valves, 16% or 4 psi, whichever is greater, above the MAWP is allowed. This provision **DOES NOT** apply to relief valve/rupture disk combinations. Pressure vessels operating at pressures above 125 psig may be equipped with a rupture disk or a second (redundant) relief valve. The rupture disk should be designed to rupture at not more than 15% above the MAWP and sized to handle the maximum flow through the vessel. Relief valves and rupture disks should be installed in the gaseous phase of a vessel, and be placed so that there is no restriction between the valve and the vessel. A locking handle full-opening ball valve can be installed below the relief valve but must remain locked in the open position. The installation of this isolation valve is so that the relief valve can be tested in place or replaced without having to take the vessel out of service to do so. Vessels that operate in a fluid-packed state should be equipped with an appropriately sized liquid service relief valve.

6.6.2.1 Product Storage

Tanks used in oil and gas production operations are all atmospheric. Gas plants and refineries use the pressurized tanks/vessels.

- *Atmospheric*—Atmospheric tanks are designed and equipped for storage of contents at atmospheric pressure. This category usually employs tanks of vertical cylindrical configuration that range in size from small shop welded to large field erected tanks. Bolted tanks, fiberglass tanks, and occasionally rectangular welded tanks are also used for atmospheric storage. API standards relating to tankage are listed in [Table 6.6.1](#) [10]. Note: 1,000 bbl tanks are the largest size that can be shop welded and transported to location. Internally coated, welded steel tanks should normally be used in hydrocarbon or brine service. Tank decks should be connected to ensure proper internal coating. Operations preferences and service conditions should be considered when selecting flat or cone bottom tank. Fiberglass tanks are typically only used in brine water service rather than for hydrocarbon due to fire safety. It is important to always ground the fluid in a fiberglass tank, bond and ground metal parts, and gas blanket the vapor space to minimize oxygen entrainment.
- *Low Pressure (0 to 2.5 psig or 0 to 17 kPa)*—Low-pressure tanks are normally used for storage of intermediates and products that require a low internal gas pressure. These are generally cylindrical in shape with flat or dished bottoms and sloped or domed roofs.

TABLE 6.6.1 API standards — tanks (partial listing) [10]

Standard Number	Title
API Spec 12B	Specification for Bolted Tanks for Storage and Production Liquids
API Spec 12D	Specification for Field Welded Tanks for Storage and Production Liquids
API Spec 12F	Specification for Shop Welded Tanks for Storage and Production Liquids
API Spec 12P	Specification for Fiberglass Reinforced Plastic Tanks
API 12R 1	Recommended Practice: Setting, Maintenance, Inspection, Operation and Repair in Production Service
API RP 620	Recommended Practice: Design and Construction of Large, Welded, Low-Pressure Storage Tanks
API RP 650	Recommended Practice: Welded Steel Tanks for Oil Storage
API Spec 653	Specification for Tank Inspection, Repair, Alteration and Reconstruction
API RP 2000	Recommended Practice: Venting Atmospheric and Low-Pressure Storage Tanks: Non-Refrigerated and Refrigerated

Low-pressure storage tanks are usually of welded. These tanks are built to API Standards 12D, 12F, 620, or 650.

- **Medium Pressure (2.5 to 15 psig or 17 to 103 kPa)**—Medium-pressure tanks are normally used for storage of higher volatility intermediates and products. The shape may be cylindrical with flat or dished bottoms and sloped or domed roofs. Medium-pressure tanks are usually of welded design. Welded spheres may also be used, particularly for pressure at or near 15 psig. These tanks are built to API Standard 620.
- **High Pressure (above 15 psig or 103 kPa)**—High-pressure tanks/vessels are generally used for the storage of refined products or fractionated components at pressures greater than 15 psig. They are welded and may be of cylindrical or spherical configuration. Because they are above 15 psig, they are designed and constructed per ASME code.

Gas processing industry liquids are commonly stored underground, in conventional or solution-mined caverns. For more details about product storage options, see [Table 6.6.2](#).

6.6.2.1.1 Walkways and stairways

Engineering controls should be installed on new tanks and walkways so that breathing equipment is not required to do routine work. Engineering controls include mechanical or electronic tank gauges that eliminate the need for daily opening of the thief hatch to measure the tank level. All readouts should be at ground level. Walkways and stairways should be constructed to API standards and be wide enough so that a person with a self-contained breathing apparatus (SCBA) can have egress without restriction (minimum of 30 in. [0.8 m] wide). Walkways should be quoted complete with all necessary supports. Engineers should carefully review standard walkways and stairways provided by manufacturers, as some do not meet the structural requirements of API or OSHA.

6.6.2.1.2 Tank Venting

All tank venting designs should be in accordance to API 2000 Standard. Oil and gas production operation tanks should be provided with both normal and emergency venting. Normal venting is typically addressed with deadweight pressure/vacuum valves. The weight is determined by the design of the tank. Tanks used for production operations typically have vent valves set at 4 oz. Emergency venting is addressed with gauge hatch covers and, if necessary, additional weighted covers. The normal operation vents must work in conjunction with the gas blanket and the vapor recovery unit (VRU) (more information on VRUs is found in “Compressors”), if installed to minimize tank emissions and blanket gas utilization. Frangible deck joints are recommended on larger tanks. These should be constructed according to API 650 with full penetration welds to facilitate internal coating of the tank.

6.6.2.1.3 Gas Blankets

Gas blankets should be used in order to minimize the possibility of an explosive atmosphere in water tanks, to prevent oxygenation of produced water, and to prevent air at the intake of a VRU if the controls fail. Gas blankets must work in coordination with the VRU and normal tank venting. Normal relief pressures should be at the widest range permissible by tank design. The source of gas for a gas blanket is typically a residue gas system, which also provides “clean” gas for fired equipment or may come off of the gas scrubber in the facility.

6.6.2.2 Prime Movers

6.6.2.2.1 Centrifugal Pumps

Centrifugal pumps are the most commonly used pumps in production operations. Single-stage ANSI pumps driven by small-horsepower electric motors are used for transfer of fluids as well as charge pumps upstream of larger

TABLE 6.6.2 Product Storage Options [11]

	Atmospheric	Low Pressure (0–2.5 psig)	Medium Pressure (2.5–15 psig)	High Pressure (Above 15 psig)	Underground

X_R, refrigerated only.

high-pressure water injection pumps. ANSI pumps are preferred in production operations because all similar pumps meeting ANSI specifications will have identical baseplate, as suction/discharge dimensions, regardless of the manufacturer. In addition, this allows for greater future utility and ease of maintenance and replacement.

Materials should be specified according to service and design life requirements. Carbon steel housing may be suitable for sweet oil service, but in corrosive service, alloys such as 316 stainless steel (SS) are justified. When sizing a pump, it is necessary to take into account current and future operating conditions in order to provide for flexibility after installation. It is much easier and is more economic to install a larger impeller in a pump than it is to replace the motor and/or pump. The engineer needs to find a balance between conservative pump size and being able to keep the pump operating at or near its best efficiency. As operating conditions fall too far to one side or the other, surge effects and cavitation can occur.

Multistage centrifugal pumps are commonly used for water injection. These pumps can move large volumes of water at relatively high pressure (less than 2,000 psi). Because of the corrosive service, these pumps are typically

made of 316 SS. They may be horizontal split case, horizontal ESP-type, or vertical “can” design. If at all possible, it is suggested that there be a spare pump set up to switch to if problems arise with the primary pump.

6.6.2.2.2 Reciprocating Positive Displacement Pumps

In a reciprocating pump, a volume of liquid is drawn into the cylinder through the suction valve on the intake stroke and is discharged under positive pressure through the outlet valves on the discharge stroke. The discharge from a reciprocating pump is pulsating and changes only when the speed of the pump is changed. This is because the intake is always a constant volume. Often a pulsation dampener is connected on the discharge side of the pump to provide a more even flow by evening out the pressure surges. Reciprocating positive displacement (PD) pumps are most often used for water injection or disposal. They are designed for high pressures and low volumes as compared to the multistage centrifugal pumps. Typically, the fluid end is 316 SS due to the corrosive nature of the fluids handled. As always, know the service conditions before specifying the material. When sizing a PD pump, it is suggested that the initial (design)

speed be less than 90% of the manufacturer's rated speed. This will enhance the reliability of the machine and allows some flexibility for increasing flow rate if necessary. By changing the speed and the plunger diameters, a fluid end can address a range of flow rates and pressures.

Reciprocating PD pumps are available in four designs:

- *Simplex*—This pump has a single liquid cylinder that forces liquid out through the top outlet on both the in and the out stroke (here up and down). This basic type of pump might be used for air pumps, feed pumps for the furnace, fire, bilge, and fuel oil service.
- *Duplex*—These are similar to the simplex pump, having two pistons instead of one, providing smoother operation. Duplex pumps have no “dead spots” because one or the other piston is always pumping. The two pistons are about 1/4 cycle out of synchronization with each other.
- *Triplex*—These are similar to the duplex pumps, having three pistons or plungers. This is the most commonly used pump in drilling and well servicing. They are also widely used for disposal wells or small waterfloods.
- *Quintuplex*—These are similar to the triplex pumps, having five pistons or plungers. These generally have reduced pulsation and overall improved reliability vs all other reciprocating PD pumps.

Piping design should carefully address the suction-side pipe hydraulics. It is critical to provide adequate Net Positive Suction Head (NPSH) to avoid cavitation and vibration problems. The use of suction and discharge pulsation dampeners is strongly recommended. Suction lines should be sized to limit the velocity to less than 5 ft./s, and discharge piping should include a relief valve and check valve upstream of the discharge block valve. The relief valve should be piped back to a tank to avoid spills.

Vibration is of major concern with PD pumps; mechanical vibration and structural stress can result in failures and spills, and so pulsation dampeners, valves, etc. should be supported. OSHA requires guards to be placed over plungers and belts.

6.6.2.2.3 Compressors

Compression in the oil field ranges from low-pressure sliding vane compressor to 2500+ high-pressure integral units. Compressors are used to boost the pressure from the wellhead or the facility to sales line pressure, to inject gas back into the reservoir for pressure maintenance or enhanced oil recovery (CO₂, nitrogen, etc.), or boost the pressure from the wellhead or facility to a central facility. Depending upon the size and the field conditions/location, they may be powered by electric motors, gas/internal combustion or by turbine engines. VRUs are the most common use of compression in surface oil production. The larger compressors are addressed in “Compressor Stations”.

VRUs are installed for the economic recovery of tank vapors, compliance with Air Emission Regulations (Federal and/or State), and for safety considerations. Emissions can be estimated or measured prior to installation. The Texas Natural Resource Commission has allowed 90 days of temporary operation under Standard Exemption 67 [12] to determine actual emissions. The majority of the VRUs on the market today use sliding vane rotary or screw compressors. Generally sliding vane compressors are used up to 4:1 compression ratios, screw compressors up to 10:1. Above 10:1 is a specialized application and a reciprocating compressor should also be considered.

6.6.2.3 Piping Guidelines

6.6.2.3.1 Materials

The most commonly used materials in oil and gas operations are carbon steel, SS (304 or 316 families), fiberglass, and polyethylene. Each one has a place when properly matched to the application. In most cases, the decision on which one to use is based on economics (material costs as well as the coating and ditching costs), corrosion resistance, land use, support requirements, proximity to the public, and impact of failures.

Much of what is addressed is risk-based analysis.

- *Carbon steel* is the most commonly used material. Most onshore operations use electric fusion welded (EFW), electric resistance welded (ERW), or grade B seamless pipe. The EFW and ERW pipe are considered acceptable for most applications and are cheaper than seamless pipe. EFW is typically only available in 16-in. or greater diameter. DOT-regulated lines cannot contain ERW pipe.
 - Bare carbon steel can be used for liquid hydrocarbon, steam, and gas service. If internally coated, it can also be used in water and acid service.
- *SS* is used when increased corrosion protection is needed. The most commonly used ones in the oil field are 316 and 304. The low-carbon versions should be used if it is to be welded. The 316L and 304L do not become sensitized during welding; hence, do not require postweld heat-treating. 316 SS is preferred in brine/salt water service, and 304 SS is may be used in wet CO₂ service. Austenitic Stainless Steels are susceptible to several forms of stress corrosion cracking, especially chloride SCC. Care should be taken when selecting these materials where high temperature and/or concentrations are expected. Post Weld Heat Treatment or alternative materials such as lined carbon steel or composites should be considered.
- *Fiberglass* is commonly used where corrosion, either internal or external, is of concern. It is available in a wide variety of diameters and pressure ratings. It is primarily

used in water systems (water injection and gathering systems as well as inplant piping at injection stations). Because of the effect of sunlight (UV) on the resins used in fiberglass pipe, it should be buried, painted, or otherwise protected from the elements. If buried, thrust blocks should be considered at the elbows to counteract the hydraulic forces. Extreme care must be taken to properly pad the trenches before burial, otherwise leaks due to rock damage can be expected.

- *Polyethylene* is commonly used due to its low cost, low weight, ease of installation, corrosion resistance, and flow characteristics. For the most part, it is not recommended for pressure above 100 psig or temperatures above 100°F, although there has been a lot of progress made in the characteristics. Poly pipe is most often used for gas gathering and flowlines, but it should be derated per manufacturer's recommendations when used in wet hydrocarbon service. Because of its composition, it should not be used to transport flammable fluids above ground.

6.6.2.3.2 Buried versus Above Ground

One of the first of these items to be addressed is whether the pipe is to be above ground or buried. OSHA requires that all nonmetallic or low-melting-point pipe carrying flammable materials to be buried. And whenever nonmetallic pipe is buried, detection tape or trace cable should be buried above the pipe to aid in locating the pipe in the future. Buried pipe may be more or less costly than aboveground systems. One should take into account the relative cost of the pipe, access, operational preferences, fire, freeze, mechanical protection, and pipe supports. It is recommended to externally coat buried pipe to avoid external corrosion. Cathodic protection may be used instead of or in conjunction with external coating systems.

It is common to paint aboveground pipe for aesthetics as well as to provide some corrosion protection (this includes painting fiberglass pipe to protect it from UV degradation). Aboveground piping should be labeled for the type of service and carrier fluid. ASME A13.1 "Scheme for the Identification of Piping Systems" can be referred to where color-coding and method of identification is required.

6.6.2.3.3 Internal Coatings and Linings

Solids production and erosion can be detrimental to some internal coatings, so these as well as the specific service and considerations of environmental risk associated with a leak should be evaluated. In most cases, internal coating should be considered for all steel piping systems. There are many different products available; the ones most commonly found in the oil field are cement lining, plastic coating, and extruded polyethylene.

6.6.2.3.4 Piping Connections

The following parameters need to be considered when determining what connections are best suited for a project:

- operations preference and experience (You *have* to get "buy-in" from the field personnel)
- operating pressure of the systems
- hydrocarbon content in the produced fluid
- H₂S concentrations in the product stream
- impact on surrounding area in the event of a failure
- expected life of the project

6.6.2.3.5 Flanged versus Threaded

Welded/flanged construction may provide the following advantages:

- less susceptible to mechanical damage (especially in vibrating service)
- greater structural joint strength
- more resistant to fatigue failure
- better hydrocarbon containment in the event of fire
- lower fugitive emissions
- make-ups are more precise than threaded

Threaded construction may provide the following advantages:

- less expensive to install
- easier and less expensive to repair
- no hot work involved
- quicker to disassemble

6.6.2.3.6 Valves

Types of valves commonly used in oil and gas production

- *Gate Valves*—A gate is a linear-motion valve that uses a typically flat closure element perpendicular to the process flow, which slides into the flow stream to provide shutoff. With a gate valve, the direction of fluid flow does not change, and the diameter through which the process fluid passes is essentially equal to that of the pipe. Hence, gate valves tend to have minimal pressure drop when opened fully. Gate valves are designed to minimize pressure drop across the valve in the fully opened position and stop the flow of fluid completely. In general, gate valves are not used to regulate fluid flow. A gate valve is closed when a tapered disk of a diameter slightly larger than that of the pipe is lowered into position against the valve seats. The valve is fully open when the disk is pulled completely out of the path of the process fluid into the neck [13]. Typically, these are used on pipelines, on gas wells, and as plant block valves.

- **Globe Valves**—A globe valve is a linear-motion valve characterized by a body with a longer face-to-face that accommodates flow passages sufficiently long enough to ensure smooth flow through the valve without any sharp turns. Globe valves are widely used to regulate fluid flow in both on/off and throttling service. The amount of flow restriction observed with valve disk (or globe) location is relative to the valve seat. The valve seat and stem are rotated 90° to the pipe. The direction of fluid flow through the valve changes several times, which increases the pressure drop across the valve. In most cases, globe valves are installed with the stem vertical and the higher-pressure fluid stream connected to the pipe side above the disk, which helps to maintain a tight seal when the valve is fully closed. Traditionally the valve disk and seat were both metal, although some modern designs use an elastomer disk seal. These valves are inexpensive and simple to repair [13].
- **Plug Valves**—Plug valves are similar to gates and work particularly well in abrasive service. These are available either lubricated or nonlubricated.
- **Ball Valves**—Ball valves are quarter-turn, straight-through flow valves that use a round closure element with matching rounded elastomeric seats that permit uniform sealing stress. These valves are limited to moderate temperature service (below 250°C) by the plastic seats that create a seal around the ball. The type of seat can vary with the valve pressure rating and materials of construction. Some valve seats are a single molded form, while other valve seats with higher-pressure ratings often incorporate a Trunion design where each face of the ball is sealed separately. They have found applications in flow control, as well as on/off use in isolating a pipe stream. The pressure drop across the valve in a fully open position is minimal for a full-port design. However, with restricted-port designs the pressure drop can be significant [13].
- **Butterfly Valves**—The butterfly valve is a quarter-turn rotary-motion valve that uses a round disk as the closure element. The sealing action of a butterfly valve is achieved by rotating a disk of approximately the same diameter, as the pipe from a globe valve is a function of the position in line with fluid flow to a position perpendicular to flow. The axial length of these valves is less than any other valve, which in cases in which flange faces are used with large pipe sizes (greater than 10 in.), these valves have the lowest initial cost. If resilient seats or piston rings on the disk are used, these valves can be sealed by relatively low operating torque on the valve stem. This sealing action is assisted by the fluid-pressure distribution that tends to close the valve. This same hydraulic unbalance requires that a latching device or worm gear be installed to prevent unwanted closure of manually operated valves. Although butterfly valves

are used for low-pressure drop applications, the pressure drop across the valve is quite high with large flow rates compared with a gate valve [13]. Lug-type body is preferred in hydrocarbon applications because there is less bolt length exposed in a fire. The lug type is also easier to flange up than the wafer type because uneven tightening of the bolts in wafer type can cause uneven pull up and leaking. High-performance butterfly valves are commonly used for throttling in both low and high-pressure applications. A SS stem with a SS or a plastic coated disc is suggested for produced water service.

- **Check Valves**—Check valves commonly used in production service are the swing, piston, or split disk styles. The swing check is used in low-velocity flows where flow reversals are infrequent. Piston checks with or without spring assists are used in high-flow rate streams with frequent reversals (i.e., compressor or high-pressure pump discharges). Split disk checks are typically used in low-pressure applications in which a minimum pressure drop across the valve is required (i.e., transfer/charge pump discharges). Because of the service, SS internals are preferred over plastic-coated in any service where they come in contact with produced water to minimize corrosion failures.
- **Relief Valve**—A pressure relief valve is a self-operating valve that is installed in a process system to protect against overpressurization of the system. Relief valves are designed to continuously modulate fluid flow to keep pressure from exceeding a preset value. There are a wide variety of designs, but most resemble diaphragm valves, globe valves, or swing check valves. With many of these designs, a helical spring or hydraulic pressure is used to maintain a constant force that acts on the backside of the valve disk or diaphragm causing the valve to normally be closed. When the force exerted by the process stream (i.e., fluid pressure) on the valve disk is greater than the constant force exerted by the spring, the valve opens, allowing process fluid to exit the valve until the fluid pressure falls below the preset value. These valves can be preset to a specific relief pressure, or they may be adjustable [13].

Materials used in valve construction are as varied as their applications. The following are the ones commonly used in the oil field. The material used in the valve body is addressed first. Valves carrying flammable fluids should be of steel or ductile iron.

Malleable iron should not be used in sour service because it does not meet NACE standards. Brass and bronze are suitable for fresh water and low-pressure air service. Nickel aluminum bronze and 316 SS are most often used in produced water applications. 304 SS is preferred for wet CO₂, whereas regular steel is acceptable for dry CO₂. Aluminum is acceptable for tank vent valves 17-4 PH should be avoided in sour service.

6.6.2.3.7 Valve trim

Elastomer selection is critical. The most commonly used elastomer in brine water and hydrocarbon service is Buna-N (nitrile). The limitation is that it should not be used when temperatures exceed 200°F for prolonged periods. A 90-derometer peroxide-cured Buna is the first choice for use in CO₂ or H₂S service. Viton is good to about 350°F and is resistant to aromatics, but should not be used with amines or high pressure CO₂. Teflon is good to somewhere between 250°F to 350°F, depending on the application, and has exceptionally good chemical resistance characteristics. Teflon is not a true elastomer because it has no physical memory.

6.6.2.4 Pressure Vessel Design — Phase Separation [11,14–16]

Practical separation techniques for liquid particles in gases are discussed. The principles used to achieve physical separation of gas and liquids or solids are momentum, gravity settling and coalescing. Any separator may employ one or more of those principles, but the fluid phases must be immiscible and have different densities for separation to occur.

6.6.2.4.1 Momentum

Fluid phases with different densities will have different momentum. If a two-phase stream changes direction sharply, greater momentum will not allow the particles of the heavier phase to turn as rapidly as the lighter fluid, so separation occurs. Momentum is usually employed for bulk separation of the two phases in a stream.

6.6.2.4.2 Gravity Settling

Liquid droplets will settle out of a gas phase if the gravitational forces acting on the droplet are greater than the drag force of the gas flowing around the droplet (Figure 6.6.4). These forces can be described mathematically. Drag force (F) on a liquid droplet in a gas stream is determine from

$$F = C_D A_p \gamma_g \frac{V_t^2}{2g} \tag{6.6.1}$$

Hence,

$$V_t = \left(\frac{2Fg}{C_D A_p \gamma_g} \right)^{0.5}$$

and from Newton’s second law

$$F = \frac{w}{g} \quad \text{and} \quad \text{if} \quad w = \frac{\gamma_L - \gamma_g}{\gamma_L} W_p$$

$$V_t = \left[\frac{2gW_p(\gamma_t - \gamma_g)}{\gamma_t \gamma_g A_p C_D} \right]^{0.5} = \left[\frac{4gD_p(\gamma_t - \gamma_g)}{3\gamma_g C_D} \right]^{0.5} \tag{6.6.2}$$

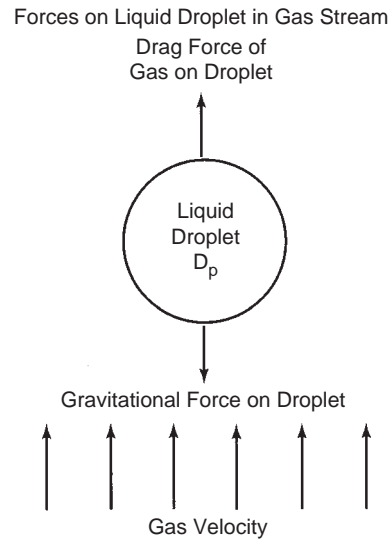

FIGURE 6.6.4 Forces on liquid input in gas system [11].

where

- F = drag force in lb
- V_t = terminal velocity in ft./s
- g = acceleration due to gravity in ft./s²
- W_p = weight of particle in lb
- γ_{L,g} = liquid and gas-phase specific weights in lb/ft.³
- A_p = particle cross-sectional area in ft.²
- D_p = droplet diameter in ft.
- C_D = drag coefficient of particle (dimensionless)

The drag coefficient has been found to be a function of the shape of the particle and the Reynolds number of the flowing gas. For the purpose of this equation, particle shape is considered to be a solid, rigid sphere.

Reynolds number is defined as

$$Re = \frac{1,488D_p V_t \gamma_g}{\mu} \tag{6.6.3}$$

Where μ = viscosity (cp)

In this form, a trial-and-error solution is required since both particle size D_p and terminal velocity V_t are involved. To avoid trial and error, values of the drag coefficient are presented in Figure 6.6.5 as a function of the product of drag coefficient C_D times the Reynolds number squared; this technique eliminates velocity from expression.

The abscissa of Figure 6.6.5 is represented by

$$C_D(Re)^2 = \frac{(0.95)(10^8)\gamma_g D_p^3(\gamma_t - \gamma_g)}{\mu^2} \tag{6.6.4}$$

For production facility design (turbulent flow), the following formula for drag coefficient is proper:

FIGURE 6.6.5 Drag coefficient of a rigid sphere [11].

FIGURE 6.6.6 Gas liquid separators: (a) vertical, (b) horizontal, (c) spherical.

$$C_D = \frac{24}{Re} + \frac{3}{(Re)^{0.5}} + 0.34 \quad (6.6.5)$$

and if D_p is expressed in micrometers $\rightarrow d_m$

$$V_t = 0.0119 \left[\left(\frac{(\gamma_L - \gamma_g)}{\gamma_g} \right) \frac{d_m}{C_D} \right]^{0.5} \quad (6.6.6)$$

Equations 6.6.5 and 6.6.6 can be solved by an iterative solution as follows

1. Write the equation for laminar flows ($C_D = 0.34$)

$$V_t = 0.0204 \left[\frac{(\gamma_L - \gamma_g)}{\gamma_g} d_m \right]^{0.5}$$

2. Calculate $Re = 0.0049(\gamma_g d_m V_t / \mu)$
3. From Equation 6.6.5 calculate C_D
4. Recalculate V_t using Equation 6.6.6. Go to step 2

The above technique is proper assuming that known diameter drops are removed (e.g., 100 μm).

6.6.3 Separator Design and Construction

There are three types of separators: vertical, horizontal (single and double tube), and sometimes spherical (Tables 6.6.3 to 6.6.5; Figure 6.6.6).

There are many vessel design software packages out on the market today, and everyone has a favorite. When the requirements are input and the program is run, one

Size (Dia. x Ht.)	Working Pressure (psi)								
		230	500	600	1000	1200	1440	1500	2000
16" x 5'		230	500	600	1000	1200	1440	1500	2000
16" x 7 1/2'		230	500	600	1000	1200	1440	1500	2000
16" x 10'		230	500	600	1000	1200	1440	1500	2000
20" x 5'		230	500	600	1000	1200	1440	1500	2000
20" x 7 1/2'		230	500	600	1000	1200	1440	1500	2000

is then armed with the information needed to talk to the vendors about a bid specification or to look at what is available within the company's used equipment inventory. When purchasing a new vessel the data and requirements should always be provided to the supplier and reviewed by engineering on both sides to obtain the best vessel fit for each application.

Vertical separators are usually selected when the gas/liquid ratio is high or total gas volumes are low. In this sort of vessel, the fluids enter the vessel striking a diverting plate that initiates primary separation. Liquid removed by the inlet diverter falls to the bottom of the vessel. The gas moves upward, usually passing through a mist extractor to remove suspended mist, and then flows out. Liquid

is removed by reservoir in the bottom. Mist extractors can significantly reduce the required diameter of vertical separators. However, if the production stream is dirty, the mist extractor will frequently plug and it may be removed. Subsequent scrubbers may need to be added or bypass lines installed to allow equipment to be cleaned with relative ease.

Horizontal separators are most often efficient for large volumes of total fluids and when large amounts of dissolved gases are present with the liquid. The greater liquid surface area provides for optimum conditions for releasing gas from the liquid.

Spherical separators are rarely used in production operations.

6.6.4 Vertical Separators

The following calculations are presented as a guide to the design and sizing of two-phase separators. Sizing should be based on the maximum expected instantaneous rate.

For practical purposes, for vertical separators, Equation 6.6.2 is written as

$$V_t = K \left(\frac{\gamma_L - \gamma_g}{\gamma_g} \right)^{0.5} \quad (6.6.7)$$

where

V_t = terminal velocity of liquid droplets or maximum allowable superficial velocity of gas in ft./s

K = a constant depending on design and separating conditions in ft./s. See Table 6.6.6 [11].

TABLE 6.6.6 Typical K-Factor Values in Equation 6.6.7

Separator Type	K factor (ft./s)
Horizontal (w/vertical pad)	0.40 to 0.50
Vertical or Horizontal (w/horizontal pad)	0.18 to 0.35
@Atm. pressure	0.35
@300 psig	0.33
@600 psig	0.30
@900 psig	0.27
@1500 psig	0.21
Spherical	0.20 to 0.35
Wet steam	0.25
Most vapors under vacuum	0.20
Salt and caustic evaporators	0.15

1. $K = 0.35$ @ 100 psig (subtract 0.01 for every 100 psi above 100 psig).
2. For glycol and amine solutions, multiply K by 0.6 to 0.8.
3. Typically use $\frac{1}{2}$ of the above K values for approximate sizing of vertical separators without woven wire de-misters.
4. For compressor suction scrubbers and expander inlet separators multiply K by 0.7 to 0.8.

Example 6.6.1

A vertical gravity separator is required to handle 10 MMscfd of 0.6 specific gravity gas at an operating pressure of 1,000 psia and a temperature of 60°F. Liquid flow = 2,000 bpd of 40° API oil, $\mu_g = 0.014$ cp.

Solution

1. Find K from Table 6.6.6 where $K = 0.26 \text{ ft./s}$.
2. Calculate minimum diameter, such that if

$$V_t = K \left(\frac{\gamma_L - \gamma_g}{\gamma_g} \right)^{0.5}$$

then

$$V_g = \frac{Q_A \text{ ft.}^3/\text{s}}{A_g \text{ ft.}^2}$$

$$A_g = \frac{\pi D^2}{4}$$

Gas-specific weight is $\gamma_g = (PM/ZRT)$

$$M = 0.6 \times 29 = 17.4$$

$$P = 1,000 \text{ psia}$$

$$T = 520^\circ\text{R}$$

$$R = 10.73 \text{ ft.}^3 \cdot \text{psia} \cdot \text{lb}_{\text{mol}}^{-1}, R^{-1}Z = 0.84 \text{ (for given P, T, M)}$$

$$\gamma_g = \frac{1,000 \times 17.4}{0.84 \times 10.73 \times 520} = 3.713 \text{ lb/ft.}^3$$

Liquid-specific weight is

$$\gamma_L = 62.4 \times SG_0 = 62.4 \frac{141.5}{131.5 + 40} = 51.48 \text{ lb/ft.}^3$$

Weight rate of flow w (lb/s) is

$$\dot{w} = \frac{Q(\text{scf}) 17.4 (\text{lb}_m/\text{lb mol})}{379.4 (\text{scf}/\text{lb mol}) \times (24 \times 3,600)\text{s}}$$

$$= \frac{10 \times 10^6 \times 17.4}{379.4 \times 86,400} = 5.3 \text{ lb/s}$$

$$Q_A = \frac{w}{\gamma_g} = \frac{5.3 \text{ lb}_m/\text{s}}{3.713 \text{ lb}_m/\text{ft.}^3} = 1.43 \text{ ft.}^3/\text{s}$$

$$V_g = \frac{Q_A}{A_g} = \frac{143 \times 4}{\pi D^2} = \frac{1.82}{D^2}$$

$$V_t = V_g$$

$$\frac{1.82}{D^2} = 0.26 \left(\frac{51.48 - 3.713}{3.713} \right)^{0.5} = 0.99 \text{ ft./s}$$

$$D = 1.39 \text{ ft.} = 16.76 \text{ in.}$$

Minimum diameter is 20 in. (see Table 6.6.3). If

$$V_t = \left[\frac{4gD_p(\gamma_L - \gamma_g)}{3\gamma_g C_D} \right]^{0.5}$$

D_p is usually 100 to 150 μm .

$$\text{Assume } D_p = 150 \mu\text{m} = 150 \times 0.00003937/12 = 4.92 \times 10^{-6} \text{ ft.}$$

From Equation 6.6.4

$$C_D(\text{Re})^2 = \frac{0.95 \times 10^8 \times 3.713(0.000492)^3(51.48 - 3.713)}{(0.014)^2}$$

$$= 10,238$$

From Figure 6.6.5

$$C_D = 0.99$$

$$V_t = \left(\frac{4 \times 32.174 \times 0.000492(51.48 - 3.713)}{(0.014)^2} \right)^{0.5}$$

$$= 0.52 \text{ ft./s}$$

$$V_g = \frac{1.82}{D^2} = 0.52 \text{ ft./s}$$

$D = 1.87 \text{ ft.} = 22.5 \text{ in.}$, and from Table 6.6.3, the minimum diameter is 24 in.

$$\text{Assume } D_p = 100 \mu\text{m} = 100 \times 0.00003937/12 = 0.000328 \text{ ft.}$$

$$C_D(\text{Re})^2 = \frac{0.95 \times 10^8 \times 3.713(0.000328)^3(51.48 - 3.713)}{(0.014)^2}$$

$$= 2,592$$

From Equation 6.6.5

$$C_D = 1.75$$

$$V_t = \frac{(4 \times 32.174 \times 0.000328 \times 48.307)}{3 \times 3.713 \times 1.75} = 0.1046 \text{ ft./s}$$

$$V_g = \frac{1.82}{D^2} = 0.1046 \text{ ft./s}$$

$$D = 4.17 \text{ ft.} = 50 \text{ in.}$$

The maximum allowable superficial velocity calculated from the factors in Table 6.6.6 is for separators normally having a wire mesh mist extractor (Figure 6.6.7). This rate should allow all liquid droplets larger than 10 μm to settle out of the gas. The maximum allowable superficial velocity should be considered for other types of mist extractors.

Further calculations refer to $D = 20 \text{ in.}$ (separator with a mist extractor). Diameters $D = 24 \text{ in.}$ and $D = 50 \text{ in.}$ refer to separator without a mist extractor.

3. Calculate liquid level h . A certain liquid storage is required to ensure that the liquid and gas reach equilibrium at separator pressure. This is defined as "retention time" where liquid is retained in the vessel assuming plug flow. The retention time is thus the volume of the liquid storage in the vessel divided by the liquid flowrate. Basic design criteria for liquid retention time in two-phase separators are generally as follows [17]:

FIGURE 6.6.7 The geometry of a vertical separator [15].

Oil Gravities	Minutes (Typical)
Above 35° API	1
20–30° API	1 to 2
10–20° API	2 to 4

$$t = \frac{\text{Vol. ft.}^3}{Q \text{ ft.}^3/\text{s}}$$

$$\text{Vol.} = \frac{\pi D^2 h}{4 \cdot 12} = \frac{\pi d^2 h}{4(144)12} = 4.545 \times 10^{-4} d^2 h$$

$$D = 20 \text{ in.}$$

$$\text{Vol.} = 0.1818h$$

$$Q_L = \text{bpd}$$

$$Q = Q_L \times 5.615 \left(\frac{\text{ft.}^3}{\text{barrel}} \right) \times \left(\frac{\text{day}}{24 \text{ hr}} \right) \times \left(\frac{\text{hr}}{3,600 \text{ s}} \right) = 0.000065 Q_L$$

$$t = \frac{0.1818h}{0.000065 Q_L} = 2,797 \frac{h}{Q_L}$$

Assume $t_r = 1 \text{ min}$ (API = 40°)

So,

$$h = \frac{t_r Q_L}{2,797} = \frac{2,000}{2,797} = 0.715 \text{ ft.} = 8.6 \text{ in.}$$

4. Calculate seam-to-seam length (L_{ss}). The seam-to-seam length of the vessel should be determined from the geometry of the vessel once a diameter and weight of liquid volume are known.

$$L_{ss} = \frac{h + 76}{12} \text{ (in.)} \quad \text{or} \quad L_{ss} = \frac{h + D + 40}{12}$$

$$= \frac{8.6 + 76}{12} = 7.05 \text{ ft.}$$

5. Compute slenderness ratio (L_{ss}/D), which is usually in the range 3 to 4, such that

$$L_{ss}/D = \frac{7.05 \times 12}{20} = 4.23$$

6. Choosing the diameter because $(L_{ss}/D) > 4$, let's assume higher diameter $D = 24$ (next higher diameter from Table 6.6.3).

$$\text{Vol} = 0.2618h$$

$$t = \frac{0.2618h}{0.000065 Q_L} = 4,028 \frac{h}{Q_L}$$

If

$$t = 1 \text{ min}$$

then

$$h = \frac{2,000}{4,028} = 0.5 \text{ ft.} = 6 \text{ in.}$$

$$L_{ss} = \frac{6 + 76}{12} = 6.83 \text{ ft.} = 82 \text{ in.}$$

$$\frac{L_{ss}}{D} = \frac{82}{24} = 3.4$$

Proper size of separator is 24 in. \times 7½ ft.

6.6.5 Horizontal Separator

In the case of horizontal separators, the gas drag force does not directly oppose the gravitational settling force. The thru droplet velocity is assumed to be the vector sum of the vertical terminal velocity and the horizontal gas velocity. The minimum length of the vessel is calculated by assuming the time for the gas to flow from the inlet to the outlet is the same as for the droplets to fall from the top of the vessel to the surface of the liquid. In calculating the gas capacity of horizontal separators, the cross-sectional area of that portion of the vessel occupied by liquid (at maximum level) is subtracted from the total vessel cross-sectional area, as shown in Figure 6.6.8.

Separators can be any length, but the ratio L_{ss} to D of a vessel is usually in the range of 2:1 to 4:1, so that

$$V_t = K \left(\frac{\gamma_L - \gamma_g}{\gamma_g} \right) \left(\frac{L}{10} \right)^{0.56} \quad (6.6.8) \quad (\text{ft./s})$$

Sometimes separators without mist extractors are sized using Equation 6.6.7 with a constant K of typically 1/2 of that used for vessels with mist extractors.

Example 6.6.2

Solve Example 6.6.1 in the case of horizontal separator with mist extractor if $F = 0.564$ and 0.436

1. Find K value from Table 6.6.6 where $K = 0.3$
2. The gas capacity constraint is determined from

$$V_g = \frac{Q}{A_g}$$

$$A_g = 0.564 \times \frac{\pi}{4} D^2 = 0.443 D^2$$

$$Q = Q_g \times \frac{10^6 \text{ scf}}{\text{MMscf}} \times \frac{\text{day}}{24 \text{ hr}} \times \frac{\text{hr}}{3,600 \text{ s}} \times \frac{14.7}{P} \times \frac{TZ}{520}$$

$$= 0.327 \frac{TZ}{P} Q_g$$

$$V_g = \frac{0.327 T Z Q_g}{0.443 D^2 P} = 0.74 \frac{T Z Q_g}{D^2 P}$$

The residence time of the gas (t_g) has to be equal to the time required for the droplet to fall to the gas-liquid interface t_f :

$$t_g = \frac{L_{\text{eff}} \text{ Effective length for separator}}{V_g \text{ Gas velocity}} = \frac{L_{\text{eff}} D^2 P}{0.74 T Z Q_g}$$

$$t_d = \frac{D - h}{V_t}$$

If $F = 0.564$, then $h/D = 0.45$, where $h = 0.45D$ and $t_d = 0.55D/V_t$. If $L_{ss} = L_{\text{eff}} + D$ for gas capacity, then

$$V_t = K \left(\frac{\gamma_L - \gamma_g}{\gamma_g} \right)^{0.5} \left(\frac{L_{\text{eff}} + D}{10} \right)^{0.56}$$

and

$$t_d = \frac{0.55D}{0.3 \left(\frac{\gamma_L - \gamma_g}{\gamma_g} \right)^{0.5} \left(\frac{L_{\text{eff}} + D}{10} \right)^{0.56}}$$

where $t_g = t_d$ and

$$\frac{L_{\text{eff}} D^2 P}{0.74 T Z Q_g} = \frac{0.55D}{0.3 \left(\frac{\gamma_L - \gamma_g}{\gamma_g} \right)^{0.5} \left(\frac{L_{\text{eff}} + D}{10} \right)^{0.56}}$$

$$D^2 L_{\text{eff}} = \frac{6D}{(L_{\text{eff}} + D)^{0.56}}$$

From the above constraint for given D , L_{eff} could be calculated, but gas capacity does not govern.

h/D	F	h/D	h/D
0	1.0	0.30	0.748
0.05	0.981	0.35	0.688
0.10	0.948	0.40	0.626
0.15	0.906	0.45	0.564
0.20	0.858	0.50	0.500
0.25	0.804	0.55	0.436

FIGURE 6.6.8 The fraction of the total area available for gas flow in a horizontal separator.

3. Liquid capacity constraint is calculated from

$$t_r = \frac{\text{Vol.}}{Q}$$

where $\text{Vol.} = (\pi D^2/4)(1 - F)L_{\text{eff}} = 0.343D^2L_{\text{eff}}$

$$Q = Q_L \times 5.615 \left(\frac{\text{ft.}^3}{\text{barrel}}\right) \times (\text{day}/24 \text{ hr}) \\ \times (\text{hr}/3,600 \text{ s}) = 0.000065 Q_L$$

$$t_r = 0.343D^2L_{\text{eff}}/0.000065 Q_L$$

$$D^2L_{\text{eff}} = (t_r \times 0.000065 Q_L) / 0.343$$

If t_r is in minutes, then $D^2L_{\text{eff}} = 0.01137 t_r Q_L$.

4. Assume retention time $t_r = 1$ min. Compute combination D (Table 6.6.4) and L_{eff} , such that

$$D = 2 \text{ ft.} \quad L_{\text{eff}} = 5.7 \text{ ft.} \quad L_{\text{ss}} = \frac{4}{3} L_{\text{eff}} = 7.6 \text{ ft.} \\ D = 2.5 \text{ ft.} \quad L_{\text{eff}} = 3.6 \text{ ft.} \quad L_{\text{ss}} = \frac{4}{3} L_{\text{eff}} = 4.9 \text{ ft.}$$

5. Compute slenderness (L_{ss}/D) = 3.8 and 1.96, respectively. $D = 2$ ft. (24 in.) is a proper size.

A second case is where $F = 0.436$. The gas capacity constant is determined from

$$V_g = \frac{Q}{A_g} \quad \text{where} \quad Q = 0.327 \frac{TZQ_g}{P}$$

$$A_g = 0.436 \times \frac{\pi}{4} D^2 = 0.342D^2$$

$$V_g = \frac{0.327TZQ_g}{0.342D^2P} = 0.96 \frac{TZQ_g}{D^2P}$$

$$t_g = \frac{L_{\text{eff}}}{V_g} = \frac{L_{\text{eff}}D^2P}{0.96TZQ_g}$$

$$t_d = (D - h) / V_t \text{ if } F = 0.436,$$

$$\frac{h}{D} = 0.55, \quad h = 0.55D$$

$$t_d = \frac{0.45D}{V_t} \quad \text{if} \quad V_t = k \times 3.587 \left(\frac{L_{\text{ss}}}{10}\right)^{0.56}$$

$L_{\text{ss}} = L_{\text{eff}} + D$ for gas capacity, such that

$$V_t = 0.988K(L_{\text{eff}} + D)^{0.56} \quad \text{where} \quad K = 0.3$$

$$t_d = \frac{1.52D}{(L_{\text{eff}} + D)^{0.56}}$$

$$t_g = t_d$$

$$\frac{L_{\text{eff}}D^2P}{0.96TZQ_g} = \frac{1.52D}{(L_{\text{eff}} + D)^{0.56}}$$

Substituting Q_g, P, T, Z gives

$$L_{\text{eff}}D^2 = \frac{6.4D}{(L_{\text{eff}} + D)^{0.56}}$$

Liquid capacity constraint is determined from

$$t_r = \frac{\text{Vol.}}{Q}$$

where $\text{Vol.} = (\pi D^2/4)(1 - F)L_{\text{eff}} = 0.443D^2L_{\text{eff}}$

$$Q = 0.000065 Q_L \text{ if } t_r \text{ is in min}$$

$$t_r = 0.443D^2L_{\text{eff}}/0.000065 Q_L$$

$$D^2L_{\text{eff}} = 0.0088 t_r Q_L$$

Assume retention time $t_r = 1$ min and $D = 2$ ft.

$$L_{\text{eff}} = \frac{0.0088 \times 1 \times 2,000}{4} = 4.4 \text{ ft.}$$

$$L_{\text{ss}} = \frac{4}{3} \times 4.4 = 5.9 \text{ ft.}$$

$$D = 2.5$$

$$L_{\text{eff}} = \frac{0.0088 \times 1 \times 2,000}{2.5 \times 2.5} = 2.8 \text{ ft.}$$

$$L_{\text{ss}} = \frac{4}{3} \times 2.8 = 3.8 \text{ ft.}$$

As you can see, the liquid level has significant meaning for separator length. Usually, the fraction of the total area F available for gas flow is equal to 0.5. The liquid level control placement of a horizontal separator is more critical than in a vertical separator and the surge space is somewhat limited.

6.6.6 Vessel Internals [18]

The proper selection of internals can significantly enhance the operation of separators. Proprietary internals often are helpful in reducing liquid carryover at design conditions. Nevertheless, they cannot overcome an improper design or operation at off-design conditions.

Production equipment involving the separation of oil and gas often uses impingement-type mist-extraction elements. This element is usually of the vane type or of knitted wire.

The vane type consists of a labyrinth formed with parallel metal sheets with suitable liquid collection "pockets." The gas, in passing between plates, is agitated and has to change direction a number of times. Obviously, some degree of centrifugation is introduced, for as the gas changes direction the heavier particles tend to be thrown to the outside and are caught in the pockets provided.

Coalescence of small particles into those large enough to settle by gravity is provided by two mechanisms: agitation

and surface. The surface of the element is usually wet, and small particles striking it are absorbed. Inasmuch as the pockets are perpendicular to the gas flow, the liquid thus formed does not have to flow against the gas. Consequently, small compact units have a large capacity.

As the plates are placed closer together and more pockets are provided, greater agitation, centrifugal force, and collection surface are provided, but the pressure drop is increased correspondingly. Thus, for a given flow rate, the collection efficiency is normally some function of the pressure drop.

In the average application, this pressure drop varies from 1.2 to 10 in. (3 to 25 cm) of water. Because of this pressure drop and to prevent gas bypassing the extractor, a liquid-collection pas incorporating a liquid seal is necessary for the liquid to drain properly.

Increased use has been made of mist extractors composed of a knitted wire mesh supported on a lightweight support. This material has given generally favorable results and has a low installed cost.

The element consists of wire knitted into a pad having a number of unaligned, asymmetrical openings. Although similar in appearance to filter media, its action is somewhat different. The latter are rather dense and have small openings. This knitted wire, on the other hand, has about 97% to 98% free voids and collects the particles primarily by impingement.

The material is available in single wound units of varying thicknesses in diameter up to 35 in. (90 cm) or in laminated strips for insertion through manholes in large process vessels.

The principle of separation is similar to that of the vane-type unit. The gas flowing through the pad is forced to change direction a number of times, although centrifugal action is not so pronounced. Impingement is the primary mechanism.

A liquid particle striking the metal surface, which it does not “wet,” flows downward where adjacent wires provide some capillary space. At these points, liquid collects and continues to flow downward. Surface tension tends to hold these drops on the lower face of the pad until they are large enough for the downward force of gravity to exceed that of the upward gas velocity and surface tension.

Efficiency is a function of the number of targets presented. This may be accomplished by increasing the pad thickness, changing wire diameter, or the closeness of the weave.

The wire mesh normally used falls within the following range:

- Wire diameter — 0.003 to 0.011 in. (0.0076 to 0.028 cm)
- Void volume — 92% to 99.4%
- Specific weight — 3 to 33 lb/ft.³ (48 to 529 kg/m³)
- Surface area — 50 to 600 ft.²/ft.³ (164 to 1970 m²/m³)

The most commonly used wire has a void volume of 97% to 98%, a bulk-specific weight approximately 12 lb/ft.³ (192 kg/m³), a surface area of 100 to 125 ft.²/ft.³ (328 to 410 m²/m³), with a wire diameter of 0.011 in. (0.028 cm). A pad thickness of 4 to 6 in. (10 to 15 cm) is sufficient for most separator applications, although thicknesses up to 3 ft. (0.9 m) have been reported. In separator service, 4 to 6 in. (10 to 15 cm) will normally suffice.

Any common metal may be used in these units, including carbon steel, SS, aluminum, monel, etc. The pressure drop is a function of the entrainment load, the pad design, and gas velocity but will not exceed 3 cm of water in the average insulation. Because of this small pressure drop, the elements do not have to be “held down” and are normally only wired to the support grid to prevent shifting unless surging flow is anticipated.

Experience has shown that the support grid should contain at least 90% free area in order to eliminate any restrictions to liquid drainage. The pads are light in weight so that a light angle-iron support is adequate. When both liquid and solids are present, a portion of the latter obviously will be scrubbed out. If only dry solids are present, the efficiency of this design is substantially less. Many vessel carryover problems are encountered. Foaming is a major culprit and requires more than simply better mist extraction. Most such problems develop by default. The vendor automatically uses the standard sizing curves and equipment, and the buyer assumes this will be good enough.

With glycols, amines, and similar materials, which tend to foam, a dual mist extractor would normally be specified—the lower one being of the vane type and the upper one being a wire mesh. A space of 6 to 12 in. (15 to 30 cm) would be left between them. The vane type will handle large volumes of liquid but is relatively inefficient on small droplets. It, therefore, serves as a bulk removal device (and helps to coalesce foam). The wire mesh, which has limited liquid capacity, may therefore operate more effectively.

When using the vane-type mist extractor, one must be careful that the pressure drop across it does not exceed the height above the liquid level if a downcomer pipe is used. Otherwise, liquid will be “sucked out” overhead. The downcomer pipe can become partially plugged to accentuate the problem. Two wire mesh pads may be used in like fashion, with the first being used as a coalescer. As a rule of thumb, the coalescer pad should have about half the free space area of the second pad. Any wire mesh pad should be installed so that the flow is perpendicular to the pad face (pad is horizontal in a vertical vessel).

With materials like glycol and amine, which wet metal very well, Teflon-coated mesh may prove desirable. Remember, the liquid must be nonwetting in order to stay as droplets that can run down the wires and coalesce into bigger droplets. A wetting fluid will tend to “run up” the wires. It has been noted that centrifugal force is an integral

part of the separation process. The standard oil and gas separator may have an inlet that utilizes centrifugal force to separate the larger droplets. The same principle is used in some mist extractor elements except that higher velocities are needed to separate the smaller droplets. The velocity needed for separation is a function of the particle diameter, particle and gas specific weight and the gas viscosity.

With a given system, the size of particle collected is inversely proportional to the square root of the velocity. Consequently, the success of a cyclonic mist extractor is dependent upon the velocity attained. Furthermore, the velocity needed to separate a given size of particle must increase, as the density of the particle becomes less. In addition to producing the necessary velocity, the mist extractor must provide an efficient means of collecting and removing the particles collected in order to prevent re-entrainment.

One common type of equipment is often called a *steam separator* because it has been widely used to separate condensate and pipe scale in steam systems. Normally, a relatively small vessel imparts a high velocity to the incoming gas and then makes the gas change direction radically to prevent re-entrainment. In general, it will separate particles 40 microns and larger very efficiently.

Another type uses the same principle but, in addition, forces the gas to pass through a labyrinth that introduces impingement effects and forces the gas to change direction a number of times. This is, in reality, a combination type and is relatively efficient. The general performance characteristics are the same as efficient mist extractors of other types. Some, however, are complex and relatively expensive.

6.6.7 Oil–Water–Gas Separation

Two liquids and gas or oil–water–gas separation can be easily accomplished in any type of separator by installing either special internal baffling to construct a water lap or crater siphon arrangement or by use of an interface liquid level control. A three-phase feature is difficult to install in a spherical separator due to the limited internal space available. With three-phase separation, two liquid level controls and two liquid dump valves are required. Figures 6.6.9 to 6.6.11 [15] illustrate schematics of some three-phase separators. The basic design aspects of three-phase separation have been covered under “Sizing of Two Phase Oil–Gas Separators”. Regardless of shape, all three-phase vessels must meet the following requirements:

- Liquid must be separated from the gas in a primary separating section.
- Gas velocity must be lowered to allow liquids to drop out.
- Gas is then scrubbed through an efficient mist extractor.
- Water and oil must be diverted to a turbulence-free section of the vessel.
- Liquids must be retained in the vessel long enough to allow separation.
- The water–oil interface must be maintained.
- Water and oil must be removed from the vessel at their respective outlets.

Sizing a three-phase separator for water removal is mainly a function of retention time; required retention time is

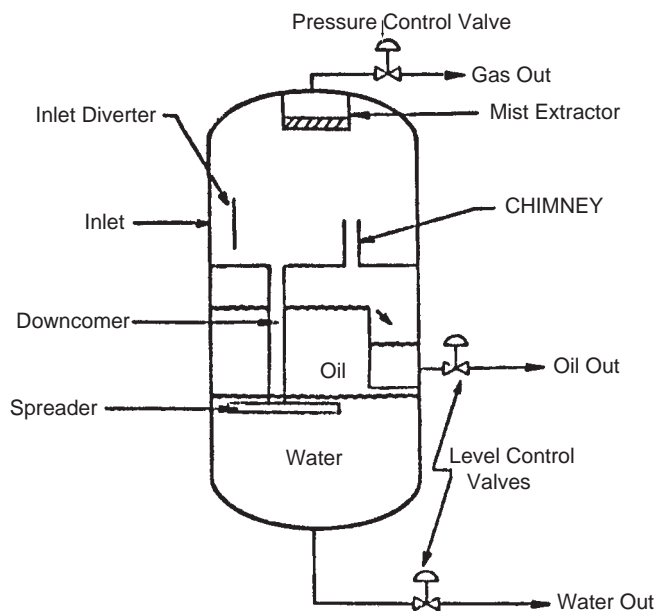

FIGURE 6.6.9 Three-phase vertical separator.

FIGURE 6.6.10 Three-phase horizontal separator.

FIGURE 6.6.11 Three-phase horizontal separator with coalescer plates.

related to the volume of the vessel, the amount of liquid to be handled and the relative specific gravities of the water and oil. The effective retention volume in a vessel is that portion of the vessel in which the oil and water remain in contact with one another. As far as oil–water separation is concerned, once either substance leaves the primary liquid section, although it may remain in the vessel in a separate compartment it cannot be considered as part of the retention volume. There are two primary considerations in specifying retention time:

- Oil settling time to allow adequate water removal from oil
- Water settling time to allow adequate oil removal from water

Basic design criteria for liquid retention time in three-phase separators are given in Table 6.6.7 [11].

Example 6.6.3

Determine the size of a vertical separator to separate 6,300 bpd of oil from its associated gas, water 500 bpd (SG =

0.75) at a pressure of 300 psig, and a temperature with $SG_g=1.03$, 100°F . The oil has a density of 49.7 lb/ft^3 and solution gas/oil ratio of 580 scf/STB at 60°F and 14.7 psia.

1. The gas capacity constraint $V_g = V_t$, such that

$$V_g = \frac{Q}{A_g} \quad Q = \frac{R_s \times Q_0}{86,400} \times \frac{14.7}{P} \times \frac{TZ}{520}$$

$$P = 300 \quad T = 560 \quad Z = 0.94 \text{ (from chart)}$$

$$Q = 2.1\text{ ft}^3/\text{s}$$

$$A_g = \frac{\pi D^2}{4} = 0.785D^2$$

$$V_t = K \left(\frac{\gamma_0 - \gamma_g}{\gamma_g} \right) \quad K = 0.33 \text{ (from Table 6.6.6)}$$

$$\gamma_0 = 49.7\text{ lb/ft}^3$$

$$\gamma_g = \frac{PM}{ZRT} = \frac{300 \times 29 \times 0.75}{0.94 \times 10.73 \times 560} = 1.155\text{ lb/ft}^3$$

$$\left(\frac{\gamma_0 - \gamma_g}{\gamma_g} \right)^{0.5} = \left(\frac{49.7 - 1.155}{1.155} \right)^{0.5} = 6.48$$

TABLE 6.6.7 Typical Retention Time for Liquid-Liquid Separation

Type of Separation	Retention Time
Hydrocarbon/water separators	
Above 35° API hydrocarbons	3 to 5 min
Below 35° API hydrocarbons	
100°F and above	5 to 10 min
80°F	10 to 20 min
60°F	20 to 30 min
Ethylene glycol/hydrocarbon separators (cold separators)	20 to 60 min
Amine/hydrocarbon separators	20 to 30 min
Coalescers, hydrocarbon/water separators	
100°F and above	5 to 10 min
80°F	10 to 20 min
60°F	20 to 30 min
Caustic/propane	30 to 45 min
Caustic/heavy gasoline	30 to 90 min

$$V_t = 2.14 \text{ ft./s}$$

$$D = 1.117 \text{ ft.} = 13.4 \text{ in.}$$

2. Calculate minimum diameter from requirement for water droplets to fall through oil layer. Use 500- μm droplets if no other information is available. For μ_o = assume 3.0 cp.

$$V_t = V_0$$

According to Stokes law

$$V_t = 2660 \frac{(\gamma_w - \gamma_o)}{\mu} D_p^2$$

$$V_t (\text{ft./s}); \quad \gamma_w, \gamma_o (\text{lb/ft.}^3); \quad D_p (\text{ft.}); \quad \mu (\text{cp})$$

$$V_0 = \frac{Q}{A} \quad Q (\text{ft.}^3/\text{s}); \quad A (\text{ft.}^2); \quad Q_0 (\text{bpd})$$

$$Q = 6.49 \times 10^{-5} Q_0$$

$$A = \frac{\pi D^2}{4} = 0.785 D^2 \quad \text{Where } D \text{ is in ft.}$$

$$V_0 = \frac{6.49 \times 10^{-5} Q_0}{0.785 D^2} = 8.27 \times 10^{-5} \frac{Q_0}{D^2}$$

$$8.27 \times 10^{-5} \frac{Q_0}{D^2} = 2660 \left(\frac{\gamma_w - \gamma_o}{\mu_o} \right) D_p^2$$

$$D_p = 500 \mu\text{m} = 500 \times 3.2808 \times 10^{-6} \text{ ft.}$$

$$D_p = 1.64 \times 10^{-3} \text{ ft.}$$

$$D = \left[\frac{8.27 \times 10^{-5} Q_0 \mu_o}{2600 (\gamma_w - \gamma_o) D_p^2} \right]^{0.5} = 4.15 \text{ ft.} = 49.8 \text{ in.}$$

3. Calculate the total weight of oil and water in separator ($h_o + h_w$)

$$t_r = \text{Vol.}/Q$$

$$\text{Vol.} = (\pi D^2/4)h$$

$$Q = 6.49 \times 10^{-5} Q_L \quad \text{If } t \text{ is in min}$$

$$t_r \text{ 60} = \frac{\pi D^2 h}{4 \times 6.49 \times 10^{-5} Q_L} \quad Q_L (\text{bpd})$$

$$D^2 h = 4.958 \times 10^{-3} Q_L t_r$$

For two-phase separator design

$$D^2 h_o = 4.958 \times 10^{-3} Q_o (t_r)_o$$

$$D^2 h_w = 4.958 \times 10^{-3} Q_w (t_r)_w$$

$$h_o + h_w = 4.958 \times 10^{-3} \frac{Q_o (t_r)_o + Q_w (t_r)_w}{D^2}$$

where h_o = height of oil pad in ft.

h_w = height from water outlet to interface in ft.

Choose a nominal diameter from Table 6.6.3, considering minimum diameter in pts 2.54 in (4.5 ft.) is a proper choice. $(t_r)_o = (t_r)_w = 5$ min from Table 6.6.7.

$$h_o + h_w = 4.958 \times 10^{-3} \frac{500 \times 5 + 6,300 \times 5}{(4.5)^2} = 8.32 \text{ ft.}$$

$$\text{If } D = 5 \text{ ft.} \quad h_o + h_w = 6.74 \text{ ft.}$$

4. Calculate seam-to-seam length and slenderness ratios for $D = 4.5$ ft.

$$L_{ss} = h_o + h_w + \frac{76}{12} = 8.32 + 6.33 = 14.6 \text{ ft.}$$

$$\frac{L_{ss}}{D} = \frac{14.6 \text{ ft.}}{4.5} = 3.2 \quad \text{for } D = 5 \text{ ft.}$$

$$L_{ss} = 6.74 + \frac{76}{12} = 13 \text{ ft.}$$

$$\frac{L_{ss}}{D} = \frac{13 \text{ ft.}}{5} = 2.6$$

Vertical three-phase separators have slenderness ratios on the order of 15 to 3. In this case, both diameters are acceptable.

Example 6.6.4

Determine the size of a horizontal separator for data given in Example 6.6.3 and $F = 0.5$.

1. Gas capacity constraint: $t_g = t_d$

$$V_g = \frac{Q}{A_g}$$

$$Q = \frac{R \times Q_0}{86,400} \times \frac{14.7}{P} \times \frac{TZ}{520} = 2.1 \text{ ft}^3/\text{s}$$

$$A_g = \frac{\pi D^2}{4} \times F = 0.393D^2$$

$$V_g = \frac{2.1 \text{ ft}^3/\text{s}}{0.393D^2} = \frac{5.34}{D^2}$$

$$t_g = \frac{L_{\text{eff}}}{V_g} = \frac{L_{\text{eff}}D^2}{5.34}$$

$$t_d = \frac{D/2}{V_t} = \frac{D}{2V_t}$$

$$V_t = K \left(\frac{\gamma_L - \gamma_g}{\gamma_g} \right)^{0.5} \left(\frac{L_{\text{ss}}}{10} \right)^{0.56}$$

$$= 0.33 \left(\frac{49.7 - 1.155}{1.155} \right)^{0.5} \left(\frac{L_{\text{eff}} + D}{10} \right)^{0.56}$$

$$= 0.589 (L_{\text{eff}} + D)^{0.56}$$

$$\frac{L_{\text{eff}}D^2}{5.34} = \frac{D}{0.589 (L_{\text{eff}} + D)^{0.56}}$$

$$L_{\text{eff}}D^2 = \frac{9.07D}{(L_{\text{eff}} + D)^{0.56}}$$

For assumed D , calculate L_{eff} :

$D(\text{ft.})$	$L_{\text{eff}}(\text{ft.})$
4.0	0.93
4.5	0.79
5.0	0.72

2. Calculate maximum oil pad thickness $(h_0)_{\text{max}}$. Use 500 μm droplet if no other information is available $t_w = t_0$:

$$t_w = \frac{h_0}{V_t} \quad V_t = 2,660 \frac{(\gamma_w - \gamma_0) D_p^2}{\mu}$$

$$t_w = \frac{h_0 \mu}{2,660 (\gamma_w - \gamma_0) D_p^2}$$

$$t_0 = 60(t_r)_0 \quad t_r(\text{min})$$

$$\frac{h_0 \mu}{2,660 (\gamma_w - \gamma_0) D_p^2} = 60(t_r)_0$$

$$h_0 = \frac{159,600 (\gamma_w - \gamma_0) D_p^2 (t_r)_0}{\mu}$$

This is the maximum thickness the oil pad can be and still allow the water droplets to settle in time $(t_r)_0$. If $D_p = 500 \mu\text{m} = 500 \times 3.2808 \times 10^{-6} \text{ ft.} = 1.64 \times 10^{-3} \text{ ft.}$

$$h_0 = \frac{0.43 (\gamma_w - \gamma_0) (t_r)_0}{\mu}$$

For a given retention time (from Table 6.6.7, is equal to 5 min) and a given water retention time (also 5 min), the maximum oil pad thickness constraint establishes a maximum diameter.

$$\gamma_w = 64.3 \text{ lb/ft}^3 \quad \gamma_0 = 49.7 \text{ lb/ft}^3 \quad \mu = 3 \text{ cp}$$

$$(h_0)_{\text{max}} = 10.46 \text{ ft.}$$

3. Calculate the fraction of the vessel cross-sectional area occupied by the water phase (see Figures 6.6.8 and 6.6.12) A, A_w, A_0 (ft^2):

$$Q(\text{ft}^3/\text{s}) \quad t(\text{s}) \quad L_{\text{eff}}(\text{ft.})$$

$$A = \frac{Q_t}{L_{\text{eff}}}$$

$$Q = 6.49 \times 10^{-5} Q_0, \quad \text{also } Q = 6.49 \times 10^{-5} Q_w$$

$$t_0 = 60(t_r)_0 \quad t = 60(t_r)_w$$

$$A_0 = 3.89 \times 10^{-3} \frac{Q_0 (t_r)_0}{L_{\text{eff}}} \quad A_w = 3.89 \times 10^{-3} \frac{Q_w (t_r)_w}{L_{\text{eff}}}$$

$$A = 2(A_0 + A_w)$$

Hence

$$\frac{A_w}{A} = \frac{3.89 \times 10^{-3} Q_w (t_r)_w L_{\text{eff}}}{2L_{\text{eff}} 3.89 \times 10^{-3} [Q_w (t_r)_w + Q_0 (t_r)_0]}$$

$$= \frac{0.5 Q_w (t_r)_w}{Q_w (t_r)_w + Q_0 (t_r)_0}$$

4. From Figure 6.6.12, determine the coefficient “ d ,” and calculate D_{max} for oil pad thickness constraint:

$$\frac{A_w}{A} = \frac{0.5(5)500}{500(5) + 6,300(5)} = 0.037$$

$$d = \frac{h_0}{D} = 0.43$$

$$D_{\text{max}} = \frac{(h_0)_{\text{max}}}{d} = \frac{10.46}{0.43} = 24.3 \text{ ft.}$$

D_{max} depends on $Q_0, Q_w, (t_r)_0$, and $(t_r)_w$.

5. Liquid retention constraint:

$$t = \frac{\text{Vol.}}{Q}$$

$$\text{Vol.} = \frac{1}{2} \left(\frac{\pi D^2}{4} L_{\text{eff}} \right) = 0.393D^2 L_{\text{eff}}$$

FIGURE 6.6.12 Coefficient “d” for a cylinder half filled with liquid [15].

$$(Vol.)_0 = 0.393D^2L_{eff} \left(\frac{A_0}{A_{liq}} \right)$$

$$(Vol.)_w = 0.393D^2L_{eff} \left(\frac{A_w}{A_{liq}} \right)$$

Q_0 and Q_w are in bpd:

$$Q = 6.49 \times 10^{-5} Q_0 \quad Q = 6.49 \times 10^{-5} Q_w$$

$$t_0 = \frac{0.393D^2L_{eff} \left[\frac{A_0}{A_{liq}} \right]}{6.49 \times 10^{-5} Q_0}$$

$$\frac{Q_0 t_0}{D^2 L_{eff}} = 6,055 \frac{A_0}{A_{liq}}, \quad \text{also} \quad \frac{Q_w t_w}{D^2 L_{eff}} = 6,055 \frac{A_w}{A_{liq}}$$

$(t_r)_0$ and $(t_r)_w$ are in min:

$$\frac{Q_0 (t_r)_0}{D^2 L_{eff}} = 101 \frac{A_0}{A_{liq}} \quad \frac{Q_w (t_r)_w}{D^2 L_{eff}} = 101 \frac{A_w}{A_{liq}}$$

Adding by sides

$$\frac{Q_0 (t_r)_0 + Q_w (t_r)_w}{D^2 L_{eff}} = 101 \frac{A_0 + A_w}{A_{liq}} = 101$$

$$D^2 L_{eff} = 0.0099 [Q_0 (t_r)_0 + Q_w (t_r)_w]$$

for given $(t_r)_0$ and $(t_r)_w = 5$ min, and

$$Q_0 = 6,300 \text{ bpd} \quad Q_w = 500 \text{ bpd}$$

$$D^2 L_{eff} = 0.0099 [500(5) + 6,300(5)] = 336.6$$

6. Compute combinations of D and L_{eff}

$$L_{ss}, \quad \text{where} \quad L_{ss} = L_{eff} \frac{4}{3} \quad \text{and} \quad \frac{L_{ss}}{D}$$

D (ft.)	L_{eff} (ft.)	L_{ss}	L_{ss}/D
5.0	13.5	18.0	3.5
5.5	11.1	14.8	2.7
4.5	16.6	22.2	4.9

For three-phase horizontal separators, slenderness ratio is in the range of 3 to 5 usually, so $D = 4.5$ and 5 ft. are proper choices. As one can see, liquid retention constraint limits three-phase separator size; gas capacity, and oil pad thickness do not govern.

6.6.8 Two-Stage Separation Systems

In high-pressure gas-condensate separation systems, it is generally accepted that a stepwise reduction of the pressure on the liquid condensate will appreciably increase the recovery of stock tank liquids. The calculation of the actual performance of the various separators in a multistage system can be made, using the initial wellstream composition and the operating temperatures and pressures of the various stages. Theoretically, three or four stages of separation would increase the liquid recovery over two stages: the net increase over two-stage separation will rarely pay out the cost of the second and/or third separator. Therefore, it has been generally accepted that two stages of separation plus the stock tank are the most optimum considered. The actual increase in liquid recovery for two-stage separation over single stage may vary from 3% to 15% (sometimes even more) depending upon the wellstream composition, operating pressures and temperatures.

The optimum high stage or first separator operating pressure is generally governed by the gas transmission line pressure and operating characteristics of the well. This will generally range in pressure from 600 to 1200 psia (41.4 to 82.7 bar). For each high or first-stage pressure, there is an optimum low-stage separation pressure that will afford the maximum liquid recovery. This operating pressure can be determined from an equation based on equal pressure ratios between the stages.

$$R = \left(\frac{P_1}{P_s} \right)^{0.5} \quad \text{or} \quad P_2 = \frac{P_1}{R} = P_s R^{n-1} \quad (6.6.9)$$

where R = pressure ratio

n = number of stages

P_1 = first-stage separator pressure in psia

P_2 = second-stage separator pressure in psia

P_s = stock tank pressure in psia

Figure 6.6.13 illustrates a schematic flow diagram of a typical high-pressure well production equipment installation [19]. The basic equipment is illustrated for two-stage separation of the high-pressure stream. From the wellhead, the high-pressure wellstream flows through a high-pressure separator and indirect heater gas production unit. In this unit the inlet stream is heated prior to choking to reduce the wellstream pressure to sales line pressure. This is done to prevent the formation of hydrates in the choke or downstream of the choke in the separator or sales line. From the indirect heater, the wellstream passes to the high-pressure separator where the initial separation of the high-pressure gas stream and produced well fluids occur.

From the high-pressure separator, the gas flows through an orifice meter and to the sales gas line. The liquid from the high-pressure separator passes through a diaphragm valve where the pressure is reduced and it is discharged to a low-pressure flash separator. In the low-pressure flash separator that would operate at approximately 100 psi (6.9 bar), a second separation occurs between the liquids and the lighter hydrocarbons in the liquids. The gas released from the low-pressure flash separator is returned back to the high-pressure unit, where it may be used for both instrument and fuel gas for the indirect heater. As illustrated in Figure 6.6.13, a secondary makeup line is shown from the high-pressure separator, which would provide additional makeup gas for the instrument gas and fuel gas, if not enough gas was released from the low-pressure separator. However, typically more gas is released than is required, and the additional low-pressure gas may be sold in a low-pressure gas gathering system and/or used for other utility purposes, such as fuel for company compressor engines or other fired equipment on that lease. This may be for reboilers on dehydrators or acid gas sweetening units, etc. From the low-pressure flash separator, the liquid is discharged through another diaphragm valve into a storage tank that is generally

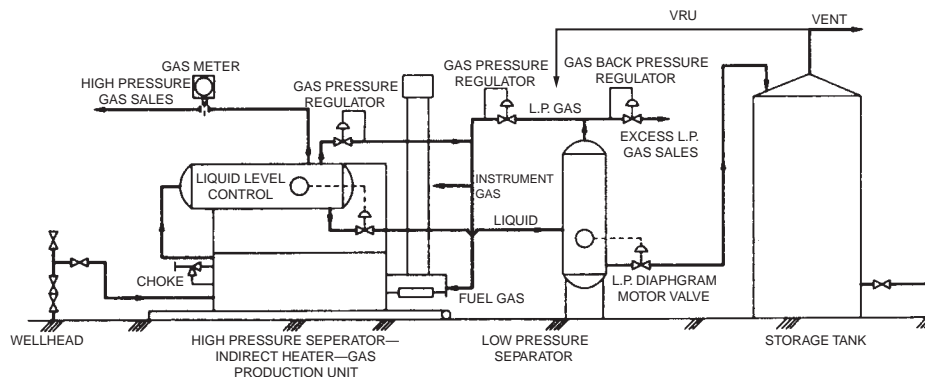

FIGURE 6.6.13 Two-stage separation system.

FIGURE 6.6.14 Low-pressure gas from flash separator [20].

operated at atmospheric pressure. Due to increased environmental consideration, a tank VRU is typically required to capture flash gases. This is typically routed to the LP gas system.

Example 6.6.5

Perform flash vaporization calculation to determine the increase recoveries that would be seen in both low-pressure flash gas as well as increased liquid recoveries in the storage tank. High-pressure gas $SG_g = 0.67$, the high-pressure separator pressures from 500 to 1,000 psi, the low-pressure separator $P = 100$ psi, and the storage tank pressure $P_s = 14.7$ psia. Temperature for all vessels is the same, 70°F .

Results

Figure 6.6.14 illustrates the gas produced from the low-pressure flash separator for the above-described wellstream at various high-pressure operating pressures (line pressure). The gas produced from the low-pressure flash separator in Mcf per year may be read from ordinate, based on the

high-pressure gas stream flow rate in MMscfd and the high-pressure separator operating pressure.

Figure 6.6.15 illustrates the increase in stock tank liquid recovery that would be achieved using the low-pressure flash separator. This chart is also based on high-pressure gas flow rate in MMscfd and the high-pressure separator operating pressure. The increase in stock tank liquid recovery may be read from the chart in bbl/year.

This additional recovery not only gives profit but also prevents the unneeded waste of precious hydrocarbon energy that would normally be vented out the stock tank using only single-stage separation.

6.6.9 Crude Oil Treating Systems

Water content of the untreated oil may vary from 1% to over 95%. Purchasers, depending on local conditions, accept a range from 0.2% to 3% of water in oil. When water forms a stable emulsion with the crude oil and cannot be removed in conventional storage tanks, emulsion-treating methods must be used.

FIGURE 6.6.15 Stock tank liquid increase with flash separator [20].

An *emulsion* is a heterogeneous liquid system consisting of two immiscible liquids with one of the liquids intimately disposed in the form of droplets in the second liquid (the water remaining is less than 10% of the oil). A common method for separating water–oil emulsion is to heat the stream. The use of heat in treating crude oil emulsions has four basic benefits:

1. Heat reduces the viscosity of the oil, making coalescence of droplets easier.
2. Heat increases the droplets' molecular movement.
3. Heat can enhance the action of treating chemicals, causing the chemicals to work faster to break the film surrounding the droplets of the dispersed phase of the emulsion.
4. Heat may increase the difference in density between the oil and the water, thus accelerating settling.

In general, at temperatures below 180°F (82°C), the addition of heat will increase the difference in density. Most light oils are treated below 180°F. For heavy crudes (below 20° API), heat may have a negative effect on difference in density.

In some cases, increased heat may cause the density of the water to be less than that of oil, as is shown in Figure 6.6.16. Adding heat changes the quality of the oil. The light ends are boiled off, and the remaining liquid has a lower API gravity and thus may have a lower value. Figures 6.6.17 and 6.6.18 illustrate typical gravity and volume losses for 33° API crude oil versus temperature. The molecules leaving the oil phase may be vented or sold. Heat can be added to the liquid by a direct heater, an indirect heater, or any type of heat exchanger.

A direct fired heater is one in which the fluid to be heated comes in direct contact with the immersion-type heating tube or element of the heater. These heaters are generally used when large amounts of heat input are required and to heat low-pressure noncorrosive liquids. These units are normally constructed so that the heating tube can be removed for cleaning, repair, or replacement.

An indirect fired heater is one in which the fluid passes through the pipe coils or tubes immersed in a bath of water, oil, salt, or other heat transfer medium that, in turn, is heated by an immersion-type heating tube similar to that used in the direct fired heater. Those heaters generally are used for

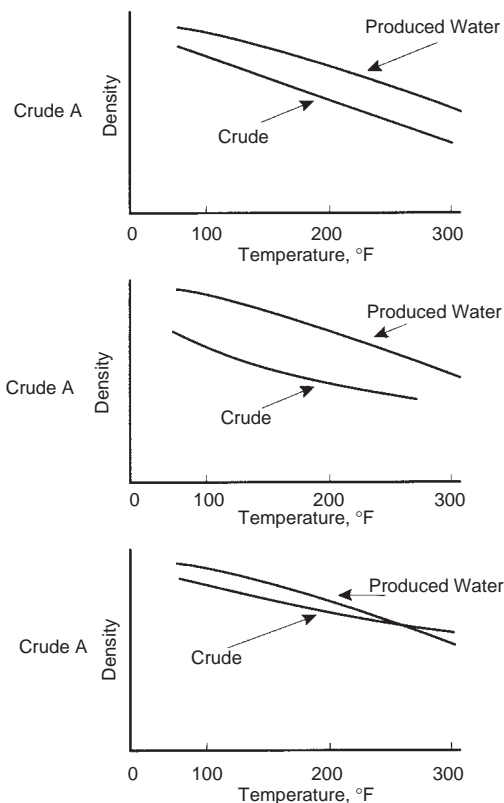

FIGURE 6.6.16 Relationship of specific gravity with temperature for these three crude oils [13].

FIGURE 6.6.17 API gravity loss versus temperature for crude oil [13].

high-corrosive fluids and are more expensive than direct fired heaters but have an advantage when considering fire safety due to tube rupture.

FIGURE 6.6.18 Percentage loss by volume versus temperature for crude oil [13].

Heat exchangers are very useful where waste heat is recovered from an engine, turbine, or other process stream or where fired heaters are prohibited.

6.6.9.1 Treating Equipment

All devices that accelerate the separation of two phases when the natural retention time is too long for commercial application, usually over 10 min, are called *treater*s. Emulsion treaters use some combination of heat, electricity, chemicals, retention time, and coalescence to separate oil and water. Treater s are designed as either vertical or horizontal vessels. The vertical heater is shown in Figure 6.6.19. Flow enters the top of the treater into a gas separation section. This section can be small if the treater is located downstream of the separator. The liquids flow through a downcomer to the base of the treater, which serves as a free-water knockout; the bottom section can be small. If the total wellstream is to be treated, this section should be sized for sufficient retention time to allow the free water to settle out. This minimizes the amount of fuel gas needed to heat the liquid stream rising through the heating section. The oil and emulsion flows upward around the fire tubes to a coalescing section, where sufficient retention time is provided to allow the small water droplets to coalesce and to settle to the water section. Treated oil flows out the oil outlet. The oil level is maintained by pneumatic or lever-operated dump valves.

It is necessary to prevent steam from being formed on the fire tubes. This can be done by employing the “40° rule.” That means that the operating pressure is kept equal to the pressure of the saturated steam at a temperature equal to the operating temperature plus 40°F (4.5°C). The normal

FIGURE 6.6.19 Vertical treater [15].

full-load temperature difference between the fire tube wall and the surrounding oil is approximately 30°F, allowing 10°F for safety; the 40° rule will prevent flashing of steam on the wall of the heating tube.

A low-pressure vertical flow treater, of large diameter, is called a “gunbarrel” (Figure 6.6.20). Most gunbarrels are unheated, although it is possible to provide heat by heating the incoming stream external to the tank, installing heat coils in the tank, or circulating water to an external heater in a closed loop as shown in Figure 6.6.21. A heated gunbarrel emulsion treater is shown in Figure 6.6.22.

For higher flow, inlet horizontal treaters are normally preferred. A typical design of a horizontal treater is shown in Figure 6.6.23. Flow enters the front section of the treater where gas is flashed. The liquid flows downward to near the oil–water interface, where the liquid is water-washed and the free water is separated. Oil and emulsion rises past the fire tubes and flows into an oil surge chamber. The oil–water interface in the inlet section of the vessel is controlled by an interface level controller, which operates a dump valve for the free water. The oil and emulsion flows through a spreader into the back or coalescing section of the vessel, which is fluid packed. The spreader distributes the flow

evenly throughout the length of this section. Treated oil is collected at the top through a collection device used to maintain uniform vertical flow of the oil. Coalescing water droplets fall counter to the rising oil. The oil–water interface level is maintained by a level controller and dump valve for this section of the vessel. A level control in the oil surge chamber operates a dump valve on the oil outlet line regulating the flow of oil out the top of the vessel and maintaining a liquid-packed condition in the coalescing section. Gas pressure on the oil in the surge section allows the coalescing section to be liquid-packed. The inlet section must be sized to handle separation of the free water and heating of the oil. The coalescing section must be sized to provide adequate retention time for coalescence to occur and to allow the coalescing water droplets to settle downward counter to the upward flow of the oil.

6.6.9.2 Heat Input Requirements [21,22]

The required heat input for an insulated vessel can be calculated as

$$Q_{th} = \dot{w}c\Delta T$$

FIGURE 6.6.20 Low-pressure settling tank with internal flume [20].

FIGURE 6.6.21 Heater and gunbarrel is forced circulation method of heating [20].

FIGURE 6.6.22 Heated gunbarrel emulsion treater [20].

FIGURE 6.6.23 Horizontal heater-treater [20].

FIGURE 6.6.24 Overall film coefficient for natural gas in indirect heaters [22].

where

- Q_{th} = heat required in Btu/hr
- \dot{w} = weight flowrate in lb/hr
- c = specific heat constant at average temperature [Btu/(lb°F)] = 0.5 for oil and = 1.0 for water
- Δt = temperature increase, assuming a water weight of 350 lb/bbl

$$Q_{th} = \frac{350}{24} q_0(SG_0)(0.5)\Delta T + \frac{350}{24} q_w(SG_w)(1.0)(\Delta T)$$

$$= 14.6\Delta T(0.5q_0SG_0 + q_wSG_w)$$

If heat loss is assumed to be 10% of the heat input, then

$$Q = \frac{Q_{th}}{0.9} = 16.2\Delta T(0.5q_0SG_0 + q_wSG_w) \quad (6.6.10)$$

An alternative way is to employ the basic heat transfer equations, which are used in indirect heat sizing as follows:

$$Q = V_0AT_m \quad \text{or} \quad A = \frac{Q}{V_0T_m} \quad (6.6.11)$$

- where Q_0, Q_w = heat required in Btu/hr
- A = total heat transfer area (coil area) in ft.²
- T_m = log mean temperature difference in °F

For low-pressure oil, about 35°API and water liquid, streams, the heat required may be determined from the following equation:

$$Q = q_t[6.25 + 8.33(X)]\Delta T \quad (6.6.12)$$

- where q_t = total liquid flowrate in bpd
- X = decimal water content in liquid
- ΔT = the difference between inlet and outlet temperature °F

The overall film or heat transfer coefficient for high-pressure gas streams may be found from Figure 6.6.24 using the gas flowrate and tube size selected. The overall film or heat transfer coefficient for water may be found from Figure 6.6.25 and the coefficient for oil from Figure 6.6.26, based on liquid flowrate and tube size. For liquid streams that are a mixture of oil and water, the overall coefficient may be averaged and calculated as

$$V_{0(mix)} = V_{0(oil)} + [V_{0(water)} - V_{0(oil)}]X \quad (6.6.13)$$

These film or heat-transfer coefficients are based on clean tubes; in other words, no allowance is made for any fouling factors. If any fouling is to be expected, excess coil area should be allowed in the heater selection.

$$T_m = \frac{GTD - LTD}{\ln\left(\frac{GTD}{LTD}\right)} \quad (6.6.14)$$

- where T_m = log mean temperature difference in °F
- GTD = greater temperature difference = water bath temperature – inlet fluid temperature
- LTD = least temperature difference = water bath temperature – outlet fluid temperature in °F

FIGURE 6.6.25 Overall film coefficient for water in indirect heaters [22].

A water bath temperature must be assumed for the calculations as mentioned before. Usually 180°F is the maximum designed temperature recommended for indirect water bath heaters.

The coil area (A) is required for indirect heaters (Figure 6.6.27) [23] can be calculated from the basic heat transfer equation after all the above factors have been determined. An indirect heater then may be selected from the standard models listed in Tables 6.6.8 and 6.6.9 [22] based on the heat and the coil area required.

By selecting a heater with a larger heat capacity and coil area than that calculated, sufficient excess will be provided

to allow for heat loss from the vessel and any fouling that may occur within the tubes, and will allow the heater to be operated at less than the maximum design water bath temperature.

Example 6.6.6

For a given date, calculate the heater size such that

- Oil flowrate = 2,500 bpd
- Water flowrate = 1,400 bpd
- Inlet temperature = 60°F
- Outlet required temperature = 100°F
- Coil size required = 3 in. cast iron

FIGURE 6.6.26 Overall film coefficient for oil in indirect heaters [22].

Heat required, from Equation 6.6.12, is

$$Q = q_t(6.25 + 8.33X)T$$

$$q_t = 2,500 + 1,400 = 3,900 \text{ bpd}$$

$$X = \frac{1,400}{3,900} = 0.36 = 36\%$$

$$\Delta T = 110 - 60 = 40^\circ\text{F}$$

$$Q = 3,900[6.25 + 8.33(0.36)]40 = 1,442,813 \text{ Btu/hr}$$

Heat transfer coefficient, from Equation 6.6.13, is

$$V_{0(\text{mix})} = V_{0(\text{oil})} + [V_{0(\text{water})} - V_{0(\text{oil})}] X$$

Oil flowrate is $q_0 = \frac{2,500}{24} = 104.2 \text{ bphr}$

From Figure 6.6.26, $V_{0(\text{oil})} = 35.7 \text{ Btu}/(\text{hr ft.}^2 \text{ }^\circ\text{F})$.

Water flowrate is $q_w = \frac{1,400}{24} = 58.4 \text{ bphr}$

from Figure 6.6.25, $V_{0(\text{water})} = 117.5 \text{ Btu}/(\text{hr ft.}^2 \text{ }^\circ\text{F})$.

$$V_{0(\text{mix})} = 35.7 + (117.5 - 35.7)0.36 = 65.15 \text{ Btu}/(\text{hr ft.}^2 \text{ }^\circ\text{F})$$

Log mean temperature difference, from Equation 6.6.14, is

$$T_m = \frac{\text{GTD} - \text{LTD}}{\ln \frac{\text{GTD}}{\text{LTD}}}$$

$$\text{GTD} = 180 - 60 = 120^\circ\text{F} \quad \text{LTD} = 180 - 100 = 80^\circ\text{F}$$

$$T_m = \frac{40}{\ln \frac{120}{80}} = 98.7^\circ\text{F}$$

Coil area, from Equation 6.6.11, is

$$A = \frac{Q}{V_0 T_m}$$

where

$$A = \frac{1,442,813}{117.5 \times 98.7} = 124.4 \text{ ft.}^2$$

		20	4" C.I.	261.8	314.1

Assume that 80% of the cross-sectional area is effective, retention time is 15 min, and treating temperature is 120°F or 150°F. Then oil viscosity = $\mu_0 = 5.5$ cp at 100°F, 4 cp at 120°F, and 2.5 cp at 150°F.

1. Settling equation:

$$V_t = V_0 \text{ (terminal velocity of water = velocity of oil)}$$

Flow around settling oil drops in water or water drops in oil is laminar, and thus Stokes law governs:

$$V_t = 2,600 \frac{\gamma_w - \gamma_0}{\mu_0} D_p^2 \text{ (ft./s)}$$

$$\gamma_w, \gamma_0 \text{ (lb/ft.}^3\text{)} \quad D_p \text{ (ft.)} \quad \mu_0 \text{ (cp)}$$

$$V_0 = \frac{Q}{A}$$

$$Q = 6.49 \times 10^{-5} Q_0$$

$$Q \text{ (ft.}^3\text{/s)} \quad A \text{ (ft.}^2\text{)} \quad Q_0 \text{ (bpd)}$$

$A = D \times L_{\text{eff}}$ is the highest cross-sectional area.

$$V_0 = \frac{6.49 \times Q_0}{10^5 D L_{\text{eff}}} = 6.5 \times 10^{-5} \frac{Q_0}{D L_{\text{eff}}}$$

$$2,600 \frac{\gamma_w - \gamma_0}{\mu_0} D_p^2 = 6.5 \times 10^{-5} \frac{Q_0}{D L_{\text{eff}}}$$

$$D L_{\text{eff}} = 2.44 \times 10^{-8} \frac{Q_0 \mu_0}{D_p^2 (\gamma_w - \gamma_0)} \quad \text{where } D_p \text{ is in ft.}$$

or

$$D L_{\text{eff}} = 2,267 \frac{Q_0 \mu_0}{D_m^2 (\gamma_w - \gamma_0)} \quad \text{where } D_m \text{ is in } \mu\text{m.}$$

The diameter of water droplets to be settled from the oil (μm) is a function of viscosity of the oil (cp) and, according to Arnold and Stewart [15], can be expressed as

$$d_m = 500(\mu_0)^{-0.675}$$

$$\text{at } 100^\circ\text{F } d_m = 500(5.5)^{-0.675} = 158 \mu\text{m}$$

$$120^\circ\text{F } d_m = 500(4)^{-0.675} = 196 \mu\text{m}$$

$$150^\circ\text{F } d_m = 500(2.5)^{-0.675} = 270 \mu\text{m}$$

$$\gamma_m = 1.03 \times 62.4 = 64.3 \text{ lb/ft.}^3$$

Assume the same for temperatures 60°F, 100°F, 120°F, and 150°F.

$$S_{G_0} \text{ at } 60^\circ\text{F} = \frac{141.5}{\text{API} + 131.5} = \frac{141.5}{32.8 + 131.5} = 0.860$$

$$S_{G_0} \text{ at } 100^\circ\text{F} = \frac{141.5}{(\text{API} - \text{loss}) + 131.5} = \frac{141.5}{32.8 + 131.5} = 0.861$$

where "loss" from Figure 6.6.17 is $0.3 - 0.1 = 0.2$:

$$SG_0 \text{ at } 120^\circ\text{F} = \frac{141.5}{32.7 + 131.5} = 0.862$$

$$SG_0 \text{ at } 150^\circ\text{F} = \frac{141.5}{32.2 + 131.5} = 0.864$$

Because specific gravity of oil as a function of temperature changes in a small range, assume constant values for oil and water specific weights:

$$\gamma_w = 64.3 \text{ lb/ft.}^3$$

$$\gamma_o = 53.7 \text{ lb/ft.}^3$$

$$\gamma_w - \rho_o = 106 \text{ lb/ft.}^3$$

	T = 100°F	T = 120°F	T = 150°F
$\gamma_w = 64.3 \text{ (lb/ft.}^3)$	10.6	10.6	10.6
$\mu_o \text{ (cp)}$	5.5	4.0	2.5
$d_m \text{ (\mu m)}$	158.0	196.0	269.0

Calculate D versus L_{eff}

- $DL_{eff} = 2,267 \times \frac{6,000 \times 4}{(196)^2 10.6} = 133.6$ if T = 120°F
- $DL_{eff} = 2,267 \times \frac{6,000 \times 25}{(-296)^2 10.6} = 44.3$ if T = 150°F

D(ft.)	$L_{eff}(a)$	$L_{eff}(b)$
2.0	66.8	22.2
4.0	33.4	11.1
4.5	30.0	9.9
5.0	26.7	8.9
6.0	22.3	7.4
9.0	14.8	4.9
15.0	8.9	3.0
30.0	4.5	1.5

2. Calculate the retention time, such that

$$t = \text{Vol.}/Q \quad \text{Vol.} = (\pi D^2/4) L_{eff} \times 0.8 = 0.63D^2 L_{eff}$$

$$Q = 6.49 \times 10^{-5} Q_0$$

$$t = \frac{0.63D^2 L_{eff}}{6.49 \times 10^{-5} Q_0} = 9,681 \frac{D^2 L_{eff}}{Q_0}$$

$$D^2 L_{eff} = 0.000103 Q_0 t$$

$(t_r)_0$ is in min

$$t = 60(t_r)_0$$

$$D^2 L_{eff} = 0.00618 Q_0 (t_r)_0$$

If the retention time $(t_r)_0 = 15$ min, then

$$D^2 L_{eff} = 0.00618 \times 6,000 \times 15 = 556.2$$

D(ft.)	2	4	4.5	5	6	9	15	30
$L_{eff}(ft.)$	139	24	27.5	22.2	15.5	6.9	2.5	0.6

If the retention time $(t_r)_0 = 20$ min, then

$$D^2 L_{eff} = 0.00618 \times 6,000 \times 20 = 741.6$$

D(ft.)	2	4	5	6	9	15	30
$L_{eff}(ft.)$	185	46	29.7	20.6	9.2	3.3	0.8

Plot Figure 6.6., D versus L_{eff} gives the solution.

For settling temperature 150°F, the minimum effective length has to be 2.7 ft. if $(t_r)_0 = 20$ min and 3.4 ft. if $(t_r)_0 = 15$ min. At lower settling temperature, L_{eff} should be 24 and 32 ft. for $(t_r)_0 = 20$ min and 15 min, respectively.

3. The heat required, from Equation 6.6.10, is

$$Q = 16.2\Delta T (0.5q_o SG_0 + q_w SG_w)$$

or

$$Q_{th} = 14.6\Delta T (0.5q_o SG_0 + q_w SG_w)$$

$q_w = 0.1\%$ of oil flow rate

$$\Delta T = 150 - 100 = 50^\circ\text{F} \text{ and } 120 - 100 = 20^\circ\text{F}$$

If $\Delta T = 50^\circ\text{F}$, then

$$Q_{thI} = 14.6 \times 50 \times (0.5 \times 6,000 \times 0.861 + 600 \times 1.03)$$

$$= 2,336,730 \text{ Btu/hr}$$

if $\Delta T = 20^\circ\text{F}$, then

$$Q_{thII} = 14.6 \times 20 \times (0.5 \times 6,000 \times 0.861 + 600 \times 1.03)$$

$$= 934,692 \text{ Btu/hr}$$

4. Conclusions are as follows. Treating temperature plays a more important role than retention time. For T = 150°F and $L_{eff} = 7.3$ ft., any diameter above retention time curves is correct. The diameter of the front section has to be the same as the coalescing section.

An economical solution would be a 6 × 20 ft. for the coalescing section and a 2.5 Btu/hr firebox rating.

6.7 GAS PRODUCTION ENGINEERING

Section reviewed by Ed Blair and Mirambek Ataushiyev

Quality specifications for natural gas are individually negotiated and prescribed in the contract between the purchaser or the pipeline companies and the producer. Gas contracts usually contain the following basic considerations:

- Minimum, maximum, and nominal delivery pressure
- Water dew point or water content
- Maximum condensable hydrocarbon content or hydrocarbon dew point
- Minimum heating value
- Contaminants such as H₂S, carbon disulfide, mercaptans, etc.
- Composition
- Maximum delivery pressure

Above quality parameters together with the price and quantity are the fundamental factors, and they determine production equipment required [1].

6.7.1 Gas–Water Systems and Dehydration Methods

Water vapor is the most common contaminant in natural gas, usually in the range of 8,000 to 10,000 ppm by volume (400 to 500 lb_M water vapor/MMscf of gas), while the pipeline specifications restrict the water content to a value no greater than 120 to 160 ppm by volume (6 to 8 lb_m water vapor/MMscf). Most gas sales contracts specify a maximum value for the amount of water vapor allowable in the gas. Typical values are 7 lb/MMscf in the southern United States, 4 lb/MMscf in the northern United States, and 2 to 4 lb/MMscf in Canada. These values correspond to dew points of approximately 32°F for 7 lb/MMscf, 20°F for 4 lb/MMscf, and 0°F for 2 lb/MMscf in a 1,000-psi gas line. In order to design and operate dehydration processes, a reliable estimate of the water content of natural gas is essential.

Figure 6.7.1 is based on experimental data and shows the solubility of water in sweet hydrocarbon liquids. In sour hydrocarbon liquids, water solubility can be substantially higher [2].

Liquid water and water vapor are removed from natural gas to:

- Prevent formation of hydrates in processing and transmission systems

FIGURE 6.7.1 Solubility of water in liquid hydrocarbons.

- Meet a water dew point requirement of the sales gas contract
- Prevent corrosion

6.7.1.1 Water Content of Natural Gases

The water content of a gas is a function of pressure, temperature, composition, and the salt content of the free water [2]. The effect of composition increases with pressure for acid gases. For lean, sweet natural gases containing over 70% methane and small amounts of “heavy ends,” pressure

temperature correlation’s are suitable. Figure 6.7.1 is an example.

Example 6.7.1

A natural gas $SG_g = 0.9$ is in contact with brine in the reservoir. The brine contains 30,000-ppm solids (approximately 3% NaCL). The pressure of the gas is 3,000 psia, and the temperature is 150°F. How much water is in the gas in pounds of water per million cubic feet of gas?

1. Follow dashed lines on Figure 6.7.2 from the general chart of Figure 6.7.2 at 3000 psia and 150°F gas would

FIGURE 6.7.2 Water content of sweet natural gas, LB PER MMscf (at 60°F and 14.7 psia) [1].

contain 105 lb of water/MMscf of 0.6 gas if the gas had been in contact with pure water.

- Correction for gas gravity from 0.6 to 0.9. From the "correction chart for gravity" follow the dashed line from the abscissa where the desired gravity is 0.9, vertically to the 150°F isotherm. Read horizontally, the correction factor for gas gravity C_g is 0.98.
- Correction for salinity of brine; see the second correction chart on the general Figure 6.7.2. At brine salinity of 3% go vertically to the correction line, and read on the ordinate the ordinate value of $C_s = 0.93$

The final answer for water content W:

$$W = 105 \times C_g \times C_s = 105 \times 0.98 \times 0.93 \\ = 95.6 \text{ lb water in the gas}$$

Experimental value for this gas was 96.2, which is satisfactory accuracy.

The McKetta and Wehe [2] chart (Figure 6.7.2) is not explicit for temperatures below the hydrate formation line. Because of this, it is better to use Campbell's [1] correlation (Figure 6.7.2) for water content of sweet gases. To determine the moisture within the pressure range of 1 to 690 bar (14.7 to 10,000 psia) and the temperature range of -40°C (-40°F) to 110°C (230°F), the following analytical expression is used:

$$W = \frac{A}{P} + B \quad \text{if } SG_g = .06$$

or

$$W = \frac{A}{P} + B \times C_G \times C_s \quad \text{if } SG_g > 0.6 \quad (6.7.1)$$

where A, B = constants; see Table 6.7.1

SG_g = specific gravity of gas or relative density

W = water content in g/m^3

P = gas pressure in atm

When natural gases contain substantial quantities of acid gases as H_2S and/or CO_2 , the water content of such a sour natural gas mixture can be considerably higher than the chart for sweet gas would indicate, especially at pressure above 70 bar (1,000 psia). Charts on Figure 6.7.5 and Figure 6.7.6 expand the pressure and temperature ranges for determining the water vapor content for sour gases to data given for sweet gases [2].

Example 6.7.2

Determine the amount of water that will drop out in a plant inlet separator from a gas stream that consists of 16% H_2S , 13% CO_2 , and 71% hydrocarbons.

$$T_{\text{res}} = 212^\circ\text{F}, \quad P = 4675 \text{ psia}, \quad T_{\text{sep}} = 80^\circ\text{F}, \\ \text{and } P_{\text{sep}} = 1000 \text{ psia.}$$

+30	32.30	0.1740	+110	1093.0	2.620

1. Reduce two-acid components CO₂ and H₂S to H₂S*:

$$\begin{aligned} \text{H}_2\text{S}^* \text{ of pseudocomposition} &= \text{H}_2\text{S} + 0.75 \times \text{CO}_2 \times 13 \\ &= 25.75\% = 16 + .075 \end{aligned}$$

2. Read water content from chart if H₂S* = 25.75 (from Figure 6.7.4)

$$\begin{aligned} W &= 1.36 \text{ lb/MMscf at } 3000 \text{ psia and } 212^\circ\text{F} \\ &= 1.13 \text{ bbl/MMscf at } 6000 \text{ psia and } 212^\circ\text{F} \end{aligned}$$

By logarithmic interpolation, the water content at 4,675 psia is determined as follows:

$$\begin{aligned} \frac{\log 4,675 - \log 6,000}{\log 3,000 - \log 6,000} &= \frac{\log x - \log 1.13}{\log 1.36 - \log 1.13} \\ \log x &= 0.0820 \\ x &= 1.21 \text{ bbl/MMscf} \end{aligned}$$

3. The water content at the separator:
If P = 1,000 psia, T = 80°F, W = 0.11 bbl/MMscf
4. Water drop out in the separator

$$1.21 - 0.11 = 1.10 \text{ bbl/MMscf}$$

6.7.1.2 Measurement of Water Content of Natural Gas

The first step in designing gas production equipment is to determine the water content of the gas (Figure 6.7.3). Many methods of measuring the amount of water in natural gases have been developed to fit various operations [1, 4]. No single method of analysis can be used under all conditions (Table 6.7.2) [5].

Dew point sensors are devices for moisture detection utilizing the physical properties of water and the laws of physics and chemistry to effect a measurement. Some of them are applicable to gas samples only. Other instruments can be used to monitor moisture in both liquid and gas samples (Table 6.7.3) [5]. Specifications for water content measurement are given in GPA Publication 2140 [2]. These include the valve freeze method, the Bureau of Mines dew point tester, and the cobalt bromide method. Cobalt bromide color change occurs at about 25 to 30 ppm (Figure 6.7.6).

The dew point tester permits the visual determination of the temperature at which water will condense from a gas onto a silvered mirror (Figure 6.7.7) [6], which is significant because it represents the actual equilibrium saturation temperature of the gas for temperatures above the hydrate-formation value. And, at temperature below the equilibrium hydrate-formation conditions, it measures a reproducible metastable equilibrium condition between gas and liquid water.

Figure 6.7.7 presents a sectional view of the apparatus without lead lines and refrigerant source. Gas entering the

FIGURE 6.7.3 Water content of CO₂ [2].

FIGURE 6.7.4 Water content of H₂S [2].

apparatus through valve A is deflected by nozzle B so as to strike the cooled mirror C. The mirror is cooled through the copper cooling rod F by the evaporation of a refrigerant, such as propane, CO₂ or some liquid gas in chiller G.

FIGURE 6.7.5 Calculated water content of acid gas mixtures to 2000 psia [4].

TABLE 6.7.2 Methods of Measuring Water Content

Method	Measurement
Electrolysis for water	Electrolysis current of sample is measured.
Dielectric constant change	Capacitance of a sample is measured.
Electric impedance	Electric impedance of the vapor of a sample is measured.
Piezoelectric crystals	Frequency of crystal with sample moisture is measured.
Heat absorption	Energy absorption and deposition of a sample is measured.
Infrared absorption	Infrared electromagnetic radiation absorption of a sample is measured.
Microwave absorption	Microwave electromagnetic radiation absorption of a sample is measured.

Pressure gages and a bulb thermometer are used to record the pressure and temperature condition for the inception of condensation or fog formation on the silvered mirror.

In the absence of interfering substances, the accuracy of the determination, given an experienced operator, is reported to be $\pm 0.1^\circ\text{C}$ down to 0°C and $\pm 0.3^\circ\text{C}$ from 0 to -18°C .

A silicon chip hygrometer [7] makes use of a tiny silicon chip to sense the presence of moisture. It can operate in environments ranging from -40°C to 45°C with no effect on accuracy, and gas flow rates from 50 to 1,500 cm^3/min . It can also operate under static or vacuum conditions.

Example 6.7.3

A natural gas dew point is measured at -4°F at a pressure of 14.7 psia. Express this water content in terms of ppm and vpm if the relative density (specific gravity) of the gas is equal to 0.7.

- (1) Water content W , in (g/m^3) and (lb/MMscf) , from Equation 6.7.1

$$W = \frac{A}{P} + B \times C_G \times C_s \quad -4^\circ\text{F} = -20^\circ\text{C}$$

$$14.7 \text{ psia} = 1.03 \text{ atm}$$

$$A = 0.960 \quad B = 0.0134 \text{ from Table 6.7.1}$$

$$W = \frac{0.96}{1.03} + 0.0134 = 0.945 \text{ g}/\text{m}^3 \quad \text{if } SG_g = 0.6$$

$$= 58.9 \text{ lb}/\text{MMscf} \quad \text{if } SG_g = 0.6$$

$$\text{for } SG_g = 0.7 \quad C_G = 1.0 \quad C_s = 1.0$$

$$W = 58.9 \text{ lb. water per MMscf}$$

- (2) Water content in terms of parts per million by weight (ppm)

$$1 \text{ lb mol} = 0.7 \times 29 = 20.3 \text{ lb}$$

$$= 379.3 \text{ ft}^3 \text{ at } 14.7 \text{ psia and } 60^\circ\text{F}$$

$$\frac{58.9 \text{ lb}}{10^6 \text{ scf}} = \frac{58.9 \text{ lb}}{2,636.43 \text{ lb mol}} = \frac{58.9 \text{ lb}}{2,636.43 \times 20.3 \text{ lb}}$$

- (3) Water content in terms of parts per million by volume (vpm)

$$\frac{58.9 \text{ lb}}{10^6 \text{ scf}} = \frac{58.9/18.00 \text{ (lb/lb mol)}}{10^6 \text{ scf}} = \frac{3.2722 \text{ lb mol}}{10^6 \text{ scf}}$$

$$= \frac{3.2722 \text{ lb mol} \times 379.4 \text{ scf/lb mol}}{10^6 \text{ scf}}$$

$$= 1,241 \text{ vpm}$$

- (4) Water content W , from Figure 6.7.2 is 57.6 lb/MMscf

6.7.2 Gas Hydrates

The amount of water soluble in a natural gas vapor is limited to temperature and pressure at the dew point. If water will condense in the pipeline and accumulate in sufficient

FIGURE 6.7.6 Calculated water content of acid gas mixtures to 6000 psia [4].

quantities, hydrate can be formed. Gas hydrates are a form of calthrate first discovered by Davy in 1810. A calthrate is any compound wherein guest molecules are entrapped in a cage structure composed of host molecules. With natural gas water molecules as shown in Figure 6.7.8 form hydrates. Contained within each lattice is a series of cavities or cages that must be occupied by enough guest molecules to stabilize this lattice crystal. The guest molecules provide stability to the lattice structure in the same manner that liquid in the pores of a subsurface sand prevents subsidence. Not all cages must be full. Therefore, there is no specific formula for hydrates. The crystal has an “ice like” appearance, which can be represented as:

Normal butane does form a hydrate, but it is very unstable. Other components of a natural gas mixture do not form hydrate.

Hydrates normally form when a gas stream is cooled below its hydrate formation temperature. At high pressure these solids may form at temperatures well above 32°F.

Hydrate formation is almost always undesirable because the crystals may cause plugging of flow lines, chokes, valves, and instrumentation; reduce line capacities; or cause physical damage.

The two major conditions that promote hydrate formation are, the gas being at the appropriate pressure and temperature and the gas being at or below its water dew point with “free water” present. As pressure increases, the hydrate formation temperature also increases. If there is no free water present, hydrates cannot form [4].

Several methods exist for determining the pressure and temperature at which hydrates begin to form: graphical, analytical and experimental. Rough data for determining the start of hydrate formation is obtained by the graphical method. With this method, for gas mixtures not containing H₂S, the curves shown in Figure 6.7.9 [2].

Example 6.7.4

Find the pressure at which hydrate forms at $T = 50^\circ\text{F}$ for a gas with the following composition:

Component	Mole fraction in gas	M	lb/mole of mixture
C ₁	0.88	16.04	14.12
C ₂	0.09	30.07	2.71
C ₃	0.02	44.10	0.88
C ₄	0.01	58.12	0.58
			18.29

$$\text{Relative Density} = \frac{M_{\text{gas}}}{M_{\text{air}}} = \frac{20.08}{28.97} = 0.693$$

From Figure 6.7.9 at 50°F

$$P = 320 \text{ psia for } SG_g = 0.7$$

To solve technological design problems, it is simple to use an analytical method to express the relationship between pressure and temperature of hydrate formation. Usually, equations of such dependence are given in the form of $\log P = a + \beta$, that is, when the dependence of P versus T has a linear character in semilog coordinates. However, as some experiments show [8], such dependence frequently does not have a linear character and may be more accurately expressed by:

$$\log P = a(t + kt^2) + \beta$$

where P = pressure in atm

SG_g = relative density (specific gravity)

a, β, k = coefficients

t = Temperature in °C or T = temperature in K

TABLE 6.7.3 Summary of Moisture Detector Features

Type	Range	Sample Phase	Sample System Required	Remarks
Electrolytic hygrometer	0–10 to 0–1,000 ppm	Clean gas. Special sampling for liquids	Yes	Sample flow must be constant
Change of capacitance	0–10 to 0–1,000 ppm	Clean gas or liquid	Yes	Sample temperature must be constant
Impedance type	0–20,000 ppm	Clean gas or liquid	For Liquids	Sample temperature of liquids must be constant
Piezoelectric type	0–5 to 0–25,000 ppm	Clean gas only	Yes	
Heat of adsorption type	0–10 to 0–5,000 ppm	Clean gas or liquid. Special sampling for liquids	Yes	Sample flow must be constant
Infrared absorption	0–0.05 to 0–50%	Liquids and slurries	Yes	
Microwave absorption	0–1 to 0–90%	Liquids, slurries and pastes	No

FIGURE 6.7.8 Schematic of natural gas hydrate formation.

CAUTION: Figures 6.7.9, 6.7.11, and 6.7.12 should only be used for first approximations of hydrate formation conditions. For more accurate determination of hydrate conditions make calculations with K_{v-s} .

FIGURE 6.7.9 Pressure temperature curves for predicting hydrate formation.

FIGURE 6.7.10 Dependence of coefficients β and k on the relative density (SG_g) [8].

Example 6.7.5

Find the pressure at which hydrate forms at $T = 50^\circ\text{F}$ for the gas from Example 6.7.4 using an analytical equation:

$$SG_g = 0.693$$

$$\log P = \beta + 0.0497 (t + kt^2) \tag{6.7.2}$$

$$\beta = 0.85 \quad k = 0.002 \text{ from Figure 6.7.10 [8]}$$

$$t = 50^\circ\text{F} = 10^\circ\text{C}$$

$$\log P = 0.85 + 0.0497[10 + 0.002 \times (10)^2]$$

$$\log P = 1.0335$$

$$P = 20.02 \text{ atm} = 294 \text{ psia}$$

Using Figure 6.7.9 we got ≈ 320 psia, it is a worst a value overestimate of 10%.

Example 6.7.6

The gas in Example 6.7.5 is to be expanded from 1,500 psia to 500 psia. What is the minimum initial temperature that will permit the expansion without hydrate formation?

From Figure 6.7.11 [2] for $SG_g = 0.6 \quad T_{\min} = 100^\circ\text{F}$

From Figure 6.7.12 [2] for $SG_g = 0.7 \quad T_{\min} = 125^\circ\text{F}$

The 1500-psia-pressure line and the 500-psia final pressure line intersect just above the 100°F curve on Figure 6.7.12. Approximately 112°F is the minimum initial temperature.

Example 6.7.7

How far may a 0.6 specific gravity (relative density) gas at 2,000 psia and 100°F be expanded without hydrate formation?

TABLE 6.7.4 Equations for the Relationship between Pressure and Temperature of Hydrate Formation for Several Gases [8]

Gas and its relative density	Temp. Interval °C	Equations
CH ₄	0 to -11	$\ln P = 5.6414 - 1154.61/T$
	0 to +23	$\ln P = 1.415 + 0.417(T + 0.01T^2)$
	+24 to +47	$\ln P = 1.602 + 0.0428T$
C ₂ H ₆	0 to -10	$\ln P = 6.9296 - 1694.86/T$
	0 to +14.5	$\ln P = 0.71 + 0.0547T$
C ₃ H ₈	0 to -12	$\ln P = 5.4242 - 1417.93/T$
	0 to +8.5	$\ln P = 0.231 + 0.0576T$
CO ₂	0 to -6	$\ln P = 13.4238 - 3369.1245/T$
	0 to +9.8	$\ln P = 1.08 + 0.056T$
H ₂ S	-32 to +29.6	$\ln P = 2.844 + 0.0466T$
C _n H _{2n+2}	0 to +25	$\ln P = \beta + 0.0497(T + kT^2)$
0.6 to 1.0		

FIGURE 6.7.12 Permissible expansion of 0.7 specific gravity natural gas without hydrate formation [2].

On Figure 6.7.11 find the intersection of 2,000 initial pressure line with the 100°F initial temperature curve. Read on the X-axis, the permissible final pressure of 1100 psia.

Example 6.7.8

How far may a 0.6 gravity gas at 2,000 psia and 140°F be expanded without hydrate formation?

On Figure 6.7.11, the 140°F initial temperature curve does not intersect the 2,000-psia initial pressure line. Therefore, the gas may be expanded to atmospheric pressure without hydrate formation.

WARNING: Figures 6.7.11 and 6.7.12 should only be used for first approximations of hydrate conditions.

6.7.3 Hydrate Prediction Based on Composition for Sweet Gases

Several correlation's have proven useful for predicting hydrate formation of sweet gases and gases having minimal amounts of CO₂ and H₂S. The most reliable ones require a gas analysis. The Katz method [9, 10] utilizes vapor solid equilibrium constants defined by Equation 6.7.2,

$$K_{v-s} = Y/X_s \quad \text{and} \quad \sum Y_i/K = 1.0 \quad (6.7.3)$$

The applicable K-value correlation's for the hydrate forming molecules (CH₄, C₂H₆, C₃H₈, i-C₄H₁₀, n-C₄H₁₀, CO₂ and H₂S) are shown in Figure 6.7.13 through 6.7.19.

FIGURE 6.7.11 Permissible expansion of 0.6 specific gravity natural gas without hydrate formation [2].

		Σ K = 0.722		Σ K = 1.457		Σ K = 1.003	

FIGURE 6.7.20 Solution sketch for Example 6.7.10.

Temperature at which hydrate will form is about 54°F.

Using Equation 6.7.2 gives 435 psia = 30.6 atm

$$\log 30.6 = 0.8 + 0.0497(t + 0.0077t^2)$$

$$0.000383t^2 + 0.0497t - 0.686 = 0$$

$$t = 12.57^\circ\text{C} = 54.6^\circ\text{F}$$

Both results are close enough.

Example 6.7.10

The gas with the composition below is at 3,500 psia and at 150°F. What will be the hydrate conditions when the gas is expanded?

Comp	Mole Fraction	Initial Pressure (psia)	Initial Temperature (°F)	Final Pressure (psia)	Final Temperature (°F)
C ₁	0.09267	3,500	150		
C ₂	0.529	3,500	150	300	38
C ₃	0.0138	3,500	150	400	45
iC ₄	0.0018	3,500	150	500	52
nC ₄	0.0034	3,500	150	600	58
nC ₅	0.0014	3,500	150	700	64
	= 1.000				

Solution

Step 1. Make several adiabatic flash calculations at different pressures and plot on a pressure versus temperature graph; see Figure 6.7.20 [2].

Step 2. Assume some temperatures (40°F, 50°F, and 60°F) and predict the hydrate pressure for this gas using the vapor-solid K data. Plot the results on Figure 6.7.20.

$$(y/K) = 1 \text{ at } 277 \text{ psia for } T = 40^\circ\text{F}$$

$$(y/K) = 1 \text{ at } 452 \text{ psia for } T = 50^\circ\text{F}$$

$$(y/K) = 1 \text{ at } 964 \text{ psia for } T = 60^\circ$$

Step 3. The intersection of the lines in Figure 6.7.20 is the point at which hydrates start to form; in this example, 500 psia and 52°F.

The constants for H₂S shown in Figure 6.7.19 should be satisfactory at concentrations up to 15–20-mol% H₂S in the gas.

At the concentration of 30% or greater, hydrates may form at about the same conditions as for pure H₂S.

Slightly better results than the K-charts method will generally give computer solutions, which have been developed for hydrate prediction applying P-V-T equations of state.

TABLE 6.7.5 Physical Properties of Selected Glycols and Methanol

<i>Diethylene Glycol 328°F Tetraethylene Glycol 460°F</i>					

6.7.4 Hydrate Inhibition [2]

The formation of hydrates can be prevented by dehydrating to prevent a free-water phase or by inhibiting hydrate formation in the free-water phase. Dehydration is usually preferable, but inhibition can often be satisfactory.

Inhibition utilizes injection of one of the glycols or methanol to lower the hydrate formation temperature for a given pressure.

Ethylene, diethylene, and triethylene glycols have been used for glycol injection. The most popular has been ethylene glycol because of its lower cost, lower viscosity, and lower solubility in liquid hydrocarbons.

Physical properties of the most common glycols are given in Table 6.7.5 [2].

Estimation of properties for glycol–water mixtures can be achieved by a weight fraction average of the appropriate

glycol curve and the water curve shown on each of the figures. To allow determination of mixture properties at lower temperatures, the pure glycol and water property curves have been extrapolated below their freezing points.

To be effective, the inhibitor must be present at the very point where the wet gas is cooled to its hydrate temperature. For example, in refrigeration plants glycol inhibitors are typically sprayed on the tube-sheet faces of the gas exchangers so that they can flow with the gas through the tubes. As water condenses, inhibitors are present to mix with the water and prevent hydrates.

Glycol and its absorbed water are separated from the gas stream possibly along with liquid hydrocarbons. The glycol–water solution and liquid hydrocarbons can emulsify when agitated or when let down together from a higher to lower pressure. Careful separator design will allow

nearly complete recovery of the glycol for regeneration and recycle.

The regenerator in a glycol injection system should be operated to produce a regenerated glycol solution that will have a freezing point below the minimum temperature encountered in the system.

Lowering the hydrate freezing point in natural gas systems by an antifreeze compound may be calculated by:

$$d = \frac{K_H(I)}{(100 - I)M_I} \quad (6.7.4)$$

where

- d = depression of gas hydrate freezing point in °F
- K_H = constant for methanol = 2335, for glycols = 4000
- I = minimum inhibitor concentration in the free water %
- M_I = molecular mass of solute inhibitor

Example 6.7.11

Estimate the methanol (MeOH) injection rate required to prevent hydrate formation in 2 MMscfd of 0.6 specific gravity (relative density) natural gas at 800 psia and 40°F.

The gas is water saturated at 1,000 psia and 100°F. No hydrocarbons are condensed.

Solution

From Figure 6.7.2:

- Water content at 100°F and 1,000 psia = 60 lb/MMscf
- Water content at 40°F and 800 psia = 10.5 lb/MMscf
- Hydrate temperature of gas = 57.5°F (Figure 6.7.9)

$$D = 57.5^\circ - 40^\circ = 17.5^\circ F$$

From Equation 6.7.4:

$$17.5 = (2,335)(I)/[(100 - I)32]$$

$$I = 19.4\%$$

From Figure 6.7.21 [2]:

$$C \frac{\text{lb MeOH/MMscf}}{19.4 \text{ wt\% MeOH}} = 0.975$$

$$\text{So } \frac{19.4}{0.975} \text{ lb MeOH/MMscf} \rightarrow \text{required for gas phase}$$

$$19.9 \times 2 + 39.8 \text{ lb MeOH/day}$$

$$\text{MeOH in liquid} = 99 \text{ lb/day } (0.194)/(1.0 - 0.199) = 23.98$$

FIGURE 6.7.21 Ratio of methanol vapor composition to methanol liquid composition [2].

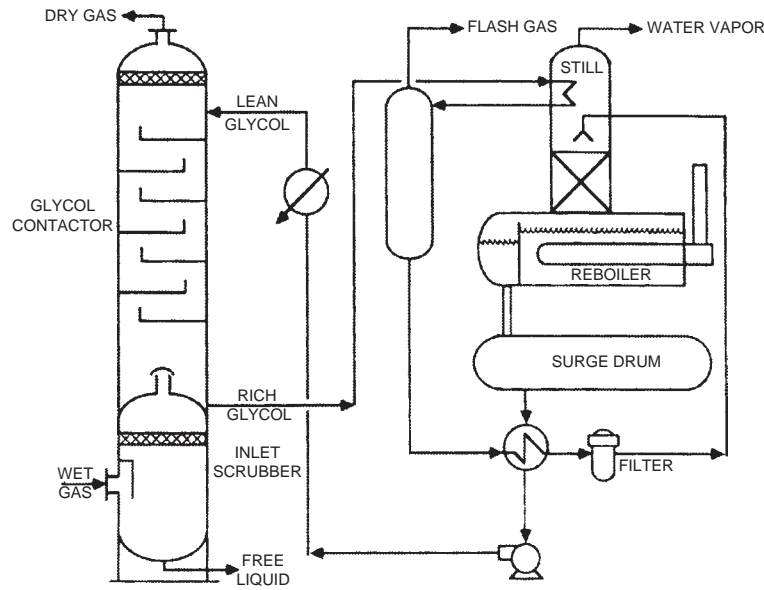

FIGURE 6.7.22 Example process flow diagram for glycol dehydration unit.

$$\begin{aligned}\text{Minimum MeOH injection rate} &= 23.98 + 39.8 \\ &= 63.8 \text{ lb/day}\end{aligned}$$

6.7.5 Gas Dehydration

In those situations in which inhibition is not feasible or practical, dehydration must be used. Both liquid and solid desiccants may be used, but economics favor liquid desiccant dehydration when it will meet the required dehydration specification.

Liquid desiccant dehydration equipment is simple to operate and maintain. It can easily be automated for unattended operation, for example, glycol dehydration at a remote production well. Liquid desiccants can be used for sour gases, but additional precautions in the design are needed due to the solubility of the acid gases in the desiccant solution.

Solid desiccants are normally used for extremely low dew point specifications as required for expander plants to recover liquid hydrocarbons.

The more common liquids in use for dehydrating natural gas are triethylene glycol (TEG), diethylene glycol (DEG), and tetraethylene glycol (TREG). In general, glycols are used for applications where dew point depressions of the order of 15 to 50°C (59 to 120°F) are required. TEG is the most commonly used glycol.

For the following description of the process and flow through a typical glycol dehydration unit refer to the schematic flow diagram as shown in Figure 6.7.22 [2].

The wet inlet gas stream first enters the unit through a separate vertical inlet gas scrubber. In this scrubber any liquid accumulations in the gas stream are removed. The

inlet scrubber is normally provided with a tangential inlet diverter that affects a circular flow of the well fluids around the wall of the vessel for centrifugal separation. The wet gas then passes out of the top of the inlet scrubber through a high-capacity, high-efficiency, stainless steel wire mesh mist eliminator that allows for virtually no liquid carryover. The separated well fluids drain into a quiet settling chamber in the bottom of the vessel and are discharged through a diaphragm-operated motor valve by liquid level control. The vertical inlet gas scrubbers may be equipped for either a two-phase (oil–gas) operation or a three phase (oil–gas–water) operation.

The wet gas leaves the top of the inlet scrubber and passes to the vertical glycol–gas contactor. The gas enters the bottom of this vessel and flows upward through the contact medium countercurrent to the glycol flow. The contact medium in the glycol–gas contactor may be valve-type trays or bubble cap trays. The operation is the same in that the liquid glycol flows down through the packing and the gas vapor flows up through the packing contacting the glycol. In trayed columns, the gas contacts the glycol on each tray as it passes through the vessel and the glycol absorbs the water vapor from the gas stream. Above the top tray in the contactor is a space for entrainment settling where most of the entrained glycol particles in the gas stream will settle out. A high-efficiency mist eliminator in the top of the contactor vessel will remove any glycol not settling out. The dry gas then leaves the contactor tower at the top.

The incoming dry lean glycol from the surge tank is cooled in a heat exchanger before it enters the contactor for a maximum contacting efficiency. The lean concentrated glycol is picked up from the surge tank by the glycol pump

and is pumped at the contactor operating pressure through the heat exchanger and into the top of the contactor column. The dry glycol enters the contactor on the top of the tray. The dry glycol flows downward through the contactor vessel by passing across each tray and spilling over the wire box on the tray, and then passing down through a downcomer to the next tray. By this concurrent flow of gas and glycol, the driest incoming glycol on the top is in contact with the driest outgoing gas for maximum dehydration of the gas stream. The bottom tray downcomer is fitted with a seal to hold the liquid seal on the trays.

The wet-rich glycol that has now absorbed the water vapor from the gas stream leaves the bottom of the glycol-gas contactor column and passes through a high-pressure glycol filter. The high-pressure glycol filter will remove any foreign solid particles that may have been picked up from the gas stream in the contactor before the glycol enters the power side of the glycol pump. This is generally considered to be the ideal location for primary filtration of the glycol stream.

From the glycol filter, water-rich glycol flows through the condenser coil, flashes off gas in the flash tank, and flows through the glycol-glycol heat exchanger to the regenerator portion of the unit. The warmed water-rich glycol enters the lower part of the stripping still column that is packed with ceramic saddles and is insulated. An atmospheric reflux condenser is integral with the stripping still at the top of the still, plus some water vapor to provide the adequate reflux required for the stripping column. This reflux condenser is also packed with ceramic saddles to assure that all the vapor to be vented will come in contact with the cool wall of the condenser.

The wet glycol, after entering the stripping still column will flow downward toward the reboiler contacting hot rising glycol vapors, water vapors, and stripping gas. The water vapor has a lower boiling point than glycol; therefore, any rising glycol vapors will be condensed in the stripping still and be returned to the reboiler section. In the reboiler, the glycol must travel a substantially horizontal path along the firebox to reach the liquid overflow exit at the opposite end. Here in the reboiler the glycol is heated to between 175°C and 200°C to remove enough water vapor to reconcentrate it to 99.5% or more. For extra dry glycol (99% plus), it may be necessary to add some stripping gas to the reboiler.

The warm wet glycol stream flows from the reboiler to a low-pressure surge tank. Next, the regenerated glycol flows through the glycol heat exchangers for cooling and is recirculated to the contactor by the glycol pump.

6.7.5.1 Dehydrator Design [1]

TEG dehydrators utilizing tray or packed column contactors may be sized from standard models by using the following procedures and associated graphs and tables.

Custom-design glycol dehydrators for specific applications may also be designed using these procedures. The following information must be available on the gas stream to be dehydrates:

- gas flowrate (MMscmd or MMscfd)
- composition or specific gravity of gas
- maximum working and operating pressure (bar or psig)
- gas inlet temperature (°C or °F)
- water dew point or water content required of the outlet gas (kg/MMscm or lb/MMscf)

From these, one can calculate:

1. the minimum concentration of TEG in the lean solution entering the top of the absorber required to meet outlet gas water specification
2. the lean (dry) TEG circulation rate required to absorb from the gas the needed amount of water
3. the total heat load on the reboiler

To obtain the answer, it is necessary to have a vapor-liquid equilibrium correlation for TEG-water system.

The *minimum lean (dry) TEG concentration*, a TEG absorber, is essentially isothermal. The heat of the solution is about 21 kJ/kg (91 BTU/lb) of water absorbed in addition to the latent heat. But, the mass of water absorbed plus the mass of TEG circulated is trivial to the mass of gas, so the inlet gases temperature controls. The temperature rise seldom exceeds 2°C except when dehydrating at a pressure below 10 bar (145 psia).

In Figure 6.7.23 [2] diagonal line represent %TEG in a TEG-water mixture entering the top of the absorber (glycol contactor).

Example 6.7.12

What equilibrium water dew point could be obtained at 80°F with a lean glycol solution containing 99.5 wt% TEG?

In Figure 6.7.22 locate 80°F on the abscissa; go vertically to the 99.5% line and the horizontally to the ordinate. The answer is -20°F.

It is theoretical water dew point, which could be attained in a test cell, but not in a real absorber. The gas and TEG are not in contact for a long enough time to reach equilibrium.

Practical tests show that a well-designed, properly operated unit will have an actual water dew point $7 \pm 1.5^\circ\text{C}$ (10°F to 15°F) higher than the equilibrium dew point.

The procedure for calculation of minimum glycol concentration is as follows:

1. Establish the desired outlet dew point needed from sales contract specification or from minimum system temperature.
2. Subtract the approach (10°F to 15°F) from the desired outlet dew point to find the corresponding equilibrium water dew point.

FIGURE 6.7.23 Equilibrium H₂O dewpoint versus temperature at various TEG concentrations.

3. Enter the value in the second step on the ordinate of Figure 6.7.23 and draw a horizontal line.
4. Draw a vertical line from the inlet gas temperature on the abscissa.
5. The intersection of the lines in Steps 3 and 4 establishes minimum lean TEG concentration required to obtain the water dew point on Step 1.

If water content is specified or calculated in mass per unit gas volume, a water content-pressure dew point temperature correlation is required (see Figure 6.7.2) [1].

Example 6.7.13

The gas sales contract specifies outlet water content of 5-lb/10⁶ scf at a pressure of 1,000 psia. The inlet gas temperature is 100°F. What minimum TEG concentration is required?

For 5-lb/10⁶ scf and 1,000 psia, the equivalent dewpoint from Figure 6.7.2 is 25°F. Using 13°F approach the equilibrium dew point is 12°F. From Figure 6.7.23 at 12°F and 100°F contact temperature wt% TEG = 98.4%

A given lean TEG concentration is produced in the reboiler and still column (regenerator) section by control of reboiler temperature, pressure, and the possible use of stripping gas. So long as no stripping gas is used, the concentration of the lean TEG leaving the reboiler is independent of the rich TEG entering. When stripping gas is used, a water material balance around the absorber finds the concentration of rich TEG leaving the absorber.

By definition:

$$\begin{aligned} & \text{Wt\% rich TEG} \\ &= \frac{(100) \text{ wt lean TEG}}{\text{Wt lean TEG} + \text{wt water absorbed} + \text{wt water in lean TEG}} \end{aligned} \quad (6.7.5)$$

The weight quantities in this equation may be found per unit of time (or per unit of gas flow). In any case, the values used depend on circulation rate. This rate depends on dew point requirements, lean TEG concentration, and amount of absorber contact and economics.

Economics dictates a rather low circulation rate. This rate usually will be a 7.5 to 22.5 L (2 to 6 gal) TEG solution per pound of absorbed water from the gas. The minimum rate governed by the rate required for effective gas-liquid contact in the absorber; the maximum is limited by economics. Because regeneration takes place at low pressure, calculations are simple. Figure 6.7.24 [11] has been used to predict regenerator performance based on Equation 6.7.5.

The minimum wt% of rich TEG on the bottom abscissa is found from Figure 6.7.24. Neglecting the small amount of water in the lean TEG, the rich TEG concentration can be determined from the following:

$$\text{Rich TEG} = \frac{8.34(\text{SG}_{\text{gL}})(\text{lean TEG})}{8.34(\text{SG}_{\text{gL}}) + 1/L_w} \quad (6.7.6)$$

FIGURE 6.7.24 Nomograph for estimating regenerator performance as a function of pressure, reboiler temperature [11].

where rich TEG = wt% in rich TEG solution
 $8.34 =$ water specific weight in lb/gal
 $(SG_{gL}) =$ relative density of lean TEG solution at operating temperature of contactor contactor
 Lean TEG = wt% TEG in lean TEG solution
 $L_w =$ glycol to water circulation rate in gal TEG/lb H_2O

The diagonal lines in the lower left part of Figure 6.7.24 represent various amounts of stripping gas. Degree of regeneration depends on temperature regeneration, pressure and quantity of stripping gas. The general procedure for using nomograph Figure 6.7.24 is as follows:

1. *Atm. Pressure, No Stripping Gas*
 wt% rich glycol is not a variable. Proceed vertically from 0 stripping gas and temperature line intersection. Read 98.8 wt% TEG at 204°C; 98.4 wt% at 193°C.
2. *Atm. Pressure, Stripping Gas*
 - a. Proceed vertically from B to temperature line and then horizontally
 - b. Proceed vertically from X
 - c. Intersection of two lines from (X) to (B) fixes amount of stripping gas.

3. Vacuum, No Stripping Gas

- a. Proceed vertically from the intersection of 0 gas line and temperature line to atmospheric line (760 mm Hg).
- b. Proceed horizontally from a point in (a) to pressure line necessary to fix value of point (c).

If both stripping gas and vacuum are used, procedure 2 and 3 are combined.

Lean TEG (99.0% to 99.9%) is available from most glycol reconcentrators. A value of 99.5% lean TEG is adequate for most design considerations.

Example 6.7.14

A 96.45-wt% rich glycol enters a regenerator using 8 scf of stripping gas per gallon of glycol solution. Reboiler temperature is 400°F. Find wt% TEG in lean glycol solution under atmospheric pressure and 400-mmHg absolute pressure.

From a bottom line for the rich glycol at 96.45-wt% flow to stripping gas, we get an injected value of 8 scf/gal. Proceed to 400°F and then vertically to get a 99.31 wt% if atmospheric pressure is used. If a vacuum is employed and the absolute pressure is 400 mmHg, the low glycol concentration is 99.52 wt%.

$$L = \frac{L_w(W_r)G}{24} \quad (6.7.7)$$

$$\text{where } W_r = \frac{(W_i - W_o)G}{24} \quad (6.7.8)$$

where L = glycol circulation rate in gal/hr

L_w = glycol to water circulation rate in gal
TEG/lb H₂O

W_i = water content of inlet gas in lb
H₂O/MMscf

G = gas flowrate in MMscfd

W_r = water removed from gas in lb/hr

W_o = outlet water content in lb/hr

The *required heat load*, for the reboiler, can be estimated from

$$Q_t = 2,000(L) \quad (6.7.9)$$

where Q_t = total heat load on the reboiler in Btu/hr

The above formula for determining the required reboiler heat load is an approximation that is accurate enough for most high-pressure glycol dehydrator sizing.

A more detailed determination of the required reboiler heat load may be made from the following procedure:

$$Q_t = Q_1 + Q_w + Q_r + Q_h \quad (6.7.10)$$

$$Q_1 = L\rho_{gl}C(T_2 - T_1) \quad (6.7.11)$$

$$Q_w = W_r \times 970.3 \text{ (G)} \quad (6.7.12)$$

$$Q_r = 0.25 Q_w \quad (6.7.13)$$

Q_h = 5,000 to 20,000 Btu/hr depending on the reboiler size

where Q_1 = sensible heat required for glycol in
Btu/hr

Q_w = heat of vaporization required for
water in Btu/hr

Q_r = heat of vaporize reflux water in still
in Btu/hr

Q_h = heat loss from reboiler and stripping
still in Btu/hr

ρ_{gl} = glycol specific weight in lb/gal

970.3 = heat of vaporization of water at
212°F, 14.7 psia in Btu/lb

T_2, T_1 = outlet and inlet temperatures in °F

L, W_i, W_o, G = as in Equation 6.7.7.

The size of the major components of a glycol dehydration unit may be estimated using the following procedures. The diameter of the inlet gas scrubber, may be estimated using techniques "Surface Oil production Systems". The diameter of the glycol contactor can be estimated from Figure 6.7.24 [11].

The height of the glycol contactors is based on the number of trays used in the column. The number of trays may be estimated using Figures 6.7.25, 6.7.26, and 6.7.27

[2], which are based on the dew point depression required and the glycol circulation rate. Typical field dehydration units use a value of 9 to 10 L (2.5 to 3 gal) of TEG per pound of water. Regardless of the type of tray, a spacing of 55 to 60 cm (22 to 24 in.) is recommended. Therefore, the total height of the contactor tower will be based on the number of trays required plus and additional 1.8 to 3 m (6 to 10 ft.) to allow space for a vapor disengagement area above the top tray and an inlet gas area at the bottom of the column.

Bubble cap trays are normally used in glycol dehydrators to facilitate low liquid loading and to offer large turndown.

Example 6.7.15

Design the tower and reboiler for a glycol dehydration unit for these given data: gas flow rate 0.7 MMscf/hr at 1,000 psia and temperature of 100°F, and an exit dew point gas of 20°F. The inlet gas is fully water saturated with a molecular mass of 20.3. For gas reboiler $T_2 = 400^\circ\text{F}$, $T_1 = 280^\circ\text{F}$.

Solution

Inlet water content (see Figures 6.7.1 and 6.7.2)

$$T = 100^\circ\text{F} \quad W_i = 60 \text{ lb/MMscf} \quad \text{for } M = 17.4$$

$$P = 1,000 \text{ psia}$$

$$W_{i(\text{at } M=20.3)} = W_{i(\text{at } M=17.4)} \times C_G = 60 \times 0.99 \\ = 59.4 \text{ lb/MMscf}$$

Outlet water content:

$$T = 20^\circ\text{F} \quad W_o = 4.2 \text{ lb/MMscf} \quad \text{for } M = 17.4$$

$$P = 1,000 \text{ psia}$$

$$W_{o(\text{at } M=20.3)} = 4.2 \times 1 = 4.2 \text{ lb/MMscf}$$

Concentration of lean glycol (see Figure 6.7.23)

For 100°F inlet gas temperature and outlet dew point 20°F, theoretical value for TEG is 97.9 wt%, but we decrease this point 10 to 15°F. Let's take 12°F for a dew point of 8°F, actual concentration of lean TEG is equal to 98.6 wt%.

Circulation rate for glycol, from Equation 6.7.7:

$$L = \frac{L_w(W_r)G}{24}$$

L_w is assumed to be 3 gal TEG/lb H₂O; a more accurate procedure is given by Campbell [1].

$$W_r = W_i - W_o = 59.4 - 4.2 = 55.2 \text{ lb/MMscf}$$

$$G = 0.7 \text{ MMscf/hr} = 16.8 \text{ MMscfd}$$

$$L = \frac{3 \times 55.2 \times 16.8}{24} = 115.9 \text{ gal/hr}$$

FIGURE 6.7.25 Glycol contactor capacity [11].

a) four actual trays

FIGURE 6.7.26 Approximate glycol flow rates, four actual trays [11].

FIGURE 6.7.27 Approximate glycol flow rates, six actual trays [11].

From Figure 6.7.28, find actual tray numbers if:

- dew point depression is $100 - 20 = 80^\circ\text{F}$
- lean glycol concentration is 98.6 wt%
- assume the $L_w = 3 \text{ gal/lb}$

Eight actual trays contactor with $L_w = 3 \text{ gal/lb}$, 80°F dew point depression and 99.1 wt% lean TEG satisfy these conditions.

Next the inside diameter of the contactor can be found from Figure 6.7.25 [11] for $Q = 16 \text{ MMscfd}$, $P = 1,000 \text{ psia}$ and $D = 3 \text{ ft}$. Based on this diameter scrubber model DHT-3610 can be chosen from Table 6.7.6 [11].

Glycol reboiler duty from Equation 6.7.10:

$$\begin{aligned}
 Q_t &= Q_1 + Q_w + Q_r + Q_h \\
 Q_1 &= L\rho_{gl}C(T_2 - T_1) = 115.9 \text{ gal/hr} \times 9.26 \text{ gal/hr} \\
 &\quad \times 0.665 \text{ Btu/lb}^\circ\text{F} \times (400 - 280) \\
 &= 85,644 \text{ Btu/hr}
 \end{aligned}$$

c) eight actual trays

FIGURE 6.7.28 Approximate glycol flow rates, eight actual trays [11].

$$\begin{aligned}
 Q_w &= 970.3 \text{ Btu/lb} \times 55.2 \text{ lb/MMscf} \times 16.8 \text{ MMscfd} \times \frac{1}{2} \\
 &= 37,492 \text{ Btu/hr} \\
 Q_h &= 10,000 \text{ Btu/hr} \\
 Q_t &= 142,509 \text{ Btu/hr}
 \end{aligned}$$

TABLE 6.7.6 Correction Factors for Gas Capacity for Trayed Glycol-Gas Contactors in Equation 6.7.14 [11]

(a)	
Operating Temp. °F	Correction Factor C_t
40	1.07
50	1.06
60	1.05
70	1.04
80	1.02
90	1.01
100	1.00
110	0.99
120	0.98
(b)	
Gas Specific Gravity	Correction Factor C_g
0.55	1.14
0.60	1.08
0.65	1.04
0.70	1.00
0.75	0.97
0.80	0.93
0.85	0.90
0.90	0.88

If $SG = 0.7$ and $T = 100^\circ\text{F}$, calculate the gas capacity of the gas-glycol contactor selected for the specific operating conditions:

$$G_o = G_s(C_t)(C_g) \quad (6.7.14)$$

where

- G_o = gas capacity of contactor at operating conditions in MMscfd
- G_s = gas capacity of contactor at $SG = 0.7$ and $T = 100^\circ\text{F}$, based on operating pressure in MMscfd
- C_t = correction factor for operating temperature (Table 6.7.6a)
- C_g = correction factor for gas specific gravity (Table 6.7.6b)

For more accurate calculation procedure, see Sivalis' *Glycol Dehydration Design Manual* [11].

Example 6.7.16

The sketch to Example 6.7.16 illustrates gas well surface facilities to reduce water content in the gas stream. The well stream arrives at the well head at 2,000 psia and 123°F and separates water in two vessels. The first separator works at 123°F and $P = 2,000$ psia, the second under pressure, $P = 800$ psia.

Calculate the following:

1. Temperature in gas separator (approximately).
2. Heat removed or added (if one is necessary) by heat exchanger before J-T expansion.
3. Does the well produce water (in liquid phase) in reservoir condition? If the well does produce water, how much does it produce?

What is the temperature in the gas separator? We calculate

$$\begin{aligned}
 & 527 \text{ vpm change in } \frac{\text{lb water}}{10^6 \text{ scf}} \\
 X &= \frac{\text{lb mole H}_2\text{O} \times 379.4 \text{ scf/mole}}{10^6 \text{ scf}} = 527 \times 10^6 \\
 X &= \frac{527}{379.4} = 1.389 \text{ mole} \\
 &= (1.389 \text{ mole} \times 18 \text{ lb H}_2\text{O})/\text{lb mole} \\
 &= 25 \text{ lb H}_2\text{O}/10^6 \text{ scf}
 \end{aligned}$$

From Figure 6.7.2 for water content of $25 \text{ lb}/10^6 \text{ scf}$ and $P = 800$ psia, dew point = 67°F

Is heat added or removed?

Use any H-S diagram for natural gas with $SG_g = 0.6$. Starting from $T = 67^\circ\text{F}$ and 800 psia at constant enthalpy (J-T expansion) to $P = 2,000$ psia gives $T = 123^\circ\text{F}$, so assuming constant enthalpy, no heat exchange is necessary.

Does the well produce water in reservoir condition? The conditions are as follows:

Dissolved water in gas at reservoir conditions: $T = 180^\circ\text{F}$ and $P = 3,000$ psia, $W = 195 \text{ lb}/10^6 \text{ scf}$.

¹Gas capacity based on 100°F, 0.7 sp gr, and vessel working pressure.

Dissolved water in gas in separator number 1: $T = 123^{\circ}\text{F}$ and $P = 2,000$ psia, $W = 70$ lb/10⁶ scf.

Hence, an amount of water from the gas stream is $(195 \text{ to } 70)10 = 1,250$ lb/d. Separator number 1 produces 1,500 lb/day water, which is more than can be condensed from the gas, which means the well produces water in liquid phase at a rate of 250 lb/d (Table 6.7.7).

6.7.6 Other Considerations

Under conventional dehydration condition, 40% to 60% of methanol in feed gas to a glycol dehydrator will be absorbed by the TEG. This will add additional heat duty on the reboiler and additional vapor load on the regenerator.

Glycol losses can be defined as mechanical carryover from the contactor, plus vaporization from the contactor and

regenerator and spillage (Tables 6.7.8 and 6.7.9). Glycol losses, exclusive of spillage, range from 0.05 gal/MMscf for high-pressure low-temperature gases to as much as 0.30 gal/MMscf for low-pressure high-temperature gases. Excessive losses usually result from foaming in the absorber or regenerator.

Glycol losses in CO₂ dehydration systems can be significantly higher than in natural gas systems particularly at pressure above 900 psia. This is due to the solubility of TEG in dense phase CO₂.

Glycol becomes corrosive with prolonged exposure to oxygen. A dry gas blanket on the glycol surge tank will help eliminate oxygen absorption.

There are several enhanced glycol concentration processes that are used for obtaining TEG purity higher than 98.7 wt%, which is the TEG purity obtained by reboiling at 400°F and atmospheric pressure. The processes are listed

Gas capacity based on 100°F, 0.7 sp gr and contactor working pressure.

on Table 6.7.10 [2]. The pH of glycol should be monitored and maintained between 7 and 8.5 with outer acceptable limits of 6 through 9. When the pH drops below 6, the glycol system is contaminated usually by corrosion and/or oxidation. Once below 6 the pH will continue to drop due to autoxidation which is the chemical decomposition of glycol.

A pH of 7 is considered neutral but as the pH drops the corrosion rate accelerates. A good rule of thumb is that the corrosion rate will double for every drop of 1 pH below 7. So if the corrosion rate is 5 mils per year at a pH of 6 it would be 10 mils per year at a pH of 5. Monitoring the corrosion rate with coupons is a good practice.

TABLE 6.7.9 Typical Liquid Desiccant Properties

	Ethylene Glycol	Diethylene Glycol	Triethylene Glycol

6.7.6.1 Solid Desiccant Dehydration (Adsorption)

There are several solid desiccants, which possess the physical characteristic to adsorb water from natural gas. These desiccants are generally used in dehydration systems consisting of two or more towers and associated regeneration equipment. See [Figure 6.7.29](#) [2], for a simple two-tower system.

The continuous process requires two (or more) vessels, with one tower onstream adsorbing water from the gas stream while the other tower is being regenerated and cooled. Generally the bed is designed to be online for 8 to 24 hr. When the bed is taken off line, hot gas is used to heat the sieve to 230°C to 290°C (450°F to 550°F). The

regeneration gas is returned to the process after it has been cooled and the free water removed. The towers are switched before the onstream tower becomes saturated.

Adsorption describes any process wherein molecules from the gas are held on the surface of a solid by surface forces. Solid desiccants that possess a total area of 500,000 to 800,000 m²/kg (2,400,000 to 3,900,000 ft.²/lb) are used as adsorbants, and desiccants in commercial use fall into one of three categories.

Alumina—a manufactured or natural occurring form of aluminum oxide that is activated by heating.

Gels—Aluminum or silica gels manufactured and conditioned to have an affinity for water.

Molecular Sieves—Manufactured or naturally occurring aluminosilicates exhibiting a degree of selectivity based on crystalline structure in their adsorption of natural gas constituents.

Alumina is a hydrated form of alumina oxide (Al₂O₃). It is used for gas and liquid dehydration and will give outlet dew points in the range of -100°F. Less heat is required to regenerate alumina than for molecular sieve, and the regeneration temperature is lower.

Silica gel is a generic name for a gel manufactured from sulfuric acid and sodium silicate. It is essentially pure silicon dioxide, SiO₂. When used for dehydration, silica gel will give outlet dew points of approximately -70° to -80°F.

Molecular sieves are a class of aluminosilicates and possess the highest capacity, will produce the lowest water dew points, and can be used to sweeten and dry gases and liquids. Their equilibrium water capacity is much less dependent on adsorption temperature and relative humidity. They are usually more expensive.

Molecular sieve dehydrators are commonly used ahead of NGL recovery plants where extremely dry gas is required. Cryogenic NGL plants designed to recover ethane produce very cold temperatures and require a very dry feed gas to prevent formation of hydrates. Dehydration to approximately 1 ppmw is possible with molecular sieves. Typical solid desiccant properties are given in [Table 6.7.11](#) [2].

Because solid desiccant units cost more to buy and operate than glycol units, their use is usually limited to applications such as very sour gases, very low water dew point requirements, simultaneous control of water, and hydrocarbons dew points, and in certain cases such as oxygen-containing gasses. In cryogenic plants, solid desiccant dehydration usually is preferred over methanol injection to prevent hydrate and ice formation. Solid desiccants are also often used for the drying and sweetening on NGL liquids. Any host source can be used to heat the regeneration gas including waste heat from engines and turbines. Heat is a major operating cost and is a major design consideration.

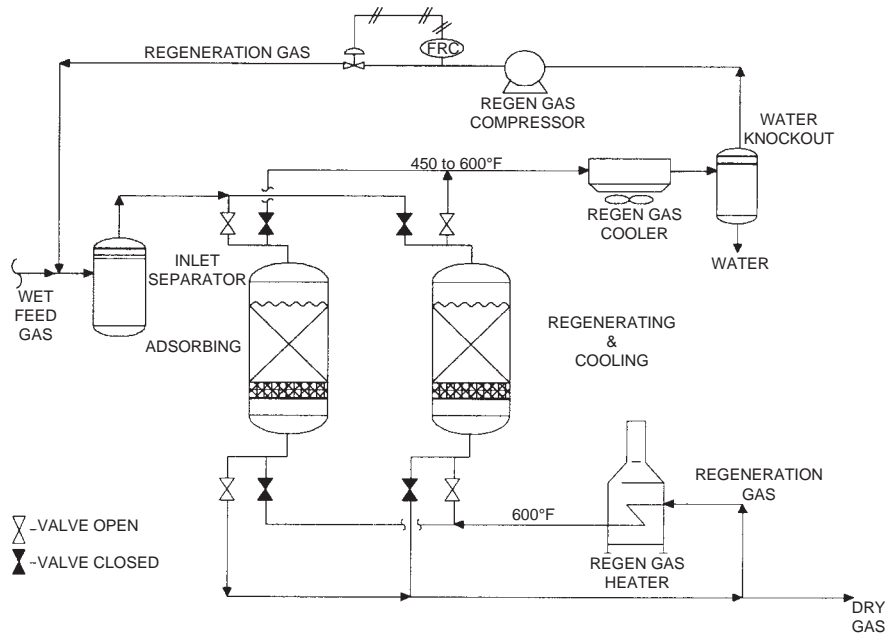

FIGURE 6.7.29 Example solid desiccant dehydrator twin-tower system.

TABLE 6.7.11 Typical Desiccant Properties

Desiccant	Shape	Bulk Density, lb/ft ³	Particle Size	Heat Capacity, Btu/(lb·°F)	Approx. Minimum Moisture Content of Effluent Gas (ppmw)
Alumina Gel Alco H-151	Spherical	52	1/4"	0.20	5–10
Activated Alumina Alcoa F-1	Granular	52	1/4"–8 mesh		0.1
Silica Gel Sorbead®-R	Spherical	49	4–8 mesh	0.25	5–10

Mole Sieve Davison-4A	Spherical	42–45	4–8 mesh or 8–12 mesh	0.24	0.1
Mole Sieve Linde-4A	Extruded Cylinder	40–44	1/8" or 1/16"	0.24	0.1

6.7.6.2 Solid Desiccant Dehydrator Design

The allowable superficial velocity through the bed is the first parameter that must be estimated. The pressure drop through the bed is related to the superficial velocity by a modified Ergun equation:

$$\frac{P}{L} = B\mu V + C\rho V^2 \quad (6.7.15)$$

where

- P = pressure drop in psi
- L = length of packed bed in ft.
- μ = viscosity in cp

V = Superficial velocity in ft./min

ρ = density in lb/ft.³

B, C = constants as below

Particle Type	B	C
1/8 in bead	0.0560	0.0000889
1/8 in extrude	0.0722	0.000124
1/16 in bead	0.152	0.000136
1/16 in extrude	0.238	0.000210

FIGURE 6.7.30 Mole sieve capacity correlation for undersaturated gas.

FIGURE 6.7.31 Mole sieve capacity correlation for temperature.

Figure 6.7.32 [2], was derived from this modified Ergun equation by assuming a gas composition and setting P/L equal to 0.333 psi/ft. The design pressure drop through the bed should be about 5 psi. A design pressure drop higher than 8 psi is not recommended. Remember to check the pressure drop after the bed height has been determined. Once the allowable superficial velocity is estimated, calculate the bed diameter:

$$D = \frac{4(\text{ACFM})}{3.14(V)} \quad (6.7.16)$$

where

D = diameter in ft.

ACFM = actual cubic feet per minute

The next step is to choose a cycle time and calculate the pounds of sieve required. Eight- to 12-hr cycles are common. Cycles greater than 12 hr may be justified, especially if the feed gas is not saturated. Long cycles mean less regeneration and longer sieve life, but larger beds and additional capital investment.

During the adsorption cycle, the bed can be thought of as operating within three zones. The top zone is called the saturation or equilibrium zone. The desiccant in this zone is in equilibrium with the wet inlet gas. The middle or mass

FIGURE 6.7.32 Allowable superficial velocity for molecular sieve dehydrator.

transfer zone (MTZ) is where the water content of the gas is reduced from saturated to <1 ppm. The bottom zone is unused desiccant and is often called the active zone. If the bed operates too long in adsorption, the mass transfer zone begins to move out the bottom of the bed causing “breakthrough.” At breakthrough, the water content of the outlet gas begins to increase and will eventually reach feed gas content when the mass transfer zone is completely displaced.

Unfortunately, both the water capacity and the rate at which the molecular sieve adsorbs water change as the molecular sieve’s age. The object of the design is to install enough sieves so that 3 to 5 years into the life of the sieve the mass transfer zone will be at the bottom of the bed at the end of the adsorption cycle.

In the saturation zone, the molecular sieve is expected to hold approximately 13 lb of water per 100 lb sieve. This capacity needs to be adjusted when the gas is not water saturated or the temperature is above 75°F. See Figures 6.7.30 and 6.7.31 [2] for the correction factors.

To determine the pounds of molecular sieve required in the saturation zone, calculate the amount of water to be removed during the cycle and divide by the sieve capacity:

$$S_s = \frac{W_r}{(0.13)(C_{ss})(C_T)} \quad (6.7.17)$$

$$L_s = \frac{(S_s)(\text{bulk density})(4)}{(3.14)(D^2)} \quad (6.7.18)$$

where

S_s = amount of molecular sieve required in the saturation zone lb/hr

W_r = water removed in lb/hr

C_{ss} = saturation correction factor for sieve

C_T = temperature correction factor

L_s = length of packed bed saturation zone in ft.

Bulk density is 42 to 45 lb/ft.³ for spherical particles and 40 to 44 lb/ft.³ for extruded cylinders.

Even though the MTZ will contain some water, the saturation zone is calculated assuming it will contain all the water to be removed.

Refer to Table 6.7.11 for bulk densities of common desiccants.

The length of the MTZ can be calculated as follows:

$$L_{MTZ} = (V/35)^{0.35} (Z) \quad (6.7.19)$$

where

$$Z = 1.70 \text{ for } 1/8 \text{ in sieve}$$

$$= 0.85 \text{ for } 1/16 \text{ in sieve}$$

The total bed height is the summation of the saturation zone and the MTZ heights. Approximately 6-ft. free space above and below the bed is needed.

6.7.7 Regeneration Calculations

The first step is to calculate the total heat required to desorb the water and heat the desiccant and vessel. A 10% heat loss is assumed

$$Q_w = (1800 \text{ Btu/lb})(\text{lbs of water on bed}) \quad (6.7.20)$$

$$Q_{si} = (\text{lb of sieve}) \frac{0.24 \text{ Btu}}{\text{lb}^\circ\text{F}} (T_{rg} - T_i) \quad (6.7.21)$$

$$Q_{st} = (\text{lb of steel}) \frac{0.12 \text{ Btu}}{\text{lb}^\circ\text{F}} (T_{rg} - T_i) \quad (6.7.22)$$

$$Q_{hl} = (\text{heat loss}) = (Q_w + Q_{si} + Q_{st})(0.10) \quad (6.7.23)$$

where

Q_w = desorption of water heat duty in Btu/hr

Q_{si} = duty required to heat mole sieve to regeneration temperature in Btu

Q_{st} = duty required to heat vessel and piping to regeneration temperature in Btu

Q_{hl} = regeneration heat loss duty in Btu/hr

T_{rg} = regeneration gas temperature in °F

T_i = inlet temperature °F

For the entire regeneration cycle, only about one-half of the heat put into the regeneration gas is utilized. This is because by the end of the cycle the gas is leaving the bed about the same temperature at which it enters.

For determination of the requirement of the regeneration gas rate, calculate the total regeneration load from:

$$Q_{tr} = (2.5)(Q_w + Q_{si} + Q_{st} + Q_{hl}) \\ = \text{total regeneration heat duty in Btu.} \quad (6.7.24)$$

The heating time is usually 50% to 60% of the total regeneration time, which must include a cooling period. Figure 6.7.33 shows a typical temperature profile for a regeneration cycle (heating and cooling). For 8-hr adsorption cycles, the regeneration normally consists of 4½ hr heating, 3 hr of cooling and ½ hour of standby and switching. For longer cycles the heating time can be lengthened as long as a minimum pressure drop of 0.01 psi/ft. is maintained

$$m_{rg} (\text{lb/hr}) = \frac{Q_{tr}}{(C_p)(600^\circ\text{F} - T_i)(\text{heating time})} \quad (6.7.25)$$

FIGURE 6.7.33 Inlet and outlet temperature during typical solid desiccant bed regeneration cycle [2].

FIGURE 6.7.34 Minimum regeneration velocity for mole sieve dehydrator [2].

Figure 6.7.34 can be used to estimate the required minimum velocity to meet 0.01 psi/ft.

6.7.8 General Comments

The regeneration cycle frequently includes depressuring/repressuring to match the regeneration gas pressure and/or to maximize the regeneration gas volume to meet the velocity criterion. Some applications, termed *pressure swing adsorption*, regenerate the bed only with depressurization and sweeping the bed with gas just above atmospheric pressure.

Bottom bed support typically includes three to five layers of inert ceramic balls in graduated sizes (smallest on top). On top of the bed, a holddown screen is provided, again covered with a layer of ceramic balls. In some cases a layer of less expensive desiccant can be installed on the top bed to catch contaminants such as free water, glycol, hydrocarbons, or amines. This may extend bed life.

Since solid desiccants can produce dust, 1- μm filters are frequently installed at the outlet of the dehydration unit to protect downstream equipment.

Operating performance must be monitored periodically to adjust cycle length to ensure adequate dehydration is obtained. The size of the unit and the frequency of regeneration cycles also affect the timing of the performance test.

6.7.9 Gas Flow Measurement

6.7.9.1 Orifice-Meter Measurement

The most common method for measuring volumes is the differential measurement device, the orifice meter, which is widely accepted for use in measuring liquids and vapors. A correctly installed and maintained orifice may provide an overall accuracy within plus or minus 2%.

The procedures presented here for calculating flow by use of an orifice meter are designed to provide approximate solutions using a hand calculator or equivalent, and do not include the rigorous, iterative solution procedures required when using the Reader-Harris/Gallagher flow equation recommended for accurate, custody transfer calculations with computing equipment. The procedures for applying the Reader-Harris/Gallagher equation can be found in Chapter 14.3 of *API Manual of Petroleum Measurement Standards* published after 1994.

The *API Manual of Petroleum Measurement Standards* is the source of a large portion on the information presented below (Table 6.7.12). Chapter 14 is of particular interest to gas processors because it applies specifically to the measurement of gas and liquefied gas products. Chapter 14 is further divided as follows:

The orifice meter consists of a static pressure and differential pressure recoding gages connected to an orifice flange

TABLE 6.7.12 API Chapter 14, Measurement Subsections

Chapter	Title

14.8	Liquefied Petroleum Gas Measurement

or orifice fitting. The orifice meter tube (meter run) consists of upstream and downstream sections of pipe for which size and tolerance have been determined through calculation, which conform to specifications set forth in ANSI/API 2530 (GPA 8185) (Table 6.7.15).

The orifice plate is held perpendicular to flow by flanges or a fitting. Bore, circumference, edge sharpness, and other tolerances must meet specification as set forth in ANSI/API 2530 (GPA 8185).

Orifice Flanges (Figure 6.7.35a–c)—When slip-on or screwed orifice flanges are used, the end of the pipe shall extend through the flanges so that there is no recess greater than $\frac{1}{4}$ in. between the end of the pipe and the orifice plate. It is preferred that no recess exists.

When weld neck flanges or weldend orifice fittings are used, the average inside diameter of the section of pipe connected to the inlet side of the fitting or flange should equal the inside diameter of the fitting or flange within the tolerance given in Figure 6.7.35a.

When flanged orifice fittings are used, they should be aligned with the inside diameter of the flange on the meter tube so there are no sharp edges or offsets at the flange connection. Where separable gaskets are used to seal on orifice plate in an orifice holder, care must be taken to assure proper alignment and prevent gasket extension into the flow stream.

Orifice flanges require that the line be shut down and depressured in order to inspect or change the orifice plate.

Single Chamber Orifice Fitting (Figure 6.7.35b)—This fitting also requires that the line be shut down and depressured in order to inspect or change the orifice plate. However, this fitting does not require breaking apart the flanges. Instead, the bolts are loosened on the cover plate and the

cover plate removed. The orifice plate holder and orifice plate are then removed from the fitting. These fittings provide precise alignment of the orifice plate.

Senior Orifice Fitting (Figure 6.7.35c)—This fitting allows the removal and inspection of an orifice plate while the line remains under pressure. It allows the orifice plate holder and orifice plate to be raised into the upper cavity for the fitting by the use of a crank handle. A valve is then closed to separate the upper cavity from the lower cavity of the fitting. The upper cavity is then depressured, the top cover plate removed, and the orifice plate cranked out.

In this section, certain terms are used which are peculiar to the measurement industry. Many of the terms are almost self-explanatory, or their general use in the industry makes it somewhat unnecessary to define them. However, in order to be specific with regard to these basic quantities, it is advisable to list the following definitions of terms commonly used in orifice meter measurement.

6.7.9.2 Definitions

Differential Taps—For meters using “flange taps,” the center of the upstream pressure tap is placed 1 in. from the upstream face of the orifice plate. The center of the downstream pressure tap is placed one inch from the downstream face of the orifice plate. In locating the pressure tap hole in the flange, an allowance of 1/16 in. is normally made for the gasket thickness. The location of the pressure tap holes in the flanges is subject to the tolerance indicated on Figure 6.7.36. For meters using “pipe taps,” the upstream pressure tap is placed two and one half times the *actual* inside pipe diameter from the upstream face of the orifice plate and the downstream pressure tap is placed eight times the *actual* inside pipe diameter from the downstream face of the orifice plate. The location of these pressure tap holes is subject to a tolerance 10 times that necessary for flange taps.

Special care should be used in selecting the values of the basic orifice flow factor since the orifice factors for the two kinds of taps are not the same.

Differential pressure—Differential pressure is the difference between two pressures. The differential pressure across an orifice meter tube is the difference between the pressure at the upstream tap before the gas passes through the orifice and the pressure at the downstream tap after it has passed through the orifice. It is commonly measured by means of a liquid in a U-tube. The upstream pressure is transmitted to one leg of the U-tube and the downstream pressure to the other leg of the U-tube. This will cause the liquid in the two legs of the U-tube to assume different levels. The difference in these levels is the differential pressure measured in inches of the liquid that may be used in the U-tube. Mercury is generally used in commercial

FIGURE 6.7.35a–c Orifice plate holders.

orifice meters of this type. The meter is calibrated so that this differential in inches of mercury is converted into inches of water, h_w , and recorded in those units on the meter chart.

Another method of obtaining differential pressure is by using a “dry,” or bellows-type manometer. This instrument measures the difference in pressure by the movement of metallic bellows, or diaphragm, against the resistance of a calibrated range spring (Table 6.7.14).

Atmospheric Pressure—The pressure acting upon each square in of the earth’s surface is equal to the weight of a column of the atmosphere one square inch in cross-section, extending vertically upward to its limit – an unknown height. The atmospheric pressure is usually measured by a barometer in inches of mercury column; such measurements are generally corrected to the height of an equivalent column of mercury at 32°F.

Average values of atmospheric pressure for various elevation above sea level are given in Table 6.7.13.

TABLE 6.7.13 Elevation versus Pressure

Elevation in feet	Inches Mercury	Pressure psia	Elevation in feet	Inches Mercury	Pressure psia
0	30.00	14.73	2000	27.98	13.74
100	29.90	14.69	2500	27.48	13.5
200	29.80	14.64	3000	26.97	13.25
300	29.70	14.59	3500	26.47	13.00
400	26.60	14.54	4000	25.96	12.75
500	29.49	14.49	4500	25.46	12.5
600	29.39	14.44	5000	24.95	12.25
800	29.19	14.34	5500	24.45	12.01
1000	28.99	14.24	6000	23.94	11.76
1500	28.49	13.99	6500	23.44	11.51

Absolute Pressure—Absolute pressure is the pressure above the absolute zero, or above a perfect vacuum. The atmospheric pressure is always expressed as an absolute pressure. If the pressure of a gas in a line is greater than the atmospheric pressure, the atmospheric pressure in psia is added to the gage pressure in psig to obtain the absolute pressure of the gas in the line. If the gage pressure is 40 psig (above atmospheric pressure) and the atmospheric pressure is 14.4 psia, the absolute pressure, p_f , is 54.4 psia.

If the line pressure is less than atmospheric pressure, the absolute pressure of the gas in the line in psia is equal to the atmospheric pressure in psia minus the gage pressure in psig. If the gage pressure is 4.0 psia (below atmospheric pressure) and the atmospheric pressure is 14.4 psia, the absolute pressure, p_f , of the gas in the line is 10.4 psia.

It is quite common to measure pressures below atmospheric pressure with gages calibrated in inches of mercury "vacuum." In such cases it is necessary to convert the "vacuum" from inches of mercury into pounds per square inch by multiplying by the conversion factor 0.491; for example, 10 in. of mercury "vacuum" = 4.91 psig (10 × 0.491) below the absolute pressure of the atmosphere.

Pressure Base—The pressure base is the pressure at which the cubic foot is the unit of measurement according to the contract. The basic orifice flow factors referred to in this handbook were calculated for a pressure base of 14.73 psia. If measurement at any other pressure is desired, then correction must be made for the effect of the change to that base. Frequently base pressures are indicated as gage pressures — as a certain number of "ounces." Such an indication would, of course, be above an assumed average atmospheric pressure. In order to definitely specify the basis for the measurement, the base pressure must be an absolute pressure. For example, a pressure base of four ounces (above an assumed atmospheric pressure of 14.4 psia) may be written as 14.65 psia. Likewise, a pressure base of eight ounces (above the assumed average atmospheric pressure of 14.7 psia), may be expressed at 15.2 psia. The use of the absolute value is definite and leaves no doubt as to the value of the absolute pressure base. The use of any expression of an actual or an assumed value of the atmospheric pressure is eliminated.

Absolute Temperature—On the Fahrenheit thermometer scale, the absolute temperature is expressed in degrees above and below an arbitrary zero, which is 32°, the freezing point of water. The absolute zero is 460° below the zero of the Fahrenheit thermometer scale. The absolute temperature is the temperature above the absolute zero and is obtained by adding 460° to the reading of the thermometer. If the reading of the Fahrenheit thermometer is 60°, the corresponding absolute temperature is 60° added to 460° or 520°F absolute. If the reading is -20°F, the absolute temperature is -20°F + 460° or 440°F absolute.

Temperature Base—The temperature base is the temperature at which the cubic foot is the unit of measurement according to the contract. The orifice flow factors referred to in this handbook were calculated for a temperature base condition of 520°F absolute (60°F). If measurement at any other temperature base is desired, then correction must be made for the effect of the change to that base.

Specific Gravity—The specific gravity of a gas is the weight of a cubic foot of gas compared to the weight of a cubic foot of dry air under the same pressure and temperature conditions. If the specific gravity of a gas is 2.0, it's twice as heavy as air, or if the specific gravity of a gas is 0.6, it is six-tenths as heavy as air.

Discharge Coefficient—The discharge coefficient is the ratio of the average velocity through the orifice divided by the theoretical velocity through the orifice. The theoretical velocity is the velocity each particle would assume if it fell through a height equal to the drop in pressure between the taps expressed in feet of fluid of the same density at the flowing fluid. The term "fluid" applies to a gas or liquid.

Referring to the well known formula,

$$V_f = 2gh$$

where

V_f = velocity in feet per second

g = Acceleration of gravity in feet per second

h = differential or drop in pressure in feet head of flowing fluid

Let us assume that air is measured through an orifice, the differential is 1.00 in. of water, the pressure is 14.4 psia and g is 32.17. One inch of water is equal to a head of 69.5 ft. of air at a pressure of 14.4 psia.

The theoretical velocity is then;

$$V_f = 2 \times 32.17 \times 69.5 = 66.9 \text{ feet per second}$$

Viscosity—Viscosity may be defined simply as the stickiness of a liquid or gas. It is that property of a liquid or gas, which tends to prevent one particle from moving faster in a stream than another particle, or it is the resistance to change of velocity between adjacent particles. Molasses is generally known as a viscous liquid. Its viscosity is greater than that of water. The viscosity of gasoline is less than that of water. The viscosity of gas is a small fraction of the viscosity of water. The viscosity of a liquid decreases with increases in temperature, but the viscosity of a gas increases with an increase in temperature.

Viscosity references are commonly given in the form of Saybolt seconds, which is the time in seconds required for 60 cc of the fluid to pass through the standard capillary tube of a Saybolt Universal viscosimeter. This viscosity index gives an indication from which the kinematic viscosity can

⊕ = The data in this column is for general guidance only.
 ⊕ = Inherent Repeatability of Primary Device is substantially greater than shown. Value used reflects limitation of differential pressure sensing device, when maximum readout accuracy is desired.
 ⊕ = Pipe size antedilates the upper limit.
 ⊕ = Practically unlimited with the probe type design.
 ⊕ = Must be conductive.
 ⊕ = Can be re-zeroed.
 ⊕ = Varies with upstream disturbance.
 ⊕ = Depends on application conditions.

be determined—the kinematic viscosity being the ratio of the absolute viscosity to the density of the fluid. Saybolt second readings are not dependable for fluids less viscous than water, and should not be used for values lower than about 32 s. For fluids having lower viscosities, the viscosity is usually indicated as a decimal fraction of the viscosity of water at 68°F.

Reynold's Number—Reynold's number is an index by which discharge coefficients for various flowing conditions can be correlated. This “number” takes into account the individual way in which discharge coefficients varies with the orifice and meter tube diameters, the fluid viscosity and density, and the rate of flow through the orifice.

For any given orifice installation the discharge coefficient is constant for various flowing conditions, which will produce the same Reynold's number when measuring any gas or liquid through that installation.

Both the discharge coefficient and the value of the Reynold's number are dimension-less numbers. For this reason, corresponding values for these quantities are identical

whether obtained with English units of measurement or with metric units — if they are consistently used.

The actual value of the Reynold's number, R_d , can be obtained from the basic equation:

$$R_d = \frac{\text{Velocity} \times \text{Diameter} \times \text{Density}}{\text{Absolute Viscosity}}$$

6.7.9.3 Various Conditions Affecting Measurement Accuracy

Measurement is very important for both the producers and the gas users; gas meter are, in fact, the cash registers for gas companies. At \$3 per 1,000 ft.³, a 1% error on 100 MMcf of standard heating value gas is \$3,000/d. A 1/10% error, better than the capability of current technology, is still equal to \$109,500 per year.

The accuracy of measurement techniques, depends on:
Condition of the Orifice Edge—The greatest source of error in the primary measuring element is probably the

TABLE 6.7.15 Minimum Motor Tube Lengths in Terms of Pipe Diameters and Beta Ratio

Use for all pipe sizes. Based on flange taps. For pipe taps and 2 diameters to A, A', and C and 8 pipe diameters to B.

possible deviation from the specification that the upstream edge of the orifice plate be square and sharp. A slight, almost imperceptible, rounding of the orifice edge can produce a considerable increase in the discharge coefficient, which results in low measurement. This is especially true with the smaller orifices in the smaller line sizes, since the effect of the edge imperfection is relative. A wire-edge burr, or fin, on the orifice edge is also undesirable since it can alter the flow pattern of the stream from that corresponding to proper measurement.

Condition of Meter Tube—Some error can be introduced as a result of a variation of the finish of the inside of the meter tube. The accepted orifice discharge coefficients were obtained from tests with meter tubes constructed

of commercial iron pipe with inside surface roughness corresponding to such commercial item. Too smooth and inside surface can introduce an error in the measurement, just as an error can be produced by too rough a surface—because either condition constitutes a deviation from the conditions under which the accepted discharge coefficients were determined. Measurement would be high with too smooth and inside surface, and low with too rough and inside surface. *Report No. 3* [13], permits the use of bored meter tubes but specifies that the finish of the inside surface of the tube correspond to that of commercial pipe. The boring of meter tubes is desirable in those instances where the pipe from which the meter tube is to be made is “out-of-round” beyond permissible limits (Figure 6.7.37).

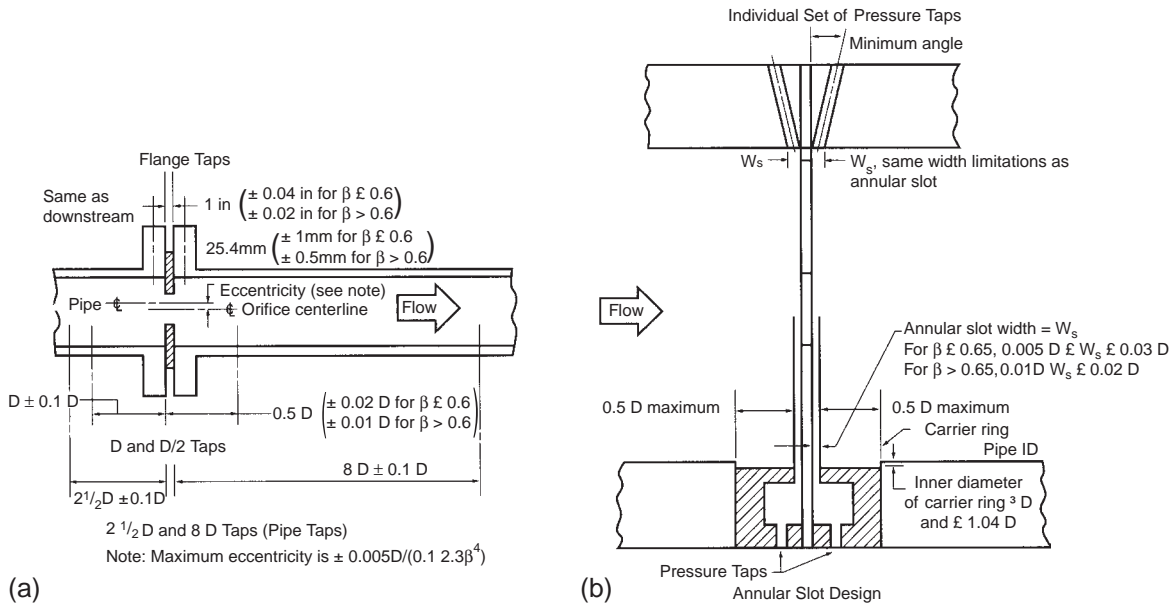

FIGURE 6.7.37 Pressure-tap spacing.

Pulsation—The effect of pressure and velocity pulsation's in the vicinity of the orifice constitutes a very indefinite phase in the measurement of gas with an orifice meter. This pulsation can be of a low frequency form such as might result from reciprocating compressors, undamped pressure regulators, chatting valves, or liquid surging back and forth at low points in the line. It might also be a high frequency pulsation caused by resonance of the pipelines themselves. The effect of the pulsation's of lower frequency probably have the greater effect on the measurement; however, no conclusive information is at present available by which the pulsation error can be completely correlated with pulsation frequency or with wave form and amplitude of those pulsations. This problem has been recognized; considerable research is underway, and more is contemplated, to determine means of either eliminating the effect of pulsations or determining the degree of error, which the pulsation might produce.

In some instances, the effect of pulsation has been largely reduced by installing restrictions in the line, which produce pressure drops up to 10% of the line pressure. In many cases, resistances, which create much smaller pressure drops, have been found satisfactory. In other instances, installing volume tanks, baffles, or dampeners in the line has minimized the effect. When any of these devices are used, they should be installed between the meter tube and the probable source of the pulsation. It has also been found advantageous to decrease the line size, thereby employing orifices with larger diameter ratios and measuring the gas with a higher differential pressure across the orifice plate.

A word of caution should be introduced regarding operations, which might be employed to obtain a smoother chart record—such as pinching gage lines or overdamping a meter. None of these operations eliminate the basic error corresponding to the pulsation in the line. Pinching gage lines valves might increase the error in the measurement. Under these conditions, a considerable error might exist without any visible indication on the instrument. Probably the best advice would be to install the meter at a point as remote as possible from the source of pulsation.

Effect of Water Vapor—In the measurement of gas containing moisture in the vapor state, the effect of moisture depends largely on the specific gravity of the gas. Natural gas is quite dry and its specific gravity is usually quite close to that of water vapor 0.62. For this reason the only appreciable correction would be a direct volume correction based upon the partial pressure of the water vapor, p_v , at flowing conditions. Under these conditions, the volume of dry gas could be determined as follows:

$$Q_{h(\text{dry})} = Q_{h(\text{moist})} \times \frac{p_f - p_v}{p_f}$$

In the measurement of gas with an orifice meter, it is the actual density of the flowing fluid, which must be considered. If the specific gravity has been obtained on a dry basis, and if the gas is measured with some moisture content, it would be necessary to correct the specific gravity to that corresponding to the flowing mixture. The flow rate should be calculated bases upon this corrected specific

gravity; subsequently, a volume correction should also be made, based upon the partial pressure of the water vapor at flowing conditions.

Wet Gas Measurement—The effect of liquid in the gas stream on measurement is a problem that has never been completely solved. Various arrangements of meter tubes, gage line piping, and drip pots have been used in an effort to minimize the hazard resulting from liquid accumulating ahead of the orifice plate at low points in the gage line or in the chambers of the meter manometer. An accumulation of liquid ahead of the orifice plate disturbs the normal flow pattern and alters the discharge coefficients for the orifice, liquid trapped in the gage line distorts the differential pressure and causes the manometer to give an incorrect indication. *Bellows-type* manometers with gage lines attached to the bottom of the manometer chambers are self-draining and, therefore, eliminate that portion of the error corresponding to liquid, which may find its way into the manometer.

6.7.10 Flow Measurement

In the measurement of gas by orifice meter, the chart contains records of the differential and the static pressures. From these records the quantity of gas measured is determined by use of the formula:

$$Q_h = C' (h_w p_f)^{0.5} \quad (6.7.26)$$

where

Q_h = rate of flow at base conditions in cubic feet per hour

C' = Orifice flow constant. It is the rate of flow in cu. Ft. per hr. at base conditions when the pressure extension, $h_w p_f = 1.000$

h_w = differential in inches of water

p_f = static pressure in psia

$(h_w p_f)^{0.5}$ = pressure extension

Orifice Flow Constant, C' —In the text of this publication, this term is called the “orifice constant,” for the sake of brevity. Its value is obtained by multiplying various factors together, as expressed by the formula:

$$C' = F_b \times F_{pb} \times F_{tb} \times F_g \times F_{tf} \times F_r \times Y \times F_{pv} \times F_m \quad (6.7.27)$$

where

F_b = basic orifice flow factor

- Flange taps (Table 6.7.16)
- Pipe taps (Table 6.7.17)

F_{pb} = pressure base factor (Table 6.7.18)

F_{tb} = temperature base factor (Table 6.7.19)

F_g = specific gravity factor (Table 6.7.20)

F_{tf} = flowing temperature factor (Table 6.7.21)

F_r = Reynold's number factor

- Flange taps (Table 6.7.22)
- Pipe taps (Table 6.7.23)

Y = expansion factor

- Flange taps, pressure upstream (Table 6.7.24)
- Pipe taps, pressure upstream (Table 6.7.25)
- Flange taps, pressure downstream (Table 6.7.26)
- Pipe taps, pressure downstream (Table 6.7.27)
- Flange taps, mean pressure (Table 6.7.28)

F_{pv} = supercompressibility factor (Figure 6.1.1)

F_m = manometer factor (Table 6.7.30)

The basic orifice factor, F_b depends upon the type of pressure taps and the pipe and orifice diameters. F_b can be calculated from an analytical equations as;

$$F_b = 338.17 d^2 K_o \quad (6.7.28)$$

where

d = actual diameter of the orifice in in.

K_o = coefficient of discharge for an infinite Reynold's number (which will be the minimum value for any particular orifice and pipe size)

and

$$K_o = \frac{K_e}{1 + \frac{15E}{1,000,000 d}}$$

where $E = d(830 - 500\beta + 9,000\beta^2 - 4,200\beta^3 + B)$

$B = 530/D^{0.5}$ (for flange taps)

$= 875/D + 75$ (for pipe taps)

$$\begin{aligned} K_e &= 0.5993 + \frac{0.007}{D} + 0.364 + \frac{0.076}{D^{0.5}} \beta^4 + 0.4 \cdot 1.6 - \frac{1}{D} \\ &\times 0.07 + \frac{0.5}{D} \beta^{5/2} - 0.009 = \frac{0.034}{D} [0.5 - \beta]^{3/2} \\ &+ \frac{65}{D^2} + 3 [\beta - 0.7]^{5/2} \text{ (for flange taps)} \\ &= 0.5925 + \frac{0.0182}{D} + 0.440 - \frac{0.06}{D} \beta^2 + 0.935 \\ &+ \frac{0.225}{D} \beta^5 \\ &+ 1.35 \beta^{14} + \frac{1.43}{D^{0.5}} (0.25 - \beta)^{5/2} \text{ (for pipe taps)} \end{aligned}$$

where D = the actual internal diameter in in.

β = the orifice diameter ratio expressed as d/D

F_b should be rounded to four decimal places

In practice, Tables 6.7.16 and 6.7.17 are used.

Basic Orifice Flow Factor, F_b — This term is called the “orifice factor” for brevity. The orifice factor is based upon the conditions: pressure base, $p_b = 14.73$ psia; temperature base, $T_b = 60^\circ\text{F}$, (520°F absolute); specific gravity, $G = 1.000$; flowing temperature, $T_f = 60^\circ\text{F}$ (520°F absolute); and under the conditions where the Reynold’s number is infinite and the expansion factor is unity. The value of this factor depends upon: the location of the differential taps; the diameter of the orifice, d ; and upon the internal diameter of the pipe, D (Tables 6.7.16 and 6.7.17).

Pressure Base Factor, F_{pb} — The orifice factors were calculated to give gas volumes at a base pressure, p_b , of 14.73 psia. If measurement at any other base pressure is desired, then a base factor must be applied. These factors, and the equations representing the factors, are shown on Table 6.7.18.

The pressure base factor, F_{pb} can be calculated by

$$F_{pb} = \frac{14.73}{P_b} \tag{6.7.29}$$

Temperature Base Factor, F_{tb} — The orifice factors were calculated to give gas volumes at a base temperature, T_b , of

60°F (520°F absolute). If measurement at any other temperature base is desired, then a temperature base factor must be applied. These factors, and the equations representing the factors are shown on Table 6.7.19.

The temperature base factor, F_{tb} can be calculated by

$$F_{tb} = \frac{T_b}{519.67} \tag{6.7.30}$$

Specific Gravity Factor, F_g — The orifice factors were calculated to give gas volumes based upon the flowing gas having a specific gravity G of 1.000. For gases having a specific gravity other than 1.000, a specific gravity factor must be applied. These factors and the equations representing the factors are shown on Table 6.7.20.

The real gas density (or specific gravity) factor F_g is to be applied to change from a real gas relative density of 1.0 to the real gas density G_r (or SG_g) of the flowing gas;

$$F_{gr} = \frac{1^{0.5}}{G_r} \tag{6.7.31}$$

where $G_r = G_i Z_b(\text{air})/Z_b(\text{gas})$ and $G_i = M_{\text{gas}}/M_{\text{air}}$

Flowing Temperature Factor, F_{tf} —The orifice factors where calculated, assuming that the gas flowing through the meter tubes at a temperature, T_f , of 60°F (520°F absolute). If measurement is to be made at any other flowing temperature, then a flowing temperature factor must be applied. These factors and the equation representing the factor are shown on [Table 6.7.21](#).

The flowing temperature factor, F_{tf} is required to change the assumed flowing temperature of 60°F to the actual flowing temperature $T_f(^{\circ}R)$

$$F_{tf} = \frac{519.67^{0.5}}{T_f} \tag{6.7.32}$$

Reynold's Number Factor, F_r —The Reynold's number factor takes into account the variations of the discharge coefficient of an orifice with Reynold's number. The discharge coefficient of the orifice decreases as the Reynold's

number increases until the Reynold's number is infinite, when the discharge coefficient will have the least possible value for that particular installation. Discharge coefficients vary considerably with the Reynold's number in the measurement of viscous liquids; they tend to become more constant as the velocity of the liquid decreases, and as the Reynold's number correspondingly increases. Within the limits of commercial measurement of gases, the discharge coefficient is practically constant, varying only slightly with Reynold's number. The variation is sufficiently slight, and the viscosities of commercial gases are sufficiently constant to arrant arbitrarily using an average value for the gas viscosity in computing Reynold's number factors. For all practical purposes, this leaves the Reynold's number factor as a function of the orifice and meter tube dimensions, the location of the differential pressure taps, and the rate of flow — a function of the pressure extension, $h_w P_f$.

The value of pressure extension may be estimated from a knowledge of the differentials and the static pressures at the meter. The pressure extension obtained in this manner will probably be sufficiently close to the average operating condition of the meter for the purpose of selecting the proper value of the Reynold's number factor. The variations in the factor corresponding to the variations in the pressure extension above or below the selected value will be compensating over any appreciable length of time.

The factor may also be based upon an average value of the pressure extensions obtained from the meter records. This is probably the simplest method since the sums of the 24 pressure extensions are generally obtained from each chart in order to compute the daily delivery.

Table of "b" factors from which the Reynold's number factor can be readily obtained are shown on [Table 6.7.22](#) for flange taps, and [Table 6.7.23](#) for pipe taps.

The Reynold's number factor, F_r , can be calculated by

$$F_r = 1 + \frac{b}{(h_w p_f)^{0.5}} \tag{6.7.33}$$

Expansion Factor, Y—When a gas flows through an orifice, the change in velocity and pressure is accompanied by a change in specific weight and a factor must be applied to the coefficient to allow for this change. The expansion factor depends upon the location of the differential taps, the location of the static pressure tap, and the ratio of the

orifice diameter to the diameter of the meter tube. It is also dependent upon the ratio of the differential pressure to the static pressure and upon the specific heats for the flowing gas. The variation in factor is slight and the ratio of the specific heats for commercial gases is sufficiently constant to warrant using an assumed constant ratio of specific heats. An assumed ratio of specific heats $k = 1.3$ was used in calculating the expansion factors in *AGA Report No. 3*. This permits the tabulation of the factors according to the diameter ratio, β , and the ratio of the differential to static pressure, h_w/p_f . In the tables p_f is indicated as p_{f1} , p_{fm} , or p_{f2} , depending upon whether the static pressure is obtained from the upstream tap, a mean of the upstream and downstream pressures, or the downstream tap.

The expansion factor may be based upon a value of the differential ratio obtained from the meter records or estimated from a knowledge of the differentials and the static pressures at the meter. The differential ratio obtained in this manner will probably be sufficiently close to the average operating condition of the meter for the purpose of selecting the proper value of the factor. The variations in the factor corresponding to the variations in the differential ratio above or below the selected value will be compensating over any appreciable length of time.

Table of expansion factor, Y, are shown on [Table 6.7.24](#) through [Table 6.7.28](#).

Supercompressibility Factor, F_{pv} —The supercompressibility factor accounts for the deviation from the "perfect

gas” laws. In the basic flow equations, gas volumes are assumed to vary with pressure and temperature in accordance with Boyle’s and Charles’ laws (the “perfect gas” laws). Actually the volume occupied by individual gases deviate, by a slight degree, from the volumes, which the “perfect gas” laws indicate. The amount of deviation is a function of the composition of the gas and varies primarily with static pressure and temperature. The actual deviation is obtained by a test conducted on a sample of the gas, carefully taken at line conditions of pressure and temperature.

Practical relationships have been established by which this deviation can be calculated and tabulated for natural gases containing normal mixtures of hydrocarbon compo-

nents, considering the presence of small quantities of CO₂ and nitrogen and also relating the deviation to the heating value of the gas.

The values of supercompressibility factor, F_{pv} , can be determined from Fig. 6.1.1.

Manometer Factor, F_m — The manometer factor is used with the mercury-type differential gage to correct the slight error in measurement caused by the weight of the unbalanced column of dense gas above the mercury. This factor is NOT applicable where measurement is made with a bellows-type differential gage because there is no unbalanced column of dense gas in a manometer of that type. Manometer factors are shown on Table 6.7.30.

Note: While F_l values are strictly manometer factors, to account for gauges being operated under gravitational forces that depart from standard location; it is suggested that it be combined with other flow constants. In which instance, F_l becomes a location factor constant and F_m , the manometer factor agreeable with standard gravity remains a variable factor, subject to change with specific gravity, ambient temperature, and static pressure.

The manometer factor, F_m , can be calculated as follows:

$$F_m = \frac{Y_m - Y_g^{0.5}}{846.324} \quad (6.7.34)$$

where

$$Y_m = 846.324[1 - 0.000101(T_a - 520)]$$

$$Y_g = 2.699053 SG_g(F_{pv})^2/T_a$$

T_a = ambient temperature in degrees Rankin (air or atmospheric temperature surrounding the orifice meter)

SG_g = specific gravity of flowing gas

F_{pv} = supercompressibility factor for the gas at ambient temperature, specific gravity and static gage location

The orifice thermal expansion factor, F_a , is introduced to correct for expansion or contraction of the orifice, when operating at temperatures appreciably different from the temperature at which the orifice was bored. It is calculated as:

$$F_a = 1 + [0.0000185(T_f - 68)]$$

(for 304 and 316 stainless steel)

$$F_a = 1 + [0.0000159(T_f - 68)] \text{ (for monel)}$$

where T_f = flowing temperature of gas at the orifice in °F

The gage location factor F_l is required when mercury orifice differential instruments are used. It compensates for differences in the weight of the gas column above the mercury reservoir for meter locations other than the standard of 45° latitude at sea level. It is a constant for any given metering location and can be combined with other flow constants or stored in the computer master file for use in calculating orifice flow (Figures 6.7.38–6.7.42). The equation for determining the gage location factor is:

$$F_l = \left(\frac{g_1}{980.665} \right)^{0.5} \quad (6.7.35)$$

where

g_1 = the ambient gravity value at the metering location can be obtained from the U.S. Coast and Geodetic Survey data in reference to aeronautical data, from the Smithsonian meteorological tables, or calculated for the midlatitudes, between 30° and 60°, as

$$g_1 = 980.665 + [0.087(°L - 45)] - 0.000094H$$

where °L = degrees latitude

H = elevation in lineal feet above sea level

TABLE 6.7.30 F_m Manometer Factors [12]

Specific Gravity, G	Flowing Pressure, psig

0.75	1.000	0.9988	0.9975	0.9959	0.9943	0.9929	0.9918

Note: Factors for intermediate values of pressure, temperature, and specific gravity should be interpolated.

Note: This table is for use with mercury manometer type recording gauges that have gas in contact with the mercury surface.

FIGURE 6.7.38 Partly closed valve upstream of meter tube.

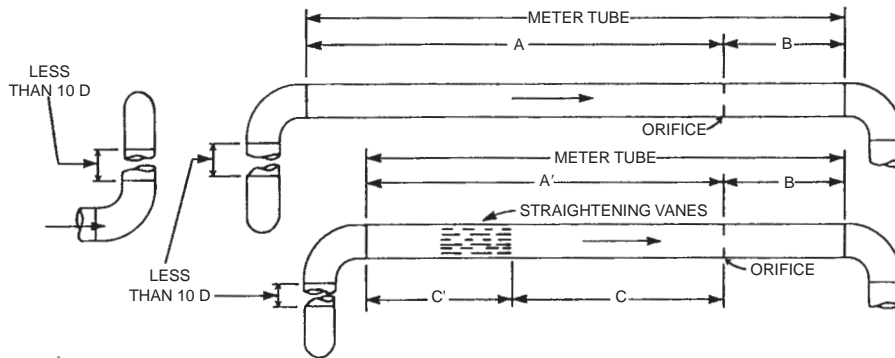

FIGURE 6.7.39 Two ells not in the same plane upstream of meter tube.

FIGURE 6.7.40 Less than 10 pipe diameters (D) between two ells in the same plane upstream of meter tube.

FIGURE 6.7.41 Greater than 10 pipe diameters (D) between two ells in the same plane upstream of meter tube.

FIGURE 6.7.42 Reducer or expander upstream of meter tube.

This gage location factor value can be read in [Table 6.7.29](#).

Example 6.7.17

A 0.7 specific gravity natural gas is measured in an orifice meter having flange taps. Determine the flow rate in scf/hr at 14.4 psia and 60°F if the following data apply:

$$h_w = 40 \text{ in. H}_2\text{O}$$

$$p_f = 143 \text{ psig (measured downstream)}$$

$$\text{average flowing temp} = 84^\circ\text{F}$$

$$\text{line size} = 4.026 \text{ in.}$$

$$\text{orifice-plate opening} = 1.50 \text{ in.}$$

Solution

The respective factors are:

$$F_b = 460.79$$

$$F_{pb} = 1.0229$$

$$F_{tb} = 1.0000$$

$$F_g = 1.1952$$

$$F_{tf} = 0.9777$$

$$F_r = 1.0004$$

$$Y = 1.0016$$

$$C' = 551.89 \text{ (the product of the above numbers)}$$

$$\text{Then } q_g = 551.89 \{ [40] \{ [143 + 14.7] \} \}^{0.5} = 43,810 \text{ scf/hr.}$$

Example 6.7.18

What is the flow rate in scf/hr for the following conditions?

$$d = \text{diameter of orifice} = 3.000 \text{ in.}$$

$$D = \text{internal diameter of meter tube} = 6.065 \text{ in.}$$

$$p_b = \text{pressure base, 8 oz. above 14.4} = 14.9 \text{ psia}$$

$$T_b = \text{temperature base} = 60^\circ\text{F}$$

$$G = \text{specific gravity} = 0.60$$

$$T_f = \text{flowing temperature} = 65^\circ\text{F}$$

$$F_b = 1891.9 \text{ (Table 6.7.16)}$$

$$F_{pb} = 0.9886 \text{ (Table 6.7.18)}$$

$$F_{tb} = 1.0000 \text{ (Table 6.7.19)}$$

$$F_g = 1.2910 \text{ (Table 6.7.20)}$$

$$F_{tf} = 0.9952 \text{ (Table 6.7.21)}$$

Static pressure obtained at downstream flange tap.

$$\text{Average differential} = 49.5 \text{ in.}$$

$$\text{Average static pressure} = 80 \text{ psia (65.6 psig)}$$

$$\beta = 3.000 \div 6.065 = 0.49$$

$$(h_w p_f)^{0.5} = \text{pressure extension (average)} = 63$$

Using [Table 6.7.22](#), for $\beta = 0.49$ and $D = 6.065$;

$$b = 0.0332$$

$$F_r = 1 + (0.0332 \div 63) = 1.0005$$

$$\text{Differential ratio, } h_w \div p_{f2} = 49.5 \div 80 = 0.62$$

Using [Table 6.7.26](#), for $\beta = 0.49$ and $h_w p_f = 0.62$;

$$Y_2 = 1.0037$$

Using [Table 6.7.30](#), $F_{pv} = 1.0046$

Manometer factor F_m , using [Table 6.7.31](#) $F_m = 0.9999$

$$\begin{aligned} \text{Therefore, } C' &= 1891.9 \times 0.9886 \times 1.000 \times 1.2910 \\ &\quad \times 0.9952 \times 1.0005 \times 1.0037 \times 1.0046 \\ &\quad \times 0.9999 = 2424.0 \end{aligned}$$

For the average pressure extension,

$$(h_w p_f)^{0.5} = (49.5 \times 80)^{0.5} = 62.929$$

$$\begin{aligned} \text{The flow rate is } Q_h &= C' (h_w p_f)^{0.5} = 2424.0 \times 62.929 \\ &= 152,540 \text{ scf/hr} \end{aligned}$$

Example 6.7.19

For a meter equipped with pipe taps, what is the flow rate in scf/hr?

$$d = \text{diameter of orifice} = 3.000 \text{ in.}$$

$$D = \text{internal diameter of meter tube} = 7.981 \text{ in.}$$

$$p_b = \text{pressure base, 4 oz. above 14.4} = 14.65 \text{ psia}$$

$$T_b = \text{temperature base} = 60^\circ\text{F}$$

$$G = \text{specific gravity} = 0.64$$

$$T_f = \text{flowing temperature} = 60^\circ\text{F}$$

$$F_b = 2012.7 \text{ (Table 6.7.17)}$$

$$F_{pb} = 1.0055 \text{ (Table 6.7.18)}$$

$$F_{tb} = 1.0000 \text{ (Table 6.7.19)}$$

$$F_g = 1.2500 \text{ (Table 6.7.20)}$$

$$F_{tf} = 1.0000 \text{ (Table 6.7.21)}$$

Static pressure obtained at upstream pipe tap

$$\text{Average differential} = 64.5 \text{ in.}$$

$$\text{Average static pressure} = 539.4 \text{ (525 psig)}$$

$$\beta = 3.000 \div 7.981 = 0.38$$

$$(h_w p_f)^{0.5} = \text{pressure extension (average)} = 187$$

$$\text{For } \beta = 0.38 \text{ and } h_w \div p_{f1} = 0.12$$

Note: Maximum percent allowable tolerance between measured upstream inside diameter and the published inside diameter refer to the published inside diameter.

FIGURE 6.7.43 Maximum percent allowable meter tube tolerance.

$$F_r = 1 + (0.0214 \div 187) = 1.0001$$

$$\text{Differential ratio, } h_w \div p_{f2} = 0.12$$

$$\text{Using Table 6.7.25, } \beta = 0.38 \text{ and } h_w \div p_{f1} = 0.12;$$

$$Y_1 = 0.9983$$

It is assumed in this example that the supercompressibility factor is not used, by terms of contract.

Using Table 6.7.31, the manometer factor, $F_m = 0.9989$

$$\text{Therefore, } C' = 2012.7 \times 1.0055 \times 1.0000$$

$$\times 1.2500 \times 1.0000 \times 1.0001$$

$$\times 0.9983 \times 0.9989 = 2522.9$$

$$\text{For an average pressure extension of } (h_w p_f)^{0.5}$$

$$= (64.5 \times 539.4)^{0.5} = 186.52$$

$$\text{The flow rate is } Q_h = C' (h_w p_f)^{0.5} = 2522.9 \times 186.52$$

$$= 470,570 \text{ scf/hr}$$

In orifice meter measurement of gases, the effect of compressibility equates to the relationship $(1/Z)^{0.5}$; this has been termed the “supercompressibility” of the gas. The supercompressibility factor, F_{pv} may be calculated from:

$$F_{pv} = \left(\frac{Z_b}{Z_{fl}} \right)^{0.5} \quad (6.7.36)$$

The best way to obtain the Z calculation is to use the Hall-Yarborough equation [16], or figures of compressibility factors for natural gas Figure 6.7.43. Also the supercompressibility factor F_{pv} may be taken from the AGA Report

No. 3 [14] and/or empirical equations as follows [17]:

$$F_{pv} = 1 + \left(\frac{2.48 P_G \times 10^{5.0+2.02 S G_g}}{T_f^{3.825}} \right)^{0.5} \quad (6.7.37a)$$

for $0.601 S G_g \leq 0.650$ and $P < 600$ psig

$$F_{pv} = 1 + \left(\frac{3.32 P_G \times 10^{5.0+1.81 S G_g}}{T_f^{3.825}} \right)^{0.5} \quad (6.7.37b)$$

for $S G_g \leq 0.600$ and $P < 600$ psig

$$F_{pv} = 1 + \left(\frac{4.66 P_G \times 10^{5.0+1.6 S G_g}}{T_f^{3.825}} \right)^{0.5} \quad (6.7.37c)$$

for $0.651 \leq S G_g \leq 0.750$ and $P < 600$ psig

$$F_{pv} = 1 + \left(\frac{7.91 P_G \times 10^{5.0+1.26 S G_g}}{T_f^{3.825}} \right)^{0.5} \quad (6.7.37d)$$

for $0.0751 \leq S G_g \leq 0.900$ and $P < 600$ psig

where P_G = gage pressure psig
 $S G_g$ = specific gravity of gas
 T_f = flowing temperature in °R

Example 6.7.20

Compute the daily flowrate of a natural gas through an orifice meter for the following conditions:

Barometric pressure = 14.5 psia

Diameter of pipe = 11.938 in.

Orifice Diameter = 4.000 in.
 Differential Pressure across meter = 27.0 in. of water
 Static pressure on meter = 600 psig
 Type of meter = Flange taps
 Temperature base (T_b) = 60°F
 Flowing temperature = 75°F
 Pressure base (P_b) = 14.65 psia
 Gas composition by volume = C_1 – 85%, C_2 – 5%, C_3
 – 3%, i- C_4 – 1%, N_2 – 6%

Comp.	Concentr.	$T_c(^{\circ}R)$	$Z_i T_{ci}$	P_c (psia)	$Z_i P_{ci}$	M	$Z_i M_i$
C_1	0.85	344	292.4	673	572.1	16	13.6
C_2	0.05	550	27.5	712	35.6	30	1.5
C_3	0.03	666	20.0	617	18.5	44	1.3
i- C_4	0.01	734	7.3	528	5.3	58	0.6
N_2	0.06	227	13.6	492	29.5	28	1.7
		Σ	360.9		661 psia		18.7

Solution

- Daily Flow Rate = $24 \times Q_N$
- $(h_{wpf})^{0.5} = [27(600 + 14.5)]^{0.5} = 128.8$
- Basic orifice factor for flange taps, F_b ; see Table 6.7.16 for $D = 12.000$ in. (11.938) and $D = 4.000$, $F_b = 3,260$
- Reynold's number factor, F_r :

$$F_r = 1 + \frac{b}{(h_{wpf})^{0.5}} = \frac{b}{128.8}$$

for b see Table 6.7.22 for given d and D

$$b = 0.0206$$

$$F_r = 1 + \frac{0.0206}{128.6} = 1.0001599 = 1.0002$$

(minimum four decimal places is required)

- Expansion Factor Y, (function of β and h/P)

$$\beta = \frac{d}{D} = \frac{4.000}{11.938} = 0.33506$$

$$\frac{h}{P} = \frac{27}{692.5} = 2.8989 \times 10^{-2} = 0.038989 = 0.039$$

From Table 6.7.24 $Y = 0.9996$ by interpolation

- Temperature base factor, F_{tb} :

$$F_{tb} = \frac{469.67 + 60}{519.67} = 1.0$$

- Pressure base factor, F_{pb} :

$$F_{pb} = \frac{14.73}{14.65} = 1.0055$$

- Flowing temperature factor, F_{tf} :

$$F_{tf} = \left(\frac{T_b}{T_f} \right)^{0.5} = \left(\frac{519.67}{459.67 + 75} \right)^{0.5} = 0.9859$$

- Gas specific gravity factor, F_g or $F_{gr} = (1/SG_g)^{0.5}$

$$SG_g = \frac{M_{gas}}{M_{air}} = \frac{18.7}{28.9625} = 0.646$$

$$F_{gr} = \left(\frac{1}{SG_g} \right)^{0.5} = 1.2442$$

- Supercompressibility factor, F_{pv} :

$$F_{pv} = \frac{1}{Z^{0.5}}$$

$$T_f = \frac{459.67 + 75}{360.9} = 1.481$$

$$P_r = \frac{692.5}{661} = 1.0477$$

from Figure 6.7.44, $Z = 0.895$

$$F_{pv} = \frac{1}{0.895^{0.5}} = 1.0564$$

or from Equation 6.7.

$$F_{pv} = 1 + \frac{3.32 \times 600 \times 10^{5.0+1.81 \times 0.646}}{534.67^{3.825}} = 1.0526$$

- Daily flow rate:

$$\begin{aligned}
 24Q_v &= 24 \times (F_b F_r Y F_{pb} F_{tb} F_{tf} F_{gr} F_{pv} (h_{wpf})^{0.5}) \\
 &= 24 \times 3260 \times 1.0002 \times 0.9996 \times 1.0055 \\
 &\quad \times 1.0 \times 0.9859 \times 1.2442 \times 1.0526 \times 128.8 \\
 &= 13.08 \text{ MMscfd}
 \end{aligned}$$

Example 6.7.21

A 1.6 MMscm daily flow rate of 0.63 relative density natural gas is to be metered at 27°C and 7 MPa in an orifice meter using flange taps. At this condition the compressibility factor $Z = 0.895$. What size orifice plate and meter run should be used?

Assume $h_w = 52$ in. of water
 $P_b = 14.5$ psia
 $T_b = 59^\circ\text{F}$

Ignore F_r & Y

FIGURE 6.7.44 Z factor chart. Source: Craft, Hawkins. Applied Petroleum Reservoir Engineering, Chemical Engineering Series. Prentice Hall.

$T = 27^{\circ}\text{C} = 80.6^{\circ}\text{F}$

$P_{\text{static on meter}} = 7 \text{ MPa} = 1,1015.26 \text{ psig}$

$Z = 0.895$

$P_b = 14.5 \text{ psia} = 100 \text{ kPa} = 1 \text{ bar}$

$T_b = 59^{\circ}\text{F} = 15^{\circ}\text{C}$

Standard conditions for SI system:

$P = 100 \text{ kPa}$

$T = 15^{\circ}\text{C}$

or

$P = 101.325 \text{ kPa}$

$T = 0^{\circ}\text{C}$

for P_{bar} assume it is the same as P_{base} if P_{bar} is unknown:

$$24 Q_v = (F_b F_r Y F_{pb} F_{tb} F_{tf} F_{gr} F_{pv} (h_w p_f)^{0.5})$$

1. Flow rate Q_v (scf/hr) at 14.73 psia and $T = 60^{\circ}\text{F}$

$24 Q_v = 1.6 \text{ MMscm}/24 \text{ hr}$

$Q_v = 1.6 \text{ MMscm}/\text{hr}$

Use the first set, where mole volume = 23.96 scm/kmol; then our T_b and P_b are exactly the same.

$P_b = 14.5 \text{ psia} = 100 \text{ kPa}$

$T_b = 59^{\circ}\text{F} = 15^{\circ}\text{C}$

Hence, $Q_v = 1.6 \times 10^6$ (scm/day)(1 kmol/23.96 scm)
 = 66,777.96 kmol/24 hr

$$= \frac{147,217.73 \text{ lb mol}}{24} \frac{\text{hr}}{\text{hr}}$$

Q_v is in the formula for orifice equations according to the AGA Report No. 3 [12] and has standard conditions, $P_{sc} = 14.73$ psia and $T_{sc} = 60^\circ\text{F}$. For those conditions the molal volume = 378.4 ft.³/lb mol.

Flowrate Q_v (scf/hr) at 14.73 psia and 60°F is equal to

$$Q_{v(\text{AGA})} = \frac{147,217.73 \text{ lb mol}}{24} \frac{\text{hr}}{\text{h}} \times 378.4 \frac{\text{scf}}{\text{lb mol}} = 2.321133 \text{ scf/hr}$$

2. Temperature base factor F_{tb}

$$F_{tb} = \frac{459.67 + 59}{519.67} = 0.9981$$

3. Pressure base factor F_{pb}

$$F_{pb} = \frac{14.73}{14.50} = 1.0159$$

4. Gas gravity factor F_{gr}

$$F_{gr} = \left(\frac{1}{SG_g} \right)^{0.5} = \frac{1}{0.63} = 1.2599$$

5. Supercompressibility factor F_{pv}

$$F_{pv} = \left(\frac{1}{Z_f} \right)^{0.5} = \frac{1}{0.895} = 1.057$$

6. Flowing temperature factor F_{tf}

$$F_{tf} = \left(\frac{T_b}{T_f} \right)^{0.5} = \left(\frac{459.67 + 59}{459.67 + 80.6} \right)^{0.5} = 0.9798$$

7. $(h_{wpf})^{0.5} = [52 \times (1015.26 + 14.5)]^{0.5} = 0.9798$

8. Solve for F_b

$$F_b = \frac{Q_v}{F_r Y F_{pb} F_{tb} F_{tf} F_{gr} F_{pv} (h_{wpf})^{0.5}} = \frac{2,321,133}{(0.9981)(1.0159)(0.9798)(1.2599)(1.2599)(1.0570)(231.4)} = 6,017.7$$

9. Selection of the meter run (see several combinations to orifice-to-pipe ratios) will fall within the recommended β ratio.

F_b	Pipe "D"		Orifice	
	Nominal	Size	"d"	β
7579.2	12	11.938	6.0	0.5026
7564.7	12	12.090	6.0	0.4963
7640.4	12	11.375	6.0	0.5274
777.8	8	8.071	5.75	0.7124

The larger the run, the lower β but the higher cost. Once a size has been chosen the values for F_r and Y_1 could be calculated, but the effect on the choice is trivial.

6.7.10.1 Uncertainty Limits and Field Problems

No two orifice meters can be built, as a rule, to give exactly the same reading when the same amount of gas is flowing. For this reason, uncertainties are necessary for the values of the constants given in this handbook. The commercial accuracy will be somewhat less than the accuracy indicated by the tolerance given for the orifice flow constants. Very exact duplication of orifice plates is not commercially possible. An example of the effect of uncertainties is provided below:

Example 6.7.22

Using the flow equation, find the overall measurement uncertainty of the flow, knowing percentage uncertainty of each variable. We use the equation:

$$Q_v = F_b F_r Y F_{pb} F_{tb} F_{tf} F_{gr} F_{pv} (h_{wpf})^{0.5}$$

As the table illustrates, the overall measurement uncertainty of the flow in this example is $\pm 0.7915\%$. The above analysis assumes constant flowrate, which is a rather theoretical case.

System design must consider monthly variations in flow, daily variations in flow and even very short form variation in flow. One of the most difficulty metering conditions is when the producers has installed intermitters on the well production. Very often in these systems, the no-flow period (or low-flow period) is of relatively long duration when compared to the flow periods. The result is a chart interpretation that is much higher than actual flow.

Sometimes in vacuum gathering systems, backflow may occur. In such a case it is possible to pay for the gas twice. The gas flow through the metering system once as it is produced; it may flow backwards through the system into the reservoir when the compressor shuts down. When the compressor is restarted, it may be drawn through the system

Variable	% Uncertainty of Variable (+)	Effect Factor	
		Exponent	Square
F_b	0.5	1	0.25
F_r	0.1	1	0.01
Y	0.25	1	0.0625
F_{pb}	0.05	1	0.0025
F_{tb}	0.03	1	0.0009
F_{tf}	0.25	$\frac{1}{2}$	0.0156
F_{gr}	0.7	$\frac{1}{2}$	0.1225
F_{pv}	0.4	$\frac{1}{2}$	0.040
h_w	0.5	$\frac{1}{2}$	0.0625
P_f	0.5	$\frac{1}{2}$	0.0625
		Sum of squares	0.6265
		Square root of sum	0.7915%

and again remetered. For that reason it is important to install check valves on the sublet of meter runs.

Electronic Measurement—The primary considerations for going to electronic measurement includes the fact that it is more accurate. Electronic metering units are more capable of following highly variable flows than a mechanical chart recorder. After installation of an electronic system it is possible to reduce the imbalance between the plant inlets vs. field volumes to less than 2% as compared with a balance that frequently runs 6% to 8% using mechanical recorders.

6.7.11 Hydrocarbon Liquid Content of Natural Gas

With the development of the unconventional plays by horizontal drilling, more and more rich gas is being produced and sold. Rich gas is typically classified as gas containing economic volumes of liquefiable liquid hydrocarbon. The amount of hydrocarbon liquid contained in natural gas adds economic value and thus should be measured accurately. The measurement is typically made in a lab and reported as a volume of ethane and heavers (C2+) per thousand cubic feet (gallons per MCF). In the field it is very important to obtain a representable sample of the rich gas for analysis. There are three types of gas sampling techniques that are commonly used: spot, continuous composite sampling, and continuous online sampling (gas chromatograph). Spot sampling is taking a sample in one point in time. Whereas

a composite sampler takes small calculated volumes of gas over a period of time (like the monthly gas sales period) to obtain an average sample for lab analysis. Small variances in liquefiable hydrocarbon can cost companies tens of thousands of dollars in a short period of time. The continuous online sampling system is the most accurate and primarily used in the gas processing plants.

6.7.12 Gas Gathering

Gas gathering systems usually consist of the piping and the processing equipment between individual wells in a gas field and the compressor station at the inlet of the transmission or distribution lines. The smallest gathering system consists simply of two or more gas well interconnected by piping and tied directly into a distribution system. For large fields and for several interconnected fields involving hundreds of miles of piping, gathering systems may include such equipment as drips, separators, meters, heaters, dehydrators, gasoline plant, sulfur plant, cleaners, and compressors, as well as piping and valves.

Depending upon local conditions, there are a few types of gathering systems. The basic systems are axial, radial, loop and their combination (see Figure 6.7.45 and 6.7.46).

The choice between the gathering systems is usually economic, but technical feasibility is also important. Special attention is paid in the solution of complex transmission systems to express the various lengths and diameters of the pipe in the system as equivalent lengths of a common diameter or equivalent diameters of a common length. Equivalent, in this case, means that both lines will have the same capacity with the same total pressure drop.

6.7.13 Flow Equations for Steady State

Commonly used equations for gas flow are given below:

1. Basic equation

$$Q_{sc} = K \left(\frac{T_{sc}}{P_{sc}} \right)^{1.000} \left[\frac{(P_1^2 - P_2^2) D^5}{f S G_g L T_m Z_m} \right]^{0.5} \quad (E) \quad (6.7.38)$$

$$\begin{aligned} \text{where } K &= 38.774 \text{ is in English units} \\ &= 5.62 \times 10^5 \text{ in in SI units} \end{aligned}$$

2. Weymouth equation

$$Q_{sc} = K \left(\frac{T_{sc}}{P_{sc}} \right)^{1.000} \left[\frac{(P_1^2 - P_2^2) D^{5.333}}{S G_g L T_m Z_m} \right]^{0.5} \quad (E) \quad (6.7.39)$$

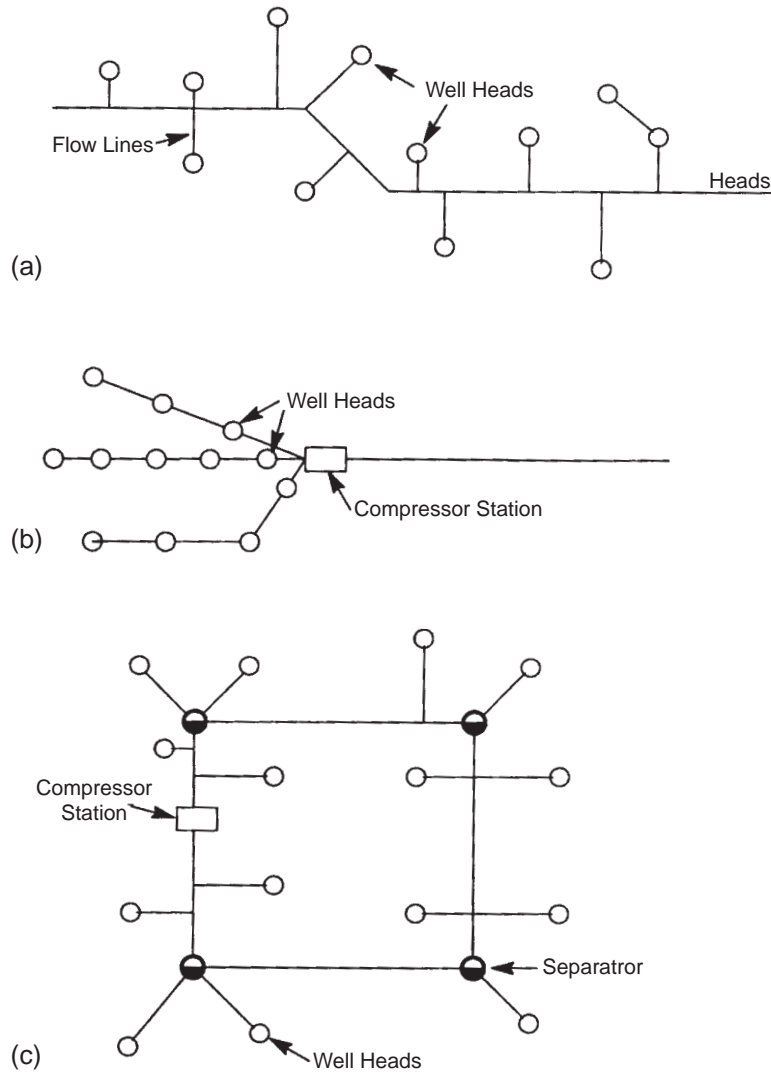

FIGURE 6.7.45 Simple gathering systems: a) an axial, b) a radial, c) loop.

where $K = 433.5$, $f = 0.008/D^{0.33}$ is in English units
 $= 1.162 \times 10^7$, $f = 0.0109/D^{0.33}$ is in SI units

3. Panhandle A equation

$$Q_{sc} = K \left(\frac{T_{sc}}{P_{sc}} \right)^{1.0788} \left[\frac{(P_1^2 - P_2^2) D^{4.854}}{SG_g^{0.854} L T_m Z_m} \right] \quad (E) \quad (6.7.40)$$

where $K = 435.9$, $f = 0.0192/(Q_{sc} SG_g/D)^{0.1461}$
 is in English units
 $= 1.198 \times 10^7$, $f = 0.0099/$
 $(Q_{sc} SG_g/D)^{0.1461}$ is in SI units

4. Panhandle B equation

$$Q_{sc} = K \left(\frac{T_{sc}}{P_{sc}} \right)^{1.020} \left[\frac{(P_1^2 - P_2^2) D^{4.961}}{SG_g^{0.961} L T_m Z_m} \right]^{0.51} \quad (E) \quad (6.7.41)$$

where $K = 737$, $f = 0.00359/$
 $(Q_{sc} SG_g/D)^{0.03922}$ is in English units
 $= 1.264 \times 10^7$, $f = 0.0030/$
 $(Q_{sc} SG_g/D)^{0.03922}$ is in SI units

5. The Clinedinst equation in English units

$$Q_{sc} = 288.7 \left(\frac{T_{sc}}{P_{sc}} \right) Z_{sc} P_{sc} \left[\frac{D^5}{SG_g T_m L f} \times \left(\int_0^{P_{r,1}} \frac{P_r}{Z} dP - \int_0^{P_{r,2}} \frac{P_r}{Z} dP_r \right) \right]^{0.5} \quad (6.7.42)$$

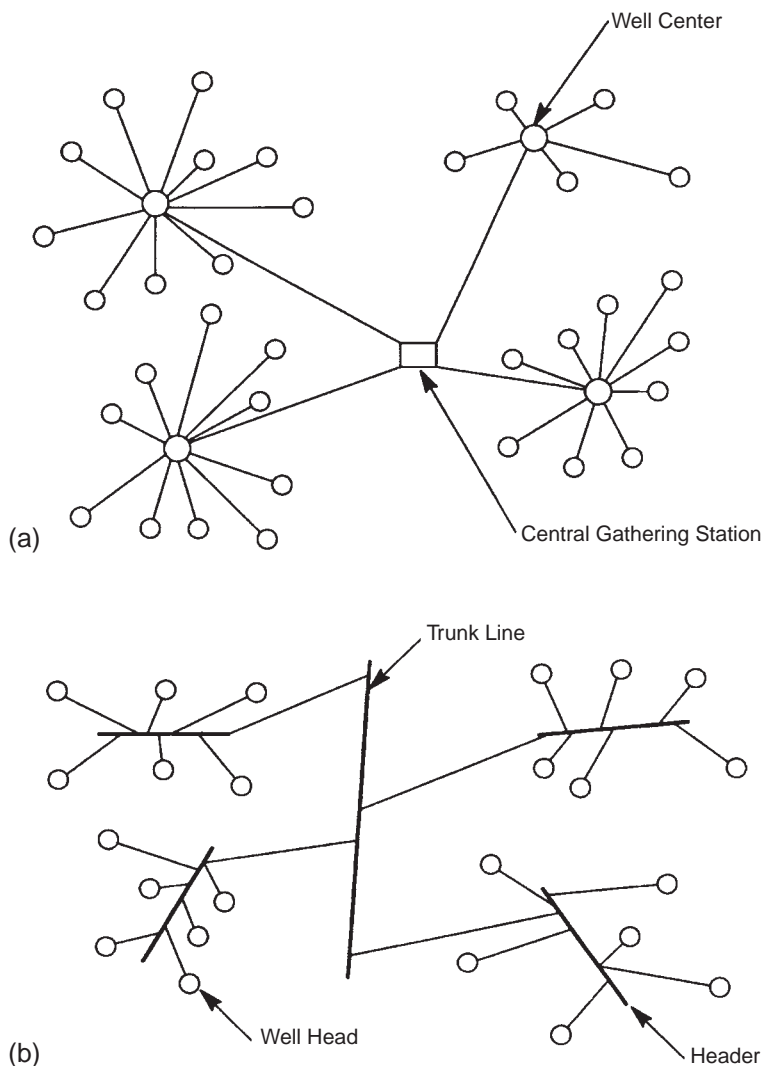

FIGURE 6.7.46 A combination of gathering systems: a) well-center, b) trunk-line.

Values of the integral functions $\int_0^{P_r} (P_r/Z) dP_r$ are tabulated in Table A-6 of Katz [144] or in Table 7-1 of Kumar [145].

The constants in the Equations 6.7.38 through 6.7.42 are as follows:

- Q_{sc} = gas flow rate at T_{sc} , P_{sc} , in scf/d or scm/d
- P , P_{sc} = absolute pressure at standard conditions in psia or kpa
- T_m , T_{sc} = mean absolute temperature of line at standard conditions in R° or K
- D = inside diameter of pipes in inches or meters
- L = Pipe length in miles or meters
- μ = viscosity in lb/(ft•s) or (Pa•s)
- γ_g = relative gas density (air = 1.0)
- Z_m = mean compressibility factor

- E = pipeline efficiency
- R_e = Reynold's number
- P_r = pseudo critical pressure

Pipeline efficiency is a correction for small amounts of liquid, general debris, weld resistance, valve installations, line bends, and other factors that reduce the gas flow rate to a point below the basic equation of state. The design value of "E" in a new clean gas line usually is estimated at 0.92. Some companies arbitrarily use a graduated "E":

- $E = 1.0$, new straight pipe without bends, very seldom used in design
- $= 0.95$, excellent conditions (with frequent pigging)
- $= 0.92$, average to good condition (normal design)
- $= 0.85$, adverse, unpigged, old dirty line

Equations 6.7.38 through 6.7.42 are equations for steady-state flow of gas through a horizontal pipe. These equations assume:

- no mechanical work is done on the gas between the points at which the pressures are measured,
- negligible kinetic energy change

The Weymouth equation was devised for sizing gas lines operating at pressure from 35 to 100 psig if $Z = 1.0$. By including the compressibility factor, the Weymouth equation showed reasonable agreement with metered volumes, for filed gathering lines operating at 1,000 to 3,200 psig. The Weymouth equation is used most often for designing gas gathering and transmission systems because it generally maximizes pipe diameter requirements for a given flowrate and pressure drop.

Example 6.7.23

A pipe line is to be designed to transmit 300 MMsf/d measured at 60°F and 15.025 psia. Specific gravity of the gas is 0.71. Flowing temperature is expected to average 60°F while barometric pressure is to average 14.3 psia. It has already been decided that 24-in. pipe will be used (ID = 23.2 in.) and that discharge and suction pressures at the compressed stations will be 800 psig and 350 psig, respectively. How far apart will the compressor stations be? Use the Weymouth and Panhandle equations, where $Z = 0.86$, $E = 0.92$.

From Equation 6.3.39

$$Q_{sc} = \left(\frac{T_{sc}}{P_{sc}} \right)^{1.000} K \left[\frac{(P_1^2 - P_2^2) D^{5.333}}{SG_g LTZ} \right]^{0.5} \quad (E)$$

Substituting the given values into the equation gives

$$\begin{aligned} 300 \times 10^6 &= \left(\frac{519.67}{15.025} \right)^{1.000} \\ &\times 433.5 \left[\frac{(814.3^2 - 364.3^2)(23.2)^{5.333}}{(0.71)L(519.67)(0.86)} \right]^{0.5} \quad (E) \\ 2855.7 \times L &= 228542 E^2 \\ &= 80.03 E^2 \end{aligned}$$

if $E = 1.0$, then $L = 80.03$ mi

if $E = 0.82$, then $L = 67.74$ mi

From Equation 6.7.40

$$Q_{sc} = K \left(\frac{T_{sc}}{P_{sc}} \right)^{1.0788} \left[\frac{(P_1^2 - P_2^2) D^{4.854}}{SG_g^{0.854} LTZ} \right]^{0.5394}$$

$$\begin{aligned} 300 \times 10^6 &= 435.87 \left(\frac{519.67}{15.025} \right)^{1.0788} \\ &\times \left[\frac{530,370 \times 23.2^{4.854}}{(0.71)^{0.854} L(519.67)(0.86)} \right]^{0.5394} \\ &\times \left[\frac{530,370 \times 4,246,964.97}{33.58L} \right]^{0.5394} \quad (E) \\ L^{0.5394} &= 13.317 E \end{aligned}$$

If $E = 1.0$, then $L = 13.317$ mi

If $E = 0.92$, then $L = 104.1$ mi

From Equation 6.7.41

$$\begin{aligned} 300 \times 10^6 &= 737 \left(\frac{519.67}{15.025} \right)^{1.02} \\ &\times \left[\frac{(814.3^2 - 364.3^2) 23.2^{4.861}}{(0.71)L(519.67)(0.86)} \right]^{0.51} \quad (E) \\ L &= 99.4 \end{aligned}$$

Panhandle equations “A” and “B” give good results for pressures higher than 100 psia and diameters larger than 8 in. and for systems operating at $Re > 10^5$.

In our example, because of the large diameter of pipe being used, $L = 104.1$ mi is the correct answer:

Example 6.7.24

Suppose that the pipeline of example 18 has been built and that at some later date the capacity of the line is to be increased to 320 MMcf/d by lowering the suction pressure at the stations. If $E = 0.95$, what suction pressure would be required? Use the Panhandle “A” and “B” equations.

Using Panhandle “A” equation

$$\begin{aligned} P_2^2 &= P_1^2 - \frac{Q_{sc}^2 P_{sc}^2 T_m Z_m \gamma_g^{0.854} L}{(KE)^{1/0.5394} (520)^2 (23.2)^{4.854}} \\ &= (84.3)^2 - \frac{(320)(10^6)^{1.8539} (15.025)(520)(0.86)}{(0.71)^{0.854} (104.1)} \\ &= 100,183 \\ P_2 &= 316.5 \text{ psia} \end{aligned}$$

Using Panhandle “B” equation

$$\begin{aligned} P_2^2 &= (814.3)^2 \\ &\quad - \frac{(320)(10^6)^{1.96} (15.025)^2 (520)(0.86)(0.71)^{0.961}}{(99.4)} \\ &\quad - \frac{(0.95)^{1.96} (737)^{1.96} (520)^2 (23.2)^{4.961}}{(99.4)} \\ &= 100,183 \\ P_2 &= 313.1 \text{ psia} \end{aligned}$$

6.7.14 Complex Gas Flow Systems

A situation often requires increasing the flowrate per unit pressure drop in a system. The common way to solve this problem is to place one or more lines parallel to the original, either partially or throughout the entire length of the system (see Figure 6.7.47a). If the lines are of equal length $(\Delta P/L)_A = (\Delta P/L)_B$ and if the line 1-2 is partially looped with B length, $L_A = L_B$

$$Q_A + Q_B = Q_C = Q_{total}$$

$$\Delta P_A = \Delta P_B$$

The pressure loss due to friction in the looped position plus that in the unlooped portion must equal the total friction loss:

$$\frac{\Delta P_f}{L_{nA}}(x) + \frac{\Delta P_f}{L_n}(L - x) = \text{total } \Delta P_f$$

The purpose of the second line B is to decrease the pressure drop between points 1 and 3, compensating for the increased pressure between points 3 and 2, the unlooped portion, with the required increased flow.

The basic Equation 6.7.38 may be used to anticipate rates and sizing of lines, which could be expressed as:

$$Q = K' \frac{D_5^{0.5}}{f_L} \quad (E)$$

The flow of gas in "n" number of horizontal parallel looped lines is shown as follows:

$$Q = K \left(\frac{T}{P} \right)_{sc} \left(\frac{P_1^2 - P_2^2}{SG_g TLZ} \right) \underbrace{\left(\frac{D_A^{2.5}}{f_A^{0.5}} + \frac{D_B^{2.5}}{f_B^{0.5}} + \dots + \frac{D_n^{2.5}}{f_n^{0.5}} \right)}_{D_e} E \quad (6.7.43)$$

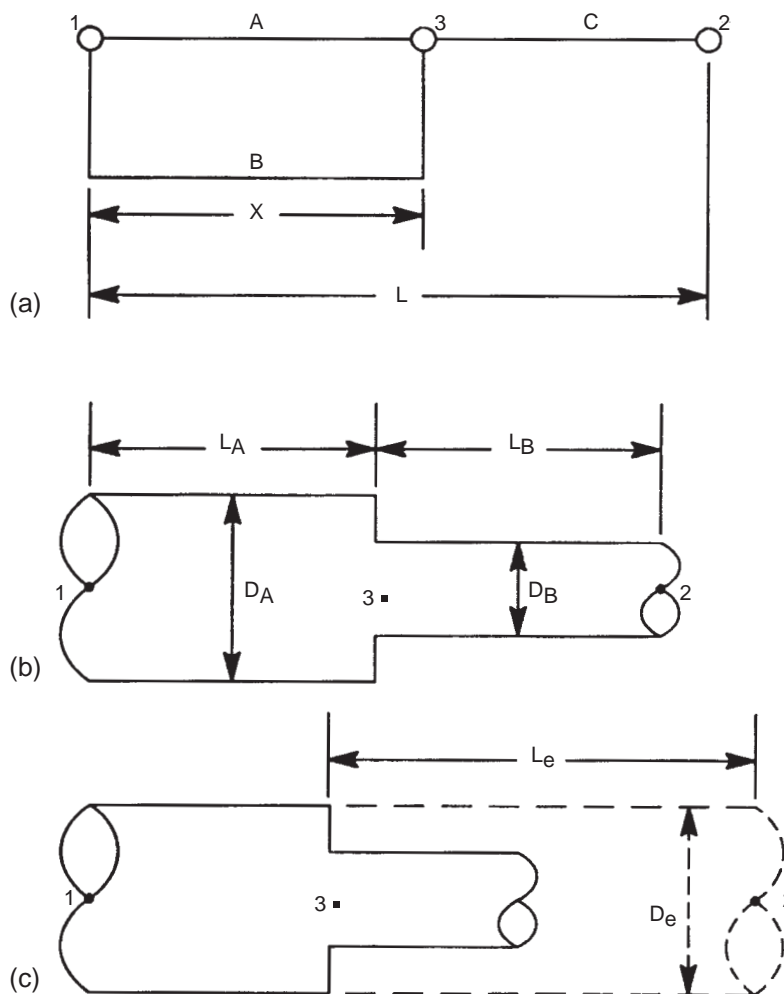

FIGURE 6.7.47 Complex pipelines a) the looped pipeline system, b) the series pipeline system, c) the equivalent length and diameter system.

The equivalent diameter D_e of a single line having the same capacity as the foregoing set of parallel lines is shown:

$$D_e^{2.5} = \left(\frac{f_e}{f_A}\right)^{0.5} D_A^{2.5} + \left(\frac{f_e}{f_B}\right)^{0.5} D_B^{2.5} + \dots + \left(\frac{f_e}{f_n}\right)^{0.5} D_n^{2.5} \tag{6.7.44}$$

Combining both an equivalent length, L_e , and equivalent diameter, D_e , terms:

$$\frac{D_e^{2.5}}{(f_e L_e)^{0.5}} = \frac{D_A^{2.5}}{(f_A L_A)^{0.5}} + \frac{D_B^{2.5}}{(f_B L_B)^{0.5}} + \dots + \frac{D_n^{2.5}}{(f_n L_n)^{0.5}} \tag{6.7.45}$$

In Equation 6.7.45, one usually chooses a diameter D_e , equal in size to the unlooped portion, then calculates the equivalent length, L_e , (corresponding to the ΔP characteristic of the actual looped section). This, L_e , is added to the length of the unlooped portion. Table 6.7.31 summarizes other complex gas flows.

Example 6.7.25

A brand line is laid to move gas a distance of 60 mi from a junction on the main line to a city. The line is to transmit 23 MMcf/d of 0.73 gravity gas, measured at 60°F and 14.65 psia. Flowing temperature will be 65°F at 14.65 psia. Pressure at the junction is 620 psia and the gas is to be delivered to the city gate at 100 psia. The objective is to minimize the investment in pipe by laying a line consisting of two sizes in series. The following sizes are available:

Nominal Size (in.)	Internal diameter (in.)
6	6.065
8	8.071
10	10.192
12	12.090

Which two of the above pipe sizes should be used, and how much of each should be laid? Disregard the compressibility factor and pipeline efficiency in this problem.

TABLE 6.7.31 Equations for Complex Gas Flow

Equation	Basic	Weymouth	Panhandle A
For Two Lines in Series			
Equivalent Diameter D_e	$D_B \left(\frac{L_A}{L_B}\right)^{1/5} \left(\frac{f_A}{f_B}\right)^{1/5}$	$D_B \left(\frac{L_A}{L_B}\right)^{3/16}$	$D_B \left(\frac{L_A}{L_B}\right)^{0.2060}$
Equivalent Diameter L_e	$L_B \left(\frac{D_A}{D_B}\right)^5 \left(\frac{f_B}{f_A}\right)$	$L_B \left(\frac{D_A}{D_B}\right)^{16/3}$	$L_B \left(\frac{D_A}{D_B}\right)^{4.854}$
For Two Lines in Series			
Equivalent Diameter or Length-Loops D_e or L_e	$\frac{D_e^{2.5}}{(f_e L_e)^{0.5}} = \frac{D_A^{2.5}}{(f_A L_A)^{0.5}} + \frac{D_B^{2.5}}{(f_B L_B)^{0.5}}$	$\frac{D_e^{8/3}}{L_e^{0.5}} = \frac{D_A^{8/3}}{L_A^{0.5}} + \frac{D_B^{8/3}}{L_B^{0.5}}$	$\frac{D_e^{2.616}}{L_e^{0.5394}} = \frac{D_A^{2.616}}{L_A^{0.5394}} + \frac{D_B^{2.616}}{L_B^{0.5394}}$
Loops-Diameters and Flows Vary X_f - Fraction Looped $D_R = \left(\frac{f_1}{f_2}\right)^{0.5} \left(\frac{D_2}{D_1}\right)^{5/2}$	$x_f = \frac{\left(\frac{Q_1}{Q_2}\right)^{0.5} - 1}{\left[\frac{1}{(1 + D_R)^2} - 1\right]}$	$x_f = \frac{1 - \left(\frac{Q_1}{Q_2}\right)^2}{1 - \left[\frac{D_1^{8/3}}{D_1^{8/3} + D_2^{8/3}}\right]^2}$	$x_f = \frac{1 - \left(\frac{Q_1}{Q_2}\right)^{1.86}}{1 - \left[\frac{1}{1 - \left(\frac{D_2}{D_1}\right)^{2.62}}\right]^{1.86}}$
Entire Line Looped		$\frac{Q_2}{Q_1} = 1 + \left(\frac{D_2}{D_1}\right)^{8/3}$	$\frac{Q_2}{Q_1} = 1 + \left(\frac{D_2}{D_1}\right)^{2.618}$
Diameters of Original and Parallel Lines are the same X_f = Fraction Looped	$x_f = \frac{4}{3} \left[1 - \left(\frac{Q_1}{Q_2}\right)^2\right]$	$x_f = \frac{4}{3} \left[1 - \left(\frac{Q_1}{Q_2}\right)^2\right]$	$x_f = \frac{4}{3} \left[1 - \left(\frac{Q_1}{Q_2}\right)^{1.86}\right]$

Find \$D_e\$ from Weymouth Equation 6.7.39:

$$D_e = \left[\frac{SG_g T_m Z_m L}{(P_1^2 - P_2^2)} \left(\frac{Q_{sc} E P_{sc}}{K T_{sc}} \right)^2 \right]^{1/5.333}$$

$$Z_m = E = 1.0$$

$$D_e = \left[\frac{0.73 \times 525 \times 60}{620^2 - 100^2} \left(\frac{23 \times 10^6 \times 14.65}{433.5 \times 520} \right)^2 \right]^{1/5.333}$$

$$= 9.19023$$

For Case I, assume \$D_A = 8.071\$, \$D_B = 10.192\$, \$L_A + L_B = 60\$, \$L_A = 60 - L_B\$, \$L_B = 60 - L_A\$ or

$$D_e = D_B \left(\frac{L_A}{L_B} \right)^{3/16} = D_B \left(\frac{L_A}{60 - L_A} \right)^{3/16}$$

$$9.19023 = 10.192 \left(\frac{L_A}{60 - L_A} \right)^{3/16}$$

$$L_A = 21.92 \text{ (} D_A = 8 \text{ in.)}$$

and

$$L_B = 38.08 \text{ (} D_B = 10 \text{ in.)}$$

For case II, assume \$D_A = 10.192\$, \$D_B = 8.071\$

$$D_e = D_B \left(\frac{L_A}{L_B} \right)^{3/16}$$

$$9.19023 = 8.071 \left(\frac{L_A}{60 - L_A} \right)^{3/16}$$

$$1.9989 = \frac{L_A}{60 - L_A}$$

$$L_A = 39.99 = 40 \text{ mi (} D_A = 10 \text{ in.)}$$

$$L_B = 20 \text{ mi (} D_B = 8 \text{ in.)}$$

Both cases, more or less, in given conditions give similar results. As a solution, it is better to take \$L_A = 21.92\$ with \$D_A = 8\$ in. and \$L_B = 38.08\$ with \$D_B = 10\$ in.

Example 6.7.26

Two lines, AC (5-in. ID, 4.5 mi long) and BC (5 in. ID, 3.8 mi long), emanating from leases A and B, respectively, terminate at the gathering station at C. From C a single 11.5-mi, 8-in. ID pipeline leads into the regional trunk line at D, where the gas must be delivered at 520 psig. Lease A produces 5 MMscfd of 0.65 gravity gas, while lease B produces 7 MMscfd of 0.68 gravity gas. What pressure should the gas be compressed to at (a) lease A and (b) lease B to enable delivery of gas to the trunk line? \$E = 0.92\$.

Assume a flowing temperature of 85°F, and horizontal flow system. \$P_{sc} = 14.73\$ psia, \$T_{sc} = 60^\circ\text{F}\$.

- AC = 4.5 mi, ID = 5 in.,
- Q = 5 MMscfd
- BC = 3.8 mi, ID = 5 in.,
- Q = 7 MMscfd
- CD = 11.5 mi, ID = 8 in.

First, the pressure at point C is necessary to find:

$$SG_{gav} = \frac{5 \times 0.65 + 7 \times 0.68}{12}$$

$$= 0.6675$$

Apply the Weymouth equation for section C–D;

$$SG_{gav} = 0.6675, \quad T_{pc} = 378^\circ\text{R}, \quad P_{pc} = 668 \text{ psia}$$

$$Z = 0.91$$

$$12 \times 10^6 = 433.5 \left(\frac{520}{14.73} \right)$$

$$\times \left[\frac{P_1^2 - (534.73)^2 8^{16/3}}{(0.6675)(11.5)(545)(0.91)} \right]^{0.5} 0.92$$

\$P_1\$ corresponds to \$P_c\$
 \$P_c = 572.8\$

Section B–C

$$SG_g = 0.68, \quad T_{pc} = 384^\circ R, \quad P_{pc} = 668 \text{ psia} \\ Z = 0.9$$

$$7 \times 10^6 = 433.5 \left(\frac{60 + 460}{14.73} \right) \\ \times \left[\frac{(P_B^2 - 572.8^2) 5^{16/3}}{(0.68)(0.9)(545)(3.8)} \right]^{0.5} 0.92$$

$$P_B = 621.8 \text{ psia}$$

Section A–C

$$SG_g = 0.65, \quad T_{pc} = 373^\circ R, \quad P_{pc} = 670 \text{ psia}, \quad Z = 0.9$$

$$5 \times 10^6 = 433.5 \left(\frac{60 + 460}{14.73} \right) \\ \times \left[\frac{(P_A^2 - 572.8^2) 5^{16/3}}{(0.65)(0.9)(545)(4.5)} \right]^{0.5} 0.92$$

$$P_A = 601.6 \text{ psia}$$

Example 6.7.27

A portion of a large gas-gathering system consists of a. ID line 9.4 mi long, handling 7.6 MMscfd of gas 0.64 gravity. The pressure at the upstream end of this section is 375 psig and the average delivery pressure is 300 psig. The average temperature is 73°F. Due to new well completions, it is desired to increase the capacity of this line by 20% by looping with additional 6.067-in. pipe. What length is required?

From Table 6.7.29, if the Weymouth equation is used, then

$$X_f = \frac{1 - \left(\frac{Q_1}{Q_2} \right)^2}{1 - \left(\frac{D_1^{8/3}}{D_1^{8/3} + D_2^{8/3}} \right)^2} = \frac{1 - \left(\frac{1}{1.2} \right)^2}{1 - \left(\frac{6.067}{6.067 + 6.067} \right)^2} \\ = 0.4074$$

The length of looping pipe required = $0.4074 \times 9.4 = 3.83$ mi.

6.7.15 Compressor Stations

A compressor station is one of the most important elements in a natural gas pipeline system. Compressor stations supply the energy to pump gas from production fields, overcome frictional losses in transmission pipeline and pump gas into storage reservoirs.

Depending on its purpose, a compressor station generally falls into one of three distinct classifications: pro-

duction, storage and transmission. Compressors are used whenever it is necessary to flow gas from a lower pressure to a higher pressure system. The differential pressure is expressed in terms of overall compressor ratio, R_T , which is defined as follows:

$$R_T = \frac{P_d}{P_s} \quad (6.7.46)$$

where R_T = overall compression ratio

P_d = discharge pressure, psia

P_s = suction pressure, psia

Production stations are used in the natural gas production field to pump gas from the well head to the pipeline system. They usually are designed for unattended operation with a life expectancy comparable to that of the production field. Unitized, skid-mounted, medium to high-speed, packages compressor units in the 50 to 1,000 hp (35 to 745 kW) range are often utilized for this type of service. Operating pressure in production systems vary widely. The suction pressure could be as high as 1,000 psig (6,900 kpa).

Storage stations are used primarily to pump gas from a transmission pipeline into an underground storage field during the injection period. In addition to injecting gas during the storage season, some are used to pump gas from the storage field to the pipeline during the withdrawal period. Most storage field compressors are designed to operate over a broad range of volumes and pressures. A typical storage station would contain several reciprocating compressor units ranging in size from 1,000 to 6,000 hp (745 to 4,475 kW) each.

Transmission stations are the most common type. They generally contain several large compressors units at one location, each having a power rating of 1,000 to 2,000 hp. Their purpose is to move gas in the transmission pipeline from one station to the next. Operating pressures seldom exceed 1,000 psig (6,900 kpa). Designed for long life, 50 years or more, and intended to operate year-round.

Independent of compressor stations, three types of compressors are used: reciprocating, centrifugal and axial. See Figure 6.7.48. Reciprocating compressors are considered for applications where the inlet gas rate is about 3,000 acfm or less. They are favored for low-flow, high pressure service, compression ratio 2:1 to 4:1. They are available in sizes up to 15,000 hp (11,190 kw).

Centrifugal compressors are used for an inlet gas rate 500 to 200,000 acfm, low compression ratio 1.1:2 and range of power 1,000 to 30,000 hp (746 to 22,380 kw).

For axial-flow compressors, with an inlet gas rate of 75,000 to 600,000 acfm, smaller axial compressors are available (down to 20,000 acfm), but centrifugal compressors are preferred at these capacities. Axial compressors are more efficient than centrifugal compressors.

FIGURE 6.7.48 Approximate ranges of application for reciprocating, centrifugal, and axial flow compressors.

6.7.15.1 Reciprocating Compressor Calculations

Figure 6.7.48 illustrates the ideal compression cycle on a pressure-volume cycle. [18]. The events of this cycle are as follows:

- *Compression (points 1 to 2)*—The piston has moved to the left, reducing the original volume of gas with an accompanying rise in pressure. Valves remain closed. The P-V diagram shows compression from point 1 to point 2 and the pressure inside the cylinder has reached that in the receiver.
- *Discharge (points 2 to 3)*—The discharge valves are opened just beyond point 2. Compressed gas is flowing out through the discharge valves to the receiver. After the piston reaches point 3, the discharge valves will close, leaving the clearance space filled with gas at discharge pressure.
- *Expansion (point 3 to 4)*—During the expansion stroke, both the inlet and discharge valves remain closed and gas trapped in the clearance space increases in volume, causing a reduction in pressure. This continues as the piston moves to the right, until the cylinder pressure drops below the inlet pressure at point 4.
- *Suction (point 4 to 1)*—At point 4 the suction valve opens and permits gas at suction pressure to enter the cylinder as the piston moves from point 4 to point 1.

To determine the quantity of gas that a specific compressor can pump, the displacement volume of gas at suction conditions and suction volumetric efficiency must be known. The displacement of a compressor is expressed in cubic feet per minute (ft.³/min), cubic feet per second (ft.³/s) or in cubic meters per second (m³/s).

Figure 6.7.49 shows the cycle as related to a single-acting compressor (compression occurs only on one end of the piston). Most reciprocating compressors in the gas industry are double-acting. Gas is compressed alternately on each end of the piston.

For single acting compressors:

$$PD = \frac{A_H \times L \times M}{1,728} \quad (\text{ft.}^3/\text{min}) \quad (6.7.47)$$

or

$$PD = \frac{A_H L N}{6 \times 10^9} \quad (\text{m}^3/\text{s})$$

For double-acting compressors:

$$PD = \frac{(A_H + A_c) \times L \times N}{1,728} \quad (\text{ft.}^3/\text{min}) \quad (6.7.48)$$

or

$$PD = \frac{(A_H + A_c) \times L \times N}{6 \times 10^9} \quad (\text{m}^3/\text{s})$$

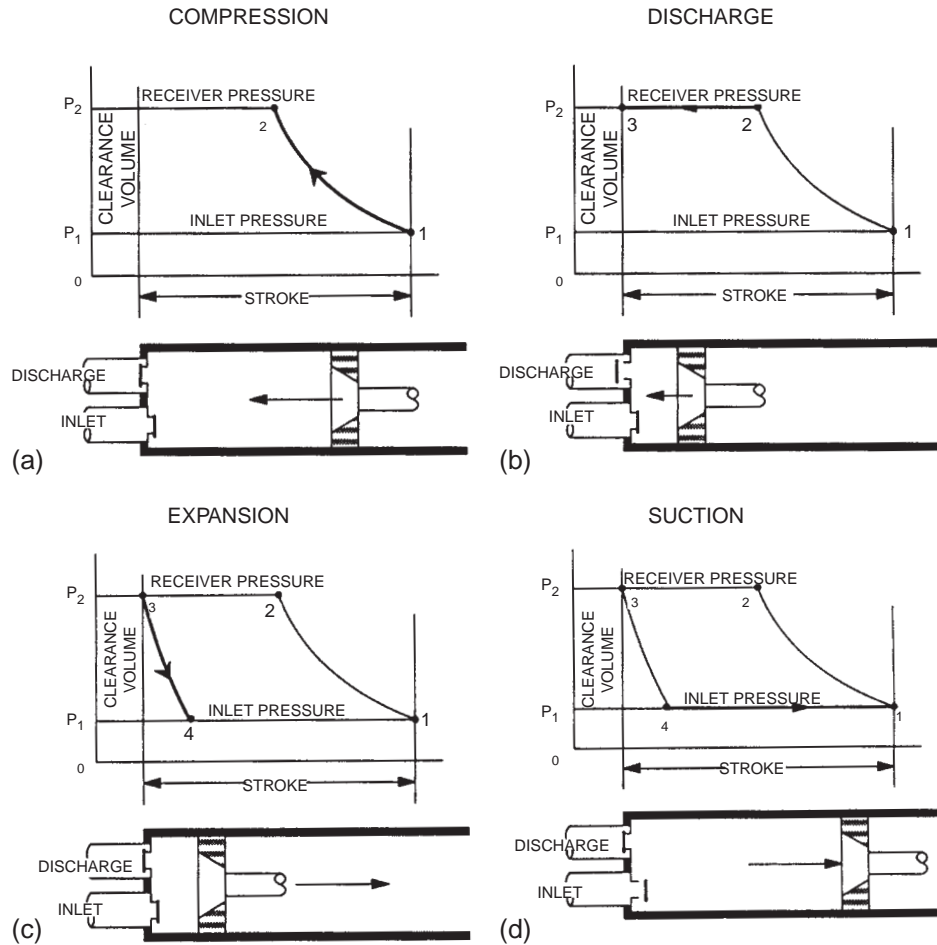

FIGURE 6.7.49 P-N diagram illustrating ideal reciprocating compression of gases.

where PD = piston displacement in ft.³/min or m³/s
 A_H = area of head end of the piston in in.²
 or mm²
 L = length of stroke in in. or mm
 N = compressor rotation speed in rpm
 A_c = area of crank end of the piston in in.²
 or mm²

Most compressor manufacturers publish data listing displacement at full compressor speed for each size cylinder that is manufactured.

Volumetric efficiency E_v , is the ratio (%) of the actual delivered volume flow rate (at inlet conditions) to the piston displacement. The volumetric efficiency factor may be calculated as follows:

$$E_v = 100 - L - Cl \times \left[\frac{Z_s}{Z_d} \left(\frac{P_d}{P_s} \right)^{1/k} - 1 \right] \quad (6.7.49)$$

where E_v = volumetric efficiency factor in %
 Cl = cylinder clearance expressed as a percentage of piston displacement
 P_d = pressure at the discharge flange in psia or kPa
 P_s = pressure at the suction flange in psia or kPa
 k = ratio of specific heat capacities (adiabatic exponent), C_p/C_v
 L = volumetric efficiency correction factor in %, $L = P_d/P_s$
 Z_s = compressibility factor at suction conditions
 Z_d = compressibility factor at discharge conditions
 P_d/P_s = r, the compression ratio

Compressor cylinder capacity Q may be found from the following:

$$Q = PD \times E_v \times P_s/P_a \times 14.4 \times 10^{-6} \text{ (MMscf/d)} \quad (6.7.50)$$

or

$$Q = PD \times E_v \times P_s/P_a \times 864 \text{ (m}^3\text{/d)}$$

where Q = cylinder capacity in desired units at the prevailing inlet temperature and the base suction pressure in MMscf/d or $\text{m}^3\text{/d}$

P_a = base reference pressure in psia or kPa

PD, E_v, P_s are as in Equation 6.7.49

If the base reference pressure is 14.4 psia (99 kPa), the cylinder capacity at the base reference pressure and prevailing temperature is:

$$Q = PD \times E_v \times P_s \times 10^{-6} \text{ (MMscf/d)} \quad (6.7.51)$$

or

$$Q = PD \times E_v \times P_s \times 8.73 \text{ (m}^3\text{/d)}$$

Q represents the actual displaced quantity of gas in MMscf/d ($\text{m}^3\text{/d}$), corrected only for pressure to a base of 14.4 psia (99 kPa) at the prevailing suction temperature. According to ISO 5024, scm has only one set of reference conditions: $P_a = 101.325$ kPa and $T = 15^\circ\text{C}$. in the United States, $T = 15.5^\circ\text{C}$ (60°F) and pressure differ in the various industries.

$$Q_{\text{std}} = \frac{Q \times P_a \times T_b}{Z_s \times P_b \times T_s} \quad (6.7.52)$$

where

Q_{std} = rate of flow in MMscf/d or scm/d

Q = rate of flow in MMcf/d or $\text{m}^3\text{/d}$

P_a = reference base pressure in psia or kPa

P_b = pressure base or standard pressure in psia or kPa

T_b = temperature base or standard in $^\circ\text{R}$ (K)

T_s = suction temperature in $^\circ\text{R}$ (K)

Z_s = compressibility factor at inlet conditions

For power P , many methods are available to determine the power required to compress a given volume of gas between two levels. The theoretical adiabatic power requirement, taking volumetric efficiency into account, can be calculated as follows:

$$P_{\text{ad}} = 4.3636 \times 10^{-5} \times P_s \times PD \times k/k - 1 [r^{(k-1)/k} - 1] E_v \quad (6.7.53a)$$

where P is in hp or, in the SI system

$$P_{\text{ad}} = 1.6672 \times 10^{-4} \times P_s \times PD \times k/k - 1 [r^{(k-1)/k} - 1] E_v \quad (6.7.53b)$$

where P is in kw.

If compressor capacity is given in mass flow rate, then for case I,

$$V_1 = V_s \rightarrow Z_1 = Z_s = 1$$

$$P_{\text{ad}} = 0.2618 \times P_s \times V_s \times k/k - 1 [r^{(k-1)/k} - 1] \quad (6.7.54a)$$

where P_{ad} power is in hp

P_s suction pressure is in psia

V_s flow rate at suction is in scf/s

And in the SI system;

$$P_{\text{ad}} = P_s \times V_s \times k/k - 1 [r^{(k-1)/k} - 1] \quad (6.7.54b)$$

where P_{ad} = power in kw

P_s = suction pressure in kPa

V_s = (scm/s) = flow rate at suction (scm/s)

$V_s = V_s \text{m}(\text{kg/s} \times \text{m}^3/\text{kg}) \rightarrow (\text{m}^3/\text{s})$

For case II

$$V_1 \neq V_s \rightarrow Z_1 \neq Z_s$$

$$P_{\text{ad}} = \text{const } V_s (P/T)_{\text{sc}} T_s Z_{\text{avg}} (k/k - 1) (r^{(k-1)/k} - 1) \quad (6.7.55)$$

where const = 0.2618 for the English system

= 1.0 for the SI system

V_s = is in scf/s or scm/s

P, T = standard conditions in psia, $^\circ\text{R}$ or kPa, K

T_s = suction temperature in $^\circ\text{R}$ or K

$Z_{\text{avg}} = (Z_s + Z_D)/2$

$T_D = T_s [(P_d/P_s)^{k-1/k}]$

The actual brake horsepower (ABHP), or the power to the shaft, is calculated as:

$$\text{ABHP} = \frac{P_{\text{ad}}}{\eta_{\text{ad}} \eta_{\text{m}}} = \frac{P_{\text{ad}}}{\eta_{\text{t}}} \quad (6.7.56)$$

The adiabatic efficiencies for commercial machines are as follows [19]:

- 0.83 to 0.94 for a cylinder of a reciprocating compressor
- 0.60 to 0.65 for Roots blower
- 0.80 to 0.85 for a screw-type rotary compressor

Compression ratio (Equation 6.7.46), $R_T = P_d/P_s$, when this value is higher than 3.5; a multiple-stage machine may have to be used. There are several reasons for considering multistage compression systems:

- to avoid high temperatures [180°C – 200°C (350°F to 380°F)]
- to optimize the mechanical design of the compressor
- to minimize compression power

The total power is a minimum when the ratio in each stage is the same.

$$R_{\text{opt}} = (R_T)^{1/s} = (P_d/P_s)^{1/s}$$

where s = number of stages required

R_{opt} = optimum compression ratio per stage

If intercoolers are provided between the stages, reduce the theoretical intake pressure of each stage by about 3%, so

$$R_{\text{opt}} = (r_T/0.97)^{1/s} \quad (6.7.57)$$

Example 6.7.28

A compressor station is to handle 54 MMscfd of 0.65 relative density gas. Suction temperature will be 70°F and suction pressure 190 psia (Figure 6.7.50). Discharge pressure will be 1,500 psia. Calculate the brake horsepower required for two-stage compression with intercooling at 70°F. Other data observed: $\eta_{\text{ad}} = 0.85$, $\eta_{\text{m}} = 0.97$, $T_{\text{sc}} = 60^\circ\text{F}$, $P_{\text{sc}} = 14.5$ psia.

$$\text{Flow rate } V = 54 \times 10^6 \text{ scf/day} = 625 \text{ scf/s}$$

$$SG_g = 0.65$$

$$T_s = 70^\circ\text{F} = 530^\circ\text{R}$$

$$P_s = 190 \text{ psia} \quad P_d = 1,500 \text{ psia}$$

1. Single-stage compression, from Equation 6.7.55, is calculated by

$$P_{\text{ad}} = 0.2618V(P/T)_{\text{sc}} T_s Z_{\text{avg}} k/k - 1 [(P_d/P_s)^{k-1/k} - 1]$$

$$Z_{\text{avg}} = (Z_s + Z_d)/Z$$

$$M = 28.96 \times 0.65 = 18.8$$

For the given molecular mass

$$P_{\text{pc}} = 674 \text{ psia}, \quad T_{\text{pc}} = 324^\circ\text{R}$$

$$P_r = 190/674 = 0.282, \quad T_r = 530/324 = 1.64,$$

$$Z_s = 0.97$$

$$T_d = 530(1500/190)^{(k-1)/k} \quad k = 1.26 \text{ (from}$$

Figure 6.5.50)

$$\text{if } T = 530^\circ\text{R}$$

$$T_d = 811.8^\circ\text{R}$$

$$P_r = 1500/674 = 2.23, \quad T_r = 811.8/324 = 2.51,$$

$$Z_d = 0.99$$

$$Z_{\text{avg}} = \frac{0.97 + 0.99}{2} = 0.98$$

$$T_{\text{avg}} = \frac{70 + 352}{2} = 211^\circ\text{F}$$

$$k = 1.23 \text{ (from Figure 6.5.50)}$$

$$P_{\text{ad}} = 0.2618 \times 625 \left(\frac{14.5}{520} \right) 530(0.98) \frac{1.23}{1.23 - 1}$$

$$\times \left[\left(\frac{1,500}{190} \right)^{0.23/1.23} - 1 \right] = 5,977$$

$$\text{ABHP} = \frac{5,977}{\eta_{\text{ad}}\eta_{\text{m}}} = \frac{5,977}{(0.85)(0.97)} = 7,249$$

2. Two-stage compression is calculated by

$$r_t = \frac{1,500}{190} = 7.89 \text{ total compression ratio}$$

$$r_{\text{opt}} = (7.89/0.97)^{0.5}$$

$$= 2.85 \text{ compression ratio per stage with intercoolers}$$

The calculation for the first stage:

$$P_{d1} = rP_{s1} = 2.85 \times 190 = 541.9$$

For

$$T_s = 70^\circ\text{F} \quad k = 1.26$$

$$T_d = 530 \left(\frac{541.9}{190} \right)^{0.26/1.26} = 658^\circ\text{R} = 198^\circ\text{F}$$

For

$$T_m = \frac{70 + 198}{2} = 134^\circ\text{F}(294^\circ\text{R}) \quad k \cong 1.26$$

$$Z_s = 0.97$$

$$P_{\text{ad}} = 0.2618 \times 6.25 \left(\frac{14.5}{520} \right) 530(0.97)$$

$$\times \frac{1.26}{0.26} \left[\left(\frac{541.9}{190} \right)^{1.26-1} - 1 \right]$$

$$= 2,744.4 \text{ hp}$$

$$\text{ABHP} = \frac{P_{\text{ad}}}{\eta_{\text{ad}}\eta_{\text{m}}} = \frac{2,744.4}{(0.85)(0.97)} = 3,328.6 \text{ hp}$$

The calculation for the second stage:

Because of intercooling

$$T_s = 70^\circ\text{F} = 530^\circ\text{R} \quad P_s = 541.9 \quad k = 1.24$$

$$T_d = T_s \left(\frac{1,500}{541.9} \right)^{(1.24-1)/1.24} = 85.2^\circ\text{F}$$

$$T_{\text{avg}} = \frac{85.2 + 70}{2} = 77.6 \quad k = 1.27$$

$$P_r = \frac{(1,500 + 541.9)/2}{674} = 1.515$$

$$T_r = \frac{77.6 + 460}{324} = 1.66$$

FIGURE 6.7.50 Approximate specific heat capacity ratios of hydrocarbon gases.

$$Z_{avg} = 0.9$$

$$H_{ad} = 0.2618 \times 625 \left(\frac{14.5}{520} \right) 530(0.9) \times \frac{1.27}{1.27 - 1} \left[\left(\frac{1,500}{541.9} \right)^{0.27/1.27} - 1 \right] = 2,473.9 \text{ hp}$$

$$ABHP = \frac{2,473.9}{0.85 \times 0.97} = 3,000.54$$

$$\text{Total ABHP} = 3,000.54 + 3,328.6 = 6,329.1 \text{ hp}$$

Example 6.7.29

A branch pipeline is to move 40.0 MMscf/d of 0.69 relative density gas from a junction on the main line to a city, a distance of 100 mi. The line will be a 10-in. line (internal diameter 9.562 in.). The gas will enter the branch line at a pressure of 750 psia and is to be delivered to the city gate at a pressure of 80 psia. The flowing temperature will be 50°F. Pressure on the pipeline is not to exceed 1,000 psia. One

compressor station will be needed. If the compressor station should be located at the midpoint of the branch line, what would the required brake horsepower be? Where should the compressor station be located for the minimum horsepower requirements? Assume that $Z = 1.0$, $k = 1.30$, $E = 1.0$, $\eta_{ad} = 0.85$, $\eta_m = 0.97$, $T_{sc} = 60^\circ\text{F}$, $P_{sc} = 14.696 \text{ psia}$.

1. Solve the Weymouth equation if the compressor is in the midpoint:

$$P_s = ?$$

$$40 \times 10^6 = 433.5 \left(\frac{519.67}{14.696} \right) \times \left[\frac{(9.562)^{16/3} (750^2 - P_s^2)}{0.69100(509.67)(1)} \right]^{0.5} \times 1.0$$

$$(1,188.16)^2 = 750^2 - P_s^2$$

It is impossible.

2. At what point downstream reaches 80 psia?

$$40 \times 10^6 = 433.5 \left(\frac{519.67}{14.696} \right) \times \left[\frac{(9.562)^{16/3} (750^2 - 80^2)}{0.69(509.67)(X) \times 1} \right]^{0.5}$$

$$X = 39.4 \text{ mi}$$

3. What is the minimum discharge pressure for compressors?

$$40 \times 10^6 = 433.5 \left(\frac{519.67}{14.696} \right) \times \left[\frac{(9.562)^{16/3} (P_d^2 - 80^2)}{0.69(509.67)(100 - 39.4)} \right]^{0.5} \quad (1)$$

$$P_d = 928.3 \text{ psia}$$

$$\text{ABHP} = \frac{0.2618(1.3)463 \times 14,696 \times 509.67}{(0.3)(0.85)(0.97)(519.67)} \times \left[\left(\frac{928.3}{80} \right)^{0.3/1.3} - 1 \right]$$

$$= 6,984.6 \text{ hp}$$

To minimize ABHP it is necessary to use stage-2 compressors because $r = 11.6$ and maximum r should not be higher than 6.

Alternative Solution

The equation for the upstream section is

$$40 \times 10^6 = \frac{433.5(519.67)}{14.696} \times \left[\frac{(9.562)^{16/3} (750^2 - P_s^2)}{(0.69)(509.67)(1)X} \right]^{0.5} \quad (1.0)$$

$$6,800,709X = 482.14(750^2 - P_s^2)$$

$$14,105.3X = 750^2 - P_s^2$$

The equations for the downstream section are

$$40 \times 10^6 = 14,338.5 \left[482.14 \frac{P_d^2 - 80^2}{100 - X} \right]^{0.5} \quad (1.0)$$

$$14,105.3(100 - X) = P_d^2 - 80^2$$

$$P_d^2 = 1,416,930 - 14,105.3X$$

Solving these two equations gives

$$14,105.3X = 1,416,930 - P_d^2$$

$$= 750^2 - P_s^2$$

$$\text{If } P_s = 80, P_d = 927.8$$

$$\text{If } P_d = 1,000, P_s = 381$$

$$\text{ABHP} = \frac{0.2619(1.3)(463)(14,696)(509.67)}{(0.3)(0.85)(0.97)(519.67)} \times \left[\left(\frac{1,000}{381} \right)^{0.3/1.3} - 1 \right]$$

$$= 2,790$$

The minimum hp requirement for suction pressure to compressor will be 381 psia. It corresponds to X equal to

$$14,105.3X = 750^2 - 381^2 = 417,339$$

$$X = 29.58 \text{ mi}$$

6.7.15.2 Using Mollier Charts for Compressor Calculations

Mollier charts are forms in which gas properties such as pressure, specific volume, temperature, entropy and enthalpy are presented. Gases are generally plotted as pressure against enthalpy or enthalpy-entropy. The enthalpy-entropy plot is a good technique for solving compression problems (isentropic compression). The key assumptions in this approach are that the process is adiabatic, $Q = 0$,

$$W = \Delta H = n(h_2 - h_1) \quad (6.7.58)$$

where

W = work done by compressor on the gas in Btu or kJ

ΔH = change in enthalpy of the gas in Btu or kJ

n = number of moles of gas being compressed in lb mole or kmol

h_1, h_2 = enthalpies of the gas at the compressor inlet and discharge, respectively, in Btu/lb mole or kJ/kmol

Necessary data include inlet gas rate, pressure, temperature and composition plus outlet pressure. The corresponding outlet temperature is found from these data by assuming $S_1 = S_2$, using an iterative process.

Figure 6.7.51 shows a qualitative sketch of an enthalpy-entropy chart, illustrating two-stage compression with intercoolers and aftercoolers. Point 1 is the initial state of the gas as it enters the compressor. Path 1-2 shows the first stage of compression. The gas is then cooled in the intercoolers at constant pressure, path 2-3; the difference in enthalpy along this path is equal to the heat removed in the intercoolers. Path 3-4 shows the second stage of compression. Path 4-5 shows cooling at a constant pressure in the aftercoolers. The temperatures at points 2 and 4 are the temperatures of the

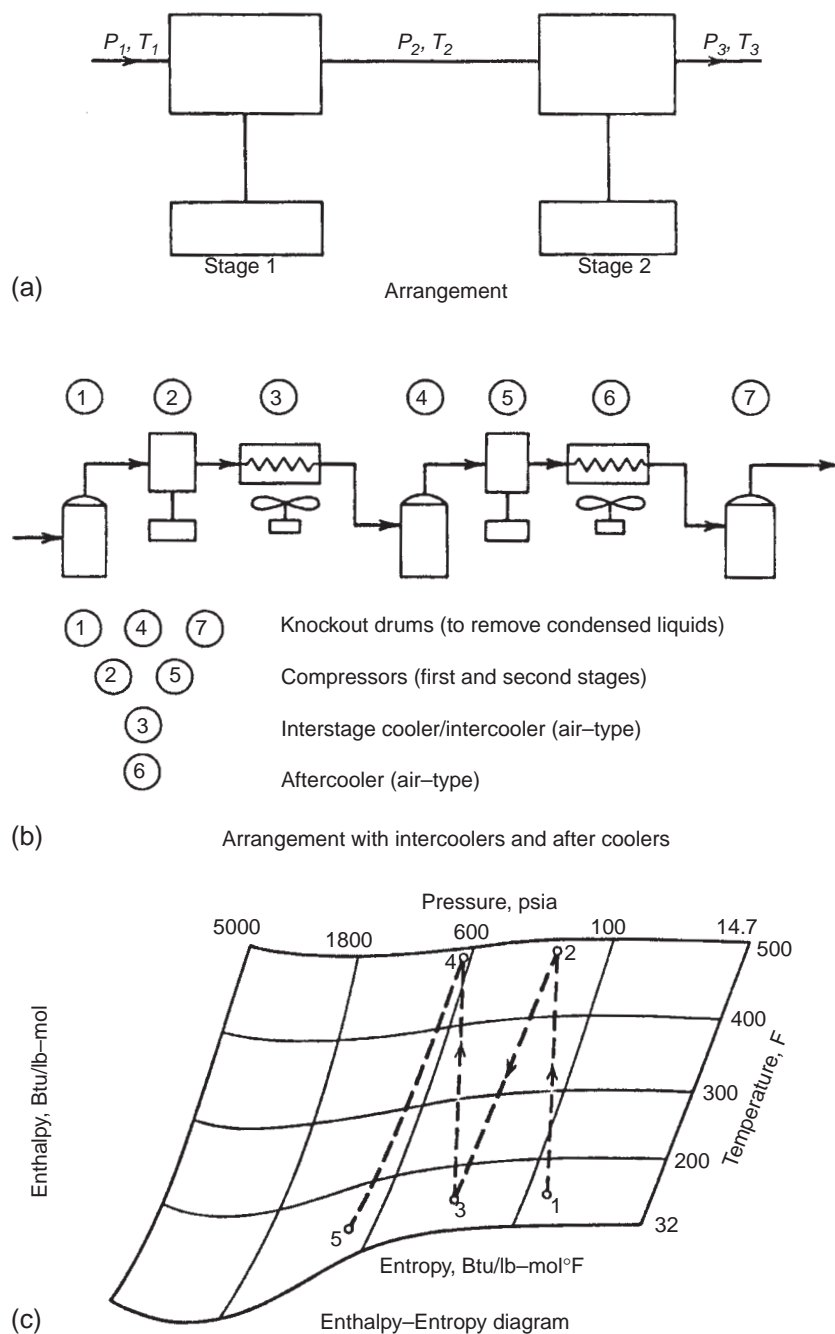

FIGURE 6.7.51 Two-stage compression.

gas at the end of the first and second stages of compression. The temperatures at points 3 and 5 are the temperatures to which the gas is cooled in the intercoolers and aftercoolers. The ideal compression power (or rate of work) required is given by:

$$P = \frac{W}{t} = \frac{n(h_2 - h_1)}{t} \quad (6.7.59)$$

where

P = compression power required in Btu/day or kJ/day
 t = time for compression in days

$$\text{Power Requirement} = \text{Btu/day} \rightarrow \text{HP}$$

$$\text{HP} = \frac{1 \text{ hp}}{33,000 \text{ ft.lbf/min}} \frac{778.2 \text{ ft.lbf/min}}{\text{Btu/min}}$$

$$\begin{aligned} & \times \frac{n(h_2 - h_1)/t \text{ Btu/d}}{1,440 \text{ min/d}} \\ & = 1.6376 \times 10^{-5} \frac{n(h_2 - h_1)}{t} \end{aligned}$$

Example 6.7.30

A reciprocating compression system is to be designed to compress 10 MMscfd from 100 psia and 80°F to 2,200 psia of the gas as follows: $C_1 = 0.9233$, $C_2 = 0.0488$, $C_3 = 0.0185$, $i-C_4 = 0.0039$, $n-C_4 = 0.0055$. The gas is cooled with intercoolers and aftercoolers to 120°F.

Find:

- molecular mass of gas and compression ratio
- brake hp using the analytical method
- brake hp using Mollier diagram method
- estimate the cooling requirements from the results of part (c)
- From the results of part (c), determine whether the first stage can be handled by a compressor with a speed of 1,200 rpm, piston diameter of 12 in. and stroke length of 3 ft. Assume that $\eta_t = 0.82$, $CL = 0.08$, $Z_s = Z_D = 1.0$

(A) For given composition calculate molecular mass

$$\begin{aligned} M &= \sum Y_i M_i = 17.64 \text{ lb}_m/\text{lb mole} \\ SG_g &= \frac{17.64}{28.97} \cong 0.61 \\ T_{pc} &= 363^\circ\text{R} \quad P_{pc} = 668 \end{aligned}$$

Using $P_s = 100$ psia, $T_s = 80^\circ\text{F}$, We find T_r and P_r and use charts

$$Z_s = 0.985, k = 1.28 \text{ at } T = 80^\circ\text{F} \text{ (from Figure 6-36)}$$

Compression ratio is calculated from

$$r = \frac{P_d}{P_s} = \frac{2,200}{100} = 22$$

Assuming two-stage compression

$$r_{opt} = (22)^{0.5} = 4.69$$

if intercooling is not provided or

$$r_{opt} = (22/0.97)^{0.5} = 4.76$$

if intercooling is provided.

(B) Brake horsepower using the analytical method, two-stage compression with intercooling, is calculated:

$$\begin{aligned} P_{ad} &= 0.2618Q \left(\frac{P}{T} \right)_{sc} T_s Z_{avg} \left(\frac{k}{k-1} \right) (r^{(k-1)/k} - 1) \\ Q &= 10 \text{ MMscfd} = 115.7 \text{ scf/s} \end{aligned}$$

$$P = 14.7 \quad T = 520$$

$$T_d = T_s \left(\frac{P_d}{P_s} \right)^{(k-1)/k} = 540 \left(\frac{476}{100} \right)^{0.28/1.29} = 760$$

$$T_{avg} = \frac{540 + 760}{2} = 650^\circ\text{R} = 190^\circ\text{F}$$

$$\text{for } T_{avg} = 190^\circ\text{F} \quad k = 1.26$$

$$\begin{aligned} P_{ad} &= 0.2618(115.7) \left(\frac{147}{520} \right) 540(1) \left(\frac{1.26}{1.26-1} \right) \\ & \quad \times (4.76^{0.26/1.26} - 1) \\ &= 851.1 \text{ hp} \end{aligned}$$

Stage II

$$T_D = 580 \left(\frac{2,200}{476} \right)^{0.26/1.26} = 795^\circ\text{R}$$

$$T_{avg} = \frac{580 + 795}{2} = 688^\circ\text{R} = 228^\circ\text{F}$$

$$k = 1.25 \quad \text{for } T_{avg} = 228^\circ\text{F}$$

$$\begin{aligned} P_{ad} &= 0.2618(115.7) \left(\frac{14.7}{520} \right) (580)(1) \left(\frac{1.25}{0.25} \right) \\ & \quad \times (4.62^{0.26/1.26} - 1) \\ &= 922.4 \text{ hp} \end{aligned}$$

$$ABHP = \frac{851.1 + 922.4}{\eta_t} = \frac{1,773.5}{0.82} = 2,163 \text{ hp}$$

(C) Brake horsepower using the Mollier diagram (use any H-S chart for natural gas with $\gamma_g = 0.61$) is calculated.

At the first stage:

$$P_1 = 100 \text{ psia at } 80^\circ\text{F} \text{ and } P_2 = 476 \text{ psia}$$

when

$$\begin{aligned} \Delta h_{1-2} &= h_2 - h_1 = 2,200 - 400 \\ &= 1,800 \text{ Btu/lb mol} \end{aligned}$$

Cooling in intercoolers at constant pressure of 476 psia to $T = 580^\circ\text{R}$ (120°F) is calculated as

$$\Delta h_{2-3} = h_3 - h_2 = 600 - 2,200 = -1,600 \text{ Btu/lb mol}$$

At the second stage:

$$\begin{aligned} P_s &= 2,200/4.76 = 462 \text{ at } 120^\circ\text{F} \quad P_D = 2,200 \text{ psia} \\ \Delta h_{3-4} &= h_4 - h_3 = 2,900 - 600 = 2,300 \text{ Btu/lb mol.} \end{aligned}$$

Cooling in aftercooler at constant pressure of 2,200 psia is

$$\begin{aligned} \Delta h_{5-4} &= h_5 - h_4 = -200 - 2,900 \\ &= -3,100 \text{ Btu/lb mol} \end{aligned}$$

Gas flow in number of moles is

$$\frac{h}{t} = \frac{10 \times 10^6 \text{ scf}}{\text{day}} \frac{\text{lb mol}}{379.3 \text{ scf}} = 26,364 \frac{\text{lb mol}}{\text{day}}$$

$$\text{HP} = 1.6376 \times 10^{-5} \left(26,364 \frac{\text{lb mol}}{\text{day}} \right)$$

$$\times \left(1,800 \frac{\text{Btu}}{\text{lb mol}} + 2,300 \frac{\text{Btu}}{\text{lb mol}} \right) = 1,770$$

$$\text{ABHP} = \frac{1,700}{0.82} = 2,159$$

(D) The cooling requirements are the following:

Heat load on intercooler is

$$\Delta h_{2-3}(n) = \left(-1,600 \frac{\text{Btu}}{\text{lb mol}} \right) \left(26,364 \frac{\text{lb mol}}{\text{day}} \right)$$

$$= -4.218 \times 10^7 \text{ Btu/day} = -691 \text{ hp}$$

Heat load aftercooler is

$$\Delta h_{4-5}(n) = \left(-3,100 \frac{\text{Btu}}{\text{lb mol}} \right) \left(26,364 \frac{\text{lb mol}}{\text{day}} \right)$$

$$= -8.173 \times 10^7 \text{ Btu/day} = -1,338 \text{ hp}$$

Total cooling requirements are

$$-691 - 1,338 = -2,029 \text{ hp}$$

(E) From the results of part (D), determine whether the first stage can be handled by a compressor with a speed of 1,200 rpm from Equation 6.7.49:

$$E_r = 100 - L - \text{CI} \left[\frac{Z_s}{Z_d} \left(\frac{P_d}{P_s} \right)^{1/k} - 1 \right]$$

$$L = \frac{P_d}{P_s} = 4.76$$

$$E_v = 100 - 4.76 - 8 \left[\left(\frac{476}{100} \right)^{1/1.26} - 1 \right] = 75.6\%$$

From Equation 6-327a

$$\text{HP} = 4.3636 \times 10^{-5} \times 100 \times \text{PD}$$

$$\times \frac{1.26}{0.26} (4.76^{0.26/1.26} - 1) 76\% = 1,726.2$$

$$\text{PD} = \frac{A_H \times L \times N}{1,728} = \frac{\pi r^2 \times 36 \times 1,200}{1,728}$$

$$= 2,827.4 \text{ ft}^3/\text{min}$$

ANSWER

Yes, it can easily handle the necessary rate. The first-stage theoretical power needed is 851.1 hp using the analytical method; it is 777.1 hp using Mollier charts.

6.7.15.3 Centrifugal Compressors

Centrifugal compressors have become very popular because they offer more power per unit weight and are essentially vibration free. This makes them particularly attractive for offshore locations or where air transportation to remote locations is necessary. The performance of centrifugal compressors usually is measured and described in terms of head, volume flow, efficiency and power.

Head is a measure of the energy input per unit mass into the gas stream by the compressor. It is produced by the velocity changes in the gas flow resulting from the action of the impeller. Since the compressor geometry remains constant (as contracted with a reciprocating or positive-displacement compressor), a variation in flow will cause changes in velocity. This, in turn, causes a varying head. A compressor operating on a given gas at a fixed speed will produce a head versus volume flow relationship that essentially remains constant; that is, for each value of flow there is a corresponding value of head. Since head is produced by velocity changes that are dependent upon volume rather than gas properties or conditions, the characteristic head versus volume characteristic can be considered constant, the pressure ratio and volume changes vary greatly from one gas to another. Theoretical head may be calculated as follows:

$$H_{ad} = Z_s R T_s \frac{k}{k-1} \left[\left(\frac{P_d}{P_s} \right)^{(k-1)/k} - 1 \right]$$

where

H_{ad} = adiabatic head is in desired units,
ft \times lb/lb or J/kg

Z_s = compressibility factor at compressor suction conditions

k = mean ratio of specific heat capacities, c_p/c_v ,
where $k = (k_s + k_d)/2$

R = specific gas constant for a particular gas:
1545.3/M [ft \times lb/lb $^\circ$ R] or 8.314/M
[J/(kg \times K)]

M = molecular mass of gas in lb/(lb mol) or
kg/kmol

In the above equation, the value of the polytropic exponent "n" may be substituted for "k". This will yield a polytropic head, which more closely will represent the actual process. The polytropic exponent must be developed experimentally. It can be seen from the above equation that the head is dependent upon the ratio of specific heat capacities, molar mass of the gas, inlet temperature, and compression ratio. Conversely, the molar mass of the gas, inlet temperature, compressibility factor and k value determine the pressure ratio resulting from the head developed by a stage of compression.

6.7.15.4 Volume Flow Rate

Variations in volume flow rate affect the head developed by an impeller. The specific shape of the head-flow curve is a function of the stage geometry, that is, the inlet guide vane angle, impeller blade angle, and outlet diffuser construction. When describing centrifugal compressor performance, it is necessary to convert the mass flow in lb/h (kg/h), or volume flow in MMscf/d (scm/d) to actual volumetric rate at the inlet conditions. This is the volume of gas that actually is entering the eye of the impeller.

To convert the volumetric flow rate from reference conditions to suction conditions, the following is used:

$$Q_{\text{act}} = 694 Q_{\text{std}} \frac{P_b T_s}{P_s T_b} \quad (\text{ft.}^3/\text{min}) \quad (6.7.60a)$$

or

$$Q_{\text{act}} = 1.1574 \times 10^{-5} Q_{\text{std}} Z_s \frac{P_b T_s}{P_s T_b} \quad (\text{m}^3/\text{s}) \quad (6.7.60b)$$

where Q_{act} = actual inlet volumetric flowrate in desired units: $\text{ft.}^3/\text{min}$ or m^3/s at T_s, P_s

Q_{act} = volumetric flowrate at base conditions in MMscf/d or scm/d at T_b, P_b

When the original data are reported as mass flow per hour, the actual volumetric flowrate can be determined by multiplying the mass flowrate by the specific volume value [$\text{ft.}^3/\text{lb}$ (m^3/kg)] and dividing it by the appropriate factor to account for differences in time base [60 min/hr (3,600 s/hr)].

6.7.15.5 Power

The theoretical equation for gas hp or kw for a centrifugal compressor is as follows:

$$P_{\text{ad}} = 8.179 \times 10^{-5} H_{\text{ad}} Q_{\text{act}} \gamma_g \frac{P_s}{A_s T_s} \quad (6.7.61a)$$

and in the SI unit system

$$P_{\text{ad}} = H_{\text{ad}} Q_{\text{act}} S G_g \frac{P_s}{287 Z_s T_s} \quad (6.7.61b)$$

where P_{ad} = input power to the gas stream in desired units, hp or kw

$S G_g$ = gas relative density

To account for the aerodynamic losses, it is necessary to replace H_{ad} with H'/η' , where H'/η' is the adiabatic or polytropic head divided by the corresponding adiabatic or polytropic efficiency.

In addition to the aerodynamic losses, there are mechanical losses due to seal and bearing friction. For service design purposes, the mechanical losses for centrifugal and

rotary compressors over 1,000 hp (746 kW) can be assumed to be 35 hp (26 kW) for bearings and 35 hp (26 kW) for oil-type shaft seals; below that size, losses will amount to 1% to 3%. In any case, these losses are included in the mechanical efficiency factor. Therefore, the required shaft power is:

$$P_{\text{shaft}} = P/\eta_m \quad (6.7.62)$$

where P_{shaft} = compressor shaft input power in desired units, hp or kw

η_m = mechanical efficiency (0.97 to 0.99)

6.7.15.6 Comparison of Reciprocating and Centrifugal Compressors

The advantages of a centrifugal compressor over reciprocating machine are:

- lower installed first cost where pressure and volume conditions are favorable
- lower maintenance expense
- greater continuity of service and dependability
- less operating attention
- greater volume capacity per unit plot area
- adaptability to high-speed low-maintenance-cost drivers

The advantages of a reciprocating machine over a centrifugal machine are:

- greater flexibility in capacity and pressure range
- higher compression efficiency and lower power cost
- capability of delivering higher pressures
- capability of handling smaller volumes
- less sensitive to changes in gas composition and density

EXAMPLE 6.7.31

Perform centrifugal compressor calculations using the following data: $M = 18.3$, $P_{\text{inlet}} = 156$ psia, $T_{\text{inlet}} = 105^\circ\text{F}$, $Q_{\text{std}} = 12,000$ scfm, $P_{\text{discharge}} = 310$ psia. The base conditions are $P = 14.73$ psia, $T = 60^\circ\text{F}$

- Calculation of the compressibility factor Z_s and k

$$T_s = 105^\circ\text{F} = 565^\circ\text{R}$$

$$M = 18.3 = S G_g = 0.63$$

$$T_{\text{pc}} = 370^\circ\text{R}, \quad P_{\text{pc}} = 670 \text{ psia}$$

$$T_r = 565/370 = 1.53, \quad P_r = 156/670 = 0.233$$

$$Z_s = 0.98$$

$$k_s = 1.27 \text{ at } 565 \text{ (from Figure 6.7.48)}$$

$$T_d = T_s (P_d/P_s)^{(k-1)/k} = 565(1.99)^{0.27/1.27} = 654^\circ\text{R} \\ = 194^\circ\text{F}$$

$$k_d = 1.25 \text{ at } 194^\circ\text{F}$$

$$k = (k_s + k_d)/2 = 1.26$$

- The actual inlet capacity, using Equation 6.7.60a, is

$$Q_{\text{act}} = 694 \times 17.28 \times \frac{14.73}{156} \frac{565}{520} = 1,230.3 \text{ acfm}$$

- The theoretical head, using Equation 6.7.61, is

$$H_{\text{ad}} = Z_s R T_s (k/k - 1) [r^{(k-1)/k} - 1]$$

$$R = \frac{1,545.3}{M} = \frac{1,545.3}{18.3} = 84.44$$

$$H_{\text{ad}} = 0.98 \times 84.44 \times 565 \times \frac{1.26}{1.26 - 1} (1.99^{0.26/1.26} - 1)$$

$$= 34,570$$

- The theoretical power, is

$$P_{\text{ad}} = 8.179 \times 10^{-5} H_{\text{ad}} Q_{\text{act}} \gamma \frac{P_s}{Z_s T_s}$$

$$= 8.179 \times 10^{-5} \times 34,570 \times 1,230.3$$

$$\times 0.63 \frac{156}{0.98 \times 565} = 617 \text{ hp}$$

- Adiabatic efficiency $\eta_{\text{ad}} = 0.7$ mechanical efficiency assuming 0.98.
- The required shaft power is

$$P_{\text{shaft}} = \frac{P_{\text{ad}}}{\eta_{\text{ad}} \eta_m} = \frac{617}{0.7 \times 0.98} = 899.4 \text{ hp}$$

6.7.16 Engine and Compressor Foundation [18]

Machinery foundations are one of the most important aspects of compressor station engineering. Such factors as soil analysis, reinforced concrete design, and dynamics of foundation systems require particular attention. There are two basic types of foundations used for compressor units in the gas industry (Figures 6.7.52 and 6.7.53). The first is a simple concrete pad that is used for most small skid-mounted reciprocating units and for high-speed centrifugal compressors. The second incorporates a combination of reinforced block and mat concepts. The block and mat design is common for large, low or medium-speed reciprocating compressors. The block provides the required load distribution so that the allowable soil-bearing capacity is not exceeded. The following minimum data should be available to the foundation designer:

- total weight of the package
- base dimensions of the package
- operating speed of the machine
- radius of the crankshaft throws
- weight of the reciprocating parts

- length of the connecting rods
- weight of the unbalanced rotating parts

The base dimension of the concrete pad or block should be such that there is 6 to 12 inches of concrete beyond all sides of the base of the unit. Manufacturers have recommended from 0.091 to 0.141 yd³ of concrete per engine hp (0.093 to 0.144 m³/kw) for low speed machines. Manufacturers also recommend a foundation that is two to five times the weight of the machine.

The combined resonant frequency of the machine, foundation and soil system is next in importance.

$$f_n = \frac{1}{2\pi} \left(\frac{K \times g}{W_f + W_s} \right) \quad (6.7.63)$$

where

f_n = natural frequency of the foundation and soil system in Hz

K = spring constant of soil mass in lb/ft or kN/m

W_f = weight of machine and foundation in lb/ft or kN

W_s = weight of soil system in lb or kN

g = acceleration of gravity in 32.174 ft/s or 9.81 m/s²

The spring constant “k” is a function of Poisson’s ratio, shear modulus and the radius of the loading area. In general, the natural frequency of the system should be at least twice the frequency of the applied forces for low-speed units, or less than one-half of the resonant frequency for machine that operate at a frequency greater than the natural frequency of the system. The natural frequency of the foundation system can be decreased by:

1. increasing the weight of the foundation
2. decreasing the base area of the foundation
3. reducing the shear modulus of the soil
4. placing the foundation deeper into the soil

6.7.16.1 The Gas Piping System

The gas piping system in a compressor station includes the valving, pulsation control equipment, overpressure protection devices, cathodic protection facilities and structural supports to route the gas through the compressor and gas conditioning facilities. Figure 6.7.53 shows a schematic diagram of such a system at a small compressor station. Figure 6.7.54 gives a general flow diagram for a storage/withdrawal compressor operation. In designing the piping system the following items must be taken into consideration:

- operating pressure and capacity
- pressure drop
- gas velocity

FIGURE 6.7.52 Typical concrete pad compressor foundations.

- mechanical strength and composition of pipe materials or in the SI system
- temperatures
- effect of corrosion and erosion
- safety
- efficiency of operations
- economy of installation

Pressure drops in compressor station piping result from energy losses caused by friction between the gas and pipe wall and should not exceed 1 to 2% of the total station power requirements.

Gas velocity can be determined as follows:

$$V = \frac{127.3 \times 10^3 Q P_b T_f Z}{D^2 P_m T_b} \quad (6.7.64a)$$

$$V = \frac{14.73 Q P_b T_f Z}{D^2 P_f T_b} \quad (6.7.64b)$$

- where
- V = velocity in desired units in ft./min or m/s
 - Q = volume rate of flow in MMcf/d or m³/d
 - P_b = base pressure in lb/in.² or kPa absolute
 - T_f = flowing temperature in °R or K
 - Z = compressibility
 - D = diameter of pipe in in. or mm
 - P_f = flowing pressure in lb/in.² or kPa absolute
 - T_b = base temperature in °R or K

FIGURE 6.7.53 Concrete block and mat compression.

Gas piping used in compressor stations must be manufactured in compliance with the standards (DOT) Code, Title 49, Part 192. (See [Table 6.7.32](#)).

6.7.16.2 Gas Cooling

Gas cooling equipment is necessary in compressor stations to remove heat from the gas stream between stages of compression (intercoolers) or after the final stage of compression (aftercoolers). Heat exchangers are used to remove heat from gas streams, reduce cooling water temperature, lower oil temperature or to cool compressed air. Several types of gas coolers are available, but the aerial cooler is one of the most common. Aerial coolers make use of air to cool hot gas. There are two kinds: forced draft and induced draft (see [Figure 6.7.56](#)), [20].

The advantages of forced draft are:

- slightly lower horsepower since the fan is in cold air; horsepower varies directly as the absolute temperature
- better accessibility of mechanical compound for maintenance
- easily adaptable for warm air recirculation for cold climates.

The disadvantages of forced draft are:

- poor distribution of air over section

- greatly increased possibility of hot air recirculation, due to low discharge velocity from the sections and absence of stack
- low natural draft capability on fan failure due to small stack effect
- total exposure of tubes to sun, rain, and hail

The advantages of induced draft are:

- better distribution of air across section
- less possibility of the hot effluent air recirculating around to the intake of sections; the hot air is discharged upward at approximately 2.5 times the velocity of the intake or about 1,500 ft./min.
- less effect of sun, rain and hail, because 60% of the face area of the sections is covered
- increased capacity in the event of fan failure, since the natural draft stack effect is much greater with induced draft

The disadvantages of induced draft are:

- Higher horsepower since the fan is located in the hot air.
- Effluent air temperature should be limited 200°F to prevent potential damage to fan blades bearing, V belts, or other mechanical components in the hot air stream.
- The fan drive components are less accessible for maintenance, which may have to be done in the hot air generated by natural convection.

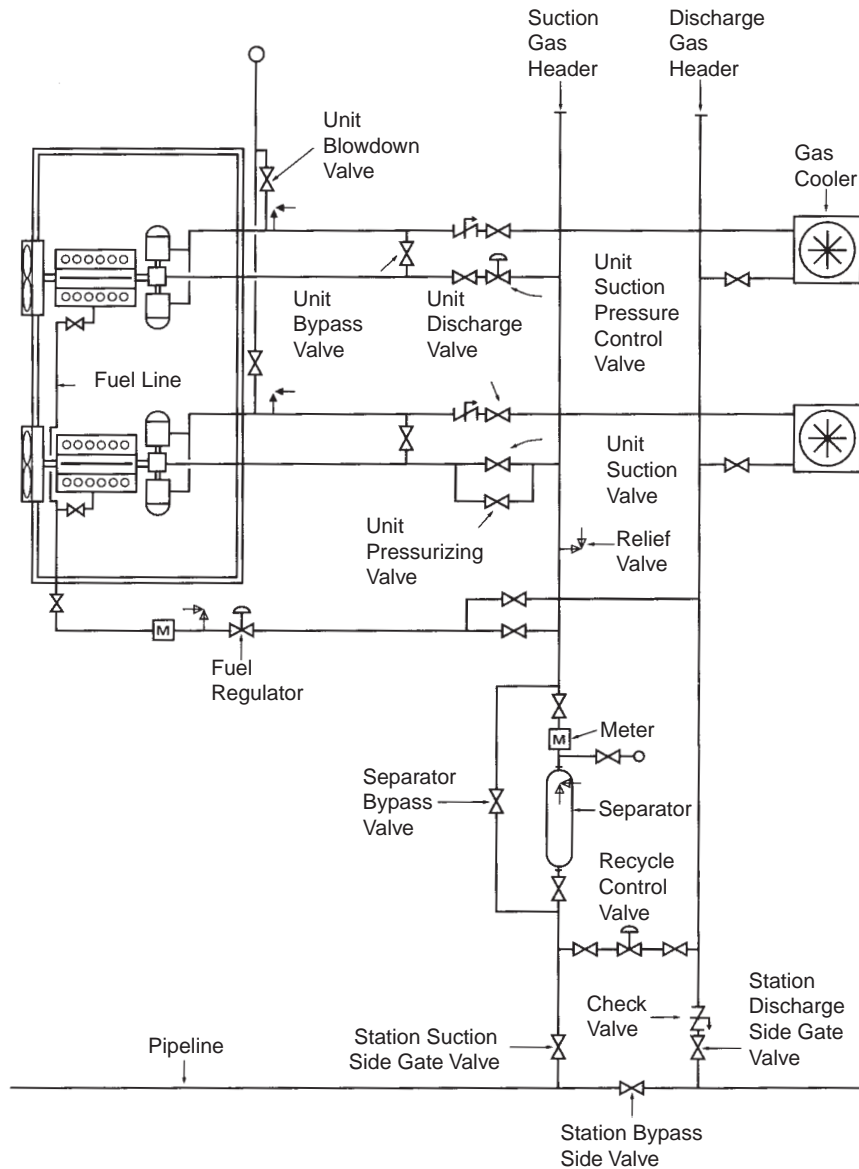

FIGURE 6.7.54 Foundation typical reciprocating compressor station piping.

- For inlet process fluids above 350°F forced draft design should be used: otherwise, fan failure could subject the fan blades and bearings to excessive temperature.

In sizing gas coolers the most important parameters are the actual heat load and design air temperature. The heat load may be found from the following:

$$Q_H = Q_{std} \rho C_p (t_1 - t_2) \quad \text{for SI units} \quad (6.7.65)$$

$$Q_H = Q_{std} \gamma C_p (t_1 - t_2) \quad \text{for English units} \quad (6.7.66)$$

where Q_H = heat load in desired units: Btu/n or W

Q_{std} = gas flow rate in scf/n or scm/s

C_p = specific heat capacity at average temperature $(T_s + T_d) / 2$ in Btu/(lb°F) or (kg°C)

t_1, t_2 = inlet and outlet temperatures in °F or °C

ρ = density (kg/scm)

γ = specific weight (lb/scf)

The design air temperature is usually average daily maximum temperature for the hottest month of the year at

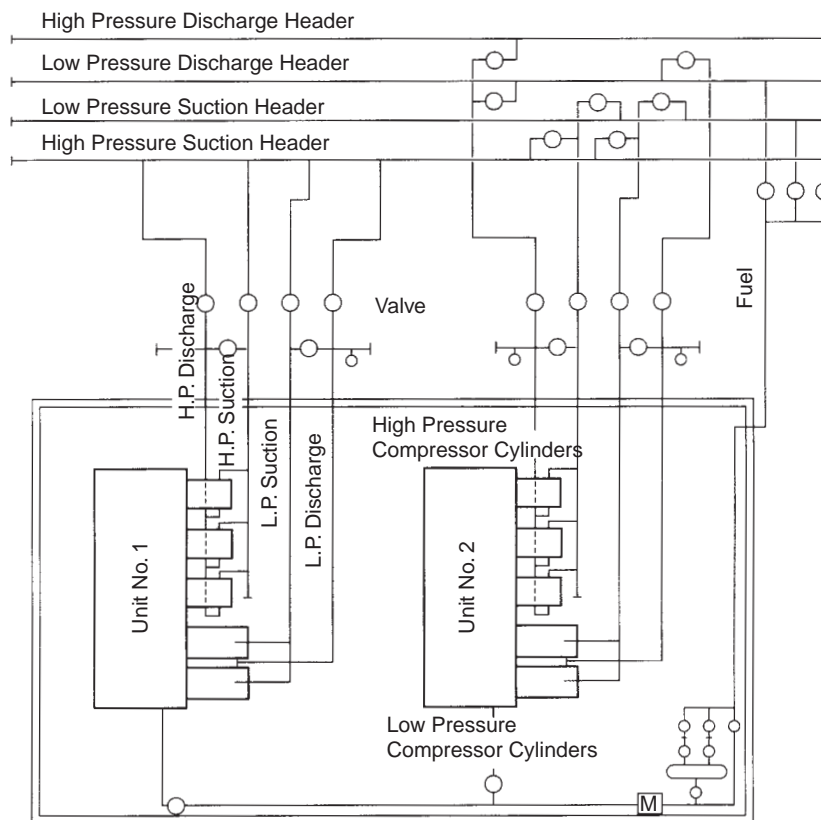

FIGURE 6.7.55 Compressor unit gas flow diagram for storage injection and withdrawal service.

TABLE 6.7.32 Centrifugal Compressor Flow Range

Nominal flow range (Inlet acfm)	Average polytropic efficiency	Average adiabatic (isentropic) efficiency	Speed to develop 10,000 ft head/wheel
100–500	0.63	0.60	20,500
500–7,500	0.74	0.70	10,500
7,500–20,000	0.77	0.73	8,200
20,000–33,000	0.77	0.73	6,500
33,000–55,000	0.77	0.73	4,900
55,000–80,000	0.77	0.73	4,300
80,000–115,000	0.77	0.73	3,600
115,000–145,000	0.77	0.73	2,800
145,000–200,000	0.77	0.73	2,500

the gas cooler location plus 3 to 5°F (1.5 to 2.5°C) correction value for the location environmental conditions.

6.7.17 Cooling Towers [20]

Cooling towers allow water to be cooled by ambient air through evaporation. They have two types of air flow, crossflow and counterflow. In crossflow towers, the air moves horizontally across the downward flow of water. In counterflow towers, the air moves vertically upward against the downward fall of the water.

There are a few types and sizes of cooling towers explained as follows:

Mechanical draft towers (Figure 6.7.57) are characterized as follows:

- Forced draft towers, where the fan is located on the airstream entering the tower.
- Induced draft tower, where the fan is located on the airstream leaving the tower.

FIGURE 6.7.56 Types of aerial heat exchanges.

- Coil shed towers, where the atmospheric coils or sections are located in the basin of the cooling tower.

Natural draft towers (Figure 6.7.58) are characterized as follows:

- Atmospheric spray towers are dependent upon atmospheric conditions; no mechanical devices are used to move the air.
- Hyperbolic natural draft towers, where a chimney or stack is used to induce air movement through the tower.

The performance characteristics of various types of towers will vary with height, fill configuration and flow arrangement: crossflow and counterflow. When rough characteristics of a specific tower are required the performance characteristic nomograph (Figure 6.7.59) can be used.

Example 6.7.32

The use of the nomograph is illustrated by the following examples covering typical changes in operating conditions.

(a) Forced draft, counterflow, blower fan tower.

(a) Atmospheric spray tower.

(b) Induced draft counterflow tower.

(b) Counterflow natural draft tower.

(c) Double-flow, crossflow tower

FIGURE 6.7.57 Mechanical draft towers.

Assume a cooling tower is operating at these known conditions: flow = 1,000 gal/min, hot water at 110°F, cold water at 86°F, wet bulb temperature = 70°F. This is commonly referred to as 110° – 86° – 70° or 24° range (110° – 86°) and 10° approach (86° – 76°).

1. What is the effect of varying wet bulb temperature (WB) on cold water temperature (CWT)? What is new CWT

FIGURE 6.7.58 Natural draft towers.

- when WB changes from 76 to 65°F with gal/min and the range remains constant? Enter the nomograph at 86° CWT, go horizontally to 76°F WB, then vertically down to 65°F WB, then read new CWT of 79.5°.
2. What is the effect of varying the cooling range on the cold water temperature? What is the CWT now when the cooling range is changed from 24° to 30° (25% increase in heat load) with gal/min and WB held constant? Enter the nomograph at 86° CWT, go horizontally to 76° WB, vertically to 24°R, horizontally to 30°R, vertically downward to 76° WB, then read new CWT 87.4°.
 3. What is the effect of varying water circulating rate and heat load on cold water temperature? What is the new CWT when water circulation is changed from 1,000 to 1,200 gal/min (50% change in heat load at constant range)? Varying the water rate, particularly over wide ranges, may require modifications to the distribution system. Enter the nomograph at 86°F CWT,

FIGURE 6.7.59 Pressure characteristic nomograph.

90 horizontally to 76°F WB, vertically to 24°R, horizontally to performance factor of 2.88. Obtain a new performance factor (PF), multiplying $(2.88)(1,200/1,000) = 3.46$, then enter the nomograph at PF = 3.46, go horizontally to 24°R, vertically down to 76°F WB, then read new CWT 88.5°F.

4. What is the effect of varying the WB temperature, range and water circulating rate on the cold water temperature? What is the new CWT when the WB changes from 76° to 65°, R changes from 24° to 25°, gal/min changes from 1,000 to 1,500². Enter the nomograph at 86° CWT, go

horizontally to 76 WB, vertically to 24°R, horizontally read PF = 2.88, then multiply $(2.88)(1,500/1,000) = 4.32$ (new PF). Enter the nomograph at PF = 432, go horizontally to 25°R, vertically down to 65° WB, then read 86.5° as the new CWT.

5. What is the effect of varying the fan hp input on the cold water temperature? What is the new CWT if the motor is changed from 25 to 30 hp in example (d)? The air flowrate varies as the cube root of the horsepower and performance varies almost directly with the ratio of water rate to air rate; therefore, the change in air flowrate

can be applied to the performance factor. Increasing the air flowrate (or hp) decreases the performance factor. PF correction factor = $(30/25)^{1/3} = 1.0627$.

Divide PF by the PF correction factor to get the new PF. Applying this to example (d), we get $4.32/1.0627 = 4.07$. Enter the nomograph to 4.07 PF (instead of 4.32), go horizontally to 25°R, vertically down to 65 WB, then read 85.5 CWT.

6. The correction factor shown in example (e) could also be used to increase the gal/min instead of decreasing the CWT, as was done in example (e). In example (d) we developed a new CWT of 86.5 when circulating 1,500 gal/min at 25°R and 65 WB. If the motor hp is increased from 25 to 30 under these conditions, with a PF correction factor of 1.0627 (as shown above), gal/min could be increased from 1,500 to $1,500 \times 1.0627 = 1,594$ gal/min.
7. Calculate the concentrations and blowdown rate for the following cooling tower.
Circulation rate = 8,000 gal/min
Water temperature drop through tower = 20°F
Type of tower = mechanically induced draft
Blowdown rate = 20 gal/min or 0.2% of circulation rate

Solution

Evaporation loss = 2% (1% for each 1° temperature drop) (All rates are based on a percent of circulation rate.)
Windage loss = 0.3% (maximum for mechanical draft tower) Number of concentrations (cycles) is

$$N = (E + B)/B = \frac{2.0 + (0.2 + 0.3)}{(0.2 + 0.3)} = 5.0$$

If the resultant concentrations are excessive and a desired concentration of 4.0 is required, what must the blowdown rate be?

$$B = \frac{E}{\text{cycles} - 1} = \frac{2.0}{4.0 - 1} = 0.67\%$$

The windage component of B is 0.3%, therefore, the blowdown rate required would be $0.67 - 0.3 = 0.37\%$ or $(8,000 \text{ gal/min})(0.0037) = 29.6 \text{ gal/min}$.

6.7.18 Surface Jet Pump

When gathering systems combine high-pressure and low-pressure flow, an alternative to compression is a surface jet pump which operates very similarly to the downhole jet pump for artificial lift. The surface jet pump uses the high-pressure flow to increase the pressure of the low-pressure flow. The application of a surface jet is optimal when the

co-mingled flow is at a pressure that is high enough to meet downstream processing requirements.

The surface jet pump consists of three parts: nozzle, mixing tube, and diffuser. The high-pressure flow goes into the nozzle which significantly increases the velocity of the high pressure flow. Downstream of the nozzle is the mixing tube where the high-velocity flow combines with the low-pressure flow. The combined flow enters the diffuser where the velocity is reduced to stabilize the pressure. There are no moving parts in a surface jet pump and thus require minimum maintenance as long as the flow streams are free of solids. For more information and sizing of a surface jet pump contact the vendors that supply the downhole jet pumps for artificial lift.

6.8 CORROSION IN PRODUCTION OPERATIONS

Section reviewed by John Farraro

6.8.1 Introduction

The corrosion problems and mitigation techniques related to oil and gas production operations are discussed here.

The production environments that were discussed in the Chapter on “Drilling and Well Completion Corrosion” are still pertinent to corrosion in production operations that is the subject of this chapter. However, there are some very important differences. First, the exposure to the production fluids is not modified by controlled drilling fluids. Second, the down hole production environment and the equipment exposed to it are not cooled through the use of recirculated or injected fluids. Third, the equipment and their constitution is markedly different from drilling equipment. Fourth, generally the service life of production equipment is measured in years. Fifth, there are new types of environments that are introduced that are different from or modify the production environment such as completion brines, CO₂ injection and water flood operations.

A wide variety of engineered tools and structures are used in the production side of the oil and gas industry. Production equipment includes production tubing, production packers, safety valves, tubing hangers, chokes, flow control equipment, valves and wellheads, gas lift equipment, sucker rods and rod pumps, submersible pumps, compressors, flow lines, and pipelines. Each of these products has different engineering requirements that equates to different metals and conditions. These products may also be exposed to a different set of environmental conditions that pose different corrosion potentials. These metals and their condition exhibit varying susceptibilities to the various potential corrosion reactions that are prevalent in the oilfield production environments.

There has been a large volume of information developed over the years on the subject of corrosion problems encountered in production operations. The solutions to these corrosion problems that we have encountered have created a knowledge base from which we can draw to avoid the many pitfalls that potentially await us in operations.

This chapter is structured to provide an introduction to the causes of corrosion in production, the equipment used in production, and the common techniques to mitigate the effects of corrosion.

6.8.2 Causes of Corrosion in Production Operations

The causes of corrosion in production operations are dependent on the stage of production operation we are considering

and the varied constituents and conditions that occur there. The segments of the production operation (or where in the production stream) are defined here as follows:

1. Downhole Segment — from the formation, the production fluids flow up production tubing; downhole accessories may assist with production or control it.
2. Wellhead — the production fluids are directed and controlled by valves and associated equipment as they exit the production tubing on the wellhead.
3. Flowlines/Pipelines — with the assistance of storage facilities and compressors, the production fluids are transported to treatment and refining facilities.

Many operational variables will change with location, and temperature is the one of the most significant. The temperature is highest at the formation and cools as it comes out of the earth through the wellhead and into pipelines and flowlines. An example of a bottom hole temperature of 175°C (350°F) may cool to about 85°C (185°F) at the wellhead and ultimately to the range of ambient temperatures in the pipelines. Another factor is phase stability because temperature and pressure will effect what phases are present. A discussion of the primary corrosion causing environments is presented below with how the environment changes or is affected by where in the production stream it is.

6.8.2.1 Acid Gas Corrosion

In production operation, corrosion is usually associated with acidity in the bulk or in localized regions. The acidity in the bulk environment is caused by the presence of acid gases that naturally occur in the formation coexisting with petroleum products or as the result of CO₂ gas injection. Acid gases, hydrogen sulfide H₂S and CO₂, are the gases that form acids in aqueous environments. As the concentration of these gases increases, the amount of acid in the water phase increases. The more acid (lower pH) there is, the greater the corrosion rate. Listed below are some factors that affect the corrosion from these acid gases.

Factors that affect acid gas corrosion

- acidity or pH from the acid gas concentration
- water/gas/oil phases
- produced water chemistry
- temperature
- chlorides
- flow rates
- composition and condition of the metals

6.8.2.1.1 CO₂ Partial Pressure and Temperature

As presented in the corrosion discussion in drilling and completion operations, the pH or acidity is directly related to the concentration of these acid gases that is usually

expressed in parts per million (ppm), partial pressure (bar or psi), or mole fraction (percent). Early researchers found that the corrosion in CO₂ containing environments was related to this concentration and temperature. DeWaard and Milliams [1] developed an equation to predict corrosion rates, and this equation is presented below.

$$\text{Log } r = 8.78 - 2.320/(T + 273) - 5.55 \times 10^{-3} \times T \times \text{log } P_{\text{CO}_2} \quad (6.8.1)$$

where r = corrosion rate in mils per year (mpy)
 T = temperature, degrees C
 P_{CO₂} is the partial pressure of CO₂ in psi

The nomograph that was the result from this equation is presented in Figure 6.8.1.

Since that early work, much progress has been made refining these relationships taking into account the stability of protective corrosion product films. The corrosion rate of steels in CO₂ containing oilfield environments as a function of partial pressure of CO₂ and temperature is presented in Figure 6.8.2.

6.8.2.1.2 Prediction Models

The relationship between environmental variables and corrosion rates in CO₂ environments continues to be refined as Figure 6.8.2 is an example. Still considering CO₂ corrosion but now allowing for small amounts of H₂S, several prediction models for corrosion of oil and gas pipelines have been developed. These models are based on either mechanistic modeling of the different processes involved in CO₂ corrosion of carbon steel or empirical correlations with laboratory or field data. The models differ considerably

FIGURE 6.8.1 Nomograph for calculation of corrosion rates as a function of carbon dioxide partial pressure and temperature [1].

FIGURE 6.8.2 Effect of temperature on CO₂ corrosion [2].

in how they predict the effect of protective corrosion films and the effect of oil wetting on CO₂ corrosion, and these two factors account for the most pronounced differences between the various models [3].

A list of some of the CO₂ corrosion models is presented in Table 6.8.1 [adapted from 4].

6.8.2.1.3 Water Content

Water content (also known as watercut) is one of variables that is related to the probability of corrosion. The most severe corrosive environments have been found to contain above approximately 40% watercut [5, 6]. When there are no appreciable amounts of acid gases present, corrosion is generally not a problem when water cuts are below about 25%. The experience found between watercut and the number of corrosive wells is presented in Figure 6.8.3.

6.8.2.1.4 Oil Phase and Flow Effects

The other phases present has a large effect as well. The presence of oil is generally a positive effect in that corrosion rates may be reduced or corrosion may be prevented. The corrosion reaction requires an electrolyte to conduct the flow of electrons, oil being nonpolar, is not a conductor. The heavier the oil (more viscous), the greater the protection provided by the oil.

In addition to the presence of a corrosion reaction that is contingent upon a contacting water phase, the characteristics of the resultant corrosion products have a role in corrosion kinetics. As discussed previously, the carbon and low alloy steels form iron carbonate films that provide corrosion resistance. In flowing conditions, these films could be removed or compromised by hydrodynamic erosion.

FIGURE 6.8.3 Relationship between watercut, and number of corrosive wells [5,6].

There are relationships between the relative amounts of the different phase, the flow regime and the potential for corrosion. The types and dispersion of phases in liquid plus gas phases in a vertical and horizontal pipe are presented in Figures 6.8.4 and 6.8.5, respectively.

The different types of flow that are predicted as a function of the relative gas and liquid velocities in Figures 6.8.4 and 6.8.5 can be used to predict corrosion severity. For

example, the maximum corrosion rates under a specific set of environmental conditions predicted as a function of the type of flow is presented in Figure 6.8.6.

6.8.2.1.5 Corrosion and Oil Weight

The corrosion rates are a function of watercut, flow rate, and a given weight of oil. The predictive relationships

FIGURE 6.8.4 Vertical flow map [after 7].

FIGURE 6.8.5 Horizontal flow map [after 7].

FIGURE 6.8.6 Horizontal flow and corrosion predictions [after 7].

FIGURE 6.8.7 CO₂ corrosion rates as a function of velocity and watercut with API specific gravity 45 oil [after 8].

FIGURE 6.8.8 CO₂ corrosion rates as a function of velocity and watercut with API specific gravity 38 oil [after 8].

for API specific Gravities 38 and 45 oils are presented in Figures 6.8.7 and 6.8.8.

What has not been discussed yet is the effect of pipe angles that are off the vertical on these flow regimes. Three modes of water wetting have been defined as they relate to the angle off vertical [8]. These modes are presented in Figure 6.8.9.

In Figure 6.8.9, mode I relates to completely emulsified liquid wetting, mode II to wetting by accumulated water volumes at locations of high deviation, and mode III to wetting by coalesced water droplets. Mode II was found to be very dependent on the angle of deviation and results in water contact with metal surfaces even at low watercuts [8].

FIGURE 6.8.9 Modes of water-oil mixtures in production tubing at an angle of deviation, α [after 8].

6.8.2.1.6 Velocity and Steels

Investigating the effects of velocity with other variables provides additional clues that we can use. For example, J.R. Vera et al [9] examined the composition of the corrosion products as a function of flow velocity for a variety of low alloy products including API 5CT [10] Grades L80 and C90 tubulars. The primary difference between the L80 and the C90 pipe was the chromium content, which was 0.5% for the L80 and 1.0% for the C90, and molybdenum content, which not present in the L80 and was 0.5% in the C90. The L80 had corrosion rates that increased with velocity up until about 4 m/s and then decreased with increasing velocity. It was found that the C90 had much lower corrosion rates at low velocities but exhibited pitting corrosion and an increasing corrosion rate at higher velocities.

These differences in corrosion rate were correlated to the proportion of corrosion product constituents that comprised the surface scale. These proportions as expressed as strong, medium, weak, and undetected are presented in Figure 6.8.10.

For steels, the combined effects of velocity and pH are presented in Figure 6.8.11.

6.8.2.1.7 Velocity and Corrosion-Resistant Alloys

The velocity effects of CO₂ environments on corrosion-resistant alloys (CRAs) have also been investigated. The velocity versus corrosion rates of 13% chromium, 13% chromium with nickel and molybdenum additions (S13Cr or Super 13Cr), and 22% chromium duplex stainless steels are presented in Figure 6.8.12.

6.8.2.1.8 Chloride Effects

There is a small or mild effect of chloride concentration on corrosion rates. The effect is related to how the chloride interferes or influences the film stability. The effect of chloride content on chromium containing low alloy steels and 13% chromium stainless steel is presented in Figure 6.8.13.

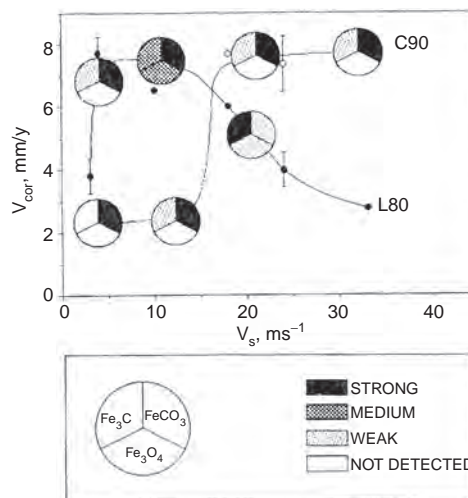

FIGURE 6.8.10 Velocity effects on corrosion product composition [after 9].

FIGURE 6.8.11 Velocity and pH effects on steel corrosion in mm/y [after 2].

FIGURE 6.8.12 Velocity effects on CRAs in CO₂ environments [after 11].

FIGURE 6.8.13 Chloride concentration effects on chromium containing low alloy steels and 13% chromium stainless steel in CO₂ environments [after 11].

6.8.2.1.9 H₂S Effects on CO₂ Corrosion

When even small amounts of H₂S are present, generally the sulfide corrosion products dominate. The iron sulfide corrosion products are much less soluble and much more stable than the iron carbonates.

Some of the models previously noted that predict CO₂ corrosion take into account the presence of small amounts of H₂S. The potential problem is that, although the H₂S contributes to increasing surface passivity, thereby lowering general corrosion rates, the H₂S increases the tendency toward localized pitting corrosion. The presence of chlorides increases this tendency.

Environmental cracking is the biggest concern with the presence of H₂S. This subject was discussed for carbon and low alloy steels in the chapter on “Corrosion in Drilling and

Completion Environments.” The environmental cracking in corrosion resistant alloys and hydrogen induced cracking in pipelines are discussed next.

6.8.2.2 Environmental Cracking

There are three types of environmental cracking that occurs in oil and gas production environments that is discussed here. First, there is cracking that is a result of hydrogen adsorption, resulting in embrittlement or cracking. Second, there is stress corrosion cracking where the cracking agent is chloride but the mechanism is assisted when H_2S is also present. Third, there is sulfide stress cracking (SSC), and this a cracking phenomenon that is related both to internal hydrogen effects and stress corrosion cracking.

The stress corrosion cracking and SSC mechanisms requires a susceptible material that is exposed to an environment that causes stress corrosion cracking of the specific material under the application of a tensile stress. The tensile stress may be imposed, tensile component of an imposed shear stress or residual stress. There is at least one set of environmental conditions in which most metals can exhibit stress corrosion cracking. The hydrogen embrittlement (result in hydrogen induced cracking) requires only a hydrogen producing corrosion reaction and a material that is susceptible to cracking.

6.8.2.2.1 H_2S —Sulfide Stress Cracking

Sulfide stress corrosion cracking, also known as SSC, is a stress corrosion cracking phenomena that occurs in the presence of H_2S . H_2S is known to cause or assist in the mechanism of cracking with many alloy types, including low carbon steels, low alloy steels, alloy steels, tool steels, martensitic stainless steels, ferritic stainless steels, austenitic stainless steels, duplex stainless steels, nickel-copper alloys, and nickel base alloys. For many of these materials, there coexists the potential for chloride stress corrosion cracking. The presence of hydrogen sulfide often increases the severity of the cracking or enlarges the range of environmental conditions where cracking occurs.

There are several competing mechanisms that result in SSC, including internal hydrogen stressing, hydrogen embrittlement, stress corrosion cracking, and combinations of these mechanisms. These competing mechanisms have complicated the identification of a universally accepted molecular mechanism that explains all the observed phenomena, that are involved. In this section, SSC will be discussed, and the cracking that is related or complicated by other cracking mechanisms will be presented in the next section, “Stress Corrosion Cracking.”

The amount of H_2S that causes SSC is conditional on the other environmental variables but the historical limit that has been listed in NACE MR0175 is 0.05 psi partial pressure

of H_2S [12]. The environmental factors that influence the existence and extent of SSC include the following:

1. H_2S concentration
2. acidity (pH)
3. time
4. temperature
5. water content (also gas/oil ratio and solids content)
6. chloride content

The effects of these variables are interrelated and also very much conditional on the specific alloy, its condition, and stress state. The other influencing variables, oxygen, and elemental sulfur are discussed in “Stress Corrosion Cracking.” The effects listed above are complicated because they are interrelated.

Generally, cracking becomes more prevalent or severe when the acidity, water content, chloride content, and H_2S content increases. The severity of the SSC generally lessens as temperature increases; however, increasing temperature could activate a potential SCC mechanism. These competing mechanisms make it difficult to determine which cracking mechanism will dominate. The complexity also makes selection of materials and estimating the environmental conditions that render them most susceptible to cracking difficult.

For example, martensitic stainless steels such as 13% chromium are not very susceptible to chloride stress corrosion cracking but are susceptible to SSC. The 13% chromium stainless steels would be expected to exhibit a maximum cracking susceptibility at temperatures closer to room temperature.

Austenitic stainless steels, such as the 18% chromium 8% nickel varieties, are primarily susceptible to chloride stress corrosion cracking. For these materials, the potential for cracking steadily increases with increasing temperature and chloride contents. The incidence rates of SSC greatly increase with increasing H_2S levels. The presence of oxygen has dramatic effects on cracking even at low levels.

In duplex stainless steels, where there are both ferritic and austenitic microstructural phases present, susceptibility to both chloride stress corrosion cracking and SSC exists. Because both susceptibilities exist, the temperature of maximum susceptibility would be expected to be some intermediate range. Barteri [14] conducted tests and demonstrated that the cracking susceptibility was greatest in the 70°C to 110°C range (160°F to 230°F range).

In nickel-based alloys, the potential cracking mechanism is controlled by both chloride and H_2S and is generally only present at elevated temperatures. The relative susceptibilities of nickel-based alloys categorized by molybdenum contents as a function of H_2S content and temperature is presented in Figure 6.8.14.

With respect to time, failures could occur in minutes in very susceptible materials in a very aggressive

FIGURE 6.8.14 Maximum use limits of nickel-based alloys [after 15].

environment. In situations in which more corrosion cracking-resistant materials are used, cracking and failures could be delayed to many months with some material environmental combinations.

6.8.2.2.2 Stress Corrosion Cracking

As discussed in the preceding section, the identification of the mechanism is complicated because there are a variety of processes and conditions that can cause stress corrosion cracking. For example, we know that stress corrosion cracking can occur as result of either anodic or cathodic corrosion reactions; it is also possible to have both anodic and cathodic reactions promoting stress corrosion cracking simultaneously.

For each alloy and condition under a specific set of environmental conditions, there is a threshold stress intensity below which stress corrosion cracking will not occur. The stress intensity is affected by the bulk-applied stress, stress concentration factors, and residual stresses.

For our purposes in considering environmental cracking in oil and gas production environments, the environmental factors that affect stress corrosion cracking are not significantly different from those that affect SSC.

6.8.2.2.3 Hydrogen-Induced Cracking

There are many forms of damage that occur as a result of hydrogen. These are typically categorized by the role of stress in the mechanism. The three types of damage that are observed are (1) hydrogen-induced cracking (HIC), (2) stress-oriented hydrogen-induced cracking (SOHIC), and (3) SSC. In HIC, the externally applied stress is low and does not interact with the cracking mechanism. In SOHIC, this is essentially the same as HIC except that the external stress influences the orientation or direction of the crack

propagation. In SSC, the stress is an integral component of the cracking mechanism and does not occur without the application of applied stress.

In the oil and gas production environments, these cracking mechanisms have been experienced in pressure vessels, pipelines, and flowlines. In HIC, failures can occur at applied stress levels that are a fraction of the yield strength. For example, there have been many well-documented [16] failures due to HIC in low-strength pipeline steels in gas transmission lines containing H_2S .

Hydrogen is evolved during corrosion-reactions, and H_2S plays a pivotal role in hydrogen related damage mechanisms. The hydrogen evolved is mono-atomic or nascent hydrogen, and its recombination into molecular hydrogen is inhibited or poisoned by the hydrogen sulfide. The result of this inhibited reaction is greater quantities of the mono-atomic hydrogen that readily diffuses into the metal lattice; the size of the mono-atomic hydrogen is minute and moves easily through metal structures. The reactions of hydrogen sulfide and iron are presented below:

The second reaction above is inhibited or poisoned.

There are several theories that explain the various types of hydrogen damage [17]. Although numerous models and theories exist with respect to HIC, the phenomenon of trapping best quantifies the metal susceptibility to hydrogen damage [18, 19]. The cracks occur when the atomic hydrogen migrates to these trap sites and then becomes “trapped.”

We know that inclusions, especially elongated manganese sulfide inclusions, increase susceptibility to HIC damage. The other known major factor is alloys segregation

in the form of banding. Banding is particularly a problem in plate and pipe formed from plate products but can be seen in seamless pipe as well.

To avoid HIC, clean steels with uniform microstructures have the best resistance to this form of cracking.

6.8.2.2.4 Testing

There are a variety of standard test methods exist to determine susceptibility to environmental cracking as a function of material and environmental details.

The tests that examine materials susceptibility to HIC is based on measuring the amount of diffusible hydrogen or quantifying the cracking that occurs in standard test environments. The most widely accepted standard test method for measuring susceptibility to HIC is NACE's TM-0284 [20]. This test method uses unstressed beams and internal cracks are assessed as a function of crack direction.

A related phenomenon of cracking that occurs that is oriented by applied stress is SOHIC.

The standard tests that measure resistance to room temperature and elevated temperature SSC are found in NACE TM0177 [21], EFC Publication 16 [22] and NACE TM0198 [23]. The tests referenced in these documents are summarized in Table 6.8.2.

The selection of tests is somewhat dependent on specimen geometry. For example, thin-walled tubulars can be tested using C-ring and either three-point or four-point bent beam type test specimens. Bars, forgings, castings and thick wall thickness tubulars can be tested by any of the tests described above.

Different values or results that indicate relative resistance to environmental cracking are determined from these tests. The uniaxial tension, three- and four-point bent beam, and C-ring tests results in a threshold stress that defines the maximum stress level at which cracking does not occur. These tests are usually run at either a minimum stress level where no failures occur in a standard period of time

(30 days) or in several stress levels at which the threshold stress can be determined.

The double cantilever beam (DCB) test results in a fracture toughness constant ($K_{I,SSC}$) that is relative to the environment in which the test is conducted. The slow strain rate tests (SSRTs) result in ductility ratios between tests conducted in air versus tests conducted in a test environment.

Jean Leyer et al. [24] compared several of the standard test methods to evaluate test selection on threshold stress. In tests using a steel that was susceptible to environmental cracking, API 5CT [10] type P110, they found the following ranking of tests in order of increasing severity:

Four-point bent beam < C-ring (ID tension)
< C-ring (OD tension) < uniaxial tension test

Therefore, the uniaxial tension test is the most severe of those evaluated.

In applying these tests for qualification purposes, the selection of tests and the test environment for steels is straight forward. The environments that are most often used are either the standard test conditions defined in NACE TM0177 [21] or a mock-up of the worst case actual production environment. The stress level required for qualification purposes by NACE/ISO 15156 [12] in the TM0177 type conditions would be at a minimum of 80% of the actual yield strength, whereas the mock-up environments would require a minimum of 90% of the actual yield strength.

Testing of corrosion-resistant alloys varies in that often more than one type test or test environment is required to determine resistance to more than one potential failure mode. For example, many stainless steels are tested for room temperature resistance to SSC and elevated temperature testing for resistance to stress corrosion cracking with H_2S .

One of the areas of concern with benchmarking CRAs has been the selection of a standard test environment. This

TABLE 6.8.2 Comparison of Standard Test Methods for Cracking in H_2S

Test Source	Method	Description	Test Type
NACE TM0177 & EFC 16	A	Uniaxial tensile	Sustained load
NACE TM0177	B	Three-point bent beam	Constant strain
EFC 16	B	Four-point bent beam	Constant strain
NACE TM0177 & EFC 16	C	C-ring	Constant strain
NACE TMO177 & EFC 16	D	Double cantilever beam	Fracture toughness
EFC 16	E	Slow strain rate	Strain to failure
NACE TM0198	—	Slow strain rate	Strain to failure

concern has been partly alleviated by the standard test levels defined in NACE MR0175 and reproduced in ISO 15156 [12]. These levels are defined in Table 6.8.3.

Most of the new materials and changes proposed to the standards that govern materials for use in H₂S containing environments will be based on tests that are conducted to one or more of the standard test conditions in Table 6.8.3.

6.8.2.3 Other Fluids in Production Operations

In addition to production fluids, production equipment is often exposed to other fluids. For example, during well completions, weighted salt (brine) environments are frequently used. These are often referred to as *packer fluids* or *packer brines*. During the life cycle of a producing well, the production from the formation will decrease and production can be stimulated through injection of acids into the formation. Often naturally occurring formation salts will deposit along metals walls, and these may clog or restrict production; these are removed through the use of scale inhibitors or removers.

In addition to production wells, there are also injection wells where CO₂ steam of fresh or salt water is injected into the formation to stimulate production. Often the same wells that are used to stimulate are used to produce the hydrocarbons, these will, therefore, alternate between being injectors and producers. Another method used to enhance production is gas lift. In these applications, produced gas is reinjected into the production tubing.

6.8.2.3.1 Brines — Completion Fluids

A variety of completion brines are used. The selection of brine is based first on the desired weight of the fluid usually expressed in pounds per gallon (ppg) and second on compatibility with contacting equipment. The brines that have been used include the following: sodium

chloride, calcium chloride, calcium bromide, zinc bromide, and cesium formate. The completion brines are often mixtures of more than one of these constituents.

There are several potential problems that stem from these completion brines. First, many of the brines are acidic and therefore are corrosive. The most acidic of the above brines is zinc bromide. An associated problem with zinc bromide is the effect on elastomers, nitrile based elastomers are degraded by contact with this brine. Second, the intrusion of production acid gases (CO₂ and H₂S) in high-pressure high-temperature (HPHT) gas wells into the brines will acidify it. When the brines become acidified, there is an increased risk of corrosion and stress corrosion cracking. There are many examples of these corrosion [25] and environmental cracking problems [26].

There continues to be incidences of failures in brines, and there is continuing efforts to use safer weighted brines. For example, there has been recent work reported on mixture of potassium and cesium formates as packer brines [27].

6.8.2.3.2 Injected Fluids — Acidizing and Scale Removers

To enhance production and remove wall deposits, a variety of fluids are injected into the formation, production tubing string, and flowlines. The primary potential problem with these fluids is accelerated general or localized corrosion attack. The selection of fluid with the proper additives (neutralizers or corrosion inhibitors) is important to prevent this corrosion attack.

During acidizing operations, even with proper fluid selection and inhibitor additions, there are two other potential problems that require evaluation. These are selection of inhibitor for all the metals being contacted and the problems with spent acid returns. The inhibitor selection is important because inhibitors often do not protect all

types of metals and may lose effectiveness under certain downhole conditions. An example of a corrosion problem on a stainless steel component in an improperly applied inhibited acid treatment is presented in Figure 6.8.15.

6.8.2.3.3 Injected Gases – Gas Lift and CO₂ Flood

Produced gas is used in gas lift operations as a means to enhance production. The injected gas is injected at points downhole in the production string to “lift” the fluids. The produced gas may contain acid gases, so the same care is required in lift operations as in the production string.

In CO₂ flood operations, the formation is stimulated by injected CO₂. Because CO₂ forms carbonic acid in water, this acidifies the formation. In the producing wells in fields

FIGURE 6.8.15 Example of improperly applied corrosion inhibition during acidizing.

where CO₂ flood operation are performed, the production tubing and facilities require attention to prevent corrosion.

6.8.2.4 Microbiologically Induced Corrosion

Microorganisms are present throughout our environment. These organisms can result in corrosion by producing a deposit on metal surfaces and/or by increasing the acidity/reducing the pH of the environment. This altering the environment can occur in the bulk of locally. This type of corrosion can be found in flowlines and pipelines where these microorganisms are inadvertently introduced during inspection and pigging operations.

There are two basic classes of microbes, anaerobic and aerobic microorganisms. Anaerobic microorganisms flourish in the absence of oxygen such as deep sea or downhole environments. Aerobic microorganisms require oxygen to survive and flourish and are found in all surface environments including salt and fresh waters.

One example of an anaerobic microorganism that is troublesome in the oilfield is the genus *Desulfovibrio*. This is a sulfate-reducing bacteria (SRB), and the resultant corrosion mechanism involves naturally occurring sulfates to H₂S. The resultant acid from the H₂S can cause or accelerate corrosion or cause HIC or SSC as discussed previously. A simplistic chemical mechanism illustrating corrosion attack on steel by SRB is presented in Figure 6.8.16.

There are many iron oxidizing types of bacteria such as *Gallionella* and *Crenothrix* that can accelerate corrosion by

FIGURE 6.8.16 Diagram of polarization of local cathode by a film of hydrogen gas bubbles (cathodic area to right of anode is polarized) [28].

releasing CO₂ as one of the corrosion products as illustrated by the following equation.

Fe(OH)₃ is not very soluble and will precipitate on the metal surface. These deposits can thus cause oxygen concentration cells resulting in corrosion beneath the deposits.

In addition to the bacteria examples above, there are also molds, yeasts, algae, and protozoa. These, like bacteria, can have either a waste product that enhances corrosion or can result in slimes or deposits beneath which oxygen concentration cells/localized corrosion attack can result.

6.8.3 Production Equipment

The operations of the various products used in the production of oil and gas are discussed elsewhere in this handbook. In this section, the different types of completions and the corresponding materials of construction are presented.

Open hole completions are not normally used today but can be used where there is only one production zone. There are many disadvantages to this type of completion including poor control over production and frequent cleanout operations being required due to formation intrusion. The general appearance of this type of completion is presented in Figure 6.8.17.

More commonly, open hole completions are assisted with the use of screen liners and slotted liners. These products keep the formation from collapsing and filter out formation sands. A schematic of this type of completion is presented in Figure 6.8.18.

Perforated casing is the common type of completion and utilize packers to isolate production from the annulus between the tubing and casing. This completion method can be used to produce single or multiple zones. Schematics of multiple-zone single-string and multiple-zone multiple-string completions are presented in Figures 6.8.19 and 6.8.20.

FIGURE 6.8.17 Open hole completion.

FIGURE 6.8.18 Open hole completion with slotted liner.

FIGURE 6.8.19 Multiple-zone single-string completion.

FIGURE 6.8.20 Multiple-zone multiple-string completion.

For small-diameter wellbores at relatively shallow depths, a tubing-less type of completion can be used. In these instances, the small-diameter casing such as 2-7/8" is cemented into place and conventionally perforated in the production zone. The casing then becomes the tubing string.

The advantage of this type of completion is that it provides a low-cost completion technique.

Deep well completions require higher strength tubulars to be able to withstand the large tensile and differential pressure stresses that are encountered. The casing programs require multiple casing sizes that telescope from the surface down into the producing formations. These completions also require specialized equipment to manage tubing movement due to expansion and contraction during heating and cooling respectively. A schematic of a typical gas well completion is presented in Figure 6.8.21.

The various components and functions of the production equipment illustrated in the preceding schematics are discussed elsewhere in this handbook. The following sections describe the typical variety of metallic materials that are used in the construction so that an understanding of the potential corrosion problems can be obtained.

6.8.3.1 Production Tubing and Casing

In normal operations, the casing is protected from the production fluids. The corrosion risk for casing lies when the casing is used for production or when formation fluids migrate through the barriers that are used such as packers and cement.

The tubing is the conduit through which petroleum products are removed from the wells. The tubing is one of the largest investments made by operators during the completion phase of oilfield operations. The tubing is therefore the single largest investment that is subjected directly to corrosive production environments and requires evaluation of potential corrosion and cracking reactions.

API 5CT [10] is the primary industry specification that governs casing and tubing materials. The compositions and

FIGURE 6.8.21 Schematic of single-zone deep gas completion.

mechanical properties of common API 5CT Grades are presented in Tables 6.8.4 and 6.8.5, respectively.

The L80-Type 1 and T95 grades are suitable for use in sour service applications without temperature restrictions. More recently, C110 products have also been qualified for sour service at temperatures below those listed in NACE MR0175/ISO 15156 [12] (current manufacturer's

qualification data should be reviewed for applicability). P110 and Q125 grades are only suitable for sour service at above 175F and 225F respectively. L80-Type 13 Cr was developed for and is extensively used in production environments that contain CO₂ levels high enough to create acidity in produced or condensed waters.

The L80 types 9Cr and 13Cr are used extensively in CO₂-containing anaerobic production environments.

The requirement for greater corrosion resistance and greater resistance to environmental has resulted in a number of corrosion-resistant alloys being used for tubing and, to a lesser extent, casing. A survey conducted by NACE in the

mid- 1990s indicated that the majority of CRA tubulars in use to that point in time were of the 13% chromium variety but that the use of corrosion resistant alloys was on the rise [29].

API 5CRA [13] specifies product requirements for corrosion resistant products used for casing, tubing and coupling stock. Table 6.8.6 presents typical compositions for commonly used alloys. With the exception of Modified 13 Cr, the corrosion resistant alloys gain their mechanical strength through cold work by use of either drawing or pilgering. Commonly specified grades are presented in Table 6.8.7.

6.8.3.2 Packers, Safety Valves, and Other Downhole Accessories

The downhole accessories such as packers and safety valves are typically made from similar materials to the tubing string. Generally, the materials are selected such that the accessory corrosion resistance is equal to or slightly better than the tubing string. One major difference between the accessories and the tubulars is the form of the raw materials; most accessories are tubular in nature but they are typically machined from bar stock. This translates to a different set of metals being used because of the inability to achieve the required mechanical properties from cold worked tubular corrosion resistant alloys in heavy sections.

To achieve the required strength levels, a different hardening mechanism is required. The common materials used in these applications utilize either a martensitic transformation, such as that present in steels and other martensitic alloys, or a precipitation hardening mechanism, such as that present in precipitation hardening stainless steels and nickel base alloys. A list of some of the common precipitation hardening stainless steels and nickel base alloys is presented in [Table 6.8.8](#) with the typical specified minimum yield strength(s). The nominal compositions of these alloys is presented in [Table 6.8.9](#). Alloy 718 should be procured in accordance with API 6A718[30].

6.8.3.3 Wellhead/Valves

The wellhead valves and assorted hardware have different material constraints than the tubulars and downhole accessories previously discussed. The equipment is typically larger because it does not have to fit through the casing. This permits new material options that encompass forgings and castings, and where corrosion resistance is required, linings and overlays can be used.

TABLE 6.8.8 Common Precipitation Hardening Corrosion-Resistant Alloys

UNS No.	Common Name	Typical Minimum Yield Strength
S17400	17-4PH	724 Mpa (105 ksi)
S45000	Custom 450	655 Mpa (95 ksi)

N07750	X-750	724 Mpa (105 ksi)
N09925	925 Alloy	758 Mpa (110 ksi)

The larger equipment results in lower stress states; therefore, lower strength materials may be used. The wellhead equipment and material properties are defined by API Specification 6A [31]. The API 6A material strength requirements are presented in [Table 6.8.10](#).

A Christmas tree is named because of its appearance as a tree with ornaments hanging off it. It is comprised of a number of valves, spools chokes, etc. An example of a Christmas tree is presented in [Figure 6.8.22](#).

Wellhead equipment has been made from a wide variety of wrought and cast steel products. Some solid corrosion-resistant alloys have been used such as the 13Cr family of materials. A variety of overlays and hardsurfacings are used in corrosion resistant wear or flow path/controlling components. Generally the selection is based on functional requirements first and corrosion resistance second. A list of

some of the common CRAs with typical strength levels is presented in [Table 6.8.11](#).

API 6A also defines classes of service and the types of materials that are used for each class; these classes are presented in [Table 6.8.12](#).

The relative corrosivity of production environments has been related by API 6A to the partial pressure of CO₂ present in the production fluids. This corrosivity as it

is defined in API 6A with service type is presented in [Table 6.8.13](#).

6.8.3.4 Artificial Lift Equipment

The purpose of lift equipment is to assist with “lifting” oil out of the ground. In most cases, the downhole pressure is insufficient for the liquid petroleum products to rise unassisted to the surface. There are many forms of lift equipment such as gas lift, plunger lift, rod pumps, hydraulic pumps, and electric submersible pumps (ESPs). Schematics of these types of lift equipment are presented in [Figure 6.8.23](#) for gas lift, [Figure 6.8.24](#) for plunger lift, [Figure 6.8.25](#) for rod pumps, [Figure 6.8.26](#) for hydraulic pumps, and [Figure 6.8.27](#) for electric submersible pumps.

The gas lift equipment is similar in nature to downhole accessories in that most of the materials used in gas lift equipment can also be found in gas lift. Additionally, there are copper nickel alloys such as alloy 400 and alloys 405 that are found gas lift equipment.

Most rods for rod pumps are made from carbon and low alloy steels. The various types of pumps described above utilize a variety of materials. Some of the most common materials that are used in these pumps are presented in [Table 6.8.14](#).

Many of the steel materials above utilize surface hardening techniques such as carburizing, nitriding, induction hardening, arc spray hardsurfacing, high-velocity oxy-fuel (HVOF) hardsurfacing, electroless nickel plating, and chromium plating.

6.8.3.5 Flowlines and Pipelines

Flowlines and Pipelines are mostly carbon steels and carbon steels with small alloying additions (high-strength low-alloy or HSLA steels) such as those defined by ASTM A106 [32],

TABLE 6.8.12 Description of Material Classes from API 6A

Material Class	Minimum Material Requirements	
	Bodies, Bonnets, End, and Outlet Connections	Stems and Pressure Controlling Parts
AA-General service	Carbon or low alloy steel	Carbon or low alloy steel
BB-General service	Carbon or low alloy steel	Stainless steel
CC-General service	Stainless steel	Stainless steel
DD-Sour service	Carbon or low alloy steel	Carbon or low alloy steel
EE-Sour service	Carbon or low alloy steel	Stainless steel
FF-Sour service	Stainless steel	Stainless steel
HH-Sour service	CRAs	CRAs

All materials for sour service shall be in compliance with NACE MR0175.

TABLE 6.8.13 Relative Corrosivity as Indicated by CO₂ Content from API 6A

Service Type	CO ₂ Partial Pressure	Relative Corrosivity
General service	< 7 psi (< 0.05 Mpa)	Noncorrosive
General service	7–30 psi (0.05–0.21 Mpa)	Slightly corrosive
General service	> 30 psi (> 0.21 Mpa)	Moderate to highly corrosive
Sour service	< 7 psi (< 0.05 Mpa)	Noncorrosive
Sour service	7–30 psi (0.05–0.21 Mpa)	Slightly corrosive
Sour service	> 30 psi (> 0.21 Mpa)	Moderate to highly corrosive

and API 5L [33]. These specifications do not define the chemical composition except to limit elements that effect weldability and impact/fracture toughness. The flowline and pipeline materials are generally field welded and, therefore, must be very weldable. After welding, most pipeline welds are left in the as-welded condition without the benefit of postweld heat treatment.

The mechanical property requirements of API 5L pipeline grades for PSL 2 (product specification level 2) are presented in Table 6.8.15.

For the transportation of corrosive production fluids in flowlines and pipelines, there have been numerous applications of clad pipe and corrosion resistant alloy pipe. The internal cladding has been a variety of austenitic and duplex stainless steels and nickel-based alloys.

Because of the welding requirements for the pipe products, most of the corrosion-resistant alloys used for pipe have been 22% to 25% chromium duplex stainless steels.

6.8.4 Mitigation Techniques

To combat corrosion, an understanding of why it occurs and knowledge of the environment is necessary. The next step is to understand the life cycle requirements of the equipment and how the operations and environments may change over the life of the equipment. Once we know these variables, we proceed to examining the equipment on which we need to control corrosion to determine where corrosion needs to be prevented and the material requirements of the components. Finally, we assess the various techniques available to us so that we can prevent or control corrosion.

The most common methods to control corrosion in the petroleum industry are (1) materials selection for corrosion resistance; (2) chemical inhibition of the corrosion reactions; (3) coatings that are either sacrificial, corrosion resistant, or barriers to corrosion; (4) cathodic protection; and (5) designing with a corrosion allowance. In this section the topics of material selection, coatings, and inhibition are presented.

6.8.4.1 Materials Selection

In addition to corrosion resistance, the factors that are to be considered in materials selection include strength level, product form, impact toughness, meeting code requirements, and cost. It is frequently the case that some of the other product requirements take precedence over the corrosion resistance. It may also be that permitting corrosion and adding a corrosion allowance to the design is the most cost effective materials design selection. The consequences of not applying mitigation techniques are component failures with all the risks that may be associated with those failures. An example of corroded production tubing in a CO₂ containing environment is presented in Figure 6.8.28.

The common materials used for typical production equipment such as production tubing and casing, downhole accessories, wellhead equipment, artificial lift equipment, and pipelines have been discussed previously under this topic of production corrosion. Within that range of materials, some of the basis for materials selection is presented herein.

Looking at alloying elements, different elements exhibit different roles in corrosion resistance. In iron-based metals

FIGURE 6.8.28 Corroded production tubing.

such as low-alloys steels, alloy steels, and stainless steels, the first alloying element considered is chromium. It is chromium that makes the stainless steels resistant to corrosion. The effect of chromium on corrosion rate in steel is presented in Figure 6.8.30.

The rationale for selection of 5% chromium, 9% chromium, and 12% chromium stainless steels is the corrosion resistance as illustrated in Figure 6.8.29. Other alloying elements in steels also increase corrosion resistance such as molybdenum and tungsten. There have been several relationships developed that relate the composition of iron-based CRAs to the relative corrosion and pitting resistance in the presence of dissolved chlorides and oxygen (salt solutions) such as salt water. The PREN relationship that exists in the ISO Standard 15156 [12] is presented below:

$$\text{PREN} = W_{\text{Cr}} + 3.3(W_{\text{Mo}} + 0.5W_{\text{W}}) + 16W_{\text{N}}$$

FIGURE 6.8.29 Effect of chromium content on corrosion rate [after 34].

where

W_{Cr} is the chromium content (% of total composition)

W_{Mo} is the molybdenum content (% of total composition)

W_{W} is the tungsten content (% of total composition)

W_{N} is the nitrogen content (% of total composition)

These percentages are based on the mass fraction of chromium in the alloy expressed as a percentage of the total composition. An example of a PREN calculation for a duplex stainless steel such as UNS S39377 with 24.8% chromium, 7% nickel, 2.5% molybdenum, 1.1% tungsten and 0.28% nitrogen would yield the following result:

$$\text{PREN} = 24.8 + 3.3 \times (2.5 + 0.5 \times 1.1) + 16 \times 0.28$$

$$\text{PREN} = 24.8 + 10.1 + 4.5 = 39.4$$

This 39.4 value of the PREN can be used to match up with design criteria or compare with other alloys to rank relative corrosion and pitting resistance. A note of caution for the PREN relationship presented here is that the relationship was developed for stainless steels, and the relationship may not be a good predictor of relative ranking when the alloys being compared includes other types of alloys such as nickel-based alloys.

From the above relationship, the higher the PREN number, the higher the resistance to general corrosion and pitting corrosion. To mitigate the effects of corrosion, we can select alloys that exhibit a high PREN number. For most metals there is a critical temperature below which pitting does not occur. This temperature is dependent on the composition and the specific environment. For stainless steels, the critical pitting temperature is related to the PREN number as expressed above.

Although this evaluation of PREN permits an initial assessment and ranks alloys by alloy content, the PREN is often not sufficient by itself as a guide to select the most economical material for the application. For example, the resistance to environmental cracking and the other property requirements of the equipment are not assessed. The PREN can be used as a tool in conjunction with (1) company experience, (2) field and customer experience, (3) literature searches, (4) industry wide experience and consultants, (5) material testing, and (6) prototype equipment tests.

For example, with production tubing and casing, there is abundant literature on performance envelopes of a wide variety of corrosion resistant alloys. This literature is based on laboratory testing and/or field experience. Some of the data that permits the determination of a performance envelope for 13% chromium stainless steels is presented in Figures 6.8.30 and 6.8.31.

Several good sources exist for corrosion data such as NACE and ASM International. An example of corrosion rate data in a wide variety of environments and materials

FIGURE 6.8.30 Corrosion rates as a function of temperature for 13Cr and modified 13Cr stainless steel in a CO₂ containing production environment [after 35].

FIGURE 6.8.32 Acceptable application range for 13Cr stainless steels [after 37].

FIGURE 6.8.31 Corrosion regime as a function of CO₂ and temperature on 13Cr and modified 13Cr stainless steel [after 35].

FIGURE 6.8.33 Acceptable application range for 316 stainless steel [after 37].

is *Handbook of Corrosion Data* [36]. An example of performance envelopes developed for the petroleum industry is *Selection Guidelines for Corrosion Resistant Alloys in the oil and Gas Industry* [37].

Some of the performance envelopes developed for production environments in the petroleum industry are presented here as an initial guide in selecting candidates for applications. The generally acceptable regions for 13Cr type martensitic stainless steels and 316 stainless steel are presented in [Figures 6.8.32](#) and [6.8.33](#) respectively. The acceptable regions defined in these figures are for those downhole environments in the absence of oxygen and H₂S.

For 13Cr stainless steels, these constituents can lead to severe corrosion pitting and, in the case of H₂S, could lead to environmental cracking. For 316 stainless steel, both oxygen and H₂S can lead to environmental cracking.

The generally acceptable regions for 22Cr type duplex stainless steel and 28Cr austenitic stainless steel are presented in [Figures 6.8.34](#) and [6.8.35](#), respectively.

The generally acceptable regions for 825 and 625 nickel-base alloys are presented in [Figures 6.8.36](#) and [6.8.37](#) respectively.

These alloys have been presented in order of increasing corrosion resistance and cost. For example, the 13Cr stainless steels have the least corrosion resistance and lowest cost, whereas the 625 nickel-based alloys has the greatest corrosion resistance and cost. The relative cost relationship

FIGURE 6.8.34 Acceptable application range for 22Cr duplex stainless steel [after 37].

FIGURE 6.8.36 Acceptable application range for 825 nickel-based alloy [after 37].

FIGURE 6.8.35 Acceptable application range for 28Cr austenitic stainless [after 37].

FIGURE 6.8.37 Acceptable range of 625 nickel-based alloy [after 37].

between low-alloy steel and some common CRAs are presented in [Table 6.8.16](#).

In [Table 6.8.16](#), the data are standardized such that the relative cost of 4130 to 4140 low-alloy steels was set to 1.0. The reader is cautioned in that these relative costs often fluctuate with commodity pricing and will vary accordingly. The relative costs in [Table 6.8.16](#) were valid in Jan 2015.

6.8.4.2 Coatings and Surfacing

There are several types of coatings that are used to prevent corrosion in production equipment. These can be broadly classed as metallic coatings, inorganic coatings and organic

coatings. With all of these classes, the one feature that has a huge role in the final success rate is the surface preparation. The surface needs to be clean and free of contaminants and exhibit the proper surface profile for the specific coating being applied.

Metallic coatings include (1) hot-dip galvanizing, (2) electroplating of nickel, chromium, copper, tin and zinc, (3) electroless nickel plating, (4) high-velocity (oxy-fuel) spray coatings — also known as HVOF, (5) metallizing (arc or flame spraying), (6) plasma vapor deposition (PVD) and ion implantation, (7) chemical vapor deposition (CVD) coatings, (8) cladding, and (9) weld overlays. The major use of these metallic coatings is to prevent corrosion on

TABLE 6.8.16 Relative Costs for Material

Alloy	Alloy Type	Relative Cost
4130–4140	Low-alloy steel	1.0
8630	Low-alloy steel	1.25
4340	Low-alloy steel	1.35
9Cr-1Mo	Highly alloyed steel	2.0
13Cr	Stainless steel	2.2
316	Austenitic stainless steel	4.5
22Cr	Duplex stainless steel	5.5
25Cr	Super duplex stainless steel	6.5
28Cr	Super austenitic stainless steel	6.5
825	Nickel-based alloy	13
K500	Nickel copper alloy	15
718	Nickel-based alloy	17
625	Nickel-based alloy	20

carbon and low-alloy steels. There are applications of copper plating and hard surfacing for reasons other than corrosion control.

The plating metals used most often in the petroleum industry are chromium and nickel. Both of these can be electroplated, and nickel is also available as an electroless plating. Chromium platings are generally very hard and exhibit numerous microcracks that precludes its use as a corrosion barrier. This problem is exasperated by the potential galvanic difference between the chromium and the substrate that can drive the initiation and propagation of localized corrosion attack, ultimately resulting in deep penetrating corrosion pits and disbondment of the chromium plating. There are very thin dense chromium platings with a coating thickness less than 0.25 mm (0.001 in.) that can be dense and crack-free. Chromium platings are often plated over thin electroplated nickel, where the nickel provides the corrosion barrier and the hard chromium provides the desired wear resistance.

Another type of plating that is not driven by applied current is electroless nickel, in which an activated metal substrate plates autocatalytically. An advantage of the electroless nickel process is that, because current density is not an issue, there are no shape and distance effects with respect to anode (source of current to complete circuit) to cathode (substrate being plated) placement. This results in a uniform plating thickness. One other aspect of electroless nickel is that phosphorus is intentionally codeposited, and this forms a hardened plating that starts to approach hardness levels

found in chromium platings. All carbon and alloy steels with a measured surface hardness of HRC 28 or higher should be undergo a bake-out heat treatment to remove residual hydrogen after any metallic plating (current driven or electroless) to prevent hydrogen related cracking.

Inorganic coatings includes include (1) surface conversions, (2) inorganic zinc silicate, (3) HVOF ceramic coatings, and (4) flame and arc spray ceramic coatings. The common surface conversions are anodizing on aluminum, phosphating and oxidizing processes on steels and chromate surface conversions on steel.

Organic coatings include (1) epoxy paints, (2) acrylic paints, (3) polyurethane paints, (4) organic zinc paints, (5) phenolic coatings, (6) epoxy-phenolic coatings, (7) fluorocarbon based coatings, (8) molybdenum disulfide coatings, and (9) silicone paints and coatings. Generally, where the word “paint” appears in the above list, the coating consists of at least two components, one a carrier and one the paint. In many cases, with two or more part products that are mixed, the paint undergoes a chemical reaction, causing or assisting in the curing and/or drying cycles. The coating listed above that do not list paint generally require a heat curing cycle that sets the coating onto the substrate.

Organic internal pipe and tubing coatings definitely provide a benefit by reducing power costs, increasing flow and eliminating corrosion [39]. Rehabilitating a pipeline with inplace internal coating versus replacement returns the line to active service. During research of flow improvement due to pipe cleaning, additional studies were made to determine the improvements in pipeline flow and corrosion protection with use of coatings [40]. The conclusion was that both flow improvement and corrosion protection were evident.

The coatings that best meet the needs of the pipeline industry are the polyamide epoxies and amine-adduct-type coatings [41]. A comparison of the two types is presented in Table 6.8.17.

McConkey has listed the following properties required for a pipeline coating [42]:

- ease of application
- good adhesion to pipe
- good resistance to impact
- flexibility
- resistance to soil stress
- resistance to flow
- water resistance
- electrical resistance
- chemical and physical stability
- resistance to soil bacteria
- resistance to cathodic disbandment

These properties relate either to the economic viability of the coating or to the ability of the coating to protect the pipeline from damage and possible failure due to corrosion.

TABLE 6.8.17 Coating Comparison [41]

Property	Coating	
	Amine	Polyamide
Hardness	5H to 6H pencil hardness, faster initial cure	4H to 5H pencil hardness, slower initial cure
Tolerance to inadequately prepared surface	Good	Very good
Brittleness	Very brittle in a few months	Same resiliency remains after a few months
Sag resistance (5–7 m wet)	Good	Good
Adhesion	Good	Good
Application characteristics	Very good	Excellent
Flexibility	—	Best
Abrasion resistance	Equal	Equal
Water resistance	—	Best

6.8.4.3 Inhibition

An *inhibitor* is a substance that slows or stops a chemical reaction. When an inhibitor is present in sufficient enough quantity to slow a corrosion reaction, the corrosion is prevented. The basic mechanisms by which inhibitors function are as follows [38]:

1. They absorb onto the corroding material as a thin film.
2. They induce formation of a thick corrosion product, which forms a passive layer.
3. They change the characteristics of the environment either by producing protective particulates or by removing or inactivating an aggressive constituent in the environments.

The corrosion inhibitors that are used in the petroleum industry are typically organic compounds, and they are usually employed at low concentration levels, generally on the order of 0.1%.

The decision to use inhibitors is determined by the following:

1. the predicted corrosion rate without inhibition
2. the predicted effectiveness of an inhibition program
3. the predicted cost of the inhibition program
4. the required equipment life and predicted life of the field
5. the cost of other mitigation techniques such as coatings and corrosion resistant alloys

The effectiveness or performance of an inhibitor is related to the temperature, flow rate (wall shear stress), metal surface condition, alloy type, oxygen, and the other specific environmental constituents. Generally inhibition is

very effective in anaerobic systems with low pressures, low temperatures, and low flow rates. Conditions that includes high temperatures, high CO₂ partial pressures and/or high velocities decrease the effectiveness of the inhibition treatments. Successful inhibition under these conditions generally require greater concentrations of inhibitors, and the selection of specific inhibitor becomes increasingly important because the inhibitor needs to be effective while wetting the surface(s) to be protected.

6.8.4.3.1 Classification of Inhibitors

Corrosion inhibitors are generally classed by the type of inhibitor or by their solubility.

As a type of material, the inhibitor may be an organic or an inorganic compound. Inorganic inhibitors include chromates (CrO₄⁻²), silicates (SiO₃⁻²), and phosphates (PO₄⁻²). The three basic types of inorganic inhibitors are anodic passivating inhibitors, cathodic inhibitors, and cathodic precipitators. There are also mixed inhibitors that suppress both anodic and cathodic reactions.

Anodic inhibitors suppress or prevent anodic reactions by assisting the natural passivation of metal surfaces or by forming films/deposits that isolate the metal from the environment. These anodic inhibitors are sometimes categorized by being either highly oxidizing or much less oxidizing. Examples of the highly oxidizing anions include chromates, nitrites, and nitrates.

The low-oxidizing anodic inhibitors include phosphates, molybdates, and tungstates. The low-oxidizing anions require an external source of oxygen for passivation. These low-oxidizing anions are sometimes referred to as

FIGURE 6.8.38 Schematic of film-forming inhibitor [44].

dangerous inhibitors because they can actually cause pitting when present in low concentrations. Anodic inhibitors are also considered dangerous because cathodic reaction may not be inhibited on unprotected areas [43].

The cathodic inhibitors suppress the cathodic chemical reaction, and these are further subgrouped by the way in which the cathodic reaction is affected. The three basic types are cathodic poisons, cathodic precipitators, and oxygen scavengers.

The organic type of inhibitors affect the entire surface of the metal by forming films on the surface. The organic inhibitors are semipolar in that the make-up of the inhibitor includes a polar (conductive) and a nonpolar (nonconductive) component. The semipolar nature renders one end of the molecule hydrophobic (water repelling) and the other hydrophilic (water loving).

These semipolar molecules bond or attach to the metal surface on the polar (conductive) end of the chemical compound. A thin film only a few molecules thick is adsorbed according to the ionic charge of the inhibitor molecule and the charge of the metal surface. These organic inhibitors can preferentially attach to either the cathode or

the anode of the system; these inhibitors are termed cationic inhibitors (positively charged) and anionic inhibitors (negatively charged). Amines are examples of organic cationic inhibitors and sulfonates are examples of organic anionic inhibitors. The bonding of these inhibitors is illustrated in Figure 6.8.38.

One advantage of the organic inhibitors is that they are typically self-healing when the inhibitor is present in sufficient concentration. If the film is damaged or removed through flowing conditions, the film reforms. Examples of organic inhibitors include primary amines, carboxylated amines, amides, imidazoline, and quaternary ammonium ion.

The other way to classify inhibitors is by their solubility. The classes based on primary solubility are presented below:

1. oil soluble
2. water soluble
3. oil or water dispersible (emulsions)
4. oil and water insoluble
5. gas phase

However, most inhibitors at least partly soluble or partly dispersible in both oil and water.

Water soluble inhibitors are used in systems with a significant water phase. Examples of water soluble inhibitors include quaternary amines, amine salts and salted imidazolines. Oil soluble inhibitors include long-chain primary amines, imidazolines, fatty acids, and phosphate esters. These inhibitors can be used in both batch and continuous inhibitor injection systems.

Batch treatments usually rely on oil-soluble or oil- and water-insoluble inhibitors. The reason is that there needs to be some insolubility in the water phase if there is a persistent film when water wet. Gas-phase inhibitors are usually low-molecular-weight amines that have high vapor pressures such as some carboxylated amines.

The inhibition systems are classified by the method by which the inhibitors are introduced into the production fluids (continuous, batch, and squeeze).

6.8.4.3.2 Choosing Inhibition for Wellhead and Downhole Equipment

During production operations, failures of tubular goods and equipment are mainly caused by the presence of carbon dioxide, hydrogen sulfide, oxygen, and water. The following general procedures for a new design are recommended.

1. Evaluate the type of corrosion that might occur. In production operations, hydrogen sulfide, carbon dioxide, oxygen, and water are the main causes of corrosion.
2. When H₂S is present, select steels and alloys that are resistant to cracking in the environmental conditions present including acidity, phases present, temperature and chloride content in addition to the level of H₂S present. While designing the tubular goods and equipment most compatible to the environment encountered, consider the metallurgical factors and alloying elements for “sweet” and “sour” oil and gas environments.
3. Select the best and most economically feasible inhibitor by considering similar situations and past experience with conditions close to those encountered. In the case of a unique condition, applicable laboratory tests should be performed to confirm the effectiveness of the inhibitor.
4. Determine a method of inhibitor application by considering its effectiveness, economy, and frequency of application.
5. Monitor and inspect the equipment and keep track of the performance to evaluate and update the program treatment.

The control the corrosion in the tubing, casing, and surface equipment for a system already in operation where the material cannot be chosen since it is already in use. In this situation, corrosion can be controlled by a judicious selection of inhibitors and practical method of applying the

inhibitor. A general procedure in an existing system is as follows:

1. Select the most effective inhibitor for the situation. If possible, investigate its performance for similar situations in field history and in the laboratory tests. For H₂S, filming amines and organic phosphates are reported to be effective corrosion inhibitors. Filming amines are also reported to be effective for carbonate dioxide.
2. Determine the most effective concentration and amount of the inhibitor.
3. Use a practical method to apply the inhibitor to the system. The continuous method, especially with a capillary system, is reported to be the most effective and economical.
4. Determine the frequency of application.
5. Monitor and evaluate the performance of the system, and adjust the treatment program according to the observation.

In water flooding not only is corrosion more severe than in primary production, but also there are scale problems. Because water is open to atmosphere, it dissolves more oxygen. Necessary water treatments include:

1. *Filtration* — to remove the suspended solids from water.
2. *Oxygen scavengers* — to reduce the oxygen concentration.
3. *Scale inhibitors* — either to prevent crystallization or prevent the adherence of crystals to the surface. It should be mentioned that improper use of scale causes pseudoscale; therefore, extensive field and laboratory tests should be performed to prevent this problem.
4. *Chemical treatment for bacteria* — to reduce or eliminate the bacteria population.
5. *Corrosion inhibition* — basically this is the same as primary production. It is more desirable to use inhibitors that reduce scale as well as effective corrosion controllers.

All three techniques, batch, continuous, and squeeze, have been used for inhibition systems for the protection of downhole equipment. Of the three, the continuous method is the most effective and preferable from a performance perspective. The continuous injection of inhibitor into the fluid stream has been recognized as the optimum treating method since the inception of corrosion control by chemical injection [45–47].

Continuous downhole injection is reported to increase the functional life of the tubing 10- to 20-fold, where no other treating methods could increase the functional life of the tubing more than three to fivefold [48]. The continuous treating method generally involves introducing the inhibitor on a continuous basis at sufficient concentrations to form a protective film on the tubing. It can be used to protect

topside equipment such as wellheads, separation facilities and flowlines as well as downhole equipment.

The batch technique is only used to handle special problems such as the protection of well tubing when downhole injection is difficult. The squeeze technique is used for scale inhibitors but is not typical for corrosion inhibitors because of the potential damage to the formations.

The use of chemical injection tubing for the continuous or batch injection of inhibitors into the well bore is presented in Figure 6.8.39. Chemical injection through the annulus of a larger tube (concentric completions) is presented in Figure 6.8.40. The use of corrosion inhibition in a Y-block completion is presented in Figure 6.8.41. The use of gas lift valves to inject inhibitors with the lift gas is presented in Figure 6.8.42, and the use of a separate chemical injection line with a side pocket mandrel (gas lift) is presented in Figure 6.8.43.

Water floods are one of the common oilfield practices that results in additional corrosion considerations. This technique is used to increase the amount of oil recovered.

FIGURE 6.8.39 Dual completion [48].

FIGURE 6.8.40 Concentric completion [48].

The water injected is natural surface water sources or reinjected produced water. In water flooding not only is corrosion more severe than in primary production, but also there are scale problems. In many instances, the produced water has insufficient volume for injection purposes and additional water is required (naturally occurring surface water). Because water is open to atmosphere, it contains dissolved oxygen and this contributes greatly to the corrosion potential. Necessary water treatments include:

1. Filtration — to remove the suspended solids from water.
2. Oxygen scavengers — to reduce the oxygen concentration.
3. Scale inhibitors — either to prevent crystallization or prevent the adherence of crystals to the surface. The improper use of scale inhibitors causes pseudoscale; therefore, field and laboratory tests should be performed to prevent this problem.
4. Chemical treatment for bacteria — to reduce or eliminate the bacteria population.

FIGURE 6.8.41 Y-block completion [48].

5. Corrosion inhibition—basically this is the same as primary production. It is more desirable to use inhibitors that reduce scale and are effective corrosion controllers.

An evaluation of the various corrosion inhibition methods is presented in Table 6.8.18 [45,46,48].

For water flood applications, the volume of water dictates that metal surfaces will be water wet. This results in the selection of inhibitors that will be soluble in water with good metal filming characteristics. The practical corrosion inhibitors in water flood applications are variations of the following compounds:

- primary monoamines
- polysubstituted monoamines
- diamines
- polyamines
- imidazolines
- quaternary ammonium compounds

Failure to properly treat injected water is the leading cause for unanticipated souring of a reservoir. If the wells are

FIGURE 6.8.42 Gas-lift well completion [48].

not completed with sour-service resistant materials, they may need to be abandoned for regulatory, health and safety requirements. Wells completed where hydraulic fracturing or water injection is planned should specify sour-service materials. While this incrementally increases the cost of completions, it is a reasonable cost to mitigate risk for the need of a future shut-in.

6.8.4.3.3 Choosing Inhibition for Flowlines and Pipelines

Internal corrosion in product pipelines, in most cases, is caused by water and oxygen dissolved in the product. Dry refined products with normal additives are noncorrosive to steel pipelines. The products are corrosive because of associated water and air. A film of liquid water adheres to the pipeline surface, and oxygen is available from air dissolved

FIGURE 6.8.43 Continuous downhole injection system (CDIS) [46].

TABLE 6.8.18 Comparison of Corrosion Treatment Methods

in the product. The solubility of air in products varies, but refined products generally carry sufficient oxygen to support corrosion. Air is introduced into the products by tank mixers, turbulence, normal tank breathing, etc.

The outside of pipelines and flowlines are exposed to ground waters, saltwater, and industrial environments. The lines may be above ground, buried, or submerged beneath fresh or saltwater. Internal corrosion can be controlled by removing one of the active ingredients, water or air, by adding an inhibitor which will make the steel inactive; or using a barrier coating on the steel. A general procedure to mitigate corrosion includes the following:

1. Select coatings and wraps for external pipeline protection.
2. Investigate cathodic protection for buried and submerged flowlines and pipelines
3. Reduce sources of oxygen in the fluids transported.
4. Reduce water content and evaluate the use of dehydration.
5. Chemical treatment for bacteria—to reduce or eliminate the bacteria population.
6. Evaluate corrosion inhibition and candidate inhibitors.
7. Determine the most effective concentration and amount of the inhibitor.
8. Use a practical method to apply the inhibitor to the system. Because the continuous method, especially with a capillary system, is reported to be the most effective and economical, this method should be considered strongly if applicable.
9. Determine the frequency of application.
10. Monitor and evaluate the performance of the system and adjust the treatment program according to the observation. Basically this is the same as primary production. It is more desirable to use inhibitors that reduce scale and are effective corrosion controllers.

Even though the product is clear when it is placed in the pipeline, indicating absence of free water, temperature drops may occur during transit and cause water to separate. [Table 6.8.19](#) shows increasing solubility of water in gasoline as temperature increases. [Table 6.8.20](#) indicates the range of solubility of water in some pure hydrocarbons. The important factor is the change in solubility per increment of temperature change. From [Table 6.8.20](#) a 8°C (17°F) increase in temperature doubles the solubility of water in n-pentane.

Dehydration can be used to control corrosion if the water is kept at low level. This method requires considerable equipment and manpower for maintenance, so the cost is high for control. Free water can be removed in the storage tank by allowing the water to settle out of the product. Free and entrained water can be removed by using water separators and coalescers.

TABLE 6.8.19 Solubility of Water in Gasoline

Temperature	Solubility
4°C (40°F)	1.8 gal/1,000 bbl
10°C (50°F)	1.8 gal/1,000 bbl
16°C (60°F)	1.8 gal/1,000 bbl
21°C (70°F)	1.8 gal/1,000 bbl
27°C (80°F)	1.8 gal/1,000 bbl
32°C (90°F)	1.8 gal/1,000 bbl
38°C (100°F)	1.8 gal/1,000 bbl
43°C (110°F)	1.8 gal/1,000 bbl

TABLE 6.8.20 Solubility of Water in Specific Hydrocarbons

Specific Hydrocarbon	Temperature °C(°F)	Solubility	
		mg/100 g	gal/1000 bbl
n-butane	20 (68)	6.5	1.5
isobutene	19 (66.2)	6.5	1.7
n-pentane	15 (59)	6.1	1.6
	24.8 (76.6)	12.0	3.2
isopentane	20 (68)	9.4	2.4
n-hexane	20 (68)	11.1	3.1
cyclohexane	20 (68)	10.0	3.3
n-heptane	20 (68)	12.6	3.6

heptene-1	20.5 (68.9)	104.7	30.8
butene-1	20 (68)	39.7	11.1

Rust particles, dirt, etc., in the product will settle out in the low section of the pipeline if the flow velocity is not sufficient to keep the particles entrained. These particles, being of dissimilar electrochemical properties to the underlying metal, will form local corrosion cells in the presence of water. These particles will be filmed with a chemical inhibitor the same as the pipe, and this causes depletion of available inhibitor to protect the line. Most filters are designed to prevent free water from entering the system. Some of the common types of filters used include (1) hay

tanks, (2) cartridge type, and (3) centrifugal type. Selection of the filter will depend on the application and design of each pipeline.

For pipelines and flowlines, the most common method employed today in controlling internal corrosion is the use of organic or oil-soluble inhibitors. These inhibitors are generally hydrocarbons (with polar group attached) that tend to form a protective film on the pipeline's internal surface [49]. Water-soluble corrosion inhibitors are also used to solve internal pipeline corrosion problems but because of the relatively short film life of water-soluble corrosion inhibitors, they are continuously injected as opposed to the batch-treatment method.

Because water on the bottom of the pipe is a source of the corrosion problems, one might assume a water-soluble inhibitor to be the answer to treating a pipeline carrying crude oil and water. However, another problem must be considered. The portion of pipe occupied by the oil and water emulsion is also a corrosive environment. Under such conditions, a water-soluble inhibitor will probably not provide adequate protection. However, there is laboratory evidence that a portion is absorbed into the oil, and this can provide some protection in the oil phase (Figures 6.8.44 and 6.8.45) [50].

Oil-soluble corrosion inhibitors are widespread in systems handling both oil and water. This type of inhibitor may do a good job protecting small-diameter pipelines because high velocity or turbulent flow prompts mixing of the inhibitor and produced fluids. However, because of reduction in velocity or turbulence, it may not provide the desired protection in large flowlines or pipelines carrying these same fluids.

The oil-soluble inhibitors have the advantage that they may be injected at the refinery during the normal blending operations and will protect the refinery piping, the pipeline, the gasoline station tanks, etc. This advantage is fully realized when a company operates its own pipeline and handles its own products. Similarly, common-product pipelines can inject inhibitor at source points only, or can require shippers to supply inhibited products [51].

Inhibition can be accomplished by one of two general methods; these are batch (intermittent) treatment or by continuous injection. Batch treatment normally entails pumping a suitable-size slug or pure or high-concentration inhibitor solution through the line. Frequency of the treatment is governed by the effectiveness of the inhibitor remaining after a given time or after a specified amount of product has been moved through the line.

FIGURE 6.8.44 Sweet corrosion wheel test [50].

FIGURE 6.8.45 Sour corrosion wheel test [50].

Continuous injection consists of adding a constant volume of inhibitor to the product being transported through the pipeline. This method is probably the most desirable and widely used.

Injection facilities vary greatly in design and operation, and in general the installation consists of the following equipment units:

1. inhibitor storage vessel
2. injection pump
3. measurement device (meter or calibrated sight glass)
4. connection to the pipeline

Positive-displacement chemical pumps, with adjustable capacity, are probably the most widely used on product pipelines [52].

Construction materials for the equipment should be suitable for continuous service when in contact with the inhibitor. Stainless steel should be considered for small-diameter piping or tubing in which even minor rusting could cause plugging and make pumping of more viscous liquids difficult. When handling nitrogen-based inhibitors (amines, amides, nitrites, etc.), the use of copper or copper-based alloys should be avoided, as stress corrosion cracking might result. Nonmetallic seals and packing material should

be checked for compatibility with the inhibitor formulation [53].

Points of injection should be chosen to provide maximum benefit in the pipeline system. Injection on the suction side of pumps takes advantage of pump turbulence to promote mixing of the inhibitor with product. Injection through a tube into the center of the pipeline aids mixing.

Premixing or dilution of the inhibitor can improve handling and promote a more rapid phase-contrast. Viscous inhibitors can be diluted with compatible hydrocarbon carriers to decrease viscosity, making pumping easier and metering more accurate, especially at low-dosage rates. Premixing water-phase inhibitors with water before injection greatly facilitates phase contact of inhibitor with entrained water.

6.8.4.3.4 Choosing Inhibition for Gas Transmission Lines

Gas transmission lines are very similar to fluid flowlines and pipelines. Here, oxygen, CO₂, and H₂S are the main corrosives in natural gas pipelines, and they are aggressive only when they are absorbed into water or condensed moisture in the lines. Most pipeline gas has been sweetened and dehydrated as well as treated otherwise before it is pumped

into transmission lines. Consequently, most of the corrosion problems in gas systems occur in the various gathering lines and in the piping and equipment used for removing liquid hydrocarbons and sulfur.

Although inhibitors may be slugged, injected, or sprayed into a gas stream, they function only to the extent that they are absorbed onto or react with the steel to set up a barrier between it and the aggressive agents [54].

Natural gas pipelines can be classified as either wet or dehydrated. Most of the internal corrosion problems discussed thus far are characteristic of wet-gas pipelines.

Dehydrated systems are usually characterized by a water vapor content in the gas less than saturation and the sporadic movement of fluids through the system. Without a contacting water phase onto the pipe walls, there is a very low potential for corrosion reactions.

The major problem in treating these lines is the distribution of inhibitor to the corrodible areas. How do we get an effective, nonvolatile inhibitor to the top and sides of a pipeline? How do we get a nonvolatile inhibitor to carry through the entire length of a pipeline? Under proper conditions, these are all possible using the simplest of application methods. According to EnDean all we need to know are [55]:

1. diameter of the line
2. length of the line
3. volume of gas in MMcf
4. pressure
5. pressure drop
6. temperature
7. volume of liquid water through the pipe
8. volume of liquid hydrocarbons

From these data, we can predict if there is annular flow in the pipeline. If there is annular flow, then all that is necessary is to add the inhibitor as a solution. Transport and distribution of the inhibitor along the pipeline is assumed. The eight variables listed define the flow conditions in a pipeline and thus determine the method and type of inhibitor treatment that is required [56].

To determine whether the concentration, based on gas volume, is sufficient, there are tests for chemical concentrations in water; these are called *residuals*. This information, combined with comprehensive monitoring, allows for maximum protection at minimum cost. It should be realized that residuals can fluctuate widely in systems where water volumes are subject to great fluctuations. These residuals are still very useful when monitored over a period of time and a statistical average determined.

6.8.4.3.5 Scale Removers

Scale can occur in downhole production tubing, flowlines, and pipelines. Scaling is the precipitation of adherent deposits on metal surfaces. Normally, precipitation of

scale-forming salts occurs when solubilities are exceeded because of high concentrations or unfavorable temperatures. The problem of scale in water flooding occurs all the way from the water injection facilities to the producing well. Generally, there are six important regions where scaling can occur during and after injection operations [57–59]. These are:

1. in the injector wellbore
2. near the injection-well bottomhole
3. in the reservoir between the injector and the producer
4. at the skin of the producer well
5. in the producer wellbore
6. at the surface facilities

The formation of these scales is harmful in many ways in the petroleum industry. Scale build-up in tubulars decreases production capability and wireline and production logging operations can also be affected. Scales can also reduce the efficiency of heat exchanger surfaces in process and refining equipment downstream.

Wide variations in temperature, total pressure and changes in pressure during production make practical control of scale deposition difficult in water-flooding operations. CaSO_4 (calcium sulfate), CaCO_3 (calcium carbonate), BaSO_4 (barium sulfate), SrSO_4 (strontium sulfate), FeCO_3 (iron carbonate), and iron hydroxides are the most common scales in oilfield environments. There are a number of reasons for precipitating scale. Temperature, pressure, and water incompatibility are known to be the major causes of scale deposition in oilfield environments. Scales are usually formed in a supersaturation condition; that is, when the solubility product of a deposit-forming material is exceeded, it precipitates. A supersaturated solution is a solution that contains a higher concentration of a particular mineral than the solution can hold under the same set of conditions with its solute in equilibrium. Each scale is deposited under certain conditions that depend on temperature, pressure, and mineral content.

There are some scale deposits in oilfield environments that are called pseudoscale, that is, the deposit of a reaction product between two or more human-introduced chemicals, or between a naturally occurring fluid and one or more human-introduced chemicals. For example, most water-soluble corrosion inhibitors have a tendency to establish pseudoscale. Also, scale inhibitors such as phosphonates and polymers react with Ca^{2+} and/or Mg^{2+} ions in oilfield brines, thus forming pseudoscales that look and behave exactly like “real” scale [59,60].

There are two states of supersaturation: metastable and labile. Figure 6.8.46 represents a normal solubility curve and two different states of supersaturation.

A scale inhibitor tends to shift the dotted line, which is a function of fluid velocity, hydrocarbon content, agitation, temperature, pressure, and pH, toward the solid line that

FIGURE 6.8.46 Variation of solubility and supersaturation with temperature [57].

represents the normal solubility curve. Normally, crystallization of scale will not occur in the stable region (undersaturated). In the metastable region, spontaneous crystallization does not occur nor do scales form rapidly. In the upper portion, above the dotted line that represents the unstable, or labile region, spontaneous crystallization is probable [57,59].

BaSO_4 crystallization and adherence will increase with decreasing temperature. Other factors that have direct influence on the solubility of BaSO_4 are increasing pressure and increasing salt content of the brine. Figure 6.8.47 shows solubility of barium sulfate as a function of temperature.

Ethylenediaminetetraacetic acid (EDTA) and nitrilotriacetic acid (NTA) are known to be the common solvents for BaSO_4 . These solvents and some other similar chelating compounds break down in BaSO_4 crystals by tying up the Ba^{2+} ions. The dissolved Ba^{2+} ions are masked or chelated. Therefore, they become incorporated into new chemical compounds that are soluble [59].

The mechanism of scale inhibitors in preventing scaling tendency is very difficult to predict under a given set of conditions. Some scale inhibitors are believed to prevent the crystallization of a scale, and others are believed to prevent the adherence of crystals to themselves or to metal surfaces in the field. Some of the common effective scale inhibitors include the derivatives of one of the following chemicals:

1. polymers (polymaleic acids, polyacrylates)
2. esters of phosphoric acid

3. phosphonates such as triethylenediaminetetra (methylene phosphonic acid)

The necessary concentration of scale inhibitor is a function of three variables: supersaturation, temperature, and the chemical composition of the scale. The higher the supersaturation and the higher the temperature, the higher will be the inhibitor concentration required to prevent the precipitation of a given amount of scale per unit volume of solution. Extensive laboratory and field experiments indicate the inhibitors listed in Table 6.8.20 are effective against the BaSO_4 scale [60,62].

There are a few disadvantages of some of the scale inhibitors that lead to formation of emulsions and pseudoscale. Basically, the inhibitor reactions with dissolved ions in oilfield brines are believed to be the main causes of pseudoscale. The pseudoscales are mostly caused by interactions between the dissolved ions such as Ba^{2+} , Ca^{2+} , and Mg^{2+} ions in the brine and the applied inhibitors. The pseudoscales act like a real scale; therefore, additional problems caused by deposition of pseudoscales can be encountered with the application of improper inhibitors. Oilfield operators have tried to solve emulsion problems by raising the temperature of the additions, but as temperature increases, more scaling is encountered. Therefore, the application of an effective inhibitor under specific conditions requires laboratory studies and field tests. To predict the emulsification tendency of an inhibitor with crude oil, a dynamic test is usually required under specific given

FIGURE 6.8.47 BaSO₄ solubility in water [61].

conditions employing kerosene and/or the specific crude oil [59,60].

CaSO₄ is also known as one of the most common scales in oilfield environments. The main reason for the scaling difficulties experienced with CaSO₄ is the solubility behavior of CaSO₄ in its three forms: dihydrate gypsum (CaSO₄·2H₂O), anhydrite (CaSO₄), and hemihydrate (CaSO₄·1/2 H₂O). Gypsum is less soluble at low temperatures, but anhydrite is formed at higher temperatures. Pressure drops play a major role in deposition of gypsum and anhydrite scales. Figure 6.8.48 shows solubility of calcium sulfate as a function of temperature. Some water-flooding operations in Texas and Wyoming have indicated significant production declines due to deposition of calcium sulfate. One of the major causes of CaSO₄ scale deposition in oil fields is known to be the presence of high quantities of native anhydrite in the reservoir formation as well as incompatibility of injection and reservoir waters [59,63].

Fracturing jobs could increase the scale problem unless scale deposition is effectively prevented. The squeeze treatment is known to be the most effective method for application of scale inhibitors to prevent calcium sulfate deposition. One of the most effective scale inhibitors to prevent CaSO₄ scale is a water solution of imidazolines and methylphosphonic acids [64].

This chemical composition as a scale inhibitor was tried in a well near Powell, Wyoming, in which CaSO₄ scale problems were known to be the only cause of the production

decline of a well from 380 to 42 bpd. After physically breaking up the scale with explosives, the scale inhibitor at 130 ppm concentration was injected by a squeeze treatment. Table 6.8.21 is the production performance of the treated well with the inhibitor noted above [64].

The majority of laboratory and field experiments show that phosphonates and low-molecular-weight polyacrylate scale inhibitors are effective in preventing the formation of calcium sulfate scale at temperatures up to 150°C (300°F). Experiments using phosphonates and polyacrylates have shown that metastable compounds such as gypsum scale were dehydrated to anhydrous CaSO₄ within the deposit. The additional influence of a phosphonate-type scale inhibitor at high temperature in a supersaturated calcium sulfate solution reduces the growth rate of rate of all three forms of calcium sulfate crystals but, at 130°C (265°F), the phosphonate-type scale inhibitors accelerate formation of anhydrite. To prevent the formation of anhydrite, the application of a low-molecular-weight polyacrylic acid is suggested [62,65–67].

CaCO₃ scale is normally encountered in primary oil production, water flooding, and CO₂ flooding. For a low CO₂ partial pressure, CaCO₃ shows lower solubility than it does at higher partial pressures. The most influential factors in precipitation of CaCO₃ include the temperature fluctuation, pH, injection water composition and produced water composition. Figure 6.8.49 shows the limiting pH level for CaCO₃ precipitation from normal seawater as a

FIGURE 6.8.48 CaSO₄ solubility in water [61].

TABLE 6.8.21 Some Effective Scale Inhibitors for BaSO₄

Scale Inhibitor		Maximum Temperature
Type	Concentration	
Esters	10–25 ppm	120°C(250°F)
Phosphonates	10–25 ppm	175°C(350°F)
Polyelectrolytes (polymer)	15–45 ppm	175°C(350°F)

**FIGURE 6.8.49** CaCO_3 scaling threshold in normal seawater [68].

function of temperature. Other waters will have similar responses.

The solubility of CaCO_3 decreases with increasing temperature. The relationship between temperature and CaCO_3 solubility is presented in Figure 6.8.50. Normally, when CO_2 comes in contact with water, it dissolves and forms carbonic acid.

The effect of CO_2 pressure on CaCO_3 solubility is shown in Figure 6.8.51. Normally, as the water is produced, the CO_2 pressure decreases as the water reaches the surface. This phenomenon upsets the chemical equilibrium, and scale deposits. Because the CaCO_3 has a higher solubility at lower temperatures (Figure 6.8.50), CaCO_3 scaling tends to be lower at the surface facilities than at the production wellbore as predicted from temperature change. Table 6.8.23

shows solubility of CaCO_3 at different CO_2 partial pressures and temperatures [70].

The use of scale inhibitors is necessary to prevent (CaCO_3) crystallization and adherence in water-flooding and CO_2 -flooding operations. Both organic and inorganic scale inhibitors have been found to be effective in preventing CaCO_3 scale formation. Most inorganic inhibitors are phosphates such as tetrasodium pyrophosphate, sodium triphosphate, sodium-calcium phosphate, and sodium-magnesium phosphate. These phosphate inhibitors are normally used in the 5 to 60 ppm range that depends upon watercut, treatment application, and type of scale [71].

The organic compounds have shown better results in inhibition of CaCO_3 and other scales formed at higher temperatures. Within these organic scale inhibitors,

FIGURE 6.8.50 Effect of temperature on the solubility of CaCO₃ [69].

phosphonate materials are the most effective. The majority of experience in actual field environments indicates that the general types of organic materials used as scale inhibitors such as phosphonates, disphosphonates, phosphate esters and polyacrylates in concentration of 10 to 100 ppm, are effective in stopping scale deposition through squeeze treatments.

6.9 ENVIRONMENTAL CONSIDERATIONS IN OIL AND GAS OPERATIONS

Section reviewed by Catherine Rivera Lyons

6.9.1 Introduction

The key role of the engineer in daily operations is the operation and maintenance of facilities. In designing a new facility or upgrading an existing one, however, the engineer should be aware of non-technical risks (NTRs) that must be identified and managed, such as: air emissions, water discharges, social stakeholders, and hazardous waste generation (see Section 4.20). The engineer needs an in-depth

understanding of the potential impact of the operation on the environment, and how decisions made during the design and construction phase of the project can circumvent or reduce these impacts. The engineer must also be aware of the regulations applicable to the facility and operations, and that permits are acquired in a timely manner.

The average well and separation facility or battery requires minor support on a daily basis. The pumper or lease operator may visit the site for a few minutes, confirm normal operations, and move on to the next location – if operations are not monitored remotely. Occasionally, a well may be worked over for maintenance, repair, or stimulation, and the activity around the wellsite or facility is increased for a short period of time. Even though the activity may be limited, the potential of environmental impacts associated with wellsites and separation facilities are not. Today managing NTRs are addressed everyday, as must be incorporated into daily operating practices as well as in facility design. In fact, as discussed in Section 4.20, a critical issues analysis should be performed to identify applicable NTRs and associated controls, plans and permits that must be prepared and obtained before beginning development of new wells and facilities, or modifying existing ones.

This section will address the most typical regulations, permit types, and best practices that are required, at a minimum, in the United States. However, regulations are rapidly changing, and this section will not include all potential requirements (including local or state-specific) that will be needed to maintain operational license. A critical issues analysis should be performed to identify all potential requirements. Fines may be levied, individuals may be sentenced, pipeline connections may be severed if the critical issues are not understood and regulatory requirements are not followed. Most importantly, the safety of both operational personal or local stakeholders may be compromised if unsafe conditions exist or an incident would occur.

6.9.2 Regulations

Each state has a governing body or bodies that are involved in day-to-day oil and gas operations and environmental permits, or they may defer to federal rules and regulations (Regs). In the United States, the Environmental Protection Agency (EPA) sets policy concerning environmental regulations. The states are then allowed primacy over jurisdiction of environmental compliance if their regulations are at least as stringent as the federal regulations. Several bodies of government may be involved in environmental decisions concerning the well site. It was at one time common in most oil and gas producing states that the oil and gas division was allowed to administer all matters covering exploration and development. However, because of varying type of regulations and potential for impact, the responsibility is

typically spread among several agencies. A good example is air quality and permitting requirements that are typically not administered by the same agency that administers the oil and gas well permits. It is primarily the responsibility of state or local agencies to protect the integrity of the state's land and water supplies from contamination due to oil and gas activity. The state oil and gas division's environmental regulations may default or mirror the EPA regulations, or may be more stringent with respect to controls, approvals, and remediation requirements. With regard to worker safety, Occupational Safety and Health Administration (OSHA) regulations (Standards 29 CFR) apply. There are also additional considerations to be addressed on federal and tribal lands. [Table 6.9.1](#) is a partial listing of federal and state Web sites for various agencies that are involved in oil and gas regulation. When more than one agency is involved there is typically a *memorandum of understanding* (MOU), which delineates specific authority for the agencies involved. Regulatory advocacy and understanding is a very dynamic side of the industry, as new rules and requirements are being approved and others modified each year. Key federal environmental law and rules are:

- *The Resource Conservation and Recovery Act (RCRA)*—enacted in 1976, required the Environmental Protection Agency (EPA) to establish procedures for indentifying solid wastes as either hazardous or nonhazardous and promulgate requirements for managing both. RCRA was amended in 1980, at that time the U.S. Congress recognized the special nature, high volume, and low toxicity of waste generated by oil and gas exploration and production operations (as well as by mining, geothermal operations, electric utilities, and cement kilns). As a result, the EPA was directed to study wastes and recommend appropriate regulatory action.
- *The Safe Drinking Water Act (SDWA)*—passed in 1974, it developed drinking water standards as well as passed regulation of underground injection wells under the Underground Injection Control program (UIC).
- *The Clean Water Act (CWA)*—enacted in 1972 primarily to control point source discharges into waters of the US.
- *The Clean Air Act (CAA)*—enacted in 1970 and most recently amended in 1990. Contains attainment provisions for air quality standards, permits, enforcement, hazardous air pollutants (HAP), acid deposition, stratospheric ozone protection, and motor vehicles and fuels.

The associated Code of Federal Regulations (CFR) and additional laws are rules listed in [Table 6.9.2](#). Because of the dynamic nature of this topic, this is a partial listing. Be aware that interpretations of these vary, so legal counsel should be sought when evaluating applicability and compliance requirements.

6.9.3 Water Pollution Prevention

One of the first permits that must be applied for is a construction general permit and development a Storm Water Pollution Prevention Plan (SWPPP), as part of the CWA–National Pollutant Discharge Elimination System (NPDES) Permitting Program. The SWPPP is developed to identify controls to reduce the the impact from pollution caused by water runoff associated with storms; a 1998 federal study of water quality showed that storm water is the major source of impairment. Sediment in storm water has shown to carry other pollutants attached to soil particles (metals, nutrients, etc.); siltation decreases water depth and impacts flood storage capacity; it directly impacts aquatic habitat and ecosystems; the increased turbidity decreases sunlight penetration; and finally costs of drinking water treatment are increased. The EPA has identified potential storm water pollutants and sources typically associated with oil and gas facilities. These are shown in [Table 6.9.3 \[1\]](#).

The oil and gas production operation requires a SWPPP because construction activity is disturbing between 1 and 5 acres of land, which requires a construction general permit. This includes all wellsites, access roads, facilities, right of ways, etc. What is exempt is “nonconstruction” industrial activity such as well drilling, well completion, well stimulation, production, equipment cleaning and repairing, and site closure activities, and is applicable when storm water is not contaminated or does not come into contact with

raw material, overburden, etc. Any oil and gas facilities that discharges “potentially contaminated” storm water is required to submit an industrial permit application under the storm water rule. Note that some states and local regulations exist that require submittal of a permit application and/or development of a SWPPP to the local agency.

Section 404 of the CWA authorizes civil and criminal penalties for violations, with civil enforcement and judicial referral if more than \$137,500 or injunctive relief is required administrative if less than \$137,500 and injunctive relief is not needed. The Administrative Penalty Order is broken down into two classes: class I, up to \$27,000 but not more than \$11,000 per violation; and class II, up to \$137,500 but not more than \$11,000 per violation. Both are filed with the regional hearing clerk, and the EPA files public notice in the newspaper. Both are resolved either by payment to the Central Accounting Finance Office and/or through a hearing before a regional judicial officer. [2]

Another EPA rule that addresses the oil and gas industry as part of the CWA, which prohibits the discharge of oil in quantities harmful to waters of the United States, is the Oil Pollution Prevention Regulation 40 CFR 112. This requires applicable facilities to implement Spill Prevention Control and Countermeasures Plans (SPCCs). In addition, the Oil Pollution Act of 1990 (OPA-90) requires facilities that, could reasonably expect to cause substantial harm to the environment with an oil discharge to implement a Facility Response Plan (FRP). Per the regulation, a facility is subject

to the SPCC requirements if it could be reasonably expected to discharge oil into navigable waters of the United States, and have:

- Total aboveground storage > 1,320 gal (containers 55 gal or more), or
- Total underground storage > 42,000 gal (1000 bbls).

Navigable water of the United States are defined as oceans, interstate waters, and intrastate lakes, rivers, streams (including intermittent streams), wetlands, mudflats, sloughs, prairies potholes, wet meadows, and ponds for which the use, degradation, or destruction of which could affect interstate commerce, including any waters that could be used for recreation, or from which fish or shellfish

TABLE 6.9.3 Activities, Pollutant Sources, and Pollutants

Activity	Pollutant Source	Pollutant
Construction of: <ul style="list-style-type: none"> ● access roads ● drill pads ● reserve pits ● personnel quarters ● surface impoundments 	Soil/dirt, leaking equipment, and vehicles	Total suspended solids (TSS), total dissolved solids (TDS), oil, and grease
Well drilling	Drilling Fluid ¹ , lubricants, mud, cuttings, produced water	TSS, TDS, oil, and grease, chemical oxygen demand (COD), chlorides, barium, naphthalene, phenanthrene, benzene, lead, arsenic
Well completion/stimulation	Fluids (used to control pressure in well), cement, residual oil, acids surfactants, solvents, produced water, sand	TSS, TDS, oil and grease, COD, pH, acetone, toluene, ethanol xylenes
Production	Produced water, oil waste sludge, tank bottoms, acids, oily debris, emulsions	Chlorides, TDS, oil and grease, TSS, pH, benzene, phenanthrene, barium, arsenic, lead, antimony
Equipment leaning and repairing	Cleaning solvents, lubricants, chemical additives	TSS, TDS, oil and grease, pH
Site closure	Residual muds, oils debris	TSS, TDS, oil and grease

¹ The potential contaminants to be found in drilling fluid varies from site to site, depending on the components of the fluid and any pollutants added due to use of the fluid. Storm water discharges that come into contact with used drilling fluids may include the following pollutants, among others: toluene, ethyl benzene, phenol, benzene, and phenanthrene. Used drilling fluids may also contain inorganic pollutants from additives or downhole exposure, such as arsenic, chromium, lead, aluminum, sulfur, and various sulfates.

could be taken and sold through interstate or foreign commerce or be used for interstate industrial commerce.

SPCC plan requirements for oil and gas facilities include the following:

- If one or more spills have occurred in the previous 12 months, description of spill, corrective actions taken, and plans for preventing recurrence are required.
- Where there is reasonable potential for spill (e.g., tank overflow), plan should include likely direction of flow and potential quantity of oil lost.
- Tank batteries and treating stations must have appropriate secondary containment to prevent discharge from reaching waterway (e.g., dikes, berms, spill diversion ponds). Drains should be closed at all times except to drain rainwater. Containment must be able to hold the entire contents of the largest tank.
- Tanks must be visually examined for maintenance needs on a scheduled basis.
- Tank batteries should be fail-safe engineered to prevent spills (e.g., adequate capacity to prevent overfills, equalization lines between tanks, high-level alarms).
- Flowlines should be examined on regular and scheduled basis (corrosion, flange connections, valves, drip pans, pipeline supports).
- Written procedures for inspections and inspection record keeping are needed.
- Personnel trained on operation and maintenance of equipment to prevent spills, and on pollution control laws, rules, and regulations.
- Have a designated person to oversee plan requirements and report to management.
- Plans must be certified by a professional engineer.
- Plan must be reviewed/updated every 3 years or amended if there are any changes in the facility design, construction, operation, or maintenance that may affect the facilities potential to discharge oil.

A FRP is also required for facilities that have the potential to cause substantial harm to the environment with a spill. Facilities that are applicable have:

- total oil storage > 1,000 bbls with over-water transfers
- total storage > 23,810 bbls with no secondary containment
- total storage > 23,810 bbls and near sensitive environments
- total storage > 23,810 bbls and near public drinking water intakes
- total storage > 23,810 bbls and spilled > 238 bbls in past 5 years

Key elements of FRP include facility description, diagrams, topography, evacuation and likely discharge paths; list of emergency equipment and personnel; identification of spill hazards and previous spills; identification of small, medium, and worst-case scenarios; a detailed implementation plan for response and disposal; records of training, exercises, and drills; security fencing; lighting; and emergency cut-off valves. If a FRP is not required, the SPCC plan must have a certification statement included in it stating that the facility does not require FRP [2].

6.9.4 Waste Management

The American Petroleum Institute (API) estimated that 149 million barrels of drilling waste, 17.9 billion barrels of produced water, and 20.6 million barrels of other associated wastes were generated in 1995 from exploration and production operations. Once generated, managing these wastes in a manner that protects human health and the environment is essential for limiting operators' legal and financial liabilities, as well as makes good business sense. Operators must also determine if the waste is subject to hazardous waste regulations. At times, this determination is misunderstood and can lead to improper waste management decisions. Prudent waste management decisions, even for nonhazardous wastes, should be based on the inherent nature of the waste. Not all waste options are appropriate for every waste. The preferred option for preventing pollution is to avoid generating wastes whenever possible (*source reduction*). Examples include process modifications to reduce waste volumes and material substitution to reduce toxicity. Understanding the procedures for determining the exempt and nonexempt status of a waste is a valuable tool, especially for operators who choose to develop voluntary waste management plans. When these procedures are used in conjunction with knowledge of the nature of the waste, the operator will be better prepared to develop site-specific waste management plans and to manage E&P wastes in a manner that protects human health and the environment [4].

6.9.4.1 Waste Management Methods

The EPA has developed an hierarchy of waste management methods that is to be used to guide generators toward waste minimization, which is a major component of pollution prevention:

- *Source Reduction* — to reduce the amount of waste at the source through:
 - material elimination
 - inventory control and management
 - material substitution
 - process modification
 - improved housekeeping
 - return of unused material to supplier
- *Recycling/Reuse* — to recycle and reuse material for the original or some other purpose, such as materials recovery or energy production; this may be onsite or offsite.
 - reuse
 - reprocess
 - underground injection for enhanced recovery
 - use as fuel
 - reclaim
 - road spreading
- *Treatment* — destroy, detoxify, and neutralize waste into less harmful substances through:
 - filtration
 - chemical treatment
 - biological treatment
 - thermal treatment
 - extraction
 - chemical Stabilization
 - incineration
 - landfarming
 - landspreading
- *Disposal* — dispose of wastes through:
 - landfills
 - NPDES discharge
 - solidification
 - burial
 - underground injection for disposal

By incorporating waste minimization practices into a waste management program, the generators can protect public health and worker health and safety; protect the environment; meet company, state, and/or national waste minimization goals; save money by reducing waste treatment and disposal costs, as well as other operating costs, and reduce potential environmental liabilities.

To achieve pollution prevention and waste minimization goals, waste management needs to be viewed as an integrated system. A good waste management system should include the following key elements:

- A system for maintaining knowledge of pertinent laws and regulations
- A system for pollution prevention/waste minimization
- A health and safety program
- An incident response preparedness program
- A training program
- A system for proper waste identification
- A transportation program
- A proper waste storage and disposal program
- A system for waste tracking, inventories, and record keeping
- A waste management auditing program

Waste management plans need to be area specific, providing guidance for each waste generated in E&P operations. It needs to be written and distributed to field operations, and

this is the basis for training, evaluation, and monitoring pollution prevention programs. The plan should be reviewed periodically and updated as technology and regulations dictate. Self-audits need to be conducted periodically to ensure the design of the plan and to identify any gaps. If gaps are found, they need to be addressed and additional training should be rolled out to all involved [2].

6.9.4.2 Waste Characterization

Congress, in an attempt to promote mineral development in the United States, has exempted most hazardous wastes produced at the well site under the Resource Conservation and Recovery Act (RCRA) Subtitle C regulations. Hazardous waste are listed by inherent characteristics of

- Toxicity
- Ignitability
- Corrosiveness
- Reactivity

Although a number of waste products at the well site are considered characteristic hazardous wastes, some wastes fall under the nonhazardous description. The regulation of these fall under RCRA Subtitle D. Initially, Subtitle D wastes were regulated to control dumping of domestic trash and city runoff. The EPA is considering promulgating regulation of certain oil and gas waste under Subtitle D [5].

Under the RCRA exemption, wastes intrinsically associated with exploration and development of oil and gas do not have to follow Subtitle C regulations for disposal. Under Subtitle C, hazardous wastes must follow strict guidelines for storage, treatment, transportation, and disposal. The cost of handling materials under the Subtitle C scenario may be extensive. Under the exemption, the operator is allowed to dispose of exempt well site waste in a prudent manner and is not obligated to use licensed hazardous waste transporters and licensed treatment, storage, and disposal facilities (TSDF).

Examples of waste covered by the exemption are drilling fluids, cuttings, completion fluids, and rig wash. Waste materials that typically not covered by the exemption are motor and chain oil wastes, thread cleaning solvents, painting waste, trash, and unused completion fluids.

A waste product, whether exempt or not, should always be recycled if economically possible. Oil-based drilling mud is typically purchased back by the vendor for reuse. Unused chemicals are similarly taken back for resale. Arrangements should be made with the mud company for partial drums or sacks of chemical. Muds also may be used on more than one hole. With the advent of closed-system drilling, the muds be moved off location in the event of a producing well.

If a waste is generated that is a listed or characteristic item, the operator must follow certain guidelines [6].

A listed hazardous waste (e.g., mercury, benzene) is considered hazardous if the concentrations in which they naturally occur above certain limitations (40 CFR 261.31 – 261.33). The listed hazardous waste may not be diluted to achieve a lesser concentration and thus become nonhazardous. A characteristic hazardous waste (40 CFR 261.21 – 261.24) may be diluted to a nonhazardous status.

Most nonexempt, nonacute hazardous waste generated on location is considered a small quantity. In this case, the waste may remain on location for 90 days. At that time, a Department of Transportation (DOT)–licensed motor carrier must transfer the waste to an EPA-certified TSDF for disposal. Appropriate documentation and packaging must conform to regulations. The operator continues to be liable for the waste as denoted by the cradle-to-grave concept [7].

Exempt wastes are usually disposed of on location after gaining permission from the state oil and gas division. Liquid wastes, if not evaporated or fixated on location, are usually injected into Class II injection wells (see Chapter 6, Environmental Considerations). Solid wastes, if not acceptable to local landfills, are remediated onsite or buried in some instances. Table 6.9.4 shows exempt and nonexempt waste, Figure 6.9.1 shows determination of exempt and nonexempt waste, and Figure 6.9.2 shows the possible waste mixtures and their exempt and nonexempt status [8].

Generally, waste that must be produced to complete the work involved in the exploration and production of oil and gas is considered exempt, allowing the operator the option of disposing of the waste in a prudent manner. A nonexempt waste (e.g., radioactive tracer waste) should be avoided if possible. These wastes must be disposed of according to federal and state regulations. Because these regulations are becoming more complicated with time, the operator should consult the primary regulator in questionable circumstances.

6.9.5 State Permits

As stated previously, this section will attempt to address most of the regulations and permits that are typical for operations in the U.S.A. However, each state has specific permits that may be required. For example, in Texas, an air quality a PI-8 emissions screening must be completed on all collection facilities. If the emissions are too great, then a PI-7 must be submitted to an approved by the Texas Commission on Environmental Quality (TCEQ). The PI-7 submission must include a plot plan of the facility, with all emission points noted with maximum outputs, and a current gas analysis. A copy of the calculations for those emissions, along with a process flow diagram and description is also required.

An operational requirement may include a permanent lined emergency overflow pit. Thus, a pit permit is required from the Texas (Railroad Commission of Texas) RRC. Open pits are not typical common anymore, but those in existence

TABLE 6.9.4 Exempt and Nonexempt Oil and Gas Production Related Wastes

Exempt Waste	Nonexempt Waste
Produced water	Unused fracturing fluids or acids
Drilling fluids	Cooling tower cleaning wastes
Drill cuttings	Used well completion/stimulation fluids
Rigwash	Radioactive traces wastes
Geothermal production fluids	Painting wastes
Hydrogen sulfide abatement wastes	Used lubrication oils
Well completion/stimulation fluids	Vacuum truck and drum rinsate containing nonexempt wastes
Basic sediment and water (BS&W) and other tank bottom material from storage facilities that hold product and exempt waste.	Refinery wastes
Accumulated materials such as hydrocarbons, solids, sand and emulsions from production separators, fluid treating vessels, and production impoundments.	Service company wastes such as empty drums, drum rinsate, vacuum truck rinsate, sandblast media, spent solvents, spilled chemicals, and waste acids
Pit sludges and contaminated bottoms from storage or disposal of exempt waste	Waste compressor oil, filters and blowdown
Workover wastes	Used hydraulic oil
Gas plant dehydration and sweetening waste	Waste solvents
Cooling tower blowdown	Caustic or acid cleaners
Spent filters, filter media, and backwash (assuming the filter itself is not hazardous and the residue in it is from an exempt waste stream)	Waste generated in transportation pipeline related pits
Packer fluids	Laboratory wastes
Produced sand	Boiler cleaning wastes
Pipe scale, hydrocarbon solids, hydrates, and other deposits removed from piping and equipment before transportation	Boiler refractory bricks
Hydrocarbon bearing soil contaminated from exempt waste streams	Boiler scrubbing fluids, sludges and ash
Pigging waste from gathering lines	Incinerator wastes
Constituents removed from produced water before it is injected or otherwise disposed of	Industrial wastes from activities other than oil and gas E&P
Waste from subsurface gas storage and retrieval	Pesticide wastes
Liquid hydrocarbons removed from the production stream but not from oil refining	Gas plant cleaning wastes
Gases from the production stream, such as H ₂ S, CO ₂ , and volatized hydrocarbons	Drums, insulation and miscellaneous solids
Materials ejected from a producing well during blowdown	Manufacturing wastes
Waste crude from primary operations and production	Contamination from refined products
Light organics volatized from exempt waste in reserve pits, impoundments, or production equipment	
Liquid and solid wastes generated by crude oil and crude tank bottom reclaimers	
Stormwater runoff contaminated by exempt materials	

Although non-E&P wastes generated from crude oil and tank bottom reclamation operations (e.g., waste equipment cleaning solvent) are nonexempt, residuals derived from exempt wastes (e.g., produced water separated from tank bottoms) are exempt.

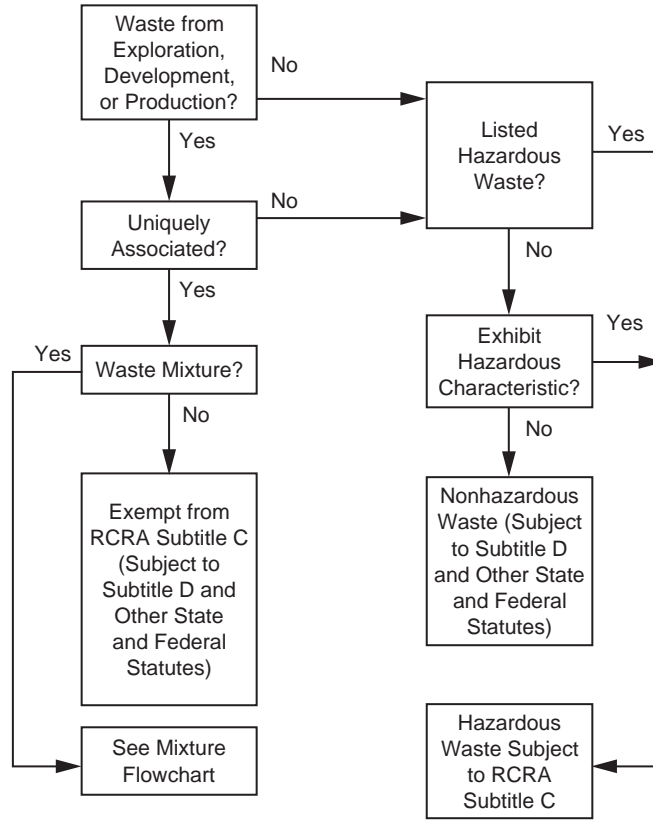

FIGURE 6.9.1 Exempt/nonexempt waste flowchart.

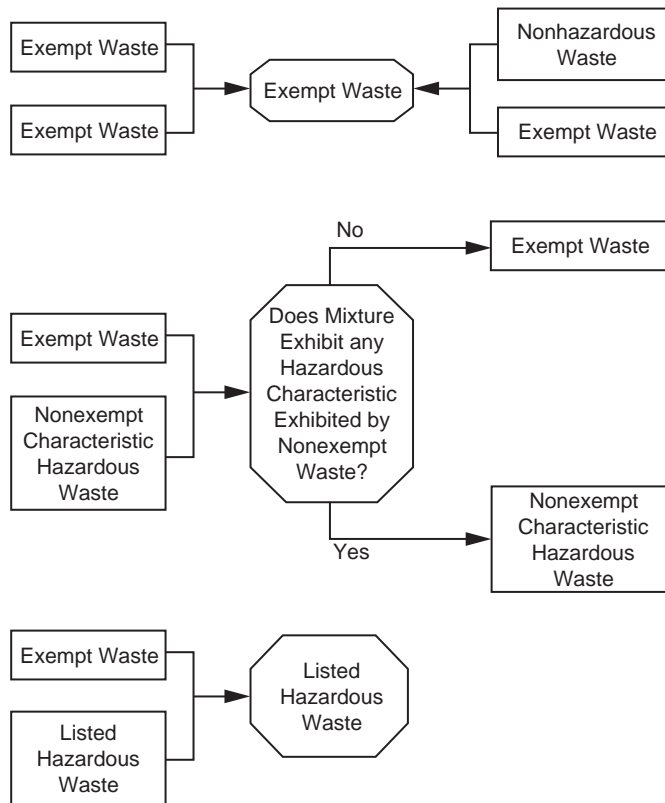

FIGURE 6.9.2 Possible waste mixtures and their exempt and nonexempt status.

must be maintained and netted so that wildlife does not enter. Inspection and maintenance records also need to be maintained. All upset conditions, which require the use of the pit, must be reported and the pit drained when operations return to normal. It is the responsibility of the operator to identify and understand all operational requirements to protect the environment, the public, the workers, and retain the “license to operate” by demonstrating compliance with all applicable regulations.

6.9.6 Spill Prevention

Spills and leaks are the most common releases encountered in oil and gas production. The spill of condensate, oil, or produced water onto the ground and the release of gas and vapors into the atmosphere exhibit the greatest liability to the environment or lease operator. Chemicals associated with operations may also leak and create an undesirable situation. Leaks and spills may be considered to be unpreventable due to equipment failure and “acts of God” (storms, natural disasters, etc.), but they are all considered containable and mitigable.

Containment of a spill is one of several preventable measure. Pumps and truck connections are regularly placed over containment pans, which should be checked on a daily basis and vacuumed out on an as-needed basis in addition to a scheduled maintenance plan. The routine scheduled maintenance and vacuuming is done to remove rainwater or blow dirt that can accumulate regularly within the containment depending upon the location. Historically, earthen berms have been placed around facilities to contain tank and piping failures. The berm design is based on the total production flowrate multiplied by the frequency of inspection. The berm design equation is

$$S_{vol} = 5.61QF_1(SF) \quad (6.9.1)$$

$$B_b = \frac{S_{vol}}{\left[B_l B_w - n \frac{\pi}{n} D_t^2 \right]} \quad (6.9.2)$$

where S_{vol} = spill volume in ft.³

SF = safety factor (2.0 to 3.0)

Q = liquid flowrate to tank in bpd

F_1 = frequency of inspection in days

B_h = height of berm in ft.

B_l = length of berm in ft.

B_w = width of berm in ft.

n = number of tanks in battery

D_t = tank diameter of n tanks in ft.

Soil containment by a spill or leak may be treated as an exempt waste provided the leaking substance is listed as an exempt waste [9]. Although all discharges must be reported to the appropriate government agency, this, in

many cases, is to be verbally at the time the spill or leak is discovered and followed by the appropriate forms in a timely manner when information is compiled. In Texas, the TRRC statewide rules that address this are as follows: Statewide Rule 8 provides that no person conducting activities subject to regulation by the commission may cause or allow pollution of surface or subsurface water in the state. Rule 20 provides that operators shall give immediate notice of a fire, leak, spill, or break, followed by a letter giving the full description of the event, including the volume of products lost. Rule 91 provides that cleanup requirements for hydrocarbon condensate spills and crude oil spills in sensitive areas will be determined on a case-by-case basis. [10].

The hydrocarbon/soil mixture may be left in place provided that all petroleum products stay on location and that it is de-watered. Operators have found that a mixture of crude and raw materials make an excellent road base and, if properly designed, create less of an environmental hazard than the traditional asphalt road base (Table 6.9.5 [11]). In Texas a minor permit from the TRRC and landowner permission is required before any spreading contaminated soil. A typical mixture of 13% heavy oil, 7.5% liquid (H₂O), and 79.5% solids make a road surface that can endure heavy road traffic [12]. This road application has been tested in northern climates where reduced volatilization of hydrocarbons is realized. In warmer climates the appearance of a sheen during runoff conditions may be apparent, thus increasing the likelihood of hydrocarbon contamination to the immediate area. It has been recognized that hydrocarbon

TABLE 6.9.5 Comparative Samples of Oil Waste Road Material and Asphalt

Parameter	Oil Waste (ppm)	Asphalt (ppm)
Arsenic	0.04	0.10
Boron	0.10	0.38
Cadmium	0.001	0.01
Chromium	0.60	0.16
Lead	0.057	0.63
Zinc	0.14	0.99
Mercury	0.0001	0.0001
Selenium	0.0017	0.0002
Barium	0.55	2.80
Copper	0.06	0.36
Phenol	0.035	0.24

contents above 20% in soil mixtures have a detrimental effect on plant life, with 1% showing no adverse effects [12]. In land farming, applications of 2% to 3% liquid hydrocarbons are common.

As a result of a spill, a hydrocarbon may pose a hazard to ground water, flora, fauna, and humans. Although many wastes produced at the wellsite are exempt, the operator is responsible for degradation of the surrounding due to imprudence, neglect, and accidental release. Hydrocarbon content in the soil that is in excess of the saturation limit may be transmitted to the surrounding environment through runoff and gravity. These hydrocarbons are loosely categorized as dense nonaqueous phase liquids (DNAPL) or light nonaqueous phase liquids (LNAPL), with DNAPLs being heavier than water. In the field both these species are present. The LNAPLs are more mobile. This mobility translates to greater relative conductivity in the soils and lesser adsorption onto the soil. However, the LNAPL possess a lower vapor pressure, allowing the liquid to more rapidly dissipate into the gaseous phase, leaving only traces of its product. Table 6.9.6 [13] shows how the hydrocarbon's partition among the phases Figure 6.9.3 shows the divisions graphically. An approximation for the volume of liquid hydrocarbon that may be retained by a volume of soil, the depth of infiltration, as well as, the lateral spread of the oil onto the top of the water table is shown in the following equation [14]:

$$V_s = \frac{0.2V_{hc}}{\Phi S_{wr}} \quad (6.9.3)$$

where

V_s = soil required to obtain residual saturation in yd^3

V_{hc} = volume spill hydrocarbon in bbl

Φ = soil porosity

S_{wr} = residual oil saturation capacity of the soil (Table 6.9.7 [15])

And knowing the area of infiltration of the soil, the depth of the spill may be determined by:

$$D = \frac{27V_s}{A} \quad (6.9.4)$$

where

D = depth in ft.

A = observed area of infiltration in $ft.^2$

In the event the spill has been determined to reach the water table, the lateral spreading onto the top of the water table

TABLE 6.9.6 Phase Distribution of Certain Petroleum Products in Percentages in Air, Soil, and Water

Compound	Adsorbed to Soil	Volatilization	Soluble in Groundwater
Aromatics			
Benzene	5	60	35
Toluene	5	75	20
Ethyl benzene	20	60	20

Phenanthrene	90	3	7
Alcohols			
Methanol	0	2	98
Ethanol	0	2	98
Phenol	9	>1	90

may be estimated as [16]:

$$S = \left(\frac{1,000}{F} \right) \left(V - \frac{Ad}{K} \right) \quad (6.9.5)$$

where

S = maximum spread of pancake shaped layer in m^2

V = volume of infiltrating hydrocarbons in m^3

A = area of infiltration

d = depth to water table in m

K = constant (Table 6.9.8)

Oil, being immiscible in water, will either float on top of the water table in the case of the LNAPL or sink to the bottom. The amount of hydrocarbon that is dissolved in the water depends primarily on the solubility and mass of the components. Only a few hydrocarbons are readily soluble in water, such as benzene, toluene, and

FIGURE 6.9.3 Partitioning of hydrocarbons during a spill.

TABLE 6.9.7 Kerosene Retention Capacities in Unsaturated Soils

Soil Type	Kerosene Retention Capacity	
	Gal/yd ³	L/m ³
Stone, course sand	1	5
Gravel, course sand	2	8
Course sand, medium sand	3	15
Medium sand, fine sand	5	25
Fine sand, silt	8	40

TABLE 6.9.8 K-Values for Equation 6.9.5

Soil Type	Gasoline	Kerosene	Light Gas Oil
Stone, course sand	400	200	100
Gravel, course sand	250	125	62
Course sand, medium sand	130	66	33
Medium sand, fine sand	80	40	20
Fine sand, silt	50	25	18

xylene. Table 6.9.9 [17] shows the solubilities for several hydrocarbons.

When a land spill occurs, the liquid petroleum will simultaneously spread over the top of the site and seep into the soil. In the event the water table is shallow, the liquid will rest on top of or below the water table and then migrate at a rate proportional to the groundwater flow.

The evaporation rate of spilled hydrocarbons may be inferred from Fick's law:

$$N_A = D_A A \frac{dC}{dX} \tag{6.9.6}$$

where

- N_A = rate of mass transport in mol/s
- D_A = mass diffusivity of hydrocarbon in air in ft.²/s
- A = transport area in ft.²
- C = concentration in M
- X = length pf path traveled in ft.

In a stagnant system, the length of the diffusing path is often unknown for a spill in a given field. In the event advection is also taking place in the presence of wind currents, the boundary layer may be inferred to be this length:

$$\delta = 5(x)(N_{Re})_x^{-0.5} \tag{6.9.7}$$

For a finite flat plate in laminar flow, the thickness is [14]:

$$(N_{Re})_x = \frac{V \times \rho}{\mu} \tag{6.9.8}$$

TABLE 6.9.9 Aqueous Solubility Data for Selected Petroleum Products

Product	Solubility (mg/L of H ₂ O)
Gasoline	50–100
1-Pentene	150
Benzene	1,761
Toluene	515
Ethyl benzene	75
Xylenes	150
n-Hexane	12
Cyclo-hexane	210
i-Octane	8 ppb
JP-4 jet fuel	<1
Kerosene	<1
Diesel	<1
Light fuel oil (#1 and #2)	<1
Heavy fuel oil (#4, #5, and #6)	<1
Lubricating oil	<1 ppb
Used oil	<1 ppb
Methanol	>100,000

where

δ = the thickness of the boundary layer in cm

x = the length of the spill in cm

N_{Re} = Reynolds Number

V = free stream velocity of the wind in cm/s

ρ = density of air in g/cm³

μ = viscosity of the air in g s⁻¹/cm

The concentration of the hydrocarbons is evaluated at the equilibrium concentrations of the vapor in the pores (C_p) and the concentration of the vapor at the soil-air interface (C_{ai}). In the presence of wind, C_{ai} may be assumed to be zero. The concentration of the vapor in the pores is estimated from Dalton's law

$$P_i = y_i P_T \quad (6.9.9)$$

and Raoult's law

$$P_i = x_i P_i^0 \quad (6.9.10)$$

where

P_i = partial pressure of the hydrocarbon in atm

y_i = mol fraction of the hydrocarbon in the gas phase

x_i = mol fraction of the hydrocarbon in the liquid phase

P_T = total pressure (1) atm in most cases)

P_i^0 = vapor pressure of the hydrocarbon in atm

Knowing the mass of the hydrocarbon at the surface, the time for disappearance of the hydrocarbon from the surface may be determined by using Equation 6.9.11. In turn, the time for the spill to evaporate from the pore space may be estimated by Equation 6.9.12, using a correlation between the diffusivity in air and the hydrocarbon's diffusivity in the pore space [18]. Figure 6.9.4 illustrates this analogy.

$$D_p = D_a \frac{\phi}{\tau} \quad (6.9.11)$$

where

D_p = mass diffusivity of the hydrocarbon in the pore space in cm²/hr

Φ/τ = ratio of porosity to tortuosity (typically 1.5 to 3.0)

The time for the spill to evaporate from the pore space may be estimated by

$$T = \frac{hM}{ZAD_p(C_p - C_{ai})} \quad (6.9.12)$$

where

T = time in hrs

M = mass of hydrocarbon in mol

h = initial thickness of the contaminated soil in cm

A = area perpendicular to flux in cm²

To accurately infer the results of a spill, onsite and laboratory studies should be performed on potentially affected media. The onsite investigation would take inventory on the effects of a worst-case scenario, such as total evacuation of a holding tank. The inventory would include the likely migration path of a spill in accordance to topography; potential threats to humans, livestock, and plants, and the relationship of the spill area to groundwater and surface water supplies. This study is required as part of the SPCC. A laboratory analysis would include hydrocarbon quantitative analysis for constituents creating potential health risks, soil analysis, and volatilization parameters.

The soil analysis determines the conductivity of the soil in regard to the liquid hydrocarbon and the absorption/desorption potential of the soil. Knowledge of this conductivity will help in determining the consequences of a spill and may in some cases divert an unwarranted emergency cleanup operation. Many times the heavier crudes will only penetrate the surface a few inches. The process

FIGURE 6.9.4 Vapor migration through soil pore space.

of determining conductivity is analogous to determining relative permeabilities in a reservoir core sample. In the present analysis, a soil core is taken and left in the core barrel with the soil water content undisturbed. The site's liquid hydrocarbon is then introduced over the soil core at a constant representative head. The time to exit the barrel will infer the influx of the hydrocarbon at partial saturation. This time is critical due to fingering of hydrocarbons. The area affected initially may be much less than the total area of the barrel. The test is continued until the sample is saturated. The conductivity is then estimated using Darcy's Law (Equation 6.9.14). The mass flowrate may then be estimated from this conductivity relationship.

$$q = K \frac{dH}{dL} \quad (6.9.13)$$

where

- q = hydrocarbon flux in m/s
- K = conductivity in m/s
- dH = differential head on core in m
- dL = length of core in m

After the conductivity is found, all residual oil is allowed to drain from the sample. The residual left in the core is the absorption capacity of the soil sample. The saturation level of a particular soil may also be found by plotting the data in the form of a sorption isotherm. After the residual oil is drained, the soil sample is washed at constant temperature with water until the hydrocarbon exists only in trace amounts in the product stream. The difference in the hydrocarbon mass introduced initially and the displaced hydrocarbon is the total residual saturation for that soil. Depending on the wellsite conditions, this amount of soil may be safely left in place without harm to the surrounding and will continue to decrease in quantity due to in situ microbial populations and through diffusion. The desorption isotherm may be constructed through the Freundlich equation:

$$C_s = KC_e^n \quad (6.9.14)$$

or

$$\ln C_s = \ln K + n \ln C_e \quad (6.9.15)$$

where

- C_s = mass of oil/mass of soil in g/g
- C_e = effluent concentration of oil/volume of water in g/cm³
- K = constant in L/g
- n = constant (unitless — often equal to one for hydrocarbons)

In the linearized form of the equation, K is recognized as the residual oil saturation for the soil sample, as shown in the Freundlich-type isotherms in Figure 6.9.5.

The constant K is a measure of the soils' volumetric capacity of hydrocarbon saturation, whereas the constant 1/n is the measure of the mutual attraction between the constituents. Once the isotherm is defined, it may then be used to predict effluent concentrations of hydrocarbons that may be transported into the groundwater.

In general, because of the nonpolar nature of hydrocarbon, a soil comprised of a high percentage of organic matter will absorb more liquid hydrocarbons. Less-soluble, heavier hydrocarbons will absorb better than lighter soluble hydrocarbons and are considerably less mobile than LNAPLs.

Solutions of gases and crude oil follow Henry's law at atmospheric pressures. Henry's constant, more commonly referred to as an equilibrium constant in the petroleum industry, may be used to find the distribution of a hydrocarbon in the aqueous and the atmospheric phases:

$$K_H = \frac{y_i}{x_i} \quad (6.9.16)$$

FIGURE 6.9.5 Freundlich type isotherms.

where K_H = Henry’s law constant (unitless)
 y_i = mole fraction of the hydrocarbons in air
 x_i = mole fraction of the hydrocarbons in liquid

Henry’s constant is most often referred to in the environmental industry in units of atm. In 1 L of water, there are 55.6 mol and 22.4 L of air per mol of air, such that

$$K_H = \frac{\text{partial pressure of gas in air}}{\text{mol hydrated gas/mol water}} \quad (6.9.17)$$

Table 6.9.10 [19] gives some values of Henry’s constant for gases in contact with air at 20°C.

TABLE 6.9.10 Henry’s Constant for Gases at 1 Atm. 20°C	
Component	Henry’s Constant (Water)
Methane	3.8×10^4
Benzene	2.4×10^2
H ₂ S	5.15×10^2
CO ₂	1.51×10^2
Toluene	3.4×10^2 (25°C)

6.9.6.1 Other Potential Sources of Spills and Contamination

Glycol and other liquids used for dehydration may occasionally leak or be spilled on the ground. They also may become contaminated, in which case the product must be replaced. Because of inherent physical properties, namely, viscosity, of dehydration liquids such as triethylene glycol (TEG), significant losses are not realized to soil seepage or evaporation. The desiccants on the whole are very toxic and completely miscible in water. Unless treated, ethylene glycol is colorless and odorless, and may be mistaken for water upon casual analysis. The greatest potential danger is then contamination of surface runoff. Any spillage should be retrieved and properly disposed of. Waste liquid desiccants should be recycled when possible. Class II injection is the most cost-effective disposal method. Solid desiccants, such as alumina, molecular sieves, and silica, become uneconomically regenerable with time. There is also loss due to structural failure. When exhausted, these materials may be sent to a disposal or buried on site. Any onsite burial must be with the landowners’ approval.

In the sweetening processes, amine treatment is the most prevalent. The amines, such as monoethanoamine (MEA), DEA, and sulfinol combine with CO₂ and H₂S at moderate temperature and are released when the combined solution temperatures is slightly raised.

The wasted H₂S and CO₂ may then be flared as allowed by the local regulations or air permit, as applicable. H₂S may be recycled into sulfur products, and the CO₂ may be collected and used in recovery projects. These gases may also be trapped in caustic solutions. In this case, the pH

of the solution is lowered and a salt is formed. These salt solutions, as with most liquid wastes, may be disposed of in class II injection wells when recycling is not feasible (also refer to "Class II Injection Wells"). The pertinent chemical reactions involved here are:

6.9.7 Production Site Remediation

In remediation, a site's contaminated material is reduced by either relocating the contaminated material to a disposal or on-site treatment. Physical treatment methods may include [20]

Gravity Separation	Dissolution
Sedimentation	Soil Washing/Flushing
Centrifugation	Chelation
Flocculation	Super Critical Solvent Extraction
Oil/Water Separation	
Dissolved Air Flotation	
Heavy Metal Separation	
Phase Changes	Size/Adsorptivity/Ionic Characteristics
Evaporation	Filtration
Air Stripping	Carbon Adsorption
Steam Stripping	Ion Exchange
Distillation	Reverse Osmosis

In addition to these physical methods, chemical alterations and biotransformation are also used in site

remediation. Table 6.9.11 [21] shows a relative cost comparison between selected treatment techniques.

6.9.7.1 Landfarming

Land farming utilizes in situ and introduced microbes such as *Bacillus cereus*, *Bacillus polymixa*, *Arthrobacter globiformous*, and *Alcanigenes porasoxus* to degrade contaminants. Heterotrophic bacteria use organic compounds as energy and the carbon source for synthesis. The heterotrophs are classic oil spill degraders. Autotrophic bacteria use CO_2 as a carbon source and oxidize inorganic compounds for energy. They are most useful in drilling mud degradation.

In some instances biodegradation of contaminants may result in harmful intermediates, such as mercury. Mercury and other minerals, in their pure metal form, may remain immobile until the introduction of reducing microbes. The altering of conditions, pH and organic content, may change the redox state of the metal. Under such conditions, the metal may then be prone to migration and thus leach into the groundwater. Also, anaerobic microbes may reduce the metal to a sulfide, and solubility is enhanced.

In the case of oil spills, onsite bioremediation has proven successful. In situ microbial strains are active in most soils. If a previous spill has been documented, a culture from the older site may be introduced in addition to other cometabolites. The successive strains have shown to genetically adapt and become more successful in regards to rate and mass consumed. Composting of contaminated material has also proven effective[21]. Assuming equivalent environments, these successive stains of biomass maybe compared quantitatively by

$$dM/dT = \phi V_s K_b C_p \quad (6.9.20)$$

where

K_b = biorate constant in hr^{-1}

C_p = concentration of petroleum in the pore space in mol/yd^3

TABLE 6.9.11 Comparison of Treatment Processes

Type of Treatment	Cost per Cubic Yard	Time Required Months	Additional Factors	Safety Issues
Incineration	250–800	6–9	Energy	Air pollution
Fixation	90–125	6–9	Transportation/monitoring	Leaching
Landfill	150–250	6–9	Monitoring	Leaching
Biotreatment	40–100	18–60	Time	Intermediary metabolites and polymerization

In this method, it is assumed that the soil is homogeneously distributed with hydrocarbons, nutrients, and biomass and that the degradation occurs in a uniformly distributed manner. The biodegradation rate constant, assumed pseudo first-order, may then be used comparatively between sites. In the event that the addition of cometabolite results in a slower rate constant, it is assumed that the previous biomass was more efficient.

In landfarming, drilled soils, mud, and contaminated soils are distributed over an area in addition to microbial nutrients (fertilizer). The mixture may be turned and fertilized periodically to enhance degradation. The microbial growth can be quantified by a number of methods. The microcosm turbidity method can be used to estimate the viability of the indigenous species to degrade the hydrocarbons present. A sample of soil or cuttings is taken and allowed to grow. A turbidimeter is then used to quantify growth periodically, and mass is calculated as a function of time [22]. CO_2 , generated by the microbes, collected in a caustic solution and the use of a respirometer are yet another growth measurement methods. Both of these use the mass of gas produced or consumed as a measure of cell growth. Figure 6.9.6 shows the characteristic growth phase of a pure culture of bacteria. Bacterial growth is typically substrate limited.

In the case of oil-based muds, several mixtures of hydrocarbon-to-fertilizer ratios have been tested for microbial response. The microbes have been found to react favorably to certain conditions. A hydrocarbon:ammonia-nitrogen:phosphate level ratio of 100:2:1 with the addition of trace minerals, improves moisture retention properties,

and adjustment of pH to neutral levels was found to increase the half-life reduction of naphthenic crude from more than 2 years to approximately 8 weeks [23]. In this same set of experiments, a hydrocarbon:ammonia-nitrogen:phosphate level ratio of 100:1:0.2 had only marginal hydrocarbon biodegradation rates, and increasing this ratio to 100:2:0.15 while controlling pH and tilling did not significantly raise the rate. Another study concluded the most productive carbon-to-phosphorus ratio was 120:1 with a pH of 7.7 at 75°F to 95°F. The soil was treated with water spray loaded with common fertilizers. The initial hydrocarbon contents were 600 to 700 ppm and degraded to 415 ppm within 2 months ($k = 0.003 \text{ mg L}^{-1} \text{ min}^{-1}$) [24].

Slurry phase bioreactors maybe used to decrease the oil and grease levels in soil and drill cuttings. Here, drilling cuttings are introduced to a tank in the presence of nutrients, oxygen, and hydrocarbon degrading microbes. The vessels are operated at pH levels from 5 to 9 and nitrogen-to-phosphorus level of 10:20. Oil and grease psudeo first-order degradation rates of $0.60 \text{ mg L}^{-1} \text{ min}^{-1}$ (k) have been recorded with pH levels below 6.5 where phosphorous is more readily soluble [25]. The slurry reactor parameters are typically designed as batch mixed at constant pressure using these design equations:

$$-r_a = kC_a \quad (6.9.21)$$

$$T_R = \int_{N_{af}}^{N_{ao}} \frac{dN_a}{V_R(-r_a)} \quad (6.9.22)$$

$$T_R = N_{ao} \int_0^{X_{af}} \frac{dX_a}{V_R(-r_a)} \quad (6.9.23)$$

FIGURE 6.9.6 Growth phases of bacteria.

where $-r_a = -(dC_a/dt)$ = the degradation rate of species "a" (hydrocarbon)

C_a = concentration of "a" in M

K = first-order rate constant M_s^{-1}

N_a = mol of "a" at time t

N_{a0} = initial mol of "a"

T_R = reactor residence time in s

V_R = reactor volume in L

X_a = fractional conversion of "a"

Here all the reactants are fed into the reactor initially and remain there for a mean residence time (T_R). Nutrients may be added occasionally until desired degradation is met. The volume attributed by the additional nutrients can usually be neglected. Equations 6.9.21 through 6.9.23 are valid for any batch-mix operation. Usually the kinetics of systems are established and then the reactor optimized to facilitate the operation [26].

Kinetics are controlled by oxygen level, moisture content, temperature, nutrients, pH, and concentration. Soils may have hydrocarbons up to 5% by weight without harmful effects, and half-lives of only 2 years may be realized for soils containing up to 14% hydrocarbons [26,27].

6.9.7.2 Landspreading

Landspreading is differentiated from landfarming in that the area over which the contaminated soil or liquid is spread but not actively manipulated to increase degradation rates. One study showed that spreading oil-based cuttings over an area of soil at thickness not over 2 in. lead to natural degradation rates of approximately 80% in the first year and 95% of the hydrocarbons were eliminated after 3 years. Further analysis proved that no significant migration or leaching of the hydrocarbons had taken place [28]. Another method of landspreading includes the reliquidifying the solids and then spreading them evenly over an area. Here the loading factors take into consideration the soil and contaminant characteristics. A cumulative salt burden of 6,000 lb/acre (3000 ppm) is considered a safe level with a hydrocarbon loading of 40,000 lb/acre (2%). These numbers are based on a 2,000,000 lb/acre soil horizon [29].

The total salt burden of the soil is calculated from the total dissolved solids contained in the contaminant/soil mixture. Applications of freshwater gels may be added at 1,000 kg Cl/ha (KCL form) and 1,400 kg Cl/ha (NaCL form) and present no limitation to the soils and may actually enhance soil characteristics for plant growth. Chloride concentrations of 1,000 to 2,600 ppm have been safely used without loss of yield in grass growth. Gypsum has been added in when sodium activity ratio (SAR) levels have increased, thus relieving the problem.

Hydrocarbons and salts inherent in some production water and drilling muds may pose threats to the local ecosystems if not properly managed. The salt concentration

may be estimated for a liquid from the electrical conductivity of the solution by

$$TDS = B (EC) \quad (6.9.24)$$

$$I = 0.016 (EC) \quad (6.9.25)$$

Electrical conductivity (EC) is measures in mmhos/cm, total dissolved solids (TDSs) as mg/L and ionic strength (I) as molarity. The values for B are held closely in agreement by several sources as 640 and 613. Although equations Equation 6.9.24 and 6.9.25 are only used as an estimate of ionic content in the soil or solution, they are accepted due to their general use in the soil sciences. EC values less than 4 mmhos/cm are generally satisfactory for crop yields. The addition of drilling mud with an EC of 1.3 to 5.3 mmhos/cm showed no adverse effects on Bermuda grass [30]. Generally an SAR < 12 and ESP < 15% is acceptable for land disposal. The ESP is another measure of sodium contained in the soil. This is

$$ESP = \frac{[NaX]}{CEC} (100) \quad (6.9.26)$$

$$SAR = \frac{[Na]}{\sqrt{\frac{[CA] + [MG]}{2}}} \quad (6.9.27)$$

where

NaX = the sodium in the solid phase

CEC = the cation exchange capacity of the soil phase in meq/100g

[] = molarity

Table 6.9.12 shows the oil tolerance for selected grasses and plants [30]. API recommends a one-time application of < 1%.

6.9.7.3 Air Stripping

In phase transformation, most often the liquid phase is let to a gaseous phase, through the addition of heat, a reduction in pressure or concentration, or may combination thereof.

TABLE 6.9.12 Oil tolerance for Selected Grasses and Plants

Grass/Plant Type	Oil and Grease for One Application
Lawn grasses	<0.5%
Rye grass, oats, wheat, corn	<1.5%
Red clover	<3.0%
Perennial grasses, trees	<3.0%

Evaporation may be used as applied through variations of Equation 6.9.33. The two film theory states the basis for most air stripping operations, and is mathematically defined by

$$dC/dt = -K_L a (c_s - c_t) \quad (6.9.28)$$

where

- C = concentration of the hydrocarbon in M
- $K_L a$ = overall rate constant in hr^{-1}
- c_s = concentration of the hydrocarbon in the gas phase at time (t) in M
- c_t = concentration of the hydrocarbon in the liquid phase at time (t) in M

Here, a gas is passed through the contaminated liquid phase, and the resulting equilibrium concentration differences between the phases drives the vaporization of the liquid. The air stripping design may be simple bubbling of air through an open tank, as shown in Equation 6.9.28, or the more effective and costly packed tower that uses these design equation[19].

$$(\text{HTU}) (\text{NTU}) = \frac{L(C_i - C_e)}{K_L a} \frac{\ln \frac{DF_e}{DF_i}}{DF_e - DF_i} \quad (6.9.29)$$

$$\text{HTU} = \frac{L}{K_L a} \quad (6.9.30)$$

$$\text{NTU} = \frac{R}{R - 1} \frac{\ln \frac{C_i}{C_e} (R - 1) + 1}{R} \quad (6.9.31)$$

$$R = \frac{K_H G}{L} \quad (6.9.32)$$

where

- HTU = height of transfer unit in m
- NTU = number of transfer unit
- L = liquid velocity through empty diameter of transfer unit in m/s
- G = gas velocity through empty diameter of transfer in m/s
- C_i = inlet concentration of contaminant in gas in M
- C_e = exit concentration of contaminant in gas in M
- Df_i = driving force at the inlet in M
- Df_e = driving force at the outlet in M
- R = stripping factor
- K_H = unitless Henry's constant for contaminate
- $K_L a = (\text{s}^{-1})$

In the stripping tower design, determination of $K_L a$ is the most important. This value is particular to the type of packing used in the tower, the type of contaminant, and a number of other parameters. The Sherwood-Holloway equation may be used to determine the $K_L a$ for a given

packing, liquid, and gas. This is

$$K_L a = D_L M \left[\frac{L}{U_L} \right]^{1-n} \frac{u_L^{0.5}}{r_L D_L} \quad (6.9.33)$$

where

- $K_L a = \text{hr}^{-1}$
- D_L = diffusion coefficient for gas of interest in water $\text{inft.}^2/\text{hr}$
- L = liquid velocity in lb water/hr-ft.^2
- u_L = liquid viscosity in lb/hr-ft.
- r_L = liquid density in lb/ft.^3

Tables 6.9.13 and 6.9.14 [19] give values for the diffusion and the constants m and n, respectively.

6.9.8 Produced Water Management

Produced water varies widely in composition with dissolved ions being the major component in these water. The TDS

TABLE 6.9.13 Diffusion Coefficients for Some Petroleum-Related Contaminants

Contaminant	Diffusion coefficient $\times 10^{10} \text{m}^2/\text{s}$ at 20°C
Methane	18.1
Trichloroethylene	8.37
Chloromethane	13.1
Benzene	8.91
Carbon dioxide	19.6 (at 25°C)
Oxygen	16.1 (at 25°C)
Hydrogen sulfide	20.3

Packing	Size (mm)	m	n
Raschig rings	50	80	0.22
Raschig rings	38	90	0.22
Raschig rings	25	100	0.22
Berl saddles	28	160	0.28
Berl saddles	25	170	0.28

content may be close to saturation at more than 300,000 mg/L TDS or be considered fresh at less than 500 mg/L TDS. The composition of the water depends on a number of factors. Some waters are the remains of the ancient sea held in formations thousands of feet below the surface. Some water may have been fresh originally but through geologic time has become saturated with the minerals contained in the surrounding rock. Still other water has changed in composition through migration through pore space and fractures, solubilizing minerals in the pathway. In a study characterizing production of produced waters from natural gas wells, it was found that less than 60% had any concentration of the heavier volatile constituents, but instead the bulk was composed of lighter hydrocarbons [31]. Table 6.9.15 shows the average water analysis for 19 natural gas wells. The components shown were found in 80% of the surveyed wells

By knowing the composition of the reservoir rock and assuming freshwater was in place at the time of deposition, water's TDS may be forecast with some accuracy for equilibrium equations. Produced water of course also carries a certain amount of hydrocarbons. These concentrations may also be calculated from equilibrium equations. For water in contact with the gas phase, Henry's law is used to predict the concentration of certain hydrocarbons. These gas-phase constituents, however, maintain equilibrium with the atmosphere when exposed. Thus, the organics may be stripped from the water by means of a packed tower, diffused aeration, or other means.

6.9.8.1 Solubility

Because of the dissolved mineral content in the water and the residual hydrocarbons, produced water must be treated for use or disposed. Safe disposal of this water is secured through injection into a secure geologic formation, evaporation in lined pits, or other approved means. The use of lined pits as the sole means for disposal has been eliminated in all but a few cases in which the evaporation rates are competitive with the well's production. Unlined pits are not considered a sound environmental approach in today's political climate. In the past, the percolation in such pits has allowed for a cost-effective means of disposal. In some cases, however, the practice has led to local groundwater contamination [32].

Guidelines have been made for the pit construction, including the following [33]:

- As much as practical, the pit shall be located on level ground and away from established drainage patterns, including intermittent/ephemeral drainage ways, and unstable ground or depressions in the area.
- The pit shall have adequate storage capacity for safe containment of all produced water, even in those periods

TABLE 6.9.15 Produced Water from Natural Gas Sites

Compound	Average Value
Total dissolved solids (TDS)	93000 mg/L
Total suspended solids (TSS)	132 mg/L
BOD ₅	1486 mg/L
Chloride	55000 mg/L
COD	11200 mg/L
Ammonia as N	72.3 mg/L
Oil and grease (62.5%)	15.6 mg/L
PH	5.83 mg/L
TOC	2280 mg/L
Barium	87.0 mg/L
Calcium	6424 mg/L
Iron	100 mg/L
Magnesium	683 mg/L
Manganese	7.47 mg/L
Sodium	18800 mg/L
Lithium	91.3 mg/L
Potassium	539 mg/L
Silicon	9.86 mg/L
Strontium	10 mg/L
Sulfur	25.9 mg/L
Phenols (62.5%)	330 ppb
Naphthalene (62.5%)	39.8 ppb
Benzene	5980 ppb
Toluene	6440 ppb
Total xylenes (75%)	3420 ppb

when evaporation rates are at a minimum. The design shall provide for a minimum of 2 ft. of free-board.

- The pit shall be fenced or enclosed to prevent access by livestock, wildlife, and unauthorized personnel. If necessary, the pit shall be equipped to deter entry by birds. Fences shall not be constructed on the levees.
- The pit levees to be constructed so that the inside grade of the levee is no steeper than 1 (vertical): 2 (horizontal), and the outside grade no steeper than 1:3.
- The top of levees shall be level and least 18 in. wide.
- The pit location shall be reclaimed pursuant to the requirements and standards of the surface management agency. On a split estate (private surface, federal

mineral) a surface owner's release statement or form is acceptable.

Lined pits shall be designed to meet following requirement and minimum standards in addition to those specified above:

- The material used in lining pits shall impervious. It shall be resistant to weather, sunlight, hydrocarbons, aqueous acids, alkalies, salt, fungi, or other substances likely to be contained in the produced water.
- If rigid materials are used, leak-proof expansion joints shall be provided, or the material shall be of sufficient thickness and length to withstand expansion without cracking, contraction, and settling movements in the underlying earth. Semirigid liners such as compacted bentonite or clay may be used provided that, considering the thickness of the lining material chosen and its degree of permeability, the liner is impervious for the expected period of use.
- If flexible membrane materials are used, they shall have adequate resistance to tears or punctures.
- Lined pits shall have an underlying gravel-filled sump and lateral system or other suitable devices for the detection of leaks.
- Method and schedules for removal of residual solids and saturated brine shall be established.

Pits used as a means of storage for treatment may be preferred over manufactured tanks due to volume considerations. Evaporation may be used in these wells and may in some instances be considerable in arid climates as calculated through the Meyers equation.

In the case of injection, steel tank storage is preferred to eliminate any contamination of the water supply by dust and other partials. In the case of class II injection, the water is often pumped into subsurface formations at less than the fracture pressure. Thus, the water must be free of particulate matter to avoid pore plugging. Pretreatment with biocides is for this same reason. The construction of a properly designed class II injection well often costs in excess of a million dollars. Thus, considerable planning is necessary to prevent early decline of injectivity.

In planning a class II well, the geology of the area must be considered as well as the number of viable injection zones presented. These zones must be separated from each other; at least one zone must be permeable and the other must impermeable from the underground source of drinking water (USDW) and be free of commercial quantities of oil or gas. They are must also be proven free of faults, cross bedding, and tonguing, and other permeability hindrances should be considered. Most states allow a radial extent of $\frac{1}{4}$ to $\frac{1}{2}$ mi. The are then available for storage is

$$V = C_t(V_f - V_i) D_{avg} Ah \phi \quad (6.9.34)$$

where

V_f = final pressure gradient in less than frac–
pressurepsi/ft.

V_i = initial pressure gradient in psi/ft.

A = aerial extent in ft.

D_{avg} = average depth of injection zone

C_t = total compressibility in psi^{-1}

h = thickness of zone in ft.

ϕ = porosity

6.9.9 NORMS in Produced Water/Gas

Radioactive contamination of production equipment is an emerging concern in the petroleum industry. Over a 20-year period, the EPA estimates that the combined production of natural gas and crude oil in the United States resulted in accumulation of 13 million metric tons of Naturally Occurring Radioactive Material (NORM), as opposed to more than 21 billion metric tons associated with metal, uranium, and phosphate mining and processing [34]. NORM can accumulate as scale or sludge in well casing, production tubing, surface equipment, gas gathering pipelines, and by-product waste streams. The sources of most of the radioactivity are isotopes of uranium-238 and thorium-226, which are naturally present in the subsurface formations from which natural gas is produced. The primary radionuclides of concern are radium-226 in the uranium-238 decay series and radium-228 in the thorium-232 decay series. Other radionuclides of concern include those resulting from the decay of radon-226 and radon-228, such as radon-222. Pipe scale and sludge accumulations are dominated by radium-226 and radium-228, whereas deposits on the interior surfaces of gas plant equipment are predominantly lead-210 and polonium-210 [35]. Radiation is normally reported in curies (Ci), rads, rems, or becquerels (Bq). The commonest way of reporting is in picocuries pCi or 10^{-12} curies. A picocurie means the quantity of radioactive material producing 2.2 nuclear transforms per minute[33]. One curie is equal to $3.7 \times 1,010$ nuclear transformations per second or 1 radium. In contract, 1 uranium had 0.36×10^{-6} Ci of activity. A rad qualifies an absorbed dose, and a rem is a dose effect ($0.1 \text{ mrem/yr} = 10^{-6}$ excess lifetime cancer risk).

$$X_{\text{rems}} = Q (\text{Yrads}) \quad (6.9.35)$$

The Q here is a quality factor based on the source of activity. Alpha particles inflict much more damage to human tissue than do beta emissions. The generation of these two particles caused the decay of the parent isotope and leads to production of the progeny, which are sometimes referred to as *daughters*. Isotopes with larger half-lives usually present lower radioactive risks. Gamma ray

emission does not produce progenies Elements that have very short half-lives are not significant in that they change rapidly in transport. Radium-228 emits beta particles, where as uranium, radon, and radium-226 are alpha emitters. The average annual dose received by humans in the United States is 200 mrem, of which only 4 mrem are attributed to drinking water. Some public water supplies have show radioactivity in excess of 10,000 pCi/L, equivalent to a dose of 100 mrem/yr [36].

Contamination may be caused by natural sources, and as such termed NORM. Radioactivity is a concern due to the widespread occurrence of radium, uranium, and radon and inherent carcinogenicity attributed to them. National Primary Drinking Water Regulations (NPDWRs or primary standards) under the 1996 amendments to the SDWA are legally enforceable standards that apply to public water systems. Primary standards protect public health by limiting the levels of contaminants in drinking water (Table 6.9.16 [37]).

In Canada, the maximum acceptable concentrations of radon-226 is 27 pCi/L (1 Bq/L) and for strontium-90 270 pCi/L (10 Bq/L). The World Health Organization sets a guideline value of 2.7 pCi/L (0.1 Bq/L) for the gross alpha activity and 27 pCi/L (1 Bq/L) for the gross beta activity.

Radon gas is common to natural gas production. It has long-lived decay products that contribute to the contamination of production equipment. Radon-222 is a highly mobile inert gas produced from radium-226. Other radon isotopes exist(thoron) but are rare and have extremely short half-lives, which cause decay even before the gas is produced at the wellhead. Because of radon's characteristics, it freely travels in groundwater, oil, and natural gas without chemical

reaction. Once produced at the wellhead, the radon-222 is compressed with the natural gas. In the refinery, radon may become concentrated in the production of propylene or ethane, with a boiling point being intermediate to these two. On the wellsite, concentrated radon gas is not expected. Table 6.9.17 [39] gives radon concentrations found worldwide at the wellhead.

Radon-222 has a short half-life at 3.8 days. Being inert, it does not accumulate in the body, 99% of the radon-222 decays into lead-210 within 25 days. Figure 6.9.7 [40] shows the complete decay series of uranium-238. In the wellsite facilities, the daughter products of radon accumulate inside the containing vessels. Because of the low concentrations, it may be difficult to measure the radioactivity from the outside of the vessels. Usually, laboratory analysis or specialized probes are needed to detect these quantities. An alpha/beta probe may register positive if held to the internal surface. Radon gas does have sufficient gamma energies to register on a gamma survey meter. These radioactive materials are not considered hazardous unless inhaled or ingested.

Radon-228 comes from the decay of thorium-232. Radon-228 has a beta intensity of 4.71MeV, and radon226 emits an alpha intensity of 0.024 Mev. Radon-226 has an initial registered gamma energy of 185.7 keB compared with 10.3 keV for radon-228. Table 6.9.18 shows Wyoming's produced water characteristics [41].

Tracer surveys are an important technology used in today's petroleum industry. The injection of low-level radioactive elements downhole allows us to follow fluid migration downhole through gamma ray logs. The federal

TABLE 6.9.16 National Primary Drinking Water Regulations for Radionuclides [38]

Radionuclides	MCLG (mg/L)	MCL or TT (mg/L)	Sources of Contaminant in Drinking Water
Alpha particles	none* — zero	15 (pCi/L)	Erosion of natural deposits of certain minerals that are radioactive and may emit a form of radiation known as alpha radiation
Beta particles and photon emitters	none — zero	4 millirems per year	Decay of natural and manmade deposits of certain minerals that are radioactive and may emit forms of radiation known as photons and beta radiation
Radium-226 and radium-228 (combined)	none* — zero	5 pCi/L	Erosion of natural deposits
Uranium	zero	30 µg/L as of 12/08/03	Erosion of natural deposits

Maximum Contaminant Level (MCL) is the highest level of a contaminant that is allowed in drinking water. MCLs are set as close to MCLGs as feasible using the best available treatment technology and taking cost into consideration. MCLs are enforceable standards.

Maximum Contaminant Level Goal (MCLG) is the level of a contaminant in drinking water below which there is no known or expected risk to health. MCLGs allow for a margin of safety and are non-enforceable public health goals.

Units are in milligrams per liter (mg/L) unless otherwise noted. Milligrams per liter are equivalent to parts per million.

*MCLGs were not established before the 1986 Amendments to the SDWA. Therefore, there is no MCLG for this contaminant.

TABLE 6.9.17 Radon Concentrations Found at the Wellhead around the World.

Location of Well	Radon Concentrations (pCi/L)
Borneo	1–3
Canada	
Alberta	10–205
British Columbia	390–540
Ontario	4–800
Germany	1–10
The Netherlands	1–45
Nigeria	1–3
North Sea	2–4
United States	
Colorado, New Mexico	1–160
Texas, Oklahoma, Kansas	1–1450
California	1–100

eral different isotopes may be injected into any one well, depending on the number of fluids that needed to be traced. The isotopes of strontium, antimony, gold, and others are frequently used. Each isotope registers a different signature on the gamma ray log.

Water or gas contaminated by radioactive tracers is to be expected. In the case of an injection well, the contamination should be documented with no further considerations. In the case of a producing gas well, precautions must be taken to protect workers from inhalation of vented gas that may contain radioactive vapor. The completion or workover fluids retrieved from the tracer operation are nonexempt subtitle “C” hazardous wastes. As such, they must be properly contained, labeled, and transported to a specially permitted TSD facility authorized to dispose of low-level radioactive waste. Low amounts of waste may be stored onsite for extended periods of time.

Cation exchange is a very effective means of radium removal because it is preferred above all other common cations found in water. An even more efficient exchange mechanism is BaSO₄ located in alumina or SAC resin. A resin impregnated with barium sulfate is used to decontaminate the spent regenerant solution from a conventional cation exchange process of radium. The process was tested on a small municipal system, the test was very successful and was still removing radium when the resin was loaded at 2.7 million pCi/L. This level, however, posted a far greater disposal problem than the initial brine solution [41].

government allows their use in confirmation for mechanical integrity in class II injection wells (40 CFR 146.8) [42]. The low-level radioisotopes are prepared in the laboratory and transported in approved containers to the site. Sev-

NORMs frequently enter the production system in the form of scale. This scale may be found in tubing, wellhead, and any surface equipment. The concentrations have been

FIGURE 6.9.7 Uranium-235 decay series

TABLE 6.9.18 Concentrations of Radon-226 in Wyoming Produced Waters

Parameter	Value
No. of wells tested	373
Max. recorded value of radon-226	2152 pCi/L
Max. recorded value of radon-226	0 pCi/L
Average value of radon-226	21.5 pCi/L
Median value of radon-226	3.7 pCi/L
No. of wells above 5 pCi/L	167

found up to 30,000 pCi/gm. In the production scale and 250 pCi. Gm in associated sediments such as BS&W. Soils surrounding locations may show radium levels up to 2000 pCi/gm [42].

The radioactive scale is often found in association with precipitates of barium, strontium, and calcium. Equilibrium calculations favor the formation of radium sulfate in excess of barium sulfate. The prevention of NORM contamination then may be prevented through scale inhibition. An equal mixture at 1 mg/L of animotrimethylene phosphonic acid and phosphinopoly-arboxylate has been found effective in eliminating radioactive scale.

The greatest health risk attributed to NORM-contained production equipment comes from production equipment comes from the cleaning and repair. The radioactive materials are not health hazards unless ingested or inhaled into the body. In the event of inhalation, dustborn particles containing NORM or a gas such as radon attach to the lung tissue where the emit alpha particles into the lung tissue, which may lead to cancer.

6.9.10 Class II Injection Wells

Class II injection wells afford an economic means of disposal of produced brine water. They are regulated through the UIC Program under the provisions of the SDWA. State and local governments may be granted primacy over UIC programs by the federal government. The underlying rules for the UIC program are found in 40 CFR 144 and 146 [43,44].

6.9.10.1 UIC Criteria and Standards

USDW includes an aquifer and the portion that supplies a public water system, contains a sufficient amount of water to supply a public water system, contains less than 10,000 ppm

TDS, and is not an exempted aquifer (40 CFR 146.3). An exempted aquifer or portion of such must meet the following criteria: does not currently serve as a source of drinking water, and cannot or will not serve as source of drinking water due to

1. commercial quantities of minerals, hydrocarbons, or geothermal energy
2. situated at a depth or allocation that makes recovery of water technically or economically impractical
3. so contaminated that recovery of water is technically or economically impractical for drinking water purposes
4. contains more than 3,000 ppm TDS but less than 10,000 ppm TDS and is not reasonably expected to supply drinking water
5. is located over a class II well mining area subject to collapse or subsidence (40 CFR 146.4)

A class II injection well inject fluids

1. that are brought to the surface in connection to conventional oil and natural gas production and may be commingled with wastewaters from integral gas plants,
2. for enhanced recovery of oil or natural gas
3. for storage of hydrocarbons that are liquid at standard temperature and pressure (40 CFR 146.5)

Class II injection wells are to be located in a formation separated from any USDW by a confining zone and be free of known open faults within the area of review. The area of review may be computed from a modified Theis equation.

$$r = \left[\frac{(2.25KHt)}{S10^x} \right]^{0.5} \quad (6.9.36)$$

$$x = \frac{4\pi KH (h_w - h_{bo} S_p G_b)}{23Q} \quad (6.9.37)$$

where

r = radius of endangering influence from injection well (length)

K = hydraulic conductivity (length/time)

H = thickness of injection zone (length)

t = time of injection

S = storage coefficient ft.

h_{bo} = observed original hydrostatic heat of injection zone as measured from the base of the lowermost SDW (length)

h_w = hydrostatic head height of USDW zone as measured from the base of the lowermost SDW (length)

$S_p G_b$ = specific gravity of the fluid in the injection zone

These equations assume homogeneous, unconfined, isotropic, and total penetration of the aquifer with $r_w \ll r_e$ (40 CFR 144.6).

Some states question the use of Equations 6.9.36 and 6.9.37 in determining the range of influence of an injection well and require a set radius. New Mexico and Texas require a set radius of influence of $\frac{1}{2}$ mi.

The requirements do not apply to those wells that were previously drilled under a state or federal regulatory system in compliance with these controls, provided well injection will not contaminate a USDW. Remedial work may be approved to bring newly drilled wells (dryholes) into compliance. Currently, amendments to 40 CFR 144 and 146 are proposed for modifying well construction and extending the scope of wells, necessitating documentation for “area of review” [45]. Under the new rulings, with some allowances, all new class II wells will be required to:

- Run surface casing through all USDWs containing $\leq 3,000$ mg/l TDS and cement same to surface
- Cement the long string casing to prevent the migration of fluid from the injection zone
- Have the tubing string landed with a packer.

6.9.10.2 UIC Permitting Process

To be granted a permit for a class II injection well, the operator must file an application to the ruling UIC program at the state, local, or EPA office. On federal leases, the BLM must also grant approval. The permit will address the following as stipulated in 40 CFR 146 [44].

1. depth of the well
2. depth to base of USDW
3. estimated maximum and average injection pressures
4. nature of the injection fluid
5. lithology of injection and confirming zones
6. external pressure, confining pressure, and axial loading
7. hole size
8. size and grade of all casing strings
9. class of cement

The permit is then reviewed and, once accepted, is let to the public for comment. After this comment period, the final permit decision is issued. Once completed the, well then may be used to dispose of:

- produced water
- waste fluids from drilling operations
- pigging fluids from within the field.
- used workover and stimulation fluids from injection, exploration, and recovery wells
- any gas used for enhanced recovery or pressure maintenance
- brine reject associated with enhanced recovery

- waste fluids from sweetening and dehydration of methane as long as the fluid is not hazardous at the point of injection
- waste oil and fluids from cleanup operations associated with primary production within the field
- waste fluids from cementing operations
- fresh water used as enhanced recovery base
- water containing chemicals used for enhanced recovery.

Monitoring of fluid composition, injection pressure, annulus pressure, flowrate, and volume is required. Reporting of regular activities is required annually, and a mechanical integrity test must be performed every 5 years, or as required by permitting authority, and each time tubing is moved. The mechanical integrity test requires that a static pressure test must be made on the well annulus and the pressure held steady for a minimum of 30 min.

6.10 OFFSHORE PRODUCTION OPERATIONS

Section reviewed by Dave Barrow

6.10.1 Offshore Development—Historical Overview

The following chapters provide a brief overview of historical and recent offshore development activity. References to governing standards, and regulatory philosophy promulgated from the perspective of the US Department of Interior are provided as appropriate [1].

Drilling and production technology in the oil and gas industry has advanced from producing oil and gas onshore to exploring in distant offshore locations in water depths up to 10,000 ft.

Some 80 years ago, locations in the marshlands were built up above the water level with oyster shells. Lumber measuring 3 in. \times 8 ft. and random lengths were laid as matting over shell fill. A land rig was then moved in by tug and barge via canal to the location where the derrick and drilling equipment was unloaded and rigged up. Drilling, completion, and related facility hookups were accomplished as on land locations.

Later developments employed rigs mounted on a barge. The barge was sunk on location in water depth limited by the freeboard of the barge before sinking.

To extend the utility of converted barges beyond shallow depths, a “posted barge” was developed with the drilling deck separated from the barge by I-beams supporting the drilling deck. With this unit, the barge could be sunk completely below the surface of the water as long as the drilling deck was above the water. The barge rig and posted barge rig were utilized in marshlands shallow lakes, and near shore areas. They are still used in such areas today. [Figure 6.10.1](#) is an illustration depicting the general layout and structural scheme for a posted barge.

Offshore drilling started in shallow water near the shore line on concrete structures. Concrete pre-stressed pilings were driven in the ocean floor, and a concrete platform was installed on the piling to support a land-type rig. After the well, or multiple wells, were completed, the rig was demobilized from the structure and production equipment was erected.

Beginning in the early 1950s steel structures were fabricated onshore and moved to offshore locations by tug and crane barge. At location, the crane was used to lift a “jacket” structure, by swinging it to one side, and lowering it onto the ocean floor. Steel jackets are then “pinned” to the sea bottom using “pilings,” hammered down through the larger jacket legs. Pilings are hammered to refusal, typically penetrating the seabed by 200–400’ using hydraulic hammers. After installing the jacket, pre-fabricated “topside” decks are installed on the structure, and a drilling rig is

FIGURE 6.10.1 Illustration—posted barge drilling rig. <http://www.wipertrip.com/drilling/shallow-water/131-posted-barge-with-land-or-modular-drilling-rig.html>.

unloaded onto the platform and rigged up for drilling. After drilling, casing, and completing the well (or multiple wells), including the Christmas tree(s), the rig would move to another location that was ready to be drilled. Once the drilling rig left the completed wells, flow lines were laid and all necessary equipment installed to transport production either to a purchaser’s pipeline, to an onshore separation facility, or to a centrally located production platform before being transported to land.

While early developments relied on the conversion of land-based drilling equipment for use offshore, offshore drilling contractors rapidly evolved the posted barge concept to “jack-up rigs,” built especially for offshore use and able to drill in increasingly deep water depths. Jack-up rigs became classified as “mobile offshore drilling units” (MODUs), capable of moving readily among multiple locations. MODUs have come to encompass semi-submersible moored rigs and now include dynamically positioned drillships capable of drilling in water depths approaching 10,000’ of “feet of salt water” (fsw). [Figure 6.10.2](#) gives the technical limit of offshore drilling as a function of year as the industry progressed toward deep water drilling capabilities. [Figure 6.10.3](#) illustrates the maximum water depth for well completions installed in the Gulf of Mexico by year through 2007 [1]. Drilling has occurred in water depths exceeding 9,000 ft.

FIGURE 6.10.2 Technical limits over time, for dry tree offshore systems.

FIGURE 6.10.3 Maximum water depth for Gulf of Mexico subsea completions by year through 2007.

Offshore producing areas are found in nearly every ocean around the world, including the arctic regions on Alaska’s northern coastline (BP’s Northstar project is located in Federal Waters adjacent to the Prudhoe Bay field [2]). The escalating weight and associated cost of ocean floor-anchored structures, however, has led to the development of floating and subsea systems, to access water depths exceeding 6–700’ fsw.

The Bureau of Safety and Environmental Enforcement defines “shallow” water as less than 1,000 ft., deepwater as 1,000 to 5,000 ft., and ultra-deepwater as more than 5,000 ft. Figure 6.10.4 and Figure 6.10.5 illustrate the trend of production volumes originating from US Gulf of Mexico

leases situated in water depths greater than 1000’ fsw [3,4]. Worldwide, the major deepwater offshore provinces include the Gulf of Mexico, offshore West Africa, Brazil, Australia, Indonesia, and the Atlantic Margin area of the North Sea. Figures 6.10.4 and 6.10.5 give the historical oil and gas production, respectively, for Gulf of Mexico leases versus years for production from wells deeper than 1000 ft [4].

6.10.2 The Role of Offshore Systems with Respect to Wells

The systems and structures for use offshore may be as simple as an early drilling platform including structures

FIGURE 6.10.4 Historical Gulf of Mexico oil production, illustrating that total Gulf of Mexico oil production is increasingly from deepwater leases greater than 1000/ fsw [4].

FIGURE 6.10.5 Historical Gulf of Mexico gas production, illustrating that total Gulf of Mexico gas production is increasingly from deepwater leases greater than 1000/ fsw [4].

used for production, quarters, or service platform. With increasingly deeper water, choices for offshore development systems have become driven by whether the tree systems will be “dry,” with the Christmas tree accessible above sea level, or subsea. Fixed platforms, tension leg platforms (TLP), compliant towers, and spars are suitable for “dry” trees and may also support subsea wellheads/trees. In the case of dry trees used on a fixed platform, TLP, spar, or compliant tower, the structure acts as a stabilizer for the well casing above the sea floor to the Christmas tree located above the surface of the water. Flowline risers, helicopter landing pads, and mooring facilities for crew boats and work boats are necessities that must be supported by the structure. In the case of dry trees on TLPs and spars, tensioning devices and buoyancy cans, respectively, are used to support the well casing. Flowline and pipeline risers and auxiliary

equipment must still be supported by the structure. Table 6.10.1 lists the permanent production platforms in water depths greater than 1,000 fsw in the Gulf of Mexico.

FPSOs and semi-submersibles utilize wet trees with flowlines leading from the subsea tree back to the surface. These flowline risers can impose tremendous forces on the production system and careful consideration must be paid to their design. Some risers are flexible while others are steel catenary riser (SCR).

6.10.3 Fixed Platforms

Fixed platforms can be either steel or concrete. Steel structures include traditional jackets with battered legs from top to bottom—the jacket’s leg spacing increases to the seafloor—and relatively new compliant towers where the

leg spacing remains constant from seafloor to surface. Figure 6.10.6 compares the profile views of fixed platform with that are considered compliant towers [5]. Table 6.10.2 gives a summary of example compliant tower installations, their water depth, their year of installation, and operating company.

Fixed platforms use steel piles driven 200 to 400 ft. into the sea floor to anchor them in place. Thousands of traditional steel jackets have been installed in water to 600 ft. Seven deepwater platforms with jackets are installed with water depths ranging from 1,025 (Cognac field in 1978) to 1,353 ft. Bullwinkle field in 1991; the Bullwinkle platform cost about \$500 million (US) to construct [2,5].

Three compliant towers installed to date have been in the Gulf of Mexico, with the other installations occurring in West African waters.

Petronius' \$70 million (US), 3,600 ton south module was dropped to the sea floor as it was lifted for final installation when a lift cable broke. The module did not damage the compliant tower, but it took 12 months to rebuild the module and successfully install it in May 2000.

Concrete gravity structures (CGSs) can be more cost effective than steel jackets in relatively shallow water. A CGS rests on the sea floor, and gravity holds it in place. A significant consideration with CGS, however, is the cost to decommission.

Figure 6.10.7 shows a CGS for the Gorgon field development offshore western Australia in 100 m water depth [2].

CGSs have been used mainly in the North Sea. The deepest CGS installed to date is in Shell's Troll field offshore Norway in 994 ft. water in 1996. Shell's Malampaya field in the Philippines was installed with a CGS in 2001. Husky Energy plans installation of a CGS for the White Rose Expansion project. Full authorization of the project is pending [2].

6.10.4 Floating Production Systems (FPS)

FPSs generally fall into four categories: semi-submersibles, ship-shaped vessels, tension-leg platforms (TLPs), and spars. The cost of these systems have ranged over the years from \$500 million to \$5.0 billion (US) and can take

FIGURE 6.10.6 Bullwinkle jacket (left, 1376' fsw, installed by Shell, 1991), and Baldpate compliant tower (1650' fsw, installed by Hess, 1998) [5].

Source: *Offshore Technology*.

from 1 to 4 years to design and construct, depending on their processing capacity and the water depth installed. Production capacities can range from 40,000 bopd for spars and TLPs to 30,000 bopd for floating production, storage, and offloading (FPSO) vessels offshore West Africa [4]. Other systems may include water injection up to 300,000 bwpd and gas re-injection up to 400 MMSCFD.

Although TLPs are anchored to the sea floor using tendons, other floating production systems are anchored using catenary mooring lines (e.g., a 12-point spread mooring for an FPSO or a nine-point spread mooring for a spar, effectively anchoring the system in place). The ship-shaped vessels, more often called FPSO vessels, can be anchored to the sea floor using a single-point mooring system (SPM) in harsh environments. The SPM can be external or internal

to the vessel, allowing the vessel to weather vane around the mooring point to face prevailing weather. Figure 6.10.8 depicts the BHP-operated FPSO Buffalo Venture, with Single Point Mooring system integrated into the vessel structure [2].

6.10.4.1 Tension Leg Platforms

The tension leg platform concept dates to the 1970s. The concept relies on tensioning a buoyant hull to the seafloor using steel “tendons” between the vessel hull and mudline piling systems. TLPs can support dry trees and can also support subsea riser systems. Design and performance considerations for TLPs are described by API Recommended Practice 2T; Planning, Designing, and Constructing Tension Leg Platforms [6]. Figure 6.10.9 illustrates three different TLP concepts that have been successfully installed in the Gulf of Mexico.

Conoco installed the first TLP on the Hutton field located in the North Sea in 486 ft. water in 1984. The worldwide fleet of TLPs comprises 31 installations, including facilities that are pending installation as well as those that have been decommissioned [7].

6.10.4.2 Spars

Owing to relatively lower capital investment requirements, the prospect for reuse as well as the prospect for supporting dry trees, spars have become a relatively popular offshore development concept. Spar hulls are similar to the tension leg platform concept in that they rely on buoyancy to support the facility, and presumably, the associated dry tree systems. Spars differ in that they take advantage of water depth to promote vessel stability, and utilize catenary mooring lines (poly, or wire rope) as opposed to steel tendons, to maintain vessel positioning.

Kerr McGee installed the first spar in their Neptune field in 1,929 ft. water in 1997. Neptune is considered to be a “Classic” Spar design. Since the installation of Neptune, some 21 other spars have been installed with the deepest being Shell’s Perdido, in 7,817 fsw Anadarko’s Red Hawk spar, installed in 2004, was decommissioned after only 10 years of service. Figure 6.10.9 shows the Shell’s Perdido Spar which is a truss design and was installed in 2010 in 7817 fsw [2,7].

Spars follow one of the three general design alternatives. Classic spars are generally single cylindrical hull designs with heavy ballast material in the bottom. A truss spar has a lower, heavyweight “soft tank” on the bottom, connected by a truss to a buoyant “hard tank,” at the top of the structure. Topside drilling and production equipment are placed on top of the “hard tank,” while the soft tank is typically filled with ballast to provide stability. A cell spar is a cylindrical outer shell structure that houses numerous smaller water-tight hulls that are ballasted at the bottom, similar to a classic

FIGURE 6.10.7 Field development concept for Gorgon, depicting integration of concrete gravity structure and subsea wells [2].

FIGURE 6.10.8 BHP-operated Buffalo Venture FPSO with single point mooring, Timor Sea.

FIGURE 6.10.9 Shell's Perdido spar, a truss design, was installed in 2010, in 7,817 fsw [2].

FIGURE 6.10.10 Bennett’s “Mindoc” spar design was utilized for the Telemark hub, installed by ATP [2].

spar. The “Mindoc” concept which utilizes three smaller size floatation cells in a triangular orientation, connected to a ballasted substructure.

Figure 6.10.9 shows the visible topside of the Perdido spar. Figure 6.10.10 shows the topside of a classic, truss and cell spar platform. Figure 6.10.10 is the Mindoc structure as deployed at the Telemark field in the Gulf of Mexico [2].

6.10.4.3 Semi-submersibles

Semi-submersible facilities are as stationery floating hulls supported by pontoons that are tethered to the seabed with mooring lines which, like spars, can be either wire rope, chains, polyester, or combinations thereof. Unlike a spar, semi-submersibles are not typically designed to accommodate dry trees. Rather, the facility acts as a host to one or more subsea systems which may be deployed to deplete one or more fields. Semi-submersibles typically export oil and gas via export risers that tie into pipeline systems. The first FPS was a converted semi-submersible drilling rig, installed on Hamilton Oil Co. Ltd.’s Argyll field offshore United Kingdom in June 1975. The deepest semi-submersible production unit installed to date is Anadarko’s Independence Hub, in 7,920 fsw, in 2007, in the Gulf of Mexico.

6.10.4.4 Floating Production Storage and Offloading Systems (FPSOs)

FPSOs are typically either reclaimed and modified tankers, or may also be large, purpose built hulls that are moored to the seabed. Crude oil is typically exported via lightering tanker. Gas is generally exported via pipeline, similar to a semi-submersible, but may also be re-injected or, in some cases, flared. The first FPSO was installed in 1984. The longest surviving FPSO installation is Vietsovpetro’s

FIGURE 6.10.11 Petrobras leased a disused VLCC converted to FPSO service, to bring the Cascade and Chinook fields online in 2012 [8].

White Tiger facility, in 50 m water depth, installed in 1985. Over 151 FPSOs are currently in service worldwide. Petrobras’ Cascade-Chinook is the deepest, installed in 8,200 fsw in 2012 [8]. Detailed information including operator, field, capacity, vessel owner, and contractor(s) for installed FPSOs is summarized by Offshore Magazine [9]. Figure 6.10.11 shows a Petrobras subsea—surface floating terminal configuration offshore Brazil. This was installed in 2012 by using a converted surface ship for a surface terminal (FPSO) to gather and transfer oil and gas production from the Cascade and Chinook fields into production.

6.10.4.5 Floating LNG (FLNG)

An emerging subset of the FPSO is floating liquefied natural gas (FLNG). Longstanding challenges associated with monetization of large, but nevertheless marginal natural gas finds, have given rise to concepts for packaging small LNG trains within offshore facilities. Challenges going forward are increasingly less technical and operational, and more commercial. Figure 6.10.12 illustrates a floating LNG facility that Shell plans for Australia, as it is under construction in South Korea [10].

6.10.5 Subsea Systems

Figure 6.10.13 shows the layout, manifold skid, and subsea wells, for the Petrobras Chinook field [2]. Subsea production systems are used in combination with new or existing FPSOs or fixed platforms. A basic subsea system consists of a wellhead, manifold, flowlines, and electrical and hydraulic

FIGURE 6.10.12 Shell's prelude floating LNG hull, slated for installation in Australia, the photograph shows the prelude hull under construction in South Korea [10].

FIGURE 6.10.13 Chinook drill center with trees, manifolds, and pump station.

control umbilicals. Early subsea systems were developed with the simple objective of gathering production streams from multiple wells so that they could be produced through a riser or risers to a surface host. The wells had to flow naturally against the backpressure of the seawater column.

Whereas dry tree systems can continue flowing until the wells deplete to near atmospheric pressure, production from subsea wells becomes truncated early owing to the pressure burden of the water column. So to enhance recovery, subsea production boosting systems have been evolving rapidly through field trials beginning in the early 2000s. Boosting systems are categorized broadly as either; (1) full wellstream boosting from the seafloor, (2) subsea gas compression, (3) subsea pumping to boost water injection volumes, or (4) subsea separation and processing.

Early trials with full wellstream boosting generally developed as retrofits to existing subsea systems installations. Pumps were “bolted onto” facilities that may or may not have been designed to accept them, and likewise had to be accommodated by host facilities that might or might not have been built with capability for handling the additional umbilical and riser requirements, from either a weight, space, or power generation standpoint (see “Life Cycle Planning,” below). Full wellstream boosting also includes the use of electrical submersible pumps, located downhole as part of the tubing string of each well. Principally, however, wellstream boosting occurs as part of a multi-well manifold shared by more than one well.

The key variable in design of full wellstream boosting systems is the percentage of gas in the flowstream, referred to as gas volume factor (GVF). GVF is simply the volumetric percentage of gas in the flowstream and is a function of reservoir fluid properties as well as ambient pressure in the process stream. GVF will vary dramatically over wells' lifetimes.

GVF will drive the selection of pump to be used as part of any subsea boosting scheme, as illustrated in [Figure 6.10.14](#) GVF effect on Pump Performance, for Various Pump Types. The styles of pump referred to by the figure are:

- (1) Single Phase—High capability but not tolerant of high GVF. Used in near “dead oil” wellstreams, or downstream of separation that removes a portion of the gas from the flow stream.
- (2) Twin Screw—Tolerant of high GVF. Used in multi-phase installations where removal of gas from the flow stream is not feasible.
- (3) Wet, and dry gas compression—designed for high GVF.

Because of the water depth, remote-operated vehicles (ROVs) are used to monitor and maintain subsea systems. ROVs typically have an attached cable to supply power and control from the surface while under water. As water depths increase, particularly in difficult metocean settings, the handling requirements associated with an ROV become challenging. Industry is currently developing reliable autonomous under water vehicles (AUVs) that do not require a cable.

[Figure 6.10.15](#) from Offshore Magazine's Poster 111 illustrates increasingly complex architectures for subsea systems, ranging from simple, unboosted flow from subsea Christmas trees, to basic separation to remove gas from the flowstream, and to inject seawater for reservoir pressure support, to full separation with boosting and reinjection of produced water at the seabed. The utilities depicted include:

- Production Christmas Trees (XT)
- Water Injection Christmas Trees (WI XT)
- Subsea Umbilical Terminal Assembly (SUTA)—for control of well Christmas Trees
- Production Subsea Umbilical Terminal Assembly (PUTA)—for control of subsea production equipment
- Pipeline End Terminal (PLET)—for connecting export pipelines and riser systems to the subsea system

Large deepwater floating production systems are being installed with the intent that they will act like hubs to accept the subsea tie-backs of relatively smaller fields. For example, the Auger TLP installed in 1994, now supports subsea tie-backs from Macaroni (1999), Serrano (2001), and Oregano (2001).

FIGURE 6.10.14 Gas volume factor effect on pump performance, for various pump types. Source: Offshore Magazine Poster No 111.

FIGURE 6.10.15 Progressive achievement in riserless light well intervention (RLWI) versus water depth [11].

6.10.5.1 Planning for Well Intervention

In addition to providing protection and support to the wells drilled for offshore developments, offshore systems must provide for the need to intervene on, or “workover” the wells hosted by the system. In the case of dry trees the process is similar to that which is utilized for land wells. The system must be capable of supporting a rig or service unit (either coiled tubing or wireline) that can access the well, and there must be space for support equipment including quarters for personnel.

For subsea wells, intervention planning has in the past typically required using a rig to partially deconstruct the well for purposes of either repairing or recompleting. Increasingly, industry is utilizing “Light Well Intervention” (LWI) methods deployable from a vessel, for accessing subsea wells without removing the subsea Christmas tree.

LWI methods include use of a lightweight, high strength riser, or a subsea lubricator and in both cases, the control umbilical that is essential for operating a package of well control valves installed temporarily on the top of the well. Figure 6.10.15 illustrates the manner in which LWI methods have been advanced in the Gulf of Mexico. Successful LWI style interventions have been reported in water depths up to 8200 fsw [11].

Effective planning for subsea well intervention includes early decisions about the style, (either horizontal or vertical) of tree [12].

Figure 6.10.16 illustrates the architectural differences between vertical and horizontal trees. Operationally, intervention on vertical trees can be accomplished by opening the Production Master and Production Swab Valves (PMV and PSV), after attaching either a lubricator or riser to the

FIGURE 6.10.16 Comparing the architecture of horizontal and vertical subsea trees [12].

top of the tree. Horizontal trees may only be accessed via removal of Crown Plugs, requiring that lubricators or risers be “full open”.

6.10.6 Life cycle Planning from Concept Through Asset Decommissioning

The foregoing paragraphs describe a wide array of alternatives in use to support development of petroleum reserves situated in offshore and near shore areas. The process for selection of the best alternative (or mix of alternatives) particularly for water depths greater than 800' fsw, has evolved into a detailed analytical effort involving competing alternatives and trade-offs, generally between capital expenditure, operating expenses, efficiency, and schedule. Figure 6.10.17 illustrates a process used by most operators to achieve outcomes that achieve the highest return from the asset. As illustrated, planning (and accordingly, expenditures for engineering or “FEED”) must begin well ahead of anticipated project startup [7]. The figure also shows the asset value through different phases, or stages of useful life, from inception through abandonment. The illustration reflects the inverse relationship between cumulative expenditure and “influence” through the lifetime of a project, implying that the objective of the engineering “FEED” and “Front End Loading” work is the methodical narrowing of alternatives so that the one that is ultimately implemented at “Sanction” is clearly best for the asset. Two references detail cases and considerations with respect to planning, for recent offshore developments [13, 14].

It is a fact that land owners (typically host governments) are increasingly involved with key decisions that impact other users as well as long-term status of their oceans and seabed. Accordingly, owners (host governments) have

implemented regulations that spell out requirements for either removing offshore assets, or for otherwise ceding control of them to an agent designated the host government. In either case, asset decommissioning, including the plugging of wells is an increasingly important consideration in the planning of offshore developments.

6.10.7 The Evolution of Regulation and Safe Practice in the Offshore

Events associated with the blowout of the Gulf of Mexico Macondo well have drawn attention to the issue of Offshore Safety. Offshore safety and pollution prevention have been an abiding concern for industry and regulators beginning with initial developments in 1932. In the United States, operations by oil companies on offshore lands have been subject to rules promulgated by the Department of Interior as the owner of the federal lands, and the US Coast Guard, which is charged with assuring unfettered navigation of waterways. Regulatory responsibilities and interests in other countries follow a similar model, and most countries follow United Nations Convention on the Law of the Sea, when it comes to oil industry practices that intersect the interests of seaborne navigation, fishing, and other uses including defense and the management of coastal zones.

Regulation and industry practice have evolved, however, in conjunction with accidents and mishaps. While the mishap with the Macondo well was related to the temporary abandonment of a subsea well, many of the most infamous incidents preceding Macondo were related the offshore producing facility as opposed to the drilling operation. Early disasters in the Gulf of Mexico were in fact related to both drilling and production operations, and resulted in the development of Standards and Recommended Practices by

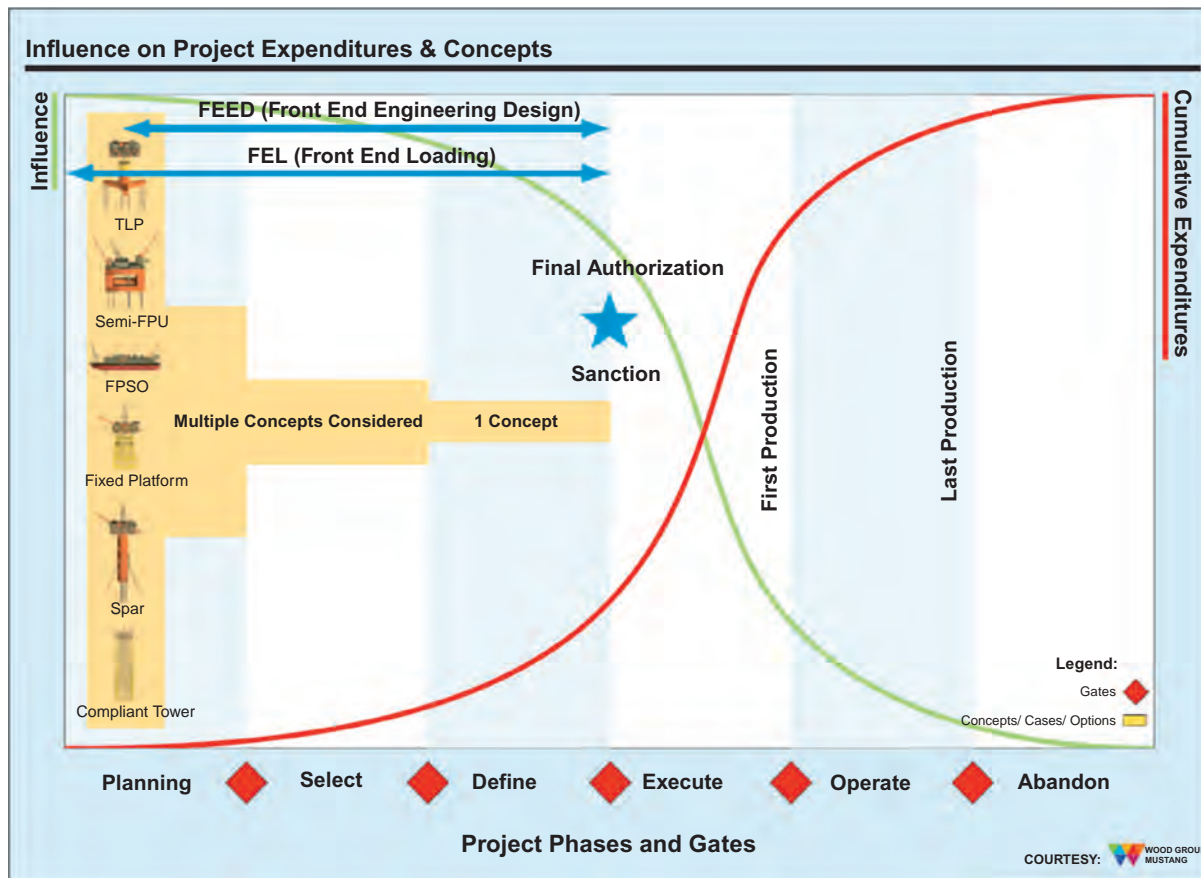

FIGURE 6.10.17 Using a stage-gate project development process for selecting the “right concept,” to achieve the “best” life of field outcome [7].

the American Petroleum Institute for the use of certified and fail safe equipment in well construction and design. APIs standards became written into US Federal Law through the creation of “OCS Orders” maintained by the Department of Interior to manage Offshore Safety. At the time, the United States Geological Survey (USGS) had charge of these regulations as well as the management of “Outer Continental Shelf (OCS) lands. Departments and staff managing the OCS were reformed by the Department of Interior into the Minerals Management Service in 1982.

Following are a short list and historical commentary for several notable offshore incidents.

6.10.7.1 Ekofisk

The capsizing of the Alexander L. Kielland, a moored drilling vessel being utilized as overflow accommodation (Flotel) during construction operations on the Ekofisk Edda production platform is regarded as Norway’s worst industrial accident. An improperly welded brace failed as the vessel was being towed away from Edda in rough weather ranging to 40 ft seas. Of 212 people aboard, 123 were killed. Aside from lessons in manufacturing quality and the need for redundancy in structural design, lessons regarding

manning levels during critical operations and risk-based exposure to low-probability, but high-consequence events were implanted within the offshore industry.

6.10.7.2 Piper Alpha (1988)

Safety in the offshore industry in general and the North Sea in particular was heavily influenced by the disaster on the Piper Alpha oil platform on July 6, 1988, in which 167 of 226 people lost their lives. Fire occurred at night within the platform’s process module, as a result of improperly securing safety devices designed to prevent condensate spillage. The resulting explosion ruptured wells and process equipment, causing secondary explosions. Importantly, crew on the platform were helplessly unable to stop flow from adjacent platforms that had been routed through Piper Alpha’s process equipment.

The UK government commissioned Lord Cullen to lead the public inquiry into the disaster. The Cullen Report, released in November 1990, made recommendations that have influenced the design and implementation of safety systems worldwide. Operators were required to develop a “Safety Case” that demonstrated that design of wells and process safety systems are properly engineered and

FIGURE 6.10.18 P-36 semi-submersible—shortly before it sank offshore Brazil.

competently operated. Notably, platforms throughout the UK Continental Shelf were retrofitted with fail safe valves designed to stem flow from adjacent facilities from feeding a prospective fire on the host.

6.10.7.3 P-36—Offshore Brazil (2011)

Petrobras installed the P-36 semi-submersible in 1998 to serve the Roncador field, located offshore Brazil in 4,462 ft. water depth. In March 2001, it experienced two explosions and sank to the sea floor over the course of 5 days. [Figure 6.10.18](#) shows the P-36 rig before it submerged.

This instance is the only time that a semi-submersible has been lost. The cause, determined by an extensive investigation, was determined to be a rupture of the emergency drain storage tank in the starboard aft column due to accidental entry of hydrocarbons, leading to explosion, damage, and loss of 11 lives [15].

6.10.7.4 Thunderhorse (2005)

Crews returning to BP's Thunderhorse Semi-submersible, following a hurricane in 2005, found the vessel listing as shown in [Figure 6.10.19](#). Fair weather lasting for 2 weeks following the hurricane allowed crews to pump water that had flooded one side of the DDS's pontoon chambers back into the sea, righting the vessel. The cause of the mishap was traced to improperly installed plumbing that connected the ballast chambers in the pontoon [16].

FIGURE 6.10.19 Thunder Horse Platform, found listing after the passage of hurricane Dennis (2005). *Source: Wikipedia / US Coast Guard, approved for re-use.*

6.10.7.5 Macondo (2010)

BP's Macondo well blew out in 2010 as a result of following well construction and well control practices in a manner that was subsequently deemed negligent by courts in the United States. Eleven workers were killed and it took some 83 days to cap the well. Many reform actions aimed at improving safety and sharpening enforcement were instituted following the Macondo blowout. Several of the more significant developments include:

- (1) Reorganizing the MMS into separate agencies within the Department of Interior;-
 - (a) The Bureau of Ocean Energy Management (BOEM) is responsible for leasing and long term strategy and policy relating to the development of federal OCS lands.
 - (b) The Bureau of Safety and Environmental Enforcement (BSEE) maintains regulatory oversight over oil and gas operations.
 - (c) The Office of Natural Resources Revenue (ONRR) is responsible for revenue collection occurring from leasing activity and production royalties from OCS lands.
- (2) The Marine Well Containment Company was formed by a consortium of deepwater operators, to share the cost of compliance with new standards of readiness in the Deepwater GoM, for capping prospective "blown" wells, and for containing the spread of prospectively spilled oil.
- (3) The National Academies (Science, Engineering) released a report detailing lessons from the Macondo incident. Recommendations from the report, including the institution of "Safety and Environmental Management Plans (SEMS)" similar to longstanding practices described within API Recommended Practice 75, were written into regulation (30 CFR 250—Oil and

FIGURE 6.10.20 Black Elk Energy's West Delta 32 field exploded and burned following a welding accident in 2012.

Gas and Sulphur Operations in the Outer Continental Shelf). Among other requirements, SEMS stipulates that organizations involved with offshore operations be able to demonstrate the competence of individual workers, and that equipment used offshore is fit for purpose.

- (4) The Center for Offshore Safety was formed by Operators and Service providers to promote sharing of knowledge and best practice relating to safe offshore operations, including means by which companies can comply with the audit and certification requirements of SEMS.

6.10.7.6 Black Elk Explosion (2012)

Figure 6.10.20 is a picture that has caught the tragic explosion crisis on the Black Elk operated West Delta 32 offshore platform production facility in the Gulf of Mexico in 2012. The explosion and resulting fire at the West Delta 32 facility claimed three lives and seriously injured many others. The explosion occurred while contractors were conducting welding operations (hot work) in the vicinity of the platform's processing equipment. Workers failed to fully de-pressurize and assure "component shut in" of the vessels to which a welding torch was applied.

As one of the first significant accidents to occur since the Macondo blowout, the incident is significant from a regulatory and policy standpoint in that BSEE leveled enforcement actions against not only Black Elk as operator, but also the contractors and engineers involved. A total of 40 violations were recommended. The following quote was extracted from the findings of the investigative panel convened by BSEE:

"The Panel found the safety culture aboard the WD 32 complex at the time of the incident to be poor at best. Due to Black Elk's failure to manage its contractors and the contractors' collective failure to adhere to established policies, the Panel found the lack of a safety culture aboard the WD 32 complex to be a contributing cause of the explosion/fire." [17]

6.10.8 Design Considerations for Offshore Systems

Figure 6.10.21 shows the variety of basic offshore structural developments of design concepts for industries progression to deeper water. Figure 6.10.22 shows the deepest water semi-submersible production installation presently operating in various part of the world. And Figure 6.10.23 shows the three alternative flow process configurations for subsea production to floating surface terminals. Figure 6.10.24 shows two conceptual designs for Spar Hulls [7] and Figure 6.10.25 three different TLP conceptual designs [7].

The following topics present high level, basic design considerations for systems and subsystems that are critical to safe and effective functioning of offshore facilities. The list is not exhaustive. Where feasible, API Standards (Specifications and Recommended Practices) are referenced. Key API Standards have a companion reference within the Geneva-based International Organization for Standardization (ISO). Compliance to ISO standards is generally required by EU countries and may also be required elsewhere.

6.10.8.1 Pollution Prevention

Offshore production facilities must include methods for containment and proper disposal of contaminants (liquids or solids containing liquid hydrocarbons, relatively high concentrations of caustic or acidic chemicals, raw sewage, trash, and inedible garbage). Waste streams including air emissions are typically regulated. In the United States, regulations are promulgated by the Environmental Protection Agency.

Guidelines are provided in API RP 75, Recommended practice for development of a safety and environmental management program for offshore operations and facilities [18]. Design and operating practices, many of which are prescribed by regulation, are outlined in the 14 series API documents [19–22].

Practical considerations include:

- All deck areas that have a source of oil leakage, spills, or drips (e.g., control valves around vessels and tanks) must be surrounded by a curbing or a continuous gutter. Normally, drip or skid pans are installed under equipment; liquids are routed to the open drain system. These drain pans serve as primary containment.
- Secondary containment must also be provided for collecting spilled hydrocarbons and rainwater from all deck areas. Solid deck areas may be drained to a gutter and routed through an open drain system of gutters or piping to a tank or container where separation takes place due to a specific gravity difference. Liquid hydrocarbons may then be skimmed off and routed into the production system and the remaining water treated by further

separation or filtration to meet the requirements of applicable government regulations before being pumped overboard.

- For installations where toilets are installed and human waste is discharged into surrounding waters, the effluent must meet requirements of applicable government agencies. Combustible solid wastes, such as paper or wood products, or other organic material, such as garbage may be disposed of by incineration (if permitted) in an approved dual burn chamber incinerator. Alternatively, the waste may be placed in containers and transported to shore for proper disposal.

6.10.8.2 Structural Design Considerations—Fixed Platforms

API RP 2A – WSD guides the design of fixed platforms from a structural point of view. Practical design loads that should be considered for fixed structures follow [23].

Dead Loads—The weights of the platform structure and any permanent equipment and appurtenant structures that do not change with the mode of operation. Dead loads should include the following:

- (a) The weight of the platform structure in air, including where appropriate the weight of piles, grout, and ballast;
- (b) The weight of equipment and appurtenant structures permanently mounted on the platform;
- (c) Hydrostatic forces acting on the structure below the waterline including external pressure and buoyancy.

Live Loads—The loads imposed on the platform during its use that may change either during a mode of operation or from one mode of operation to another. Live loads should include the following:

- (a) The weight of drilling and production equipment, which can be added or removed from the platform;
- (b) The weight of living quarters, heliport, and other life support equipment, life-saving equipment, diving equipment, and utilities equipment, which can be added or removed from the platform;
- (c) The weight of consumable supplies and liquids in storage tanks;
- (d) The forces exerted on the structure from operations such as drilling, material handling, vessel mooring, and helicopter loadings;
- (e) The forces exerted on the structure from deck crane usage. These forces are derived from consideration of the suspended load and its movement as well as dead load.

Additional load types that must be considered include environmental loads imposed by natural phenomenon (wind, wave, earthquake, snow, ice, etc.), construction and

removal loads, and dynamic loads, especially of a cyclical nature imposed by rotating machinery and waves, or ship collision.

The above considerations originated with design of fixed platforms and many apply as well to floating systems including TLPs. Refer to API RP 2FPS [24] and API RP2T for guidelines specific to designing FPSs and TLPs, respectively [6]. FPSs must be classified for service by an agency such as Det Norske Veritas (DnV), Lloyds, or American Bureau of Shipping (ABS) [25], “classed” floating facilities can be on station for 10 years before undergoing an extensive inspection, implying a drydock overhaul.

6.10.8.3 Environmental Considerations

In establishing structure orientation, engineers and designers consider prevailing seas, swells, currents, and winds. Weather conditions (typically referred to as “Met-ocean requirements”) are also a factor when planning for heliports, docking facilities, flare and relief systems, support cranes and hoists, and escape systems.

Weather conditions, such as temperature, precipitation, humidity, and winds, have a significant effect on the overall arrangement of the production facility structure. For example, in cold climates, enclosed structures are desirable. Enclosures in turn affect design considerations such as ventilation and communication systems.

General information on the various types of storms that might affect the platform site should be used to supplement other data developed for operational conditions. Statistics can be compiled, giving the expected occurrence of storms by the seasons, direction of approach, etc. Of special interest for construction planning is the duration of installation activity. Also of major importance is the ability to forecast storms in the vicinity of a platform.

The probability of personnel being quartered on the platform should be considered, and transportation made available to remove personnel from the platform on short notice.

API Recommended Practice 2MET provides additional detail relating to the derivation of “Met-ocean” criteria for consideration in offshore facility design [26].

6.10.8.4 Geographical Considerations

Knowledge of the soil conditions at the site of construction of any sizable structure is necessary for safe and economical design. Onsite soil investigations that outline the various soil strata and strength parameters should be made if sufficient knowledge has not been gained in a particular locality from previous soil investigations. Soundings should also be gathered during the onsite studies. These data should be combined with an understanding of the geology of the region to develop the required foundation design parameters. These studies should extend throughout the depth

of the soil to be affected by installation of the foundation elements. The bearing capacity of mat and spread footing foundations and the lateral capacity of the pile foundations are largely determined by the strength of the soil close to the sea floor. Consequently, particular attention should be paid to developing complete information on these soils.

The distance between the platform and shoreside terminal will be a definite consideration when planning pipelines, shipping pumps, gas compressors, storage requirements, and waste water-handling facilities.

API Recommended Practice 2GEO provides additional detail relating to the evaluation of soils as the matter relates to offshore facility design [27].

6.10.8.5 *Flowlines Risers and Flow Assurance*

Subsea flowlines are designed broadly to ASME B31.4 [28] for oil lines or ASMEI B31.8 [29] for gas lines, and more specifically according to API RP1111 [30], for an offshore, under water setting. API RP 17A [31], and ABS guidelines [32] deal with external factors such as geotechnical conditions, environmental effects, strength criteria, and span rectification relating to design of subsea pipelines and flowlines. Flow assurance is of the utmost importance as the sea floor temperature remains constant around 34 °F, and both hydrates and paraffin deposition become major concerns. Additional information on hydrates may be found in the GPSA Engineering Data Book [33].

Design guidelines for risers are available in API RP 2RD [34].

6.10.8.6 *Operational and Design Considerations*

Adequate space should be provided around machinery, tanks, vessels, and pipe headers to permit easy access for maintenance. Crane ways or lifting points should be provided for the ease of handling of equipment and supplies. Work areas should be well lighted and ventilated with adequate provisions for communication between personnel.

In determining spacing for production facilities on an offshore structure, many factors should be considered. Some of the major items to be considered are:

- space of operation and operating personnel
- space for maintenance access
- space to provide safety from inadvertent mechanical damage
- space to protect against sources of ignition
- space to provide access for control of fires
- space to limit exposure of important equipment and utilities to possible fire

Space limitations imposed by the nature of offshore structures will make compromises necessary. However,

production facilities can be arranged to provide a safe, pollution-free operation.

The safety of operating personnel is the primary consideration in designing production facilities. Requirements for egress, or means of escape; personnel landings; guard rails; and lifesaving appliances are specified.

Floating structures must comply with Safety of Life at sea (SOLAS) published by the International Maritime Organization (IMO). The United Nations formed the IMO as an International body devoted exclusively to maritime matters such as improving maritime safety and preventing marine pollution.

All equipment should be designed in accordance with the latest standards and in compliance with correct government regulations. The Gas Processors Supplier Association's (GPSA) Engineering Data Book [33], API RP Series 12, and API RP Series 11 offer design considerations for equipment such as glycol units and separators. As described earlier, API RP Series 14 offers design considerations for offshore safety and anti-pollution.

Equipment should be arranged to provide well-defined corridors of egress from all structural areas. Two exit routes in opposite directions from each area should be provided where possible. Enclosed areas containing a source of fuel should have at least two exits opening to a nonhazardous area.

Piping in all areas should be planned to minimize the number of bends, corrosion, and erosion and also provide easy access and egress from the functional parts of each piece of equipment.

In planning utility systems, consideration should be given to number and type of wells, oil and gas processing facilities, remoteness from shore, anticipated production volume, number of people to be housed on the structure, type of the fighting system, type of control system, and electric power source. For example, a single-well caisson structure typically used in 8–10 ft. deep coastal waters may require only minimal utility support, whereas the self-contained manned structure or vessel further offshore may require a full suite of utilities for sustaining continuously manned operation.

6.10.8.7 *Ventilation*

Enclosed structures require a thorough review to ensure adequate ventilation. Areas enclosed on all sides that contain equipment considered a source of ignition, such as control rooms, should be pressurized to prevent hydrocarbons entry. The air intake for the pressurizing system should be located to preclude entry of hydrocarbons into that system. Enclosed areas containing hydrocarbon fuel sources should be vented with an exhaust system to ensure removal of any escaping hydrocarbons. Also, enclosed areas where welding is to be conducted should be ventilated with an exhaust

system to ensure removal of gas evolved during welding operations. Air intake for this system should be located to preclude entry of hydrocarbons.

Equipment areas located on open-type structures should be arranged to allow the natural ventilation caused by winds and convection currents. Care should be taken around fired process equipment to ensure that adequate draft for the equipment is provided. Also, the equipment should be arranged to take advantage of the prevailing winds to keep escaping hydrocarbons from being carried toward equipment considered to be a source of ignition. Care should be taken in the use of protective walls to ensure proper ventilation, and consideration should be given to ventilation of the wellhead areas. This area should be as open as possible, with a minimum of two sides of the structure open.

6.10.8.8 Transportation Considerations—Personnel and Equipment

In designing support facilities for the transportation of personnel and equipment on offshore structures, one must consider the prevailing meteorological and oceanographic conditions. The location of transportation facilities, vessels, and associated mooring lines relative to prevailing wind, waves, and currents may control the orientation and layout of the entire structure, including pipelines and flowlines.

On fixed platforms, boat landings and docks should be located on the lee side of the structure. Cranes in turn must be located over the boat landing for convenience in loading and offloading equipment. Storage areas for pipe and bulk materials should be located within or adjacent to the area covered by crane boom. On floating facilities, personnel that do not fly out by helicopter are usually transferred from boat to facility by a crane using a personnel carrier.

Helicopter pads should be located so as to give clear landing approaches for the helicopters. Stacks, guy wires, crane booms, antennas, etc., should be arranged so as not to intrude into the approach or departure paths of the helicopters. The lack of other structures in the area may dictate the need for landing space for two or more helicopters.

6.10.8.9 Flare and Emergency Relief Systems

Flare and emergency relief systems associated with process equipment should be designed and located with consideration of the amount of combustibles to be relieved, prevailing winds, location of other equipment (including rigs, personnel quarters, fresh air intake systems, and helicopter approaches), and other factors affecting the safe, normal flaring or emergency relieving of the process fluids and gases.

The relief system is an emergency system for quickly discharging gas by manual or controlled means or by an automatic pressure relief valve from a pressured vessel or

pipng system to the atmosphere for the purpose of relieving pressures in excess of rated working pressures. It is also used to depressurize, or “blow down,” the facility during unsafe conditions. The relief system normally includes a relief valve or rupture disc, the collection piping, a gas scrubber for liquid separation, and a gas flare or vent.

Major equipment items also have an automated blow-down valve to depressurize large gas volumes in the equipment in less than 1 to 2 min should an unsafe condition occur (e.g., fire). The tremendous pressure drops associated with relief valves and blowdown valves can create cryogenic conditions. So material selection for valves and downstream piping is a concern. Another consideration is the instantaneous gas flow rate in a relief or blow-down condition. This rate can exceed the design capacity of the scrubber and flare system if the system is not carefully designed. Additional design considerations for relief systems may be found in GPSA Engineering Data Book [33].

Larger facilities may have a flare system for discharging gas through a control valve from a pressured system to the atmosphere during normal operations. The flare system normally includes a flare control valve, collection piping, the gas liquid scrubber, and gas flare. This discharge may be either continuous or intermittent. Continuous flaring is not allowed in the Gulf of Mexico and most countries. Produced gas must be processed for gas sales or re-injected. Continuous flaring still occurs in remote areas with no market for the gas. On some platforms, considerable quantities (e.g., upward of 300 MMSCFD on a single facility) are flared. However, these countries realize the lost resources are revenues cannot be replaced, and they are moving to eliminate flaring.

Flare systems today normally have a dual flare tip (low pressure and high pressure) to enable quick, simultaneous depressurization of low- and high-pressure production systems. It is important that no air flow back into the flare system piping because it would create a potentially explosive mixture. Heat radiation from the flare tip during relief and blowdown is a major concern for not only operating personnel but also nearby equipment.

6.10.8.10 Surface Safety Systems

A properly designed safety shutdown system will sense an abnormal operational or equipment condition and react to this condition by shutting in or isolating necessary system components or even the entire system. Other actions, such as sounding alarms, starting fire extinguishing systems, and depressurizing all piping and pressure vessels, may also be initiated by the shut-down system. The actions to be taken will depend on the level of criticality of the abnormal conditions. The three primary purposes for installing shut-down systems are to:

- protect human life
- prevent ecological damage
- protect the investment

In planning and designing shut-down systems, it is first necessary to determine which events could endanger life, environment, or investment. Inspection, maintenance, and failure documentation are definite considerations in planning shut-down systems. Inspection procedures that call for in-place functional tests or component removal should be carefully planned. Production facilities arrangements should include locating shutdown system components for easy access for the inspection and test. The personnel who perform inspections should have a technical education and have formal pertinent practical training.

API Recommended Practice 14C is the key standard for surface safety systems. All offshore Gulf of Mexico facilities must have surface safety systems per API RP 14C [20]. Many areas of the world also use this recommended practice.

6.11 INDUSTRY STANDARDS FOR PRODUCTION FACILITIES

Section reviewed by Michael C. Jackson

The oil and gas industry uses codes and standards from many organizations. Industry standards used in each production facility are specified in the general and equipment specifications developed for the facility by the operator(s). Specified standards normally conform to the laws and legal codes of the host country or the laws of a country mutually agreed by both the operator and the governing agencies.

6.11.1 Commonly Referenced Industry Standards

Because the United States played a large part in the development of the oil and gas industry, many commonly used industry standards originated with organizations based in the United States. Some regions of the world with more severe environmental conditions, such as the North Sea, moved toward more localized standards. Other standards were developed for national reasons. For example, pipe thread standards include those of the National Standards Institute American (ANSI), British Standards Institute, and German Institute for Standardization. Standards from both the international maritime industry and the oil and gas industry are used in the development of floating production systems. Today, the oil and gas industry is moving toward international standards that are discussed in the following section.

The main standards body in the United States is the ANSI (www.ansi.org). It is a private, nonprofit organization that administers and coordinates the U.S. voluntary standardization and conformity assessment system. Founded in 1918, the Institute remains a private, nonprofit membership organization supported by private and public sector organization. ANSI does not develop standards but facilitates development by establishing consensus among qualified groups.

Many U.S. standards can be purchased at ANSI's Electronic Standards Store (<http://webstore.ansi.org>). Global standards can be found at NSSN: A National Resource for Global Standards at <http://www.nssn.org>. Tables 6.11.1 and 6.11.2 identify the organizations commonly referenced for the design and construction of production facilities along with some of their more common guidelines, standards, and codes.

6.11.2 International Standards Under Development

The scope of the Geneva-based International Organization for Standardization (ISO) (www.iso.org) is all standards other than those involving electrical, electronic, and related technologies that are the focus of the International Electrochemical Commission (IEC) (www.iec.org). The field of information technology is handled by a joint ISO/IEC committee known as JTC 1. IEC was founded in 1906 and has over 50 participating countries. ISO was established in 1947, and its membership comprises 130 countries. Both organizations are based in Switzerland.

Telecommunications has traditionally been a government activity, and the International Telecommunications Union (ITU) (www.itu.int) is the global body in this field. Its membership is generally government telecommunications companies or regulators.

In the United States, ANSI is the official U.S. representative to the International Accreditation Forum (IAF), ISO, and, via the U.S. National Committee, the IEC. ANSI was a founding member of the ISO and plays an active role in its governance. ANSI is one of five permanent members of the governing ISO Council, and one of four permanent members of ISO's Technical Management Board.

In Europe, European Committee for Standardization (CEN) (www.cenorm.be) promotes voluntary technical harmonization in Europe in conjunction with worldwide bodies and its partners in Europe. In Europe, CEN works in partnership with the European Committee for Electrotechnical Standardization (CENELEC) (www.cenelec.org) and the European Telecommunications Standards Institute (ETSI) (www.etsi.org).

ISO has been issuing standards for the petroleum industry since 1999. ISO Technical Committee 67 (ISO/TC67) is charged with preparing standards for a wide selection of materials, equipment, and offshore structures for the petroleum, petrochemical, and natural gas industries. ISO/TC67 is composed of nine work groups (WGs) and seven subcommittees (SCs).

In a parallel effort, CEN Technical Committee 12 (CEN/TC 12) is charged with standardization of the materials, equipment, and offshore structures used in drilling, production, refining, and the transport by pipelines

ISO Standards for use in the oil & gas industry

OGP NEW STANDARDS SOLUTION

OGP continues to offer ISO/TC67 and other work groups a platform to work and drafting standards in a secured environment. At present 1,500 engineers are registered for work in this area and a number of projects are ongoing. In a very positive meeting between OGP and ISO management in August, ISO proposed a new way to replace the interim Solution. This new proposal has been found legally compliant and OGP is presently working to design the process to go along with such a solution. This solution looks

very much like the interim Solution, but is now based on current ISO Directives and the fact that OGP holds a liaison status with ISO/TC67. Once in place, OGP will be able to send draft standards to ISO for ballot and/or publication. In the meantime WGs can continue and are welcome to work under OGP's auspices.

VALUE OF STANDARDS

The ISO/TC67 standards are developed using a consensus process that includes more than 3,000 oil & gas industry experts from around the globe and an international review and approval process. The international oil and gas industry, the International Regulators Forum (IRF) and national standardization organizations support these standards for worldwide applications. The oil and gas industry uses international standards to enhance technical integrity, improve safety, facilitate global operations and reduce the environmental impact

of operations worldwide. A lot has been achieved by the industry over the past two decades. For industry, they will reduce costs and delivery times, and facilitate trade across national borders. For regulators, they offer support for goal-setting and functional regulations, while achieving higher levels of safety through better design. These standards are now being implemented widely in oil and gas provinces around the world, replacing existing industry, regional and national standards and eliminating or reducing the need for company-

specific specifications. For details on standards available from ISO/TC67 see poster above at www.iso.org

FIGURE 6.11.1 ISO/TC67 Standards Through 2013 [1].

of petroleum and natural gas, excluding on and supply systems used by the gas supply industry and those aspects of offshore structures covered by IMO requirements (ISO/TC 8).

To strive for truly international standards, ISO and CEN reached the ISO-CEN Vienna Agreement, 2001, providing for various forms of technical liaison and cooperation between ISO and CEN. Of primary interest to ISO/TC67 and to CEN/TC12 is that the work program adopted by CEN/TC12 can be transferred to ISO/TC67 in order to develop international standards with global application. ISO/TC67 then assumes the obligation to deliver standards that can be adopted by CEN. CEN/TC12 appoints European project leaders to the ISO Working Groups, whose role is to ensure that CEN interests are recognized. The Vienna Agreement reflects the priority of international standardization, establishing ISO as the lead on most standardization issues. Significant progress has been made in globalization of national oil and gas standards through the ISO/TC67

working groups. A table of applicable standards is provided in Figure 6.11.1. A complete listing can be found in the OGP Report No. 4210.

Recently, though, severe challenges to the globalization vision have been experienced. The two primary challenges are ownership of intellectual property and participation in ISO by countries with US sanctions. A task force was established between API and OGP to develop a process for the continued development of globally accepted standards for the oil and gas industry. The task force will develop the process to maximize globalization, however, allowing development of standalone standards where required for legal reasons.

Petroleum Economic Evaluation

The purpose of petroleum engineering is to examine, define, and implement methods and procedures for developing and extracting oil, gas and associated products so as to (1) optimize profits, and (2) obtain a return-on-investment that is commensurate with the risk incurred in making the investment. The term *optimize* is used because there are factors other than financial considerations that influence both the decision to make an investment in an oil and gas project and the return to be obtained from the investment. The goal of this chapter is to outline the methods and processes used to evaluate the economic potential of an oil and/or gas property. In this discussion, the terms *property* and *project* are used interchangeably as the objects of evaluation. Also, to avoid repetition of the phrase *oil and/or gas*, the term *oil* is used as a reference to both oil and gas unless specific reference to one or the other is necessary.

Economic evaluation consists of two major objectives:

- Estimation of the amount of producible oil and/or gas attributable to a property or project and prediction of a schedule of recovery of the producible volume
- Estimation of the economic value of the predicted future production

These are not separate functions: some aspects of the first objective are necessary to accomplish the second objective, and in that respect, the two functions meld at the boundary so that one influences the other. Conversely, it is not necessary to complete the first objective in order to accomplish the second. The first part of this discussion will deal with the first objective of estimating the amount of producible oil and gas along with estimating the future production schedule. The second part will take up the examination of the methods for estimating the values of future production.

7.1 ESTIMATING PRODUCIBLE VOLUMES AND FUTURE OF PRODUCTION

Section reviewed by Ronald M. Brimhall

7.1.1 The Concept of Resources and Reserves

One of the most prevalent, enduring, important and misunderstood concepts in the evaluation of oil and gas properties is that of “*resources*” and “*reserves*” and the relationship between the two. There is often confusion about the relation of reserves to resources and even greater confusion about the classification of hydrocarbon volumes within the two categories. Part of the confusion arises out of differing usage of the terms within the petroleum industry and among the financial/investment/regulatory communities associated with and directly or indirectly impacted by industry practice (Fig. 7.1.1).

7.1.1.1 What are Reserves?

Before delving into a comparison of various definitions and an extended discussion of the estimation of reserves, it may be useful to consider the concept of “reserves” and to examine the necessity for definition of the term. Irrespective of which of several definitions is used, reserves are expressed as a volume of oil gas, or other product that is a function of the *expected* future production of oil and of certain expected economic conditions. It is not a physical volume in the sense that it can be examined, measured and moved from place to place. Reserves do not connote a physical entity in the way that “building” connotes a three-dimensional structure that one can see and feel and walk into and out of if one so desires or the sense that “rock” connotes a hard object that has an obvious tactile presence,

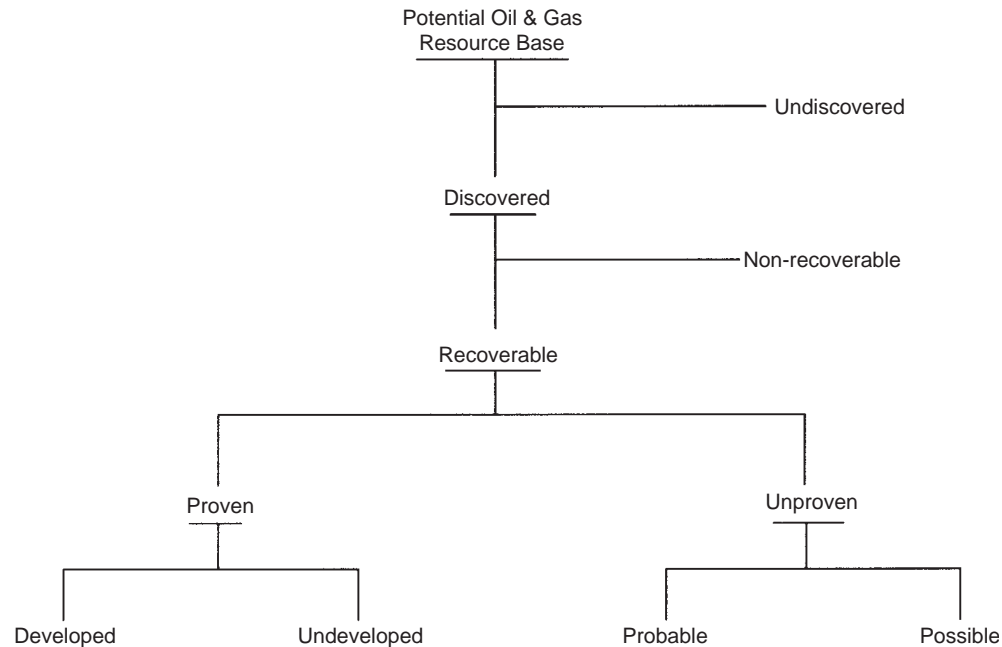

FIGURE 7.1.1 Table of resources and reserves.

size, shape, color, and direct use as a tool. *Reserves* is an abstract concept that describes the total volume of future oil production that could be expected to be recovered, assuming that certain physical and economic conditions exist and continue to prevail for however long is required to obtain the production. A comparison to an office building is illustrative: an office building retains the same physical size and character whether the rents for the building go up or down. Reserves, on the other hand, may increase or decline with changes in oil and/or gas price.

The primary objective of oil production is the income to be derived from the sales of the produced oil, not the oil itself. However, potential total income is difficult to compare among properties in any useful manner. Therefore, “reserves” is used as an euphemism for the future income and provides a means of keeping track of that future income and of comparing one property or company to another. Reserves are also used as a commonly accepted repository of the value of a property, even though the values is derived from the income resulting from production and sale of the oil that makes up the reserve. Unfortunately, both expected income and the related reserves are transitory, and neither is entirely satisfactory as a measure.

Because reserves depend on the expectation of future production and sales of oil and because different persons can have differing expectations for production and sales from a property, the reserves of that property can never be a fixed volume, but can and do change from observer to observer and from time to time, or both. For that reason, reserves as such cannot have value but can only represent value, and then only in an abstract sense. For example, if

all conditions are identical, a property with greater reserves can be construed to have a greater value. But all conditions are never identical.

7.1.1.2 Reserves: Definitions and Conditions [1–5]

The distinction between *resources* and *reserves* is significant but can be described in relatively simple terms. Paraphrasing from the Department of Energy (DOE), “*The total resource base of oil and gas is the total volume formed and trapped-in-place within the earth before any production*” [1]. A large portion of this resource base is unrecoverable by current or foreseeable technology because either it is dispersed in low concentrations or it is simply cannot be extracted due to economics, intractable physical forces, or both. The remainder is the recoverable resource base that consists of discovered and undiscovered resources. Discovered resources include recoverable and nonrecoverable resources, where the recoverable resources include cumulative production, if any, to date and reserves. If there has been no production, then all the recoverable resource is classed as *reserves*. DOE describes discovered recoverable resources as “...those economically recoverable quantities of oil and gas for which specific locations are known.” [2] DOE further classifies resources as economically recoverable or economically unrecoverable.

On the other hand, U.S. Geological Survey (USGS) classifies the undiscovered resource base into accumulations that are of sufficient size and quality that they could be technically recoverable with existing technology, but

without consideration of economic viability. This USGS concern is of abstract interest, but because the economic circumstances are not considered, the USGS concept falls outside the purpose of this discussion. Further, the DOE concept of resources and reserves, although of more direct interest, is important only from the standpoint of a definable framework within which to examine industry practice. DOE does make estimates of both resources and reserves as well as compiling reserves estimates provided by industry.

The petroleum industry and related interests have created an elaborate hierarchy of resources and reserves, coupled with a more restrictive terminology that includes a significant concern for economics. Although it is not possible in this space to explore all the definitions and terminology, the concept of reserves is vital to petroleum economics and must, of necessity, be thoroughly understood. The resources concept is not further discussed.

The American Petroleum Institute (API) is usually credited with publishing the first definition of proved reserves. However, the Society of Petroleum Engineers (SPE) has been the industry leader in establishing terms of reference for reserves and has over several decades proposed and recommended at least four definitions for reserves of oil and gas starting in 1964–1965. The 1964 SPE definition considered only a portion of total reserves by defining proved reserves as:

“The quantities of crude oil, natural gas and natural gas liquids which geological and engineering data demonstrate with reasonable certainty to be recoverable in the future from known oil and gas reservoirs under existing economic and operating conditions. They represent strictly technical judgments, and are not knowingly influenced by attitudes of conservatism or optimism.”[3]

SPE adds some explanation regarding proved reserves:

“When evaluating an individual property in an existing oil or gas field, the proved reserves within the framework of the above definition are those quantities indicated to be recoverable commercially from the subject property at current prices and costs, under existing regulatory practices, and with conventional methods and equipment.”[4]

Proved reserves are further categorized as proved developed producing (PDP), proved developed nonproducing (PDNP), and proved undeveloped (PUD), with the latter two categories deriving, in part, from the scale of expected investment necessary to obtain the production.

These early definitions, along with explanations, were relatively simple and succinct. However, as noted by the Society of Petroleum Evaluation Engineers (SPEE):

“The continuing process of updating and revising reserve definitions is a reflection of both the changing nature of the petroleum industry with time and the difficulty of writing a comprehensive definition of reserves and guidelines that will serve the broad needs of industry without excess complexity.”[5]

The reserves concept becomes even more abstract when the number of conditions used to define reserves is expanded to include risk. In this case, the reserves can be subdivided into categories such as proved and unproved based on the relative risk of recovery of the reserves in each category. Here again, the risk is not in the reserves per se, but in the likelihood that the expectations for future production and economic conditions will be met. The risk is accounted for by assigning the anticipated future volume of oil production to a certain category of reserve based upon that risk (Fig. 7.1.2).

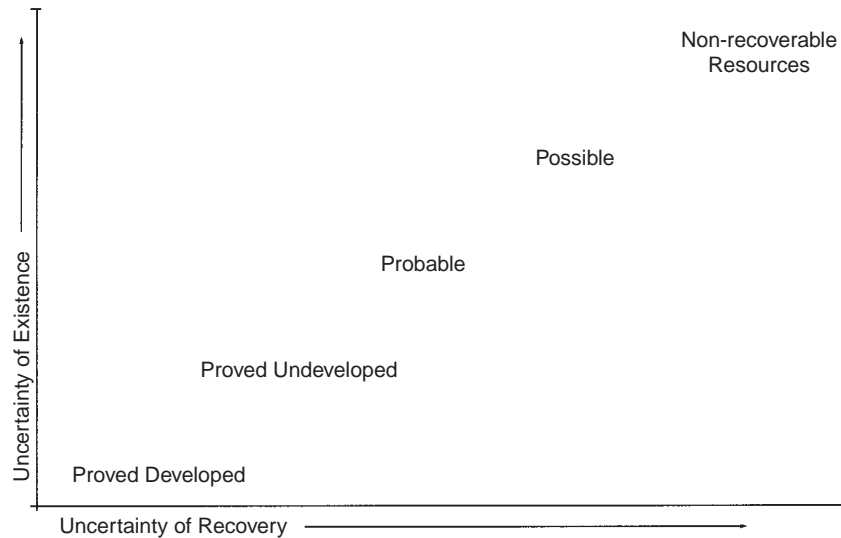

FIGURE 7.1.2 Reserve class vs. uncertainty.

If *reserves* are a function of the interaction of a set of expectations for future production and economic conditions, and if those expected conditions are variable in both time and space, then *reserves* are relative. To avoid a situation in which *reserves* lose all meaning as a comparative measure, a definition for reserves is necessary in order to provide some broadly accepted constraints on the conditions that would result in the estimation of a particular volume of *reserves*. Without a definition as a guideline or reference, a volume labeled as “*reserves*” could be anything, but would have no meaning to anyone.

The events of the 1970s and resulting changes in the oil industry led to the issuance of definitions by the Security and Exchange Commission (SEC) in 1979, by SPE in 1981, and by the World Petroleum Congress (WPC) in 1983. SPE revised its definitions in 1987 and, in cooperation with WPC, again in 1997. Until 1983 all reserves definitions, at least those issued by recognized authorities such as API and SPE, were for proved reserves only. The WPC definitions of 1983 include d categories ranging from proved to “speculative” reserves. The 1987 SPE definitions were the first to formally define proved, probable. This does not mean that the terms were not in use or that probable and possible reserves had not been calculated and reported. Producing companies, consulting firms, banks, and government agencies developed their own criteria for unproved reserves and used them.

Regarding the 1987 SPE definition, SPEE wrote:

“The definitions for oil and gas reserves were designed to address many of these problems. Until now, there has been no industry standard for probable and possible reserves. The need to categorize such reserves has long been recognized. The many definitions that have been advanced for probable and possible reserves have contributed to the confusion of those attempting to use these higher-risk reserves estimates.

In addition, there has been a need to reexamine and expand definitions used for improved recovery reserves where technology has expanded rapidly. Supplemental recovery methods include both conventional methods (waterflooding and gas injection) and enhanced methods (steam injection, in situ combustion, polymer and miscible flooding).”[6]

The most recent definitions adopted by SPE and the WPC in 1997 are relatively complex and fill several pages. In the 1997 SPE/WPC definitions, “*reserves*” are:

“...those quantities of petroleum which are anticipated to be commercially recovered from known accumulations from a given date forward. All reserve estimates involve some degree of uncertainty. The uncertainty depends chiefly on the amount of reliable geologic and engineering data available at the time of the estimate and the interpretation of these data. The relative degree of uncertainty may be conveyed

by placing reserves into one of two principal classifications, either proved or unproved. Unproved reserves are less certain to be recovered than proved reserves and may be further subclassified as probable and possible reserves to denote progressively increasing uncertainty in their recoverability.”[7]

Within the term “*reserves*” are two subcategories of proved and unproved where *proved reserves* are:

“...those quantities of petroleum, which by analysis of geological and engineering data, can be estimated with reasonable certainty to be commercially recoverable, from a given data forward, from known reservoirs and under current economic conditions, operating methods and government regulations. Proved reserves can be categorized as developed or underdeveloped.

If deterministic methods are used, the term reasonable certainty is intended to express a high degree of confidence that the quantities will be recovered. If probabilistic methods are used, there should be at least an 90% probability that the quantities actually recovered will equal or exceed the estimate.

Establishment of current economic conditions should include relevant historical petroleum prices and associated costs and may involve an averaging period that is consistent with the purpose of the reserves estimate, appropriate contract obligations, corporate procedures, and government regulations involved in reporting these reserves.”[8]

In addition to the SPE/WPC, other definitions of reserves, particularly Proved reserves, are offered for specific purposes. More often than not, these definitions incorporate the SPE definitions although they may change a word here or a phrase there. The DOE uses the SPE definition, as do many evaluation organizations and taxing authorities. The significant exception of this discussion is the SEC, which defines Proved reserves as:

“Proved oil and gas reserves are the estimated quantities of crude oil, natural gas, and natural gas liquids which geological and engineering data demonstrate with reasonable certainty to be recoverable in future years from known reservoirs under existing economic and operating conditions, i.e., prices and costs as of the date the estimate is made. Prices include consideration of changes in existing prices provided only by contractual arrangements, but not on escalations based upon future conditions.”[9]

This is virtually identical to the then existing SPE (1965) definition except for the addition of the phrase, “*i.e., prices and costs as of the date the estimate is made*”[10] and also the final sentence.

The intent of Rule 4-10 was very simple. Having decided that reserves would be reported by public companies as notes to the financial statements, as standard and unambiguous definition was required. So-called SEC

reserves serve only one purpose, which is to allow a comparison of public companies by providing some information regarding a company's reserves of oil and gas. This was to be done by estimating the volume of reserves on the last day of the company's fiscal year using the prices (and costs) in effect on that date with no escalation (increase or decrease) from those prices and costs. The company also reports a dollar value of these reserves using the fixed price/cost projection discounted at a standard 10% before income tax.

The purpose of including this information in the financial report of a company was ostensibly to provide investors with data with which to compare companies. In that context, the fixed price/cost and the 10% discount rate are appropriate to providing a relative comparison. It may not be accurate or emulate the real world, and it certainly does not represent market value, but it does allow a reasonably informed investor to compare Company A with Company B, particularly over time.

The SEC reserves definitions have very limited application and utility and will not be further discussed. However, it is essential to be aware of the differences between the SEC and the SPE definitions.

7.1.2 Classification of Petroleum Products [6–8]

The petroleum products that may be subject to evaluation can be grouped as:

- crude oil
- natural gas
- associated products

Crude oil is a liquid composite of many hydrocarbon compounds that, depending on the composition, has differing properties such as oil gravity, viscosity, and pour-point which, at least in part, define the quality of the oil for potential end use and also influence the methods that would be used to develop and produce the oil. Crude oil that has a high API gravity, and low viscosity is generally easier to produce than low-gravity, high-viscosity oil that may require stimulation to maintain production rates. The characteristics of the oil can, and often do, influence everything from well spacing to pump size to life of production — all of which has an impact on the economic value of the producing property.

Crude oil is a market commodity and is subject to considerable variation in its economic value. Oil prices vary based on location, gravity, sulfur content, and competition from other fuel sources. As an example, crude oil produced in California is consistently priced \$3 to 4/bbl below similar oil in the midcontinent in part because of oil gravity but also because of the sulfur content and the lack of access to

other markets. At times, such as under the windfall profit tax (WPT) crude oil has been economically stratified based on when it was put on production and the status of the producing company as defined by the regulating agency.

Natural gas is a fluid also composed of many hydrocarbon compounds, although generally not as complex as crude oil. The primary differences between gases are (1) the heating value (generally the methane content), (2) the nonhydrocarbon gas (N₂, O₂, H₂S, etc.) content, and (3) the amount of liquid of heavy ends that can be obtained as natural gas liquids (NGLs).

The economic value of natural gas is directly related to its composition. A gas with no nonhydrocarbons and that is entirely methane and ethane has a high heating value. If it contains propanes and other stripable ends, the value increases. Natural gas enjoys a relatively high economic value because it has a low cost of production. However, it is highly regulated through pipeline and utility controls on transportation and pricing so that it rarely achieves equivalent value with crude oil on a \$/BTU basis. In addition, because of the ease of transporting gas, there is substantial competition among gas producing regions, which acts as a control on gas prices.

Associated products include (a) NGLs that can include propane, butane, natural gasoline, and virtually any other hydrocarbon that can be stripped from gas; (b) sulfur; (c) nonhydrocarbon gases. The NGLs can have substantial economic value but require investment in specialized stripping plants. Pricing tends to be driven by the local market and can be volatile with demand. Sulfur is a common by-product in many Canadian fields and in some areas of the United States. The economic value tends to fluctuate considerably, and sulfur production may often be more of a nuisance than an economic benefit. Nonhydrocarbon gases such as nitrogen, carbon dioxide, and helium can be economic by-products, but in most cases where this occurs the nonhydrocarbon becomes the primary product and the natural gas is secondary.

The economics of crude oil, natural gas, and associated products can differ significantly depending on market conditions.

7.1.3 Methods For Estimating Reserves [9–11]

The true reserves of a property are known only after production has ceased and the property has been abandoned. Reserves determination is never more than an estimate. Some estimates are based on more knowledge and analysis than others, but a large part of the estimate is the evaluator's perception of future production and economic conditions. Information is critical and the proper usage of available data is vital.

A review of the reserves definitions that were discussed above suggest that the estimation of reserves could be broken down into a series of steps, each of which would narrow the final estimate. Those steps are built on the components of the reserves definitions.

- Step One: Estimate Oil-in-Place Producing Volume
- Step Two: Define Production Mechanism
- Step Three: Estimate Method and Rate of Production
- Step Four: Determine the Economically Producing Volume

The volume derived under Step Four could be the volume of reserves for most applications.

Steps One and Two can be accomplished separately, but as a practical matter the producible volume and the production mechanism are essentially inseparable. Step Three is interactive with Steps One and Two in the sense that the information gained from the analysis in those steps can lead to a decision about: whether to produce by flowing or pumped production, the development well density, whether to use horizontal or straight-hole wells, when to introduce a method of production stimulation, or when to begin enhanced oil recovery (EOR) operations. A decision on production mechanism may in turn influence the estimation of the producible volume and/or the rate(s) of production.

7.1.3.1 Primary Production in Oil Reservoirs

Primary production uses the natural reservoir energy of dissolved gas, encroaching water, gravity or other source as the recovery mechanism. There are a number of methods available for reserves estimation, which can be used alone or in concert. The use of the methods depends on the stage of life of the property and the amount and quality of data that are available. These methods can be generally grouped as (1) volumetric, (2) material balance, (3) production performance. Each method has its attributes and drawbacks.

Volumetric methods [12,13] are used early in the life of a property, before significant production has occurred. This is a subjective criteria; volumetric methods can be and often are used long after production has reached maturity. Volumetric methods attempt to determine the amount of oil and/or gas-in-place and reserves by calculating a volume from the physical properties of the reservoir(s). The method requires a knowledge of the size of the reservoir, and the physical properties of the reservoir rock(s) and fluids(s). The volume of original oil in place (OOIP) in a segment of the reservoir is equal to:

$$\begin{aligned} \text{Volume } V &= \text{Amount of pore space} \\ &\quad \times (\text{amount of oil} - \text{amount of water}) \\ \text{OOIP} = V_0 &= V(\phi) \times S_h \end{aligned} \quad (7.1.1)$$

- where V = specified volume of reservoir measured in acre feet
- ϕ = porosity-% of void space in V
- S_h = hydrocarbon saturation as a % of fluid content
- $= 1 - S_w$, where S_w is the water saturation as a % of fluid content
- $= S_o + S_g$ if there is a free gas cap

In practical use, the equation is

$$V_0 = \frac{7758V(\phi)(1 - S_w)}{B_{oi}} \text{ bbl STO} \quad (7.1.2)$$

in which 7,758 is the conversion from acre-feet to barrels and B_o is a factor to convert the fluid volume at reservoir pressure and temperature to stock tank barrels.

In free-gas reservoirs or in the gas cap of oil reservoirs, the volume of gas-in-place is

$$V_g = \frac{43,560V(\phi)(1 - S_w)}{B_{gi}} \text{ scf} \quad (7.1.3)$$

where 43,560 is the conversion from acre-feet to cubic feet. The gas formation volume factor (B_g) may be estimated for various combinations of pressure, temperature and gas gravity from published tables.

The volume of dissolved gas in an oil reservoir is given by

$$V_g = \frac{7758V(\phi)(1 - S_w)R_s}{B_g} \quad (7.1.4)$$

where R_s is the volume of dissolved gas per barrel of oil at reservoir conditions.

The volumetric method can be subject to considerable error because (1) it is often used to evaluate a property when little specific data may be available and (2) it requires the estimation of reservoir rock and fluid properties and reservoir volumes from spot measurements of the properties that are then applied to the entire reservoir. Porosity and water saturation are obtained from well logs and/or core samples that are measured from a small volume of the reservoir and which under the best circumstances, only approximate the conditions in the reservoir. The areal extent of the reservoir is rarely known until many wells are drilled, while volume is estimated using a zone thickness measured at one or more points in the reservoir. While techniques of core analysis and, especially, electric and other well log measurement and analysis have become very sophisticated, and have been advanced by three-dimensional and other seismic and geophysical methods, the volumetric method remains only a gross estimate of oil-in-place.

Conversion of a volumetric oil-in-place to ultimate recovery requires the use of a *recovery factor*, R_f , which can be either a unit recovery (bbl or Mcf/acre ft) or a percentage of OOIP.

Recovery factors can be determined from the performance of similar reservoirs, from laboratory analysis of cores, or computer simulation of anticipated performance. Unit recovery can also be calculated assuming information if available from reservoir fluids and core analysis.

$$\text{Ultimate recovery} = V_0 \times \text{recovery factor}$$

For solution gas drive or depletion drive reservoirs:

$$N = 7758 (\phi) \left(\frac{1 - S_w}{B_{oi}} - \frac{1 - S_w - S_{gr}}{B_{oa}} \right) \text{ STB/acre ft} \quad (7.1.5)$$

where recovery is the difference between OOIP at initial reservoir conditions and OIP at abandonment conditions.

In a water drive reservoir:

$$N = 7758 (\phi) \left(\frac{1 - S_{oi}}{B_{oi}} - \frac{S_{or}}{11B_{oa}} \right) \text{ STB/acre ft} \quad (7.1.6)$$

The volumetric method has certain data requirements. In checklist form:

Reservoir volume:

- accurate mapping of gross and net sand
- determination of oil–water and gas–oil contacts
- calculation of reservoir volume (acre/ft)

Rock properties:

- determine porosity—from logs, cores or both
- determine water saturation—from logs, cores or both
- determine residual S_o and S_w —from core tests

Fluid properties:

- determine B_o at initial and abandonment conditions from PVT analysis.

The *material balance* [14–16] is a more complex method of estimating producible volume, but has the advantage of providing an estimate of recovery over time under certain conditions. The method has several forms and requires both an extensive pressure–volume–temperature (PVT) analysis of reservoir fluids and an accurate pressure history of the reservoir. The latter obviously requires that some production (5% to 10% of ultimate recovery) occur before the method can be used. The method is not a substitute for the volumetric method but can be used along with the volumetric method later in the life of the property and is often used to obtain a recovery factor for volumetric calculations. The material balance method could also be used if reliable pressure history data can be obtained for a reservoir with similar rock and fluid properties.

The material balance is a practical application of conservation of mass and energy principles used to balance the withdrawals from a reservoir with changes in volume of the original reservoir fluids and the influx of additional fluids. The method has been modified, adapted and simplified by many authors. The several forms attempt to model reservoir performance over time by equating the expansion of reservoir fluids, as pressure decline occurs during production, to the change in voidage of the reservoir caused by withdrawal of oil, gas, and water (less any water influx). The method requires an iterative solution of sequential pressure drops caused by production. The values for each successive step in the analysis are taken from PVT analysis of the reservoir fluids.

The general equation is:

$$N = \frac{N_p [B_t + 0.1781 B_g (R_p - R_{si})] - (W_e - W_p)}{B_{oi} \left[m \left(\frac{B_g}{B_{gi}} \right) + \frac{B_t}{B_{oi}} - (m + 1) \left(1 - \frac{\Delta p (C_f + S_w C_w)}{1 - S_w} \right) \right]} \quad (7.1.7)$$

where N is the OOIP, which, by definition, must remain the same through each step of pressure decline. The general equation assumes that all components of the reservoir react to production. By using the pressure–production history of the reservoir to obtain a relation of N_p (production) to ΔP (change in reservoir pressure), a projection of $N_p/\Delta P$ can be used as the basis for a material balance estimate of future production to the point of pressure depletion. At that point, ultimate *primary* recovery is obtained and

$$R_f = N_p/N$$

The material balance may be thought of as:

$$\text{Initial oil in place} = \text{oil remaining} + \text{oil produced at time (t)}$$

However, it is more convenient to treat the balance as:

$$\text{Initial gas in place} = \text{gas remaining} + \text{gas produced}$$

In this form the general equation becomes:

$$N = \frac{N_p [B_o + B_g (R_p - R_s)] - B_w (W_e - W_p)}{m B_{oi} \left(\frac{B_g}{B_{gi}} - 1 \right) + B_g (R_{si} - R_s) - (B_{oi} - B_o)} \quad (7.1.8)$$

where $N_p [B_o + B_g (R_p - R_s)]$ is the reservoir volume of produced oil and gas; $B_w (W_e - W_p)$ is the total amount of water influx retained in the reservoir; $m B_{oi} (B_g/B_{gi} - 1)$ is the expansion of the gas cap; and $B_g (R_{si} - R_s)$ is the reduction in the amount of solution gas at reservoir conditions occurring with production of N_p barrels of oil [17, 18].

If there is no gas cap and no water influx, then:

$$N = \frac{N_p [B_o + B_g (R_p - R_s)] + B_w W_p}{B_g (R_{si} - R_s) - (B_{oi} - B_o)} \quad (7.1.9)$$

If the reservoir is above the bubble point [19], then B_g remains constant; R_p , R_s and R_{si} are equal and:

$$N = \frac{N_p B_o + W_p B_w}{B_a - B_{oi}} \quad (7.1.10)$$

B_w can often be ignored if reservoir pressure is low; however, data on water compressibility are readily available. Where reservoir fluid property data indicate measurable change in the compressibility of oil, water, and rock with changes in pressure, then the equation(s) would be modified by using an effective oil compressibility term:

$$N = \frac{N_p B_o + W_p B_w}{C_{oe} B_{oi} (P_i - P)} \quad (7.1.11)$$

where:

$$C_{oe} = C_o + \left(\frac{S_w}{1 - S_w} \right) C_w + \left(\frac{1 - \phi}{\phi (1 - S_w)} \right) C_f \quad (7.1.12)$$

In water drive reservoirs [20,21]:

$$N = \frac{N_p [B_o + B_g (R_p - R_s)] + B_w W_p}{D_i} - \frac{W_e B_w}{D} = N_i - \frac{W_e B_w}{D_i} \quad (7.1.13)$$

where:

$$D_i = B_g (R_{si} - R_s) - (B_{oi} - B_o) \quad (7.1.13a)$$

Water influx (W_e) is rarely known or measurable; however, where water influx occurs, calculated values of N_i over time would increase. N could be estimated by plotting N_i versus time and extrapolating back to $t = 0$ where $N_i(t = 0) = N$. This approach includes a significant potential for error if the plotted points are not a straight line. Several authors have presented means of improving this approach (Figure 7.1.3).

In reservoirs with an active gas cap and no active oil/gas segregation with production:

$$N = \frac{N_p [B_o + B_q (R_p - R_s)] + B_w W_p}{mB_{ob} \left(\frac{B_g}{B_{gi}} - 1 \right) + B_g (R_{sb} - R_s) - (B_{ob} - B_o)} \quad (7.1.14)$$

where subscript b refers to the bubble point (BP).

FIGURE 7.1.3 Calculated N vs. cumulative N_p .

In reservoirs with a combination of drives:

$$N = \frac{N_p [B_o + B_g (R_p - R_s)] - B_w (W_e - W_p)}{mB_{ob} \left(\frac{B_g}{B_{gi}} - 1 \right) + B_g (R_{sb} - R_s) - (B_{ob} - B_o)} \quad (7.1.15)$$

or

$$N = \frac{N_p [B_o + B_g (R_c - R_s)] + B_w W_p}{D_i} - \frac{B_w W_e}{D_i} \quad (7.1.16)$$

where

$$D_i = mB_{ob} \left(\frac{B_g}{B_{gi}} - 1 \right) + B_g (R_{sb} - R_s) - (B_{ob} - B_o) \quad (7.1.17)$$

Several authors have presented variations in the calculation procedure to obtain material balance recovery factors. Muskat's method [22–24] calculates the change in oil saturation with change in pressure as production occurs:

$$\frac{\Delta S_o}{\Delta p} = \frac{S_o \left[\left(\frac{B_g dR_s}{B_o dp} \right) + (1 - S_o - S_w) \left[B_g \frac{d(1/B_g)}{dp} \right] + S_o \left(\frac{\mu_o k_{rq}}{\mu_g k_{ro}} \frac{dB_o}{B_o dp} \right) \right]}{1 + \frac{\mu_o k_{rq}}{\mu_g k_{ro}}} \quad (7.1.18)$$

At depletion,

$$S_{oa} = S_{oi} - \Delta S_o \quad (7.1.19)$$

$$R_f = \frac{S_{oi} - S_{oa}}{S_{oi}} (\%) \quad (7.1.20)$$

Muskat's method assumes uniform oil saturation (no gas segregation) and relatively low permeability. The method requires small pressure increments but is readily adapted

to computer analysis, thereby reducing the tedium of the calculation. The results are converted into recovery per acre foot by:

$$N_p = 7758 (\phi) \left(\frac{1 - S_w}{B_{oi}} - \frac{S_o}{B_o} \right) \text{ STB/acre ft.} \quad (7.1.21)$$

Cumulative recovery as a percentage of OOIP can be determined by:

$$\frac{N_p}{N} = 1 - \left(\frac{S_o}{1 - S_w} \right) \left(\frac{B_{oi}}{B_o} \right) \quad (7.1.22)$$

and gas/oil ratio performance by:

$$R = R_s + 5.615 \left(\frac{B_o \mu_o k_{rg}}{B_{oi} \mu_g k_{ro}} \right) \text{ SCF/STB} \quad (7.1.23)$$

Relative production can be calculated from:

$$q_o = q_{oi} \left(\frac{k_o \mu_{oi} p}{k_{oi} \mu_o p_t} \right) \text{ STB/Day} \quad (7.1.24)$$

Turner's method [25, 26] for use in solution gas reservoirs below the BP, requires a simultaneous solution of the material balance equation and the instantaneous gas/oil ratio equation. The procedure is to calculate the cumulative oil (N_p) and gas (G_p) for a pressure drop ($p_1 - p_2$) as follows:

1. $N_p = 0$ at BP.

$$\begin{aligned} 2. (G_p)_2 &= (N_p)_2 (R_p)_2 \\ &= N \left[(R_{si} - R_s) - 5.615 \left(\frac{B_{oi} - B_o}{B_g} \right) \right] \\ &\quad - (N_p)_2 \left(5.615 \frac{B_o}{B_g} - R_s \right) \end{aligned} \quad (7.1.25)$$

$$3. (S_t)_2 = S_w + (1 - S_w) \frac{B_o}{B_{oi}} \left[1 - \frac{(N_p)_2}{N} \right] \quad (7.1.26)$$

4. Determine k_{rg}/k_{ro} at $(S_t)_2$:

$$R_2 = R_s + 5.615 \left(\frac{B_o}{B_g} \right) \left(\frac{\mu_o}{\mu_g} \right) \left(\frac{k_{ro}}{k_{rg}} \right) \text{ at } p_2 \quad (7.1.27)$$

5. Compute

$$(G_p)_2 = (G_p)_1 + \frac{R_1 + R_2}{Z} [(N_p)_2 - (N_p)_1] @ p_2 \quad (7.1.28)$$

6. Make three good estimates of $(N_p)_2$ and the corresponding $(G_p)_2$ from steps 2 and 5. Plot $(N_p)_2$ versus $(G_p)_2$ for step 2 and for step 5 and take the intersection of the curves as satisfying both equations.

Published tables of recovery factors, calculated using the Muskat and Turner methods, can be used where no

detailed data regarding reservoir fluids or rock properties is available.

7.1.3.2 Non-Associated Gas Reservoirs [27,28]

The estimation of producible volumes for gas reservoirs is less complex than for oil reservoirs, if only because the fluid dynamics are simpler and similar field performance is more directly applicable. The basic principles of volumetric gas-in-place and recovery factor are the same as for crude oil.

$$\text{OGIP} = G = \frac{43,560 V_g (\phi) (1 - S_w)}{B_g} \text{ SCF} \quad (7.1.29)$$

$$\Delta G_p = 43,560 (\phi) (1 - S_w) \left(\frac{1}{B_{gi}} - \frac{1}{B_{ga}} \right) \text{ SCF/acre ft.} \quad (7.1.30)$$

The gas formation volume factor (B_g) at abandonment (B_{ga}) is calculated at abandonment pressure (P_a), which can be based on pipeline pressure or the minimum pressure to which the reservoir can be reduced for the conditions of reservoir depth, tubing size or other constraint(s).

7.1.4 Estimating Future Production

7.1.4.1 Production Performance—Oil Reservoirs

The volumetric and material balance methods of estimating reserves are valuable tools but are often limited by paucity of data; mathematical calculations that, in being simplified, leave out or assume certain reservoir conditions to be true; and/or the assumption of uniformity of conditions throughout the reservoir. In contrast, the *production performance* [29–33] *approach* implicitly includes all reservoir and production operating conditions that would effect performance. When production is not curtailed by regulatory or other artificial conditions, the volume of production from the well is a direct result of the interaction, however great or small or uniformly dispersed, of all reservoir rock and fluid properties with the existing wellbore and operating conditions. Because oil reservoirs are finite in volume, production over time causes a reduction in pressure that, in turn, causes a decline in the rate of production per unit time. The combination of time, production rate and cumulative production can be used to determine both remaining reserves and productive life.

When there has been sufficient history to establish a production trend for a property, the three variables may be plotted as graphs, commonly known as *decline curves*, which can then be extrapolated to determine future production and reserves. The most common approach is the rate-time plot where time is plotted as the independent variable (X) and production rate is plotted as the dependent variable (Y). This curve, with sufficient definition, can be

extrapolated into the future to estimate future production and reserves.

The only requirements for extrapolation are that the curve demonstrate uniformity of shape and that there be an end point. The uniformity of shape is required to ensure that performance is the result of interaction of reservoir and operating condition and is not being altered by changing operating or other artificial conditions. It is important to carefully analyze all data used to define production performance and to equate production during short production periods (February) and downtime (during pump changes or other well work) to production during “normal” periods. Changes in production caused by mechanical alterations, such as opening or closing flow valves, pump changes or pump speeds, must be equated and may require additional graphical analysis. The use of sales data must equate the time between sales to the production time. Often sales occur when a certain tank volume is accumulated, not on a strict time basis, so that, over time, the period between sales may increase while the volume appears to be constant. The production rate, however, may well be declining.

The decline curve may generally demonstrate one of three forms: *exponential*, essentially a straight line of constant slope; *hyperbolic*, a continuously flattening curve that can be described mathematically; and *harmonic*, a special case of the hyperbolic decline (Figure 7.1.4).

The decline can be described in two ways: the nominal decline rate is the negative slope of the curve of the natural log of the production ratio (q) at time (t), or

$$D = -\frac{d \ln q}{dt} = -\frac{dq/dt}{q} \quad (7.1.31)$$

The effective decline rate is more common in actual practice and has the form of a loss rate:

$$D_e = \frac{q_i - q_1}{q_i} \quad (7.1.32)$$

FIGURE 7.1.4 Decline curve—rate/time (exponential, harmonic, hyperbolic).

Decline rate is normally expressed as an annual rate for comparison among properties.

For exponential or constant-percentage decline, the nominal rate is

$$D = -\frac{dq/dt}{q} \quad (7.1.33)$$

where, after integration,

$$q = q_i e^{-Dt} \quad (7.1.34)$$

where t is the time period over which q is to be calculated and to which D must conform. Further integration yields

$$N_p = \frac{q_i - q}{D} \quad (7.1.35)$$

where N_p is the cumulative production during the period between q_i and q. If q_a at abandonment is substituted for q, then N_p is the ultimate recovery at decline rate D.

Hyperbolic decline may only become evident later in the life of a property and may require careful analysis to be discerned. In fact, most primary production occurs as hyperbolic decline, but in practice, constant rate decline is often used to approximate future production. In the late life of production, hyperbolic decline approaches asymptotic conditions and can very well be approximated by an exponential decline. For the early life:

$$D = \frac{-dq/dt}{q} = bq^n \quad (7.1.36)$$

where n is a fractional power of the production rate between 0 and 1 and b is a constant determined at initial conditions:

$$b = \frac{D_i}{q_i^n} \quad (7.1.37)$$

$$q = q_i (1 + nD_i t)^{-1/n} \quad (7.1.38)$$

$$N_p = \frac{q_i^n (q_i^{1-n} - q^{1-n})}{(1-n) D_i} \quad (7.1.39)$$

For harmonic decline:

$$D = -\frac{dq/dt}{q} = bq \quad (7.1.40)$$

where:

$$b = \frac{D_i}{q_i} \quad (7.1.41)$$

and, after integrating,

$$q = \frac{q_i}{1 + D_i t} \quad (7.1.42)$$

$$N_p = \frac{q_i}{D_i} \ln \frac{q_i}{q} = \frac{q_i}{D_i} \ln r \quad (7.1.43)$$

Nominal and effective declines can be related:

$$\text{Exponential: } D_e = 1 - e^{-D} \quad (7.1.44)$$

$$D_n = -\ln(1 - D_e) \quad (7.1.45)$$

$$\text{Hyperbolic: } D_{ei} = 1 - (1 + nD_i)^{-1/n} \quad (7.1.46)$$

$$D_{ni} = \frac{1}{n} [(1 - d_{ei})^{-n} - 1] \quad (7.1.47)$$

$$\text{Harmonic: } D_{ei} = \frac{D_i}{1 + D_i} \quad (7.1.48)$$

$$D_{ni} = \frac{D_{ei}}{1 - D_{ei}} \quad (7.1.49)$$

Most decline curves are hyperbolic with values of $n = 0.0$ and 0.7 , whereas the majority are between 0.0 and 0.4 . Published tables relating time to loss rate and N_p for various decline rates may be useful.

7.1.4.1.1 Economic Limit

In addition to the requirement for a uniform trend, estimation of reserves from production performance requires an end point. This can be an imposed limit, such as the flowrate at a certain wellhead pressure for gas wells, but is most commonly an *economic limit*.

The economic limit is the production rate at which the revenue from sale of production equals the cost of production at the same time. Continued production at or below the economic limit rate creates no economic gain and would serve no economic purpose. Of course, there may be other reasons to continue production—as many operators did after the price declines of 1986–1990—but the estimated amount of that production is not, by definition, reserves.

$$\begin{aligned} \text{Economic limit} &= \text{Production} \times \text{product price} \\ &\quad \text{minus royalty} \\ &\quad \text{minus production and } ad \text{ valorem tax} \\ &\quad \text{minus operating costs} \\ &= \text{zero} \end{aligned}$$

or

$$\begin{aligned} \text{Economic limit} &= \frac{\text{Costs of production/unit time}}{\text{Product price/bbl or Mcf}} \\ &= \text{Production/unit time} \end{aligned}$$

Other forms of production performance analysis may be useful as an adjunct to the time-rate curve.

In Section 7.4 the expected economic life for a potential drilling investment project is defined as the expected year when the present value of cash inflows (e.g., revenues) is exceeded by the present value of cash flows (e.g., costs).

This is modeled as an expected value because of the use of a probabilistic model for price forecasts. Inclusion of appropriate probability models in cash-flow forecasts for

evaluation of drilling projects is appropriate, especially for long-term projects where contracts for price and delivery are not available. The result of this from an analytical point of view will be probabilistic outcomes, such as expected Net Present Value (NPV) and expected year(s) of economic life.

7.1.4.2 Production Rate—Cumulative Production

A plot of exponential production rate versus cumulative production on cartesian scale often yields a straight line. Extrapolation of this line to the economic limit production rate yields the ultimate oil or gas recovery (under the assumed economic conditions).

$$\text{Reserves} = \text{ultimate recovery} - \text{cumulative recovery}$$

7.1.4.3 Water–Oil Ratio (WOR)—Cumulative Production

In water drive reservoirs or in most waterflood or stream-flooding operations, ultimate recovery can be estimated by plotting the ratio of water to oil produced (WOR) against cumulative recovery (Figure 7.1.5). The maximum WOR that can be sustained under the assumed economic conditions can be used as an economic limit. The cumulative production at that point is ultimate recovery and reserves can be estimated as above. A variation on this method is to use water cut (water as a % of total produced fluid) rather than WOR (Figure 7.1.6).

FIGURE 7.1.5 Water/oil ratio and cumulative decline curve.

FIGURE 7.1.6 Water cut and cumulative decline curve.

7.1.4.4 Gas–Oil Ratio (GOR)—Cumulative Oil Production

Use of a rate-cum or WOR-cum analysis can be used along with a material balance calculation to estimate periodic and ultimate GOR, which can then be converted to gas production. Conversely, if gas volume is a limitation on production (such as where gas cannot be sold) requiring that gas production be restricted, then GOR versus cumulative oil can be used to estimate recovery.

Analysis of production rate-cum and other variations using hyperbolic or harmonic decline trends may require semi-log or log-log treatment.

In the instance where the property being evaluated does not have sufficient history to be fully definitive, the *performance of similar properties* may be used to estimate producible volumes for the subject property. The similar property may be another well on the same lease if the subject property is a new well, or it may be a group of wells on an adjacent lease, or even a group of wells in a nearby field that produces from the same reservoir. “Similar” is a broad term and must be used with care. Similar does not necessarily mean identical—no two wells or fields are identical. The properties must, however, share the reservoir rock and fluid characteristics and operating conditions that would allow the evaluator to expect that they would perform much the same way over time. Wells in the same field (or portions thereof) and reservoir should perform in a similar manner, whereas wells in different reservoirs may perform very differently. In some cases, however, even wells in the same reservoir may perform differently if the conditions are changed. Analysis and comparison of the performance of a field or lease developed in the 1950s, for example, may not be relevant to a property developed with more modern methods in the late 1990s. The performance of infill wells may be very different from the original wells if the infill wells reduce the drainage areas of all wells.

Single-well comparisons require extreme care, but can be used by imposing the historical performance decline of one well on a new well. Multiwell or “family” curves combine the performance of several wells by overlaying the decline curve of each well and defining a composite curve through the set. The steps to this are:

1. Select the comparable wells or leases.
2. Plot the decline curves for each well or lease with initial production points set at (a) a common zero point of the wells that went on production at near the same time or (b) at date of first production. Some judgment is needed here.
3. Define a composite decline curve through the curve set.
4. Use the family curve to project the new well or lease.

Fetkovich [34,35] and others [36] have developed methods of decline curve (rate-time) analysis that are described

as “type-curve” analysis. The methods are based on the idea that wells or groups of wells with similar reservoir characteristics will describe similar decline curves over time when compared on a dimensionless time-rate basis. The method requires production history sufficient to demonstrate some depletion but can then be used to determine (a) the form of the decline (including the hyperbolic constant), and (b) certain reservoir properties (assuming other data are available). Type-curve matching requires an overlay of actual rate-time data on a set of dimensionless time-rate curves. The dimensionless decline trend that best fits the actual rate-time curve can then be transferred directly to the actual curve to define the future decline trend. The method can employ a number of forms of dimensionless curves.

The match points can then be used to calculate certain reservoir properties, such as kh , using the dimensionless equations:

$$q_{Dd} = \frac{q(t)}{q_i} = q_D \left[\ln \left(\frac{r_e}{r_w} \right) - \frac{1}{2} \right] = \frac{q(t)}{kh(P_i - P_{wf})} \quad (7.1.50)$$

$$t_{Dd} = \frac{t_d}{\frac{1}{2} \left[\left(\frac{r_e}{r_w} \right)^2 - 1 \right] \left[\ln \left(\frac{r_e}{r_w} \right) - \frac{1}{2} \right]} = \frac{0.00634kt}{\phi \mu C_i r_w^2} \left[\ln \left(\frac{r_e}{r_w} \right) - \frac{1}{2} \right] \quad (7.1.51)$$

Type-curve matching is similar-well analysis on a highly technical level. The method has a potential advantage in allowing an evaluator to define a decline form and quantify the hyperbolic constant earlier in the life of a property than would be the case using “eyeball” methods.

For primary reserves estimation, the production performance method is the most reliable method assuming the data are available and are properly analyzed. The characteristics of the various methods allow them to be used in progression from volumetric to performance with increasing accuracy and reliability. In practice, the methods can be shown to be complementary over time so that one method may be used as a check on another method, all other things being equal.

7.1.4.5 Production Performance in Gas Reservoirs

Estimation of future recovery from natural gas reservoirs uses the same rate-time and rate-cumulative relations as

FIGURE 7.1.7 Nonassociated gas—Pressure/cumulative decline.

discussed for oil reservoirs, however, the fluid characteristics of gas gives greater effect to pressure. A useful relation for estimating gas reserves is the P/Z -cumulative relation (Figure 7.1.7) which plots reservoir pressure divided by the compressibility factor, Z , at time t against cumulative gas Ng . Extrapolation to the economic limit yields an estimate of ultimate recovery.

7.1.4.5.1 A Note on Production Data

Use of the production performance methods of evaluation, either alone or in combination with other methods, requires the collection and analysis of historical production data to formulate a trend that can be extrapolated into the future in the form of a production schedule. There are numerous sources of data, including, but not limited to, company production records, sales records, well tests, reports to regulatory agencies and public data gathering and reporting firms. All data, regardless of the source, must be carefully reviewed for accuracy and to define any variations that may have occurred.

The most common variations in performance are those caused by (a) short producing periods, (b) mechanical changes, (c) regulatory restrictions, and (d) capacity restrictions.

Review and check production data for:

Duration of producing period:

- short months (February)
- wells produced less than full month

Mechanical changes:

- production reductions due to well downtime for repairs, etc.
- increase production due to change in flow valves; pump size, stroke length, or speed; workovers
- decline in production due to increasing fluid levels, etc.

Regulatory restrictions:

- proration (regulatory or contractual)
- limits on gas disposal

- limits on water disposal
- air emission requirements

Capacity restrictions:

- limited pipeline or other shipping facilities

7.1.4.6 Production Stimulation

A subset of the estimation of primary oil (and gas) reserves is the evaluation of properties that are subject to production stimulation techniques. These are methods such as cyclic steaming, fracturing, and acidizing, among others, that alter the reservoir and, possibly, operating conditions of a property but continue to rely on the natural reservoir energy to cause production to occur. These methods add no new energy and are therefore not secondary or enhanced recovery methods and, except in some arguable cases, do not add reserves; they simply act to speed the recovery of oil and/or gas that would be ultimately recovered at some time in the future. On the other hand, the stimulation of eventual production sooner rather than later *can* have important economic benefits and may result in additional reserves being credited to the property where *economic conditions* alone would suggest that the property should be shut-in or abandoned.

Cyclic steaming [37–40] is a common method in oil fields where the oil is high viscosity or has a physical composition that causes production to occur at low rates. Steam is injected into a producing well for periods of up to several days. The well is then returned to production after a period of time. The steam is used to transfer heat to the reservoir where the heat serves two primary purposes in varying degrees. Heat reduces the viscosity of the oil. It also “cleans up” the wellbore by steam cleaning the perforations and/or liner slots and the sand face of accumulated tar and sand thereby improving permeability near the wellbore.

The combination of effects may cause production to increase as much as 10 to 20 times the presteam rate. Wells that have been steamed generally increase to a peak immediately following the steaming and then decline in a definable manner over time. The production cycle may last from a few months to as much as 2 years. Wells can be steamed repeatedly, but the stimulation effect will noticeably diminish with repeated cycles as reservoir energy in the near wellbore region depletes. Eventually, the production declines to a point where the cost of steaming is equal to the incremental return and cycling steaming is stopped.

Fracturing [41–45]—the use of hydraulic energy to create fractures in the reservoir—and acidizing—the use of acid to improve near wellbore permeability—are production stimulation methods that alter the reservoir characteristics, permanently or temporarily, in such a way as to

cause production to increase over a period of time. As with cyclic steaming, the methods generally increase the rate of production and, thereby, have an economic benefit but do not usually add reserves.

Estimation of reserves and future production from stimulated wells generally requires an overlay of production performance and volumetric methods. Some experience with performance using a stimulation method is necessary before a reliable projection method can be defined. Estimation of recovery from cyclic steaming must be based solely on experience and analysis of actual performance of the same or similar properties. The construction of “family” curves of wells, grouped according to the number of cycles common to the wells, can be used to estimate the change in q_p to q_s with each cycle and the point on the decline curve where the stimulated production will begin. Several authors have published methods of estimating production performance from fractured and acidized wells and these may be used as part of an estimation of reserves.

7.1.4.7 Secondary Recovery and EOR Methods

There are many differing definitions of secondary recovery and enhanced oil recovery (EOR). As used in this discussion, EOR will include recovery methods that might also be described as secondary or tertiary depending on the timing of the project and the circumstances of the reservoir. The essential difference between these methods and primary recovery is that EOR methods result in additional production by adding energy to the reservoir, whereas primary recovery uses only the natural energy of the reservoir. The purpose of EOR is to increase the reserves and production from reservoirs that can be, or have been, produced by primary means.

7.1.4.7.1 General Considerations

EOR methods can be put in three general groups:

1. Gas injection—the use of natural gas or other gas as an injection fluid
2. Water injection—use of unheated water as an injection fluid
3. Thermal methods including
 - steam and/or hot water injection
 - *in situ* combustion

These basic methods have many variants depending on reservoir conditions and the use of additives in the injection fluids. Indeed, each project design can be considered a unique method if the design is based on specific reservoir characteristics. It is not possible in this space to adequately discuss the many variations of the basic methods or even to discuss in detail the basic methods. The list of references at

the end of this chapter is intended to provide a starting point for further discussion.

In virtually all EOR methods, a fluid is injected into the reservoir at one point with the intention of sweeping or flushing oil from that point to other points in the reservoir where the oil can be produced. For analysis purposes, this is most often pictured as a piston-type mechanism where the injected fluid occupies an increasingly larger part of the reservoir pushing a “bank” of oil ahead of it to producing wells.

The success or failure of an EOR project generally depends on:

1. The mobility ratio (M), where:

$$M = \frac{\text{Mobility of displacing fluid}}{\text{Mobility of displaced fluid}} = \frac{\lambda_1}{\lambda_2} \quad (7.1.52)$$

and where

$$\lambda = K/\mu = \frac{\text{permeability}}{\text{viscosity}} \quad (7.1.53)$$

If $M = 1$, the fluid mobilities are identical

Favorable ($M = 1$) Unfavorable

2. *Areal and vertical sweep efficiency*—the relative proportion (%) of reservoir area and net thickness that is swept by the displacing fluid. This is largely a function of geology although mobility also plays a part.

Regardless of the EOR method used, the project must be designed to consider and account for both mobility and sweep efficiency. Most of the variations in the basic methods result from attempts to alter and improve mobility or sweep efficiency or both.

Gas Injection

The injection of natural gas either as a pressure maintenance or EOR method is by far the oldest form of injection method for increasing oil recovery. Before the time when natural gas became a major fuel source and could be transported, most produced gas was either burned off or injected into the same or another reservoir. Gas injection is virtually unknown in the United States today.

Gas can be a very efficient injection medium but is generally limited (by mobility ratio) to light oil reservoirs with thin sand sections. The method is most efficient when injection can occur in the top of a structure or into an existing gas cap where it then performs as a piston moving downward, pushing oil down or out to producing wells.

Water Injection

Water injection or waterflooding has been around for a long time. Waterflooding may be done by reinjecting produced water from the reservoir; injecting water from other reservoirs; or by mixing produced waters from various sources.

Freshwater and seawater have also been used. In addition, there are many varieties of materials such as soap, carbon dioxide and other more exotic material that may be added to the water to improve mobility and/or sweep efficiency. Some of these agents act to reduce the viscosity of the oil or to increase the viscosity of the water while others act to improve the relative permeability to water which often results in stripping more oil off of such surfaces. Various mechanical methods are also used to improve sweep efficiency.

The basis for most waterflooding recovery methodologies is the Buckley-Leverett [46–48] or *frontal advance method*. The Buckley-Leverett method assumes a linear oil-bearing zone in a depleted state. The method requires a knowledge of the change in reservoir properties of k_o , k_w , μ_o , and μ_w with change in water saturation S_w . Assuming immiscible, steady-state conditions the flow through a linear block of reservoir can be modeled where

$$f_D = \frac{1 - \frac{1.127k_o}{q_t\mu_o} \left[\frac{\partial P_c}{\partial \mu} + 0.434 (\Delta p) \sin \alpha \right]}{1 + \left(\frac{k_o \mu_w}{k_w \mu_o} \right)} \quad (7.1.54)$$

where f_D is the fraction of displacing fluid flowing at a given point in the system and q_i is the total flowrate per cross-sectional area. If the capillary pressure gradient $\partial P_c / \partial u$ is small and the zone is essentially flat, so that the gravitational function can be dropped, the equation can be simplified to

$$f_D = \frac{1}{1 + \left(\frac{k_o \mu_w}{k_w \mu_o} \right)} \quad (7.1.55)$$

The distance (u) that a plane of constant S_w has advanced at time (t), can be calculated as

$$u = \frac{Q_t}{A\phi} \left(\frac{\partial f_D}{\partial S_D} \right) t \quad (7.1.56)$$

where Q_t is the injection rate which is assumed constant. The slope $\partial f_D / \partial S_D$ is obtained by plotting f_D for various values of S_D . The time to water breakthrough is then

$$t_B = \frac{AL\phi (\bar{S}_{wf} - S_{wi})}{Q_t}$$

where S_{wf} is the mean water saturation in the system. S_{wf} is obtained by projecting a line from S_{wi} tangent to the $\partial f_D / \partial S_D$ curve to $f_D = 1$. If water is the displacing fluid and S_{wi} is the irreducible saturation, then oil production (q_o) until breakthrough is equal to water injected (q_{wi}).

If water is mobile, then $q_t = q_o + q_w = q_{wi}$ and the water/oil ratio is

$$\text{WOR}_{\text{surf}} = \frac{k_w \mu_o B_o}{k_o \mu_w B_w} \quad (7.1.57)$$

and

$$q_o = \frac{(1 - f_w) Q_t}{B_o} = \frac{Q_t}{B_o + (\text{WOR}) B_w} \quad \text{at time } t \quad (7.1.58)$$

After breakthrough, oil production is determined by obtaining values of S_{wf} at various values of f_w up to an abandonment f_w ; calculating t for each value of S_{wf} ; determining WOR at each f_w ; and calculating q_o for each value of WOR.

The Stiles [49] method takes a frontal advance approach but assumes the zone is composed of layers of constant thickness but each layer may have a different permeability. Stiles requires a constant q_i and predetermined S_o after flooding. The method extends the frontal advance approach to determine ultimate recoverable oil and then uses f_w to determine the recovered fraction as a function of time. The method allows a direct derivation of q_o , cumulative oil and WOR.

Suder and Calhoun presented another frontal advance method that allows calculation of injection rates and assumes radial flow up to a point. The method requires a predetermined value for S_{or} .

Dykstra and Parsons [50] also presented a method based on permeability stratification and Johnson [51] converted the method to a graphical approach. The method allows a consideration of permeability variation. The Johnson graphical approach is particularly useful for quick estimates before engaging in one of the more detailed calculations. The set of four graphs is defined at producing WOR of 1, 5, 25, and 100 and result in values of recovery factor R_f for each WOR. Assuming recoverable oil and injection rate can be estimated, the method allows calculation of production rates and cumulative recovery over time. The method works well as a first approximation and is simple enough to use that several analyses can be done for varying conditions

There have been many variations of these methods proposed and used. In addition, the inclusion of variations in reservoir fluid or rock conditions is only a matter of how much work the evaluator is willing to do. These basic methods underlie most if not all computer models used to simulate waterflooding.

Heat Injection Methods

[52] The primary purpose of heat injection using steam or hot water is to transfer heat from the injected fluid to the crude oil and reservoir rocks to reduce oil viscosity. Reduction of viscosity in the oil—at least at the water-oil contact—results in an improved mobility ratio, thereby allowing high viscosity oils to be recovered.

Steam is particularly useful for this purpose because steam can carry a much greater quantity of heat per unit volume than can hot water or heated gasses.

Although some attempts to use superheated steam have occurred, in practice steam at about 80% quality (80% vapor/20% liquid) is most commonly used. Heat injection is a costly process due to the requirement to burn fuel to generate steam or hot water. The major limitation on heat injection methods is heat loss in surface facilities, distribution lines, wellbores, and in the reservoir, to over and underlying rocks and to water in the reservoir. Because of the heat losses in the wellbore, steam injection is normally limited to 3,000 ft. or less in depth. Reservoir heat losses cause the injected fluid to continually cool as the steam front advances from the injection sand face. Continual steam injection is required to attempt to maintain a heated oil–water interface at the flow front. Many authors have described and quantified the heat losses in surface, wellbore and reservoir rocks and reference should be made to those sources.

Marx and Langenheim [53] have presented a series of equations designed to determine the radial distance at which the heat loss ratio in the reservoir equals the heat injection rate.

The inclusion of cost factors (\$h and \$0) allows the calculation to be thought of as an economic limit as well as a physical limit. The calculation assumes no breakthrough but otherwise could be used to define well spacing for a continuing flood.

$$\left[e^{x^2} \operatorname{erfc} x \right]_1 = \left(5.618 \times 10^{-6} \right) \left[\frac{\$hM(\Delta T)}{\$o\phi(S_o - S_{or})} \right] \quad (7.1.59)$$

where

$$x = \frac{2k_{ob}t^{1/2}}{Mh\sqrt{aD}}, \quad \text{dimensionless time} \quad (7.1.60)$$

and

$$M = (1 - \phi) \rho_f C_f + S_w \phi \rho_w C_w + S_o \phi \rho_o C_o \quad (7.1.61)$$

The cumulative heated area (ft.²) can be calculated at time(t):

$$A(t) = \frac{H_o M h \alpha_D}{4k_{ob}^2 (\Delta T)} \left(e^{x^2} \operatorname{erfc} x + \frac{2x}{\sqrt{\pi}} - 1 \right) \quad (7.1.62)$$

where H_o = constant injection rate in Btu/hr

Several approaches have been presented for estimating steam drive performance. In essence, steamflooding is analogous to cold waterflooding and the same principles apply with additional recovery due to:

1. thermal expansion of the oil
2. viscosity reduction, which improves mobility
3. steam distillation of some light oil components

Thermal expansion and viscosity reduction can be determined in laboratory analysis and the effects can be built into

the calculation. Estimation of results from distillation are more difficult to assess and include.

One author has proposed methods of determining steam drive performance that envisions a series of displacements occurring. A cold water–oil displacement front; a hot water and condensate oil front; and a steam-condensate and hot water displacement which is partially miscible.

The radial position of the steam front is calculated as

$$R_{ST}^2 = \frac{14.6i_{st}H_{fg}}{k(T_{ST} - T_f)} \sqrt{\frac{\alpha}{\pi}} \left[\frac{\sqrt{t}}{2} - \frac{h}{8} \sqrt{\frac{\pi}{K}} \frac{(\rho C_p)_f}{(\rho C_p)_{OB}} \right] \times \ln \left(\frac{4}{h} \sqrt{\frac{\alpha}{\pi}} \frac{(\rho C_p)_{OB}}{(\rho C_p)_f} \sqrt{t} + 1 \right) \quad (7.1.63)$$

The steam injection rate must increase as the flood front expands in order to maintain temperature. The required steam rate is

$$i_{st} = \frac{\pi R_{ST}^2 (T_{ST} - T_f)}{14.6H_{fg}t} \left[h(\rho C_p)_f + 4k \sqrt{\frac{t}{\pi \alpha}} \right] \quad (7.1.64)$$

In general, however, the Buckley-Leverett approach used for waterflood can be modified for steamflood. For a radial system,

$$\left[\frac{\partial (R^2)}{\partial t} \right]_{S=\text{const}} = \frac{i_w}{13.43} \left(\frac{\partial f_w}{\partial S_w} \right)_{S=\text{const}} \quad (7.1.65)$$

where i_w = effective injection rate in bbl/day of steam, and

$$f_w = \frac{1}{1 + \frac{k_o \mu_w}{k_w \mu_o}} \quad (7.1.66)$$

Both i_w and f_w (as a function of S_w) are functions of temperature; therefore, the above equation is modified to

$$(R^2)_{S=\text{const}} = \frac{1}{13.43} \int_0^t i_w \left(\frac{\partial f_w}{\partial S_w} \right)_{S=\text{const}} dt \quad (7.1.67)$$

which is amenable to graphical solution as outlined above for waterflood, assuming isothermal steps.

Given the complexity of these calculations and the many variations presented by authors, the evaluator is well advised to make maximum use of data from heat injection projects in similar fields to determine reservoir and production performance over time. Data on many EOR projects have been published in the 1970s and 1980s as the result of DOE projects and a high level of interest in industry.

In 1980, Gomaa [54] presented a method of estimating steamflood performance based on correlations to reservoir characteristics with steamflood injection rates, pattern sizes and shapes, and other factors from existing projects and laboratory studies. The method uses a series of graphical correlations to provide an estimate of reserves and recovery

rate. The method is useful in quick evaluations of steam-flood project potential.

Heat injection methods of EOR have numerous advantages and disadvantages.

Advantages:

- increase recovery from high viscosity oil reservoirs
- increase production rates from high viscosity reservoirs

Disadvantages:

- requires extensive reservoir, rock, and fluid analysis
- high capital investment of steam generators, new injection wells, and surface systems.
- high operating costs for steam or hot water generation, hot fluid and feedwater treating, and personnel
- subject to environmental and other regulatory constraints

Topics covered in the next three sections of this chapter are as follows:

- 7.2:** Factors influencing oil prices and an oil-price forecasting modeling procedure are the topics of the next section. Given the financialization of commodities that has occurred in the last 15 years, the capacity of markets (such as crude oil spot and futures markets) to quickly respond to factors that might be expected to influence prices is perhaps the key overall short-term driver of prices. However, most drilling projects need to be concerned with developing a model of long-term prices that may be used in a cash-flow model (such as the one presented in Section 7.4).
- 7.3:** An overview of risk analysis and the process of risk identification and modeling, with an emphasis on the subjective aspects of this process is presented.
- 7.4:** An example of evaluation of a single primary recovery project via the use of a stochastic price model (presented in Section 7.2) is presented. This chapter provides an overview of the basics of risk modeling and analysis and project evaluation. In particular, the latter topic is restricted to a very limited presentation of the idea of real options. Furthermore, the context for the example is a single, multiple-well project. There is no discussion of alternative drilling patterns and timing (an application of real options), and the fact the example is built around a single example project—rather than a set of possible drilling capital investment projects. Evaluation of multiple, possibly competing projects requires a portfolio approach to capital budgeting, preferably done using a real-options approach in which downstream decisions (such as moderating or increasing production, abandonment, buying/selling shares in the project at hand, etc) are formally considered. The information in this chapter is meant as an introduction and overview that the drilling

professional can use to evaluate individual projects or as a springboard to a more in-depth analysis of more complicated drilling capital investment situations.

7.2 PRICE FORECASTING FOR DRILLING CAPITAL INVESTMENT ANALYSIS

Peter Anselmo

7.2.1 Oil Price Forecasting Basics

Oil price forecasting is very important for making large capital investment decisions associated with drilling projects. Oil price forecasting, especially over the long term (any time period more than a year away) is also very difficult and challenging. Conventional statistical approaches will generate long-term forecasts that are, at best, very noisy because of the need to specifically consider the risks of generating price forecasts for periods relatively far-removed from the present.

Price risk exists because there are price levels at which drilling projects will not be good investments. The issue, of course, is that prices change over time. A large capital commitment made at a time of high prices may become a financial burden if prices drop and stay low for some time. On the other hand, investing at a time of relatively depressed prices will lower development costs and may turn out to be a very good investment if prices increase over the life of the project, especially in the early years.

Both of these general scenarios are examples of price risk. Price risk is not just the risk that prices will go down; rather, price risk should be thought of as the chance that prices will change over time in unpredictable ways. Known price changes are not risky—it's the unknown price changes to which we wish to attend with a reasonable price forecasting model and process.

One alternative to forecasting prices—and, therefore, price risk—is a scenario-based approach where decision makers attempt to forge consensus on sequences of potential scenarios that can be used for price forecasting purposes. This approach is used by large companies (for an example in the cases of BP and Deutsche Bank, see [1, 2]). In these forecasts, intuitive expert judgment is used to forecast some of the key factors impacting supply and demand that are briefly mentioned below. These judgments usually are the result of an organized process in which experts individually (first) and collectively (second) pool their judgments and arrive at consensus predictions about critical factors. These predictions may or may not be quantitative in nature, and even quantitative predictions may be combined for an overall picture of the future in an intuitive way.

These intuitive (also called informal) methods are used because of the difficulties in developing statistically based models for factors that might be very difficult to quantify. The other main reason for use of informal methods is the inherent uncertainty associated with long-term forecasts of any variable using any method. If a variable—such as the future price of WTI crude—is subject to multiple complex and difficult-to-predict forces, informal methods may be the only viable alternative for price forecasting.

Simulation is an alternative valuation method that will allow for explicit consideration of price risk in evaluation of drilling alternatives (including the alternative of not drilling). A good capital-investment simulation model will result in outputs that will explicitly include capital investment risk based on changing prices over time. Obviously, the quality of the price model will be a major factor influencing the utility of the simulation approach, and numerical simulations cannot be carried out without a mathematical model of some type.

This section of the chapter is directed toward issues impacting both short term (generally, a time horizon of less than 1 year) and longer term (generally, a time horizon of longer than 1 year). For many drilling projects, the projected time horizon can be decades in length at the time of evaluation, meaning that some type of price-forecasting model that considers long-term price risk must be implemented.

There are many statistical and/or analytical ways of doing price forecasting. Economists and financial researchers have long delved into details regarding supply and demand, short and long-term impacts on prices, and the appropriate statistical models to use in forecasting demand [3]. As noted above, there are also multiple entities using informal methods. There are pros and cons to any approach, and these are summarized in [4]. We also use the same definition of “informal” methods as the author in [4] in this discussion.

Statistically based methods known as time-series analyses attempt to use past prices to generate a theoretically sound price model that can be used for prediction of prices

in the future subject to an increasing statistical confidence interval around point estimates as the time horizon for the forecast(s) increases. As noted above, theoretically consistent time-series-based forecasts result in increasingly noisy and difficult to use forecasts as the time horizon increases. These models can also be difficult to develop and implement.

An alternative is forecasting based on a more informal consideration of individual factors (see below) that may influence oil prices in the future. It is likely that factors considered in this process will be factors known to decision makers at the time the forecasting exercise takes place. Future, currently unknown factors—or factors with very low probabilities of occurrence—are difficult to incorporate into factor-based price forecasts.

As an alternative to the difficulties in development of useful price forecasts, many practitioners use constant prices, or point estimates for all future prices, in their evaluation models. We do not support or advocate for this method. We do present an alternative methodology based around sequences of future factor scenarios, and as a starting point sequences of different point estimates may be generated as a first step in this process.

7.2.2 Factors to Consider in Forecasting Oil Prices

Many factors can be considered in prediction of oil prices. As we show below in Table 7.2.1, there is no reason to expect consensus across forecasts because of the complexities involved. At the time of the development of this chapter, major factors thought to influence oil prices include the Greek debt situation and other geopolitical factors, the status of the Chinese economy (and, in the very short term, the Chinese stock market), United States shale-oil production, consumer behavior (will increasing prices cause changes in consumer energy-consumption?), and OPEC production decisions.

Each of these is an example of a factor that is difficult to quantify and therefore difficult to model in a time-series or other econometric fashion. The factors are important, and are modeled using informal methods. Further, some (such as the financial situation in Greece) are less important by themselves than they are important for their impacts on the global economy—in this case, on the exchange rate of the euro and on the global banking system.

Thus factors that are complex by themselves—in that there are multiple underlying variables and potential outcomes—are also connected to other complex factors. The result of these linkages and the fact that oil contracts are widely and instantly traded worldwide [5] are a complex world financial and economic system that will have short- and long-term impacts on oil prices and the way that

TABLE 7.2.1 Price Forecasts from Several Sources. WB Denotes the World Bank (Forecast Date April 2015), IMF is the International Monetary Fund (forecast Date June 2015), EIU is the Economist Intelligence Unit (Forecast Date June 2015), and DB is Deutsche Bank (Forecast Date December 2014).

	2015	2016	2017	2018	2019	2020	2021	2022	2023
WB	53.2	57.2	61.1	65.2	69.6	74.3	79.3	84.7	90.5
IMF	58.9	64.2	67.1	69.9	71	71.5			
EIU	60.21	69.26	79.87	86.38	89.25				
DB	67.5	72	79						

these prices are forecasted. Discussion of a comprehensive model capturing major factors, reasonable models of those factors, and their interconnections in order to develop an encompassing oil-price forecast is beyond the scope of this chapter. However, the possibilities associated with such a global approach should not be discounted, and this approach is currently in development by a variety of firms and research institutions.

A general list of factors impacting oil prices (and, possibly, energy prices in general) in the short and long term is below.

7.2.2.1 Shorter Term Factors

Short-term factors are variables that may impact the oil price of oil in a timeframe of 1 year or less. Whether any of these should be formally considered in a price forecast is up to the modeler; at a minimum some of these factors should be considered in an informal approach.

Volatility—volatility, possibly influenced by increasing levels of price speculation [6–9], is always present in commodity prices. Unusual levels of volatility, as measured by the variance or standard deviation of prices and/or price changes, can have a negative impact on project evaluation because the possibility of sequences of low prices early in a project increases as volatility increases. Volatility can be formally considered in a price model because standard deviation/variance should be considered as a parameter and/or an error term in any reasonable financial model.

Refinery and Other Infrastructure—refining capacity, pipeline capacity, port capacities, and other infrastructure, especially in the United States, are the key short-term price drivers. Further, the presence of capacity does not mean that output will match capabilities. Inclusion of this factor in a price forecast is likely to be done via informal methods, where forecasts are altered based on expert judgments regarding infrastructure. This is considered a short-term variable because the

market should respond to an insufficient infrastructure issue.

Production Controls and Unconventional Resource Development—OPEC was noteworthy because of recent production increases, particularly by Saudi Arabia, in 2014. World supply has also continued to be greatly impacted by continued development of shale-based resources in the United States. Shale production is a numerical value that by itself can be forecasted, and statistical relationships between production levels and price can be used in forecasting prices based on shale oil production forecasts. Forecasting production controls, and their impact on short-term future prices, is more difficult, though this factor may be a major source of price risk during the critical early years of a development project.

Consumer and Investor Perceptions—these factors can have short-term impacts on prices, though they are difficult to incorporate into a price forecast. The degree to which consumers see climate change as a man-made problem will have obvious short- and long-term impacts on demand for both energy and policies influencing energy consumption.

7.2.2.2 Longer Term

Geopolitics—probably the hardest factor to formally model, this is also a factor that will always be impactful on energy prices and oil prices in particular. A very complex topic, most organizations who attempt to consider geopolitics in oil price forecasts do so in an informal, perhaps scenario-based, manner.

US Supply—the future of US supply, as briefly mentioned above, is a key driver of both short and longer-term price risk. While analytical models may be appropriate for contributions to short-term price forecasts, longer-term forecasts formally incorporating US supply will be difficult to implement.

Worldwide Economic Growth—this factor is generally viewed as the key driver of the runup in prices in the

second half of the first decade of the 2000s, and is likely to be a major factor impacting long-term prices. As with many key variables, substantial data exist for this factor and it can be forecasted and used as part of a longer-term, analytically based forecast. Output from an econometric growth forecast can also be combined with inputs from other factors, such as geopolitics.

US and Worldwide Demand—this is the ultimate result of worldwide and US economic growth as well as consumer behavioral patterns. Many datasets and data sources exist for US and global demand, and inclusion of this factor in an econometric price forecast (where demand is forecast and then its impact on prices is also forecast using mathematical techniques) is somewhat straightforward. However, forecasts based on analytical models are all subject to increasing predictive uncertainty with time.

Efficiencies and Alternative Energy Sources—energy efficiency via use reductions, renewables, and other methods is a well-understood concept among consumers worldwide. Technology is driving increasing efficiencies in existing and alternative energy sources, particularly with respect to power but also with regard to transportation. This is another complex set of factors that is difficult to forecast formally, but that should be considered (informally) in any price forecast for projects lasting longer than 10 years.

Regardless of the factor(s) considered in oil price forecasting, the facts that fast, nearly instant information dispersion characterizes most financial and commodity markets and the interconnectivity of energy and financial markets means that forecasting becomes a challenging task [9]. The best course of action, especially for forecasts longer than 1 year in duration, is likely to be an informal combination of data from quantitative models and qualitative assessments of critical variables.

7.2.3 Some Examples of Existing Price Forecasts

Many public and quasi-public-sector entities produce oil price forecasts. Three are shown below in [Table 7.2.1](#); forecasts from the World Bank in April, 2015 for the period 2015–2015, the International Monetary Fund (IMF) for the period 2015–2020, and the Economist Intelligence Unit (a unit of www.economist.com) for the period 2015–2019. All prices in the table are weighted averages of projected annual average prices for WTI, Brent, and Dubai crude.

Note that there is substantial divergence of opinion, even for the average price that will ensue for 2015.¹ The

general forecasted direction (up) is the same, but forecast average prices are not consistent across all three agencies. Some of this, such as the relative enthusiasm of the DB forecasts, may be explained by the timing of the forecast. However, the EIU and IMF forecasts are contemporaneous, indicating that even the presence of experts is no guarantee of consensus or consistency across forecasted time.

These forecasts are likely to have been done via indirect methods in which information about key factors, such as geopolitical risk and OPEC production levels, is combined in a heuristic (that is, an informal intuitively and not analytically based) way. Even when these informal forecasts are done by experts, differences of opinion can result in different forecasts as can be seen in the table above.

It may be possible to explain differences in forecasts according to weights on different factors. For example, forecasts emphasizing technological advances and conservation will be pessimistic with regard to long-term price trends [10]. On the other hand, forecasts placing more weight on factors such as Asian demand, particularly from China and India, will be optimistic with regard to long-term price trends, and will feature increasing prices over the period of the forecast.

7.2.4 Geometric Brownian Motion-Based Scenario Approach

In light of the preceding discussion, a method for combining analytical forecasts and non-quantitative expert judgments is presented. This method combines well-known quantitative modeling with an informal method for picking parameters for the well-known models. It is presented as one alternative hybrid forecasting method. Specific documentation and other information are available from the author or from [11].

We use WTI oil price historical data from 2 January 1986 to 11 May 2015. The price graph is shown below in [Figure 7.2.1](#) (source: US Energy Information Agency, www.eia.gov). The objective is to develop a reasonable statistical model of the price path over the 30-year period. Many modeling methods exist and have been tried; one notable method is geometric Brownian motion (GBM). The general equation for a GBM model with mean reversion [12] to estimate a change in a variable at time t is generally written as

$$dx = \alpha (\bar{x} - x) dt + \sigma x dz \quad (7.2.1)$$

where dx denotes the last change, α is the speed of mean reversion, \bar{x} is the expected return and σ is the dispersion (variance) parameter. dz is a Weiner process with mean 0 and standard deviation \sqrt{t} .

We may reformulate [Equation 7.2.1](#) in terms of the change in price from period to period—in this case, day to day. We note that the daily return may be written as

1. The World Bank also forecasts average prices of \$96.8 and \$103.4 for the years 2024 and 2025, respectively.

FIGURE 7.2.1 WTI crude spot prices. 2 January 1986–11 May 2015. Source: www.eia.gov.

FIGURE 7.2.2 Quarterly WTI crude prices as average of daily prices. 1 January 1986–11 May 2015.

$$r_t = \frac{P_t}{P_{t-1}}$$

where P denotes price. Using periodic changes (aka returns) rather than actual prices is preferred because return distributions are usually unimodal and therefore may be modeled with normal or lognormal distributions. This is not usually the case with price distributions, which often are multimodal and are therefore inappropriate for some of the conventional statistical and forecasting techniques considered here.

Equation 7.2.1 can be rewritten in terms of natural logarithms and returns r so that

$$dr_t = \alpha (\bar{r} - r) dt + \sigma dz$$

which, in turn [12], may be rewritten as

$$\ln(r_t) = \bar{r}(1 - e^{-\alpha}) + (e^{-\alpha} - 1)r_{t-1} + \epsilon_t$$

where ϵ is a standard normal random variable.

Our goal is to estimate α and σ (we also need to estimate \bar{r} , as it will be changing over time), and this will be accomplished by estimating different parameters for different intervals of the WTI quarterly price history that is shown

in Figure 7.2.2.² Rather than have a single parameter set for the entire price history, the method presented here allows for development of different (α_s, σ_s) pairs, where s denotes a unique price segment, or scenario, in the original data.

Standard regression of the form $y = a + bx$ is used to estimate \bar{r} , α , and σ . The data regressed are the logs of daily returns and price (P), so that the actual regression model is

$$\ln(r_t) - \ln(r_{t-1}) = a + b \ln(r_{t-1}) + \epsilon_t \quad (7.2.2)$$

and estimates for α and σ are found by the relations

$$\begin{aligned} \bar{x} &= -\frac{\hat{a}}{\hat{b}} \\ \hat{\alpha} &= -\ln(1 + \hat{b}) \\ \hat{\sigma} &= \sigma_e \sqrt{\frac{\ln(1 + \hat{b})}{(1 + \hat{b})^2 - 1}} \end{aligned}$$

2. While forecasting of daily prices is attractive conceptually, forecasting quarterly prices allows for fewer actual forecasts to develop a long-term price model.

where \hat{a} denotes the regression estimate for a , etc. and σ_e is the standard error computed as a result of the regression results.

Once the model parameters are estimated, the actual price-forecasting model may be implemented. Generally,

$$E(P_T^f) = P_0 e^{r^f T} \tag{7.2.3}$$

The expected (forecasted—hence the superscript f) price at future time T is a function of the initial (possibly last-observed) price and the forecasted rate of return r^f . The forecasted rate of log return is normally distributed and is a function of the model in Equation 7.2.1 as follows [12]:

$$r_t^f = r_f^{t-1} + dr_t$$

However, the idea of a single model for a complex, multi-factor-influenced price series as is shown in Figures 7.2.1 and 7.2.2 is insufficient. Instead, a piecewise method is proposed, where statistically significant parameter sets are estimated for segments (or windows) of the overall price series. These individual sub models may then be used to generate an informal, factor-based forecast where periods of dominance by one or more factors may be specifically compared and defined in terms of comparable periods in the past for which a unique set of parameters have been generated.

The size of the forecast window is a modeling decision variable. Regardless of the window size, as long as the window size is smaller than the total number of observations, the process consists of running the regressions (in this case, the model in Equation 7.2.2) on the data contained in the window. The \hat{a} and \hat{b} estimates are checked for statistical significance—the confidence levels for each are specified by the modeler—and significant parameters are then used to estimate the model parameters in Equation 7.2.1.

The window is then shifted by one data point—so that the first one is omitted and the next one in the data sample is included—and the process is repeated. Once complete, each set of significant parameters³ is identified as a scenario. Some scenarios are very short-lived, as their predecessor and successor scenarios may occur in the preceding/succeeding window. Others are longer-lived.

Data for each scenario are recorded and may be used to generate forecasts themselves, or may be used to provide insights into parameter ranges for informal forecasts. It is important to note that, even in informal forecasts using this method, the source for data and insights into development of the parameter sets for the forecasts is the original rolling-window regressions.

Forecast examples presented below are generated using a VBA/Excel model implementing the model presented

above. To restate, scenarios are defined according to significant regression parameters, which are driven by several key user-specified parameters. A scenario is a stand-alone set of statistically significant regression parameters. A rolling-window method is used to generate new model parameters by adding/subtracting individual datapoints and re-computing the regression coefficients. Data windows providing regression coefficients that are significantly different from their predecessors denote a new scenario—a new pattern in the historical data. Data windows providing non-significant regression coefficients are ignored, and the data are assumed to be part of the most recently defined scenario. Details about both the model and computational methods used are available from [11].

The first key parameter is the length of the modeling window—the number of price observations that will be used to develop parameter models. The second and third are confidence levels required for significant parameter estimates for the intercept and slope parameters. These parameter selections will greatly impact the resulting scenarios.

7.2.4.1 Example WTI Price Forecast Using Quarterly Data

While daily spot price⁴ data are most desirable for forecasting and planning, as well as trend analyses, quarterly data are preferred for longer-term forecasts because fewer data points must be projected. The sample dataset of actual prices that is used for forecasting was collected by computing quarterly average prices over the interval shown in the historical-price graph on Figure 7.2.1. Figure 7.2.2 depicts quarterly historical WTI prices over the period from 1 January 1986 through 11 May 2015 (data source: www.eia.gov). The last observation in the dataset reflects a partial quarter from 1 April–11 May 2015. The decision to include this last observation is up to the modeler; in this case the facts that about half of the quarterly data were available and the relative price stability at the time lead to the decision to include the observation.

Note the overall quarterly and daily price patterns are similar. This heuristic observation lends some credibility to using quarterly, instead of daily, price forecasts for the drilling capital budgeting decision process.

Once reliable historical quarterly prices are in place, the forecasting process can begin. The overall process may be summarized as follows:

1. Obtain reliable, quality historical (sample) data to be used to develop the statistical model that will be used to provide parameter information for the forecasts.

3. It is also possible to consider only significant values for \hat{b} in the presence of non-significant intercept estimates. In this case, $\hat{a} = 0$ which means that $\bar{r} = 0$.

4. The spot price is the price paid at the current time and date for a barrel of WTI crude. While this amount will vary across locales and time of day, the generally recognized measurement for WTI spot is the price at Cushing, Oklahoma at 4 pm on the day in question.

FIGURE 7.2.3 Example 10-year quarterly price paths for 2-scenario forecast.

FIGURE 7.2.4 Example 10-year quarterly price paths for 4-scenario forecast.

2. Graph the data and start thinking about how historical events in the oil industry have impacted historical prices. For example, in both Figures 7.2.1 and 7.2.2 one can (generally) identify the points where increasing demand sources, primarily in Asia, contributed to an upward change in the price trend and where electronic commodities trading contributed to price volatility. This is particularly apparent in the daily price data shown in Figure 7.2.1.⁵
3. Select a model. As noted above, a large range of choices exist ranging from formal, time-series models to heuristic, informal approaches.

In this chapter, we describe a combined formal/informal approach that depends on implementation of a geometric Brownian motion with mean reversion (Equation 7.2.1) approach to modeling and forecasting WTI spot prices.

4. For a formal model, develop model parameters. Expert opinion about key factors, especially over the longer term, may be used to help select among competing parameter sets—hence the formal/informal approach.
5. Carefully implement the forecasting model. If the forecasts are acceptable in the context of expert judgment about key factors, forecasts may be used in a stochastic capital-budgeting model simulation.

7.2.4.2 Example WTI Price Model Results

Results from two different forecasting models used to predict 10 years—40 quarters—of WTI spot prices are shown in Figures 7.2.3 and 7.2.4. Tables 7.2.2 and 7.2.3 contain parameter data for the results in the figures.

The first forecasting model, which is shown below in Figure 7.2.4, was derived from a model fit to the data with the parameters as shown in Table 7.2.2:

Simulation step denotes the last point in the scenario; Scenario 1 runs from observation 1 to 49, and Scenario 2

5. Academic research generally points to electronic commodities trading, such as the heavily traded NYMEX WTI futures contracts, as contributing to price volatility but not influencing the prices themselves.

TABLE 7.2.2 Example Output from Rolling-Window Scenario Generation Process.

Scenario	Simulation Step	Average	Alpha	Sigma
1	49	-0.0253	.4548	.0503
2	110	0.0256	.6757	.0504

TABLE 7.2.3 Scenario Lengths and Parameter Estimates for 4-Scenario Forecast

Scenario	Begin	Length	End	Average	Alpha	Sigma
1	1	8	9	-0.00039	.5415	.0992
2	9	8	17	0.1025	.6185	.0672
3	17	8	25	-0.0388	.5414	.0995
4	25	16	40	0.025	.2505	.08

runs from observation 50 to observation 110. There is no scenario generated for the last nine quarters of data.

Informal integration of the model scenarios, which may also be seen as providing an intuitive explanation for the two scenarios, might be summarized as follows:

Scenario 1-1: Depressed global demand due to ongoing debt crises, slowing Asian economies, and actions of the US Federal Reserve to raise interest rates combine to create a quarterly expected price change of about $-2.4\%(e^{-.0253 + (.0503)^2/2} = .976)$. Duration: 4 years (16 quarters)

Scenario 1-2: The effects of reduced supply from the US and (possibly) OPEC combine with slowly recovering world economies to produce an expected quarterly return of about $2.7\%(e^{.0256 + (.0504)^2/2} = 1.027)$. Duration: 6 years (24 quarters).

Plugging that the values for the two scenarios in the log returns Equation 7.2.1, and noting that the forecast price P_t^f at time t is expressed as in Equation 7.2.2 provide the forecasted price paths shown in Figure 7.2.3.

The optimal forecast [12], the non-varying curve is the forecast with no uncertainty. This forecast should be at the center of all forecasts that incorporate uncertainty. The change in scenario can be seen in the optimal forecast. It is important to note that the optimal forecast provides a baseline; one should never use the optimal forecast in a drilling project financial analysis unless one was sure that the forecasted prices would be the actual future prices.

The non-optimal forecasts differ because of the random term σdz , which, as the forecast proceeds, is multiplied by

\sqrt{t} . The overall pattern (similar to the World Bank forecast presented above) is that of declining prices for the next 4–5 years, followed by a gradual recovery. Note that this is a 40-quarter quarterly price forecast. Forecasts that attempt to provide insights on future prices should be considered very carefully, and the degree of caution should increase rapidly as the time-horizon of the forecast(s) increases. Thus, one should have some degree of confidence in forecasts for the next few periods, and this confidence level should decrease as the number of out periods increases, and should decrease rapidly as the forecast period goes past 20 or so.

However, a statistical model such as the one presented here can be useful, and if there is sufficient variability in the σdz term then using statistical models in Net Present Value simulations—provided the cash-flow model is a reasonable representation of the problem at hand with regard to the reservoir model, cost models, depreciation, taxes, and other factors—is a reasonable course of action in evaluating risky drilling prospects.

The second example forecasting model was implemented with 4 scenarios as follows:

Scenario 2-1: Factors such as slowing Asian demand and international currency issues will put downward pressure on WTI crude prices for the next 2 years (8 quarters)

Scenario 2-2: Cumulative reduced supply result in increased prices as the world economy as a whole begins to prosper for the next 2 years (8 quarters)

Scenario 2-3: Major downward price pressure as OPEC increases productivity and more US supply comes on line in a time of a depressed business cycle for next 2 years (8 quarters)

Scenario 2-4: Slow, steady price recovery for next 4 years (16 quarters)

Four example price paths for this overall, 10-year set of scenarios are shown above in Figure 7.2.4.

Forecasts shown in Figure 7.2.4 exhibit volatility that is increasing in time, an important feature of an acceptable analytical approach. The jagged, peaks-and-valleys nature of the forecasted price paths is due to the mean-reversion model. This pattern of over-mean-return projections followed by under-mean projection is common and is a sign that the model is performing as intended.

The parameters used to generate these price paths using the model for log returns in Equation 7.2.1 are shown in Table 7.2.3.

The parameters above in Table 7.2.3 provide a poor fit to the actual sample data. These parameters were developed based on informal scenario projections based on the key factors listed above, and the purpose of these numbers is to provide a second example. In a real forecast, the average return parameters might be selected based on expert judgment, and the alpha parameters—for speed of regression

to the expected log returns—could be selected based on a combination of expert judgment and regression parameters from various model fits on the sample data. Thus the parameters in Table 7.2.3 would represent a synthesis of expert judgment and parameters derived from the quarterly WTI price data.

Note that the volatilities for all price paths are higher—and the range of possible prices larger—than in the case of the first example scenario. The standard deviations (σ) are larger, as are the log expected returns for each scenario.

It is important to restate the fact that all numbers in Tables 7.2.2 and 7.2.3 are (or should be) derived from a combination of expert judgment and (we recommend) sliding-window regression results. The combination of expert judgment with statistical results—themselves subject to expert judgment because an expert should pick the window size and parameter confidence intervals for the regressions—makes this method an informal one.

7.2.5 Summary

Time series and other types of statistical and econometric forecasts look for patterns in the data themselves and/or patterns in the co-occurrences of several variables and try to extrapolate to forecasts. As the forecast timeframe increases, the forecast confidence interval expands rapidly making long-term forecasts very difficult. Further, many variables are difficult to forecast formally, and must therefore be forecasted using informal—perhaps hybrid—methods.

This section has been concerned with a general discussion of oil price forecasting issues and the need for a combination of formal and informal tools and processes to create long-term forecasts that are necessary for evaluation of drilling projects—as well as just about any development process in the energy sector.

There is no generally accepted step-by-step process for long-term price forecasting. The method suggested here involves combining an analytical process with expert judgment. Parameter judgments are (or can be) made based on historical, statistically defined scenarios, and new, forward-looking scenarios may be generated as inputs to a price-forecasting process.

7.3 RISK ANALYSIS

Peter Anselmo

7.3.1 Introduction to Risk Analysis

The primary goal of risk analysis is to make objective, rational decisions—usually capital investment decisions because drilling is a capital-intensive activity—using the best information available. Key variables, such as market price for oil/gas and total capital and operating costs, are obviously unknown at the time the investment decision must be made. The best that decision-makers can do is to develop methodologically sound, situation-appropriate models for evaluation of risky investment alternatives based on accurate, defensible risk analyses.

The focus of this section is identification of and alternative techniques for modeling of key risks. A key risk is a variable that can have significant impact on return on investment (ROI) and/or other objective measures. Once a risk has been identified, it may be necessary to model and formally consider a risk before determining whether it is key and therefore should be included in the overall decision risk model. A successful modeling process will result in a decision-situation model that includes all appropriate alternatives and key risks. Such a model is considered to be a requisite model.

A requisite model of a risky drilling decision is a model that offers maximum insights into the decision situation [1]. No additional information can add to or otherwise enhance the decision situation, and reduction of the requisite model—usually by removal of model risk variables or alternatives—results in a loss of understanding and insight about the problem. A requisite model is also a valid model,

where validity is defined conventionally as a model that is an accurate representation of the problem.

The degree to which a model is valid and is a requisite model will depend on the quality of the decision and risk-modeling process. Participation by subject-matter experts, decision-makers (if different from the subject-matter experts), and other important personnel within the firm is critical if the modeling process is to succeed. Once the team is assembled and alternatives and risk factors are identified, there are established techniques and methodologies available for risk analyses, and some of these are introduced in this chapter.

It is up to the firm to designate the individual or team to be responsible for developing a decision model for decisions involving major financial commitments. The designated individual(s) must take care to ensure that the risk analysis process results in a well-developed, valid, requisite model of the decision problem.

7.3.2 Risk Analysis Steps

The first step in the risk analysis process is to characterize the firm/organizational values [2] that will drive the specification of alternatives. In a drilling context, this may be straightforward and it may not be necessary to re-invent the wheel for each drilling decision. However, the fact that the alternative set should be grounded in firm values and values-driven objectives should not be forgotten. This is known as setting the decision frame, in which firm personnel determine the givens in a decision problem, decisions to be made now, and decisions to be made later [3].

Risk analysis is about developing scales and measures for different risky variables and then using those measures to evaluate already-developed alternatives. The process of developing alternatives is important, and, to restate, should be driven by firm values and objectives. While the formal risk-analysis process may be separated from the alternative-generation process, those involved in the specification of alternatives should be somewhat familiar with the major risks faced by the firm.

Once alternatives are specified, then key risks must be identified. Identification is just that, naming and verbal descriptions of factors that are unknown, but may assume different values or levels that may differentially impact a drilling project. Identification can be an iterative process; as the risk and decision analysis process proceeds, the actual (key) risks to be considered may be revisited and/or reevaluated.

Once risks are identified and verbally defined, the risk analysis process can begin. A good place to start is with an influence diagram in which decisions and key risks are connected in a way that accurately represents the decision at hand. An influence diagram, as shown below, is useful for decomposing risks into component factors. Once this is

done, the level of risk analysis detail as well as the variables to be modeled may be determined by the modeling team.

In this chapter two general risk analysis methods are presented; qualitative and quantitative assessments. A qualitative assessment may be less arduous than a quantitative assessment of one or more risky variables, but the qualitative assessment is likely to be less useful in valuing investments or determining expected returns.

7.3.3 Risk and Risk Analysis Definitions

Uncertainty is generally defined as a lack of knowledge about the nature of future events, in this case, related to drilling and/or development decisions. One goal of risk analysis is transformation of variables from uncertain (no specific knowledge about possible future outcomes) to risky status. The uncertain variable must be identified, but will be otherwise unspecified. As noted above, the uncertain variable must be considered key, or potentially impactful to the drilling-investment decision.

In that case, a risk analysis for the uncertain variable—and other key uncertain factors—is appropriate prior to undertaking a drilling project or other development-related capital investment decision. We define a risky factor, event, or, generally, variable with one or more possible outcomes that, preferably, have been specified and modeled with a probability distribution.

Given the above general definition of risk, risk analysis can be defined as the process of identifying, specifying, and understanding the key factors influencing a drilling or other development decision. Understanding consists of measuring risk by identification of either potential impacts (qualitative risk assessment and analysis) or specific measurable outcomes and associated probabilities (quantitative risk assessment and analysis).

Prior to presenting summaries of qualitative and quantitative risk analysis techniques, we present an example of an influence diagram. Development of an influence diagram should follow the risk-identification step in the risk-analysis process.

7.3.4 Influence Diagrams for Risk Assessments

An influence diagram is a general representation of key identified risks, alternatives, and outcomes in a way that represents their interconnectivities and relative ordering [4, 5]. As a tool to be used in risky decision making, the main purpose of an influence diagram is three-fold:

- Engage experts and other key personnel in the drilling-investment decision-modeling process
- A model of how important decision factors interact that all involved can see and understand and

- Identification of key uncertainties that need to be explicitly modeled, either qualitatively or quantitatively

As is the case in a decision tree, an influence diagram depicts risks as circular nodes and decisions as square nodes. In an influence diagram a single square node can represent a range of decision alternatives as long as the alternatives represented by the node are mutually exclusive and are to be considered simultaneously. Outcomes, such as performance and/or profitability measures, are depicted as diamonds. Arcs connect key variables, but variables should only be connected if there is directional influence, that is, if one variable precedes the variable(s) to which it has a connecting arc. Feedback loops are not usually considered in influence diagrams, and feedback loops usually suggest a time factor in a decision model. Most influence diagrams are used for static representations of a situation, but they can be the basis for a dynamic model and diagrams can be expanded to include a time factor.

The key first step in construction of an influence diagram is specification of alternatives—which should be driven by firm goals and objectives—and key risks. Alternatives and important risks should be stipulated as a result of a process where inputs from key experts and decision makers are gathered and synthesized in a way that enables the clear definition of alternatives and risks. Once this process is complete the influence diagram may be constructed.

A simplified example influence diagram for a hypothetical drilling investment decision is shown below in Figure 7.3.1. In the example, hypothetical diagram, there are three initial factors to be considered and modeled as risks: the local regulatory environment, consumer preferences, and geopolitics. These, in turn, influence other risky factors. Examples of risky factors impacted by these three variables, as shown in Figure 7.3.1, include demand (influenced by local regulatory environment and consumer preferences), international production (influenced by local regulatory environment and geopolitics), and supply (influenced by local regulatory environment, consumer preferences, and geopolitics). These factors, in turn, influence price, which then influences ROI. Reservoir features influence the decision to drill, which also influences ROI. Costs also influence ROI.

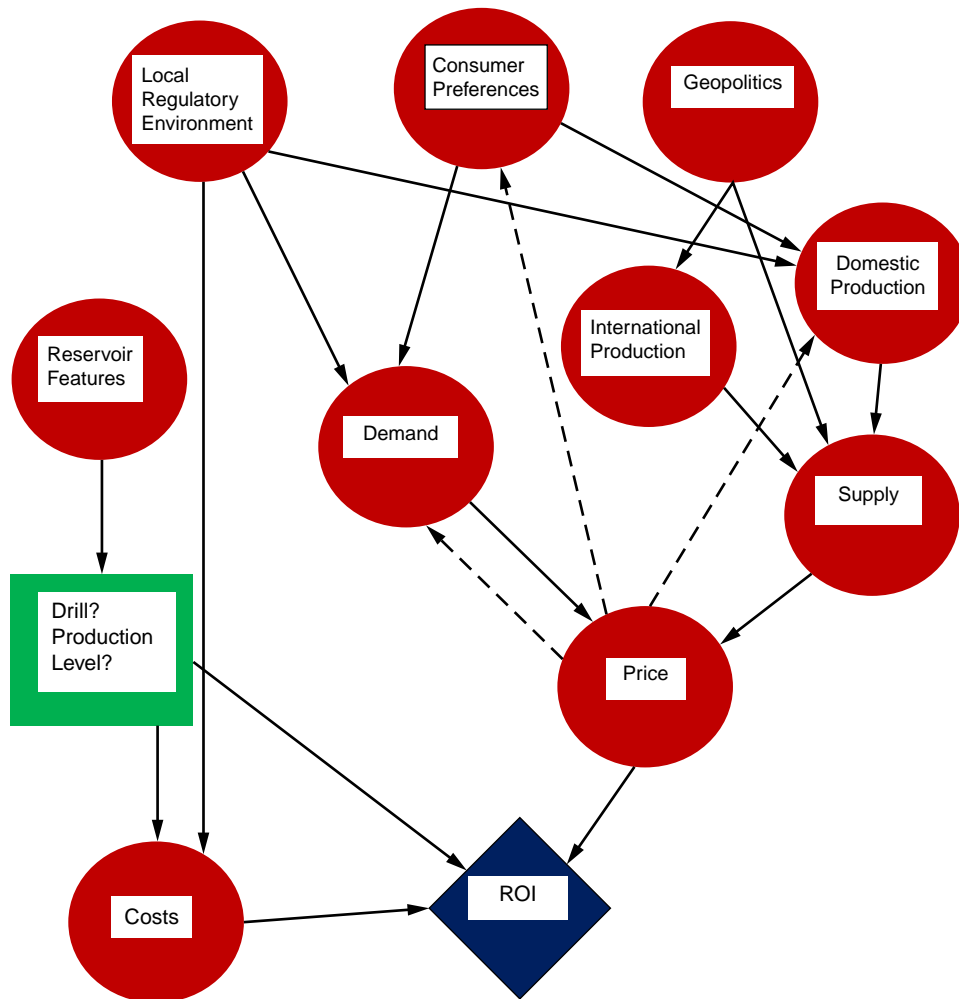

FIGURE 7.3.1 Example Influence diagram for a drilling-investment decision. The diagram includes both quantitative and qualitative risks, all of which can be assessed depending on the magnitude of the investment and the expected lifetime of the project. This example is hypothetical and is intended only to show an example influence diagram, which in this case would be generated near the start of the decision-making process.

geopolitics), domestic production (like demand, influenced by local regulatory environment and consumer preferences), and cost (influenced by the local regulatory environment).

Supply, another risky variable, is impacted by geopolitics, domestic production, and international production. Then supply and demand combine to influence price, which is a key factor—along with the drilling decision taken—in success as measured by ROI.

Examples of feedback arcs are shown as dotted lines in Figure 7.3.1. Thus price, which is influenced in this simple example by all linked preceding factors, in turn influences consumer preferences, domestic production, and overall demand. Note that price can influence both consumer preferences—which will have an impact on demand and, directly, demand. Both arcs are included because it is possible for demand to change as price changes without consumer preferences changing. If multiple time periods and feedback loops are to be considered, then the diagram would expand horizontally and would maintain the directed-graph nature of an influence diagram.

The drilling decision, and the alternative ultimately selected, can directly impact ROI and costs. This is because of the possibility different drilling locations, equipment used, and other specific decision components. Note that the drilling decision does not impact demand, price, or any other risk variables save cost—as some alternatives may have different cost factors than others—in this example.

Once the influence diagram is complete—and most or all parties to the modeling process agree it is complete—then risky variables that require more detailed modeling can be identified. In a situation such as is shown in Figure 7.3.1, the team may decide to model each individual variable or the team may decide to model only price. The process of modeling multiple variables is summarized below in the quantitative risk analysis section.

If variables such as the local regulatory environment are modeled, a qualitative approach—as presented below—can be a reasonable way to analyze drilling risks, especially if the project is long-term and features multiple connected risky variables. However, a purely qualitative approach to risk assessment cannot be used to do more than filter alternatives and, possibly, generate alternative rankings.

Qualitative risk analyses cannot generate net present value (NPV) or ROI measures. In order to generate numerical evaluation measures for risky drilling decisions, quantitative risk assessment and analysis methods are required.

7.3.5 Qualitative Risk Analysis

Often drilling decision situations involve alternatives that must be evaluated subjectively because of limited financial and/or physical assets available to the drilling company. When multiple risky variables have been identified,

and their general interrelationships have been specified—possibly via use of an influence diagram—a qualitative risk analysis may be a useful initial method for screening alternatives.

Because risk analyses in general will require inputs from experts, including individuals who will be working on the drilling project, the process of generating risk measures can provide side benefits resulting from participation in the risk assessment and analysis process. Examples include team building, intra-firm communication, and the motivational benefits that accrue when all levels are involved in decision framing.

Qualitative risk analyses can be used to screen and initially rank drilling alternatives. Qualitative risk analyses should not be used to estimate probabilistic risk models, NPV, or measures of returns on investment (ROI). Nor should qualitative risk scores be aggregated in any numerical way without an extended modeling effort. The use of qualitative risk assessments for decision making—actual selection of drilling projects—should be limited to filtering unacceptable alternatives and, perhaps, ranking alternatives based on subjective evaluation and aggregation of the qualitative assessments for each alternative.

7.3.5.1 Qualitative Analysis for a Single Risky Variable

In a development environment and business climate where many possible investment alternatives exist, qualitative risk assessments can be used as an initial screening mechanism—much as they may also be used as a way to identify key risks that are candidates for quantitative modeling efforts. At the project level, firms may elect to delay or deny investment in projects with more than one “unfavorable” risk. Series of qualitative assessments may also be used to rank projects prior to proceeding with more analytical approaches to analyzing risks.

In a qualitative risk assessment and analysis, the risky variable in question will be defined verbally (as opposed to probabilistically; see below) in terms of potential impacts to the firm (or other decision-making entity). It is preferable to use a verbal scale with pre-defined terms that are understood and agreed-upon by all involved in the risk assessment process.

As an example of a qualitative definition of a risky variable, consider the regulatory environment variable—and in the case of a dynamic political environment the environment may be difficult to specify during the planning stages of a drilling project—that might be determined as a variable to be considered in the process of evaluating drilling investment alternatives. Suppose that the scale of potential verbal assessments ranges from “Favorable” to “Mixed” to “Unfavorable.” An example of how these terms might be defined is presented below.

Limiting possible qualitative assessments to pre-defined terms will define and shape the risk-analysis discussion and should increase the efficiency of the overall process. Doing the a priori work to develop and define the verbal categories will also help sell the risk analysis process to those who may be skeptical about moving away from an unstructured, subjective decision-making process that may be perceived to have been successful in the past.

Suppose that the status of the regulatory environment at the time of the start of a project—if it is indeed started—is unknown, but the firm wishes to model the possible range of outcomes for capital-planning purposes. From the perspective of the firm, the three potential outcomes of the environmental assessment could be defined as follows:

Favorable: the development project as proposed will be in compliance and will not face major regulatory issues regarding water disposal, emissions, noise, added safety regulations, or other factors. Projected impacts on project cost and time-to-completion are minimal.

Mixed: the development project as proposed may not be in complete compliance with regulations concerning water disposal, emissions, noise, added safety regulations, or other factors. The projected cost and time-to-completion impacts for making the drilling project compliant are moderate.

Unfavorable: the development project as proposed will not be in compliance with several or many existing and anticipated regulations. Projected cost and time-to-completion impacts if project is to be made compliant are extreme.

Note that, in this example, cost is an explicit measure of the potential impact, but this unknown-in-advance (and therefore risky) variable is not directly specified. Instead, it is assessed as minimal, moderate, or extreme. In a qualitative assessment the analyst would strive to develop numerical measures, whether discrete or continuous, for the cost variable. Thus the “minimal,” “moderate,” and “extreme” scale used in the example above would be abandoned in favor of a quantitative assessment of potential costs in each of the three regulatory scenarios, which could mean three distinct cost models with each contingent on one regulatory scenario.

Qualitative assessments are often achievable relatively quickly vis-à-vis qualitative assessments, and the assessment costs are also likely to be lower. However, qualitative assessments do not enable computations such as NPV or ROI because the assessment is not numerical.

7.3.5.2 Multiple Variable Qualitative Risk Assessments

Often in capital investment analyses that must precede drilling decisions, a risk analysis may result in identification

of many variables that are difficult to quantify or, while numerical in nature, are difficult to measure. It should be noted that, even if a variable is easy to identify and measure—price is an example—development of a quantitative or qualitative model that is accurate and relevant is not likely to be easy.

Many firms develop tables of summary data for difficult-to-quantify risks consisting of the verbal score for an alternative on each of the qualitatively measured risky variables considered. An example of such a table, with each of three variables (labeled as Risk 1, Risk 2, and Risk 3) rated on a “favorable,” “mixed,” or “unfavorable” scale as presented above is shown in [Table 7.3.1](#).

Note that based on the table (and, of course, on accurate and consistent verbal scores) alternative 1 can be disqualified from the list of possible courses of action because alternative 2 is equal or better on each variable. No decision between alternatives 2 and 3 (or, for that matter, between alternatives 1 and 3) can be made based on the data in [Table 7.3.1](#).

A situation such as is shown in [Table 7.3.1](#) can lead to the development of numerical scores for alternatives and risks.

7.3.5.3 Numerical Scoring

Numerical scoring is another commonly used qualitative way to differentiate between alternatives within different risk categories. This topic is considered a qualitative risk analysis methodology in this chapter because the numerical scores are ordinal. A higher score may be construed as being better than a lower score, but we cannot conclude the degree to which a higher score is better. Just as we cannot exactly specify the difference between “favorable” and “mixed” or “mixed” and “unfavorable”, the difference between scores of 7 and 5 and 4 and 2 may not be equal in an ordinal scale.

This is because of the subjectivity inherent in development of the numerical scores, which should be assessed carefully and repeatedly to ensure consistency. It is possible to develop quantitative scales and measures for difficult-to-quantify variables, but this involves a more complex

TABLE 7.3.1 Examples of Quantitative Scores for Three Alternatives on Three Risks Using the Favorable, Mixed, Unfavorable Subjective Qualitative Scoring Method.

Alternative	Risk 1	Risk 2	Risk 3
1	Favorable	Unfavorable	Mixed
2	Favorable	Mixed	Favorable
3	Unfavorable	Favorable	Mixed

technique than subjective assignment of numerical scores. Thus, decision makers should resist the temptation to use ordinal scores for anything more than alternative comparisons similar to the example in Table 7.3.1.

Sometimes drilling (and, generally, oil and gas) firms develop risk matrices where either verbal categories such as those presented in the single-variable case above are generated for each variable, or ordinal scores are generated for each variable, or both. These often result in large matrices with ordinal scores in individual cells. In these cases the idea is the same; the matrix maybe used as a filter to identify undesirable, dominated alternatives.

Using qualitative analysis as a filter to remove drilling and/or drilling-investment alternatives that are dominated by others as was shown in the simple example above in Table 7.3.1. In order to proceed with a multi-objective analysis, further assessments must be made in order to develop utility scales for each evaluation measure and criteria weights must be established in order to implement an alternative-selection model [2]. The process for doing a quantitative multi-attribute decision model is beyond the scope of this chapter; the reader is encouraged to consult one or more of the many decision analysis references on this topic.

7.3.6 Quantitative Risk Analysis

If one or more identified and defined risks are to be quantitatively modeled, then all possible realizations must be defined in a numerically measurable way and must all have associated probabilities. A quantitative measure must therefore be established. Money is an obvious measure, but the risk-analysis methods presented here are applicable to non-financial measures that are cardinal—as opposed to the ordinal measures discussed above—measures. A cardinal measure is one where the differences between levels on the measure are meaningful. Thus, the difference between \$100 and \$50 is easily understood. In the case of an ordinal measure, all that can be concluded from scores of 100 and 50 is that one is greater than the other. Any conclusions about relative worth cannot safely be reached in the case of ordinal measures.

The quantitative characterization of the risk must be complete—all possible outcomes measured on the dimension of interest (such as money) must be identified and the sum of the outcome probabilities must be one. A qualitative risk assessment may be useful as a precursor to a quantitative assessment, particularly when a decision situation features many risky variables with multiple interactions. The qualitative assessment can be used as a risk filter to help analysts and decision makers identify the variables that are most critical and therefore should be subject to the time and effort (by eliminating undesirable alternatives) associated with a correct quantitative modeling analysis.

7.3.6.1 Assessment of Risk Distributions

Risky variables have to be modeled in order to be useful in an analytical capital-investment decision process. We present an example modeling exercise in which the objective is, as of 3 April 2015, the estimation a distribution of the spot price for WTI crude oil in April, 2016. The objective of the risk assessment is specification of a distribution instead of a point estimate. Assessing a probability distribution for critical variables can be a painstaking—perhaps even painful—process, but for major decisions with critical risks, it is a process that should be undertaken. Use of point estimates for critical variables, particularly variables that are easily measured (though not necessarily easily modeled), is not conducive to development of a valid risk or decision model.

Anytime a risky variable can be characterized by an exhaustive list of outcomes and associated probabilities, that risky variable may be said to be modeled by a probability distribution. Of course, a valid probability distribution—where outcomes and probabilities together comprise an accurate representation of the risky variable at hand—is very important. Many bad decisions can be made based on invalid probability distributions. Much of what follows in this assessment section is a discussion of methods that may be used to generate valid and useful probability models for critical risks.

First, though, a short review of probability distributions is presented.

7.3.6.2 Review of Probability Distributions

If we define a discrete random variable (that is, a measure of a risk that may take more than one integer value in a non-deterministic way) Y , then the probability that $Y = y$, where y is some possible realization of Y , is written as $\Pr(Y = y)$. Discrete drilling risks that could be modeled include the number of major problems—either in total or of a specific type—in a pre-specified time period or on a per-well basis.

If there are I possible outcomes for Y and the list of those outcomes is exhaustive, then

$$\sum_{i=1}^I \Pr(Y = y_i) = 1 \quad (7.3.1)$$

And the expected number of events may be computed as

$$E(Y) = \sum_{i=1}^I Y \Pr(Y = y_i) \quad (7.3.2)$$

The variance (Var) of Y may be computed as

$$\text{Var}(Y) = \sum_{i=1}^I \Pr(Y = y_i)(E(Y) - y_i)^2 \quad (7.3.3)$$

Once the distribution has been assessed by determining outcomes and probabilities, the distribution can be used in decision making as is shown below.

For a continuous distribution, the probability measures are for intervals rather than specific values. For example, instead of $\Pr(Y = y)$, the measure is whether the realization of the random variable is less (or greater) than y : $\Pr(Y \leq y)$. If $\Pr(Y \leq y) = k$, then y is expressed as the “ k ” or “ k th” fractile of the distribution.

For the overall distribution probability density function (pdf),

$$\int_a^b f(Y)dY = 1 \quad (7.3.4)$$

where a and b are lower and upper bounds for the risky variable with probability distribution $f(Y)$. Note that, unlike the discrete-distribution case, the use of $f(Y)$ implies a specific probability distribution function has been implemented. Examples include the well-known normal distribution $(a, b) = (-\infty, +\infty)$; the beta distribution, the exponential distribution, and the triangular distribution—for all of these (a, b) can be determined on a case-by-case basis.

In order to develop a model for a variable characterized by a continuous probability distribution, the assessment process should result in specification of at least three distribution fractiles for the risky variable under consideration.

The example presented here is development of a probability distribution for the price of WTI crude oil in mid-April, 2016 as hypothetically assessed in April, 2015. Assessing a distribution as an input to the capital investment decision making process instead of a static, single-price estimate is preferred because (a) the distribution will allow the riskiness of the decision to be formally represented, and (b) the process of assessment of the distribution will require that decision makers think hard about this (or any other) very important risky input [1, 6, 7].

The goal of assessment for a key variable is to develop probability and outcome information for that variable. This provides the decision maker(s) with a probability distribution that may be used in many different types of decision models. Assessment provides a way to avoid merely asking an expert for a number or series of numbers [8, 9]. Instead, utilizing a proven assessment methodology allows the expert to provide thoughtful estimates based on comparisons between hypothetical decision scenarios (see below).

A y -fractile X_y of a distribution, in this case a continuous probability distribution, is the value for which the probability of actually observing that value is less than or equal to y . In the case of a forecast price distribution for price P in April 2016, $X_{0.95}$ is the 95% fractile of the price distribution if the consensus is that the actual, realized price P will be less than or equal to $X_{0.95}$ with a probability of 0.95. In other words, the experts providing the assessment are 95%

certain that the actual price will be less than or equal to $X_{0.95}$. Thus,

$$\text{Probability}(P \leq X_{0.95}) = 0.95 \quad (7.3.5)$$

At least three values for the distribution of the risky variable should be developed using the assessment process summarized below. Inputs to the assessment process should be provided by an expert with help from an analyst who can assist the expert in thinking through the hypothetical scenarios required by the assessment methodology.

Preferably, the $X_{0.95}$, $X_{0.05}$, and $X_{0.5}$ (the median) fractiles should be assessed. This is advantageous from a modeling perspective. However, many people may struggle with the notion of probabilities of 0.95 or 0.05. Unless the individual(s) being assessed are well-versed in probability and in assessment (as discussed above), the assessment must be done with great care. Some practice will help, and the modeler(s) should be aware that assessment of the three fractiles should be done in several sessions to ensure consistency (Figure 7.3.2, Page 33).

Note that both outcomes represent gains in this hypothetical case. The desirable outcome should be much “better” than the acceptable outcome, but the acceptable outcome should be just that. Care should be taken to ensure that hypothetical outcomes are relevant for the decision maker/expert—they need not be relevant to the firm because the objective is to “extract” probabilistic information from the subject.

Examples of desirable outcomes might include all-expense-paid vacations, sporting-event tickets and associated transportation and hotel rooms, or other outcomes that are desirable to the expert whose distribution is being assessed. Note that the outcomes are not, and should not be, measured in financial terms.

On the other hand, an example of an acceptable outcome might be a good lunch or an afternoon off.

The analyst should assist in the process by iteratively changing X values in a manner that encourages the expert to think hard about the value for which he is truly indifferent. Once the X value associated with a probability of 0.5 for receiving the desirable outcome in Alternative B, the median fractile of the price distribution has been assessed. The next step should be to assess at least two more fractiles, preferably toward the ends of the future-price distribution. Thus the next two fractiles should be the (0.05, 0.95) fractiles—or the (0.1, 0.9) fractiles.

The human mind uses some well-known heuristics when confronted with the need to specify specific values such as X in this assessment example [10, 11]. For that reason, it is probably preferable to begin the assessment with one of the end values—either 0.05 (or 0.1) or 0.95 (or 0.9), and do the median assessment last.

Once the assessment is complete, the distribution will be estimated with at least three subjective, but

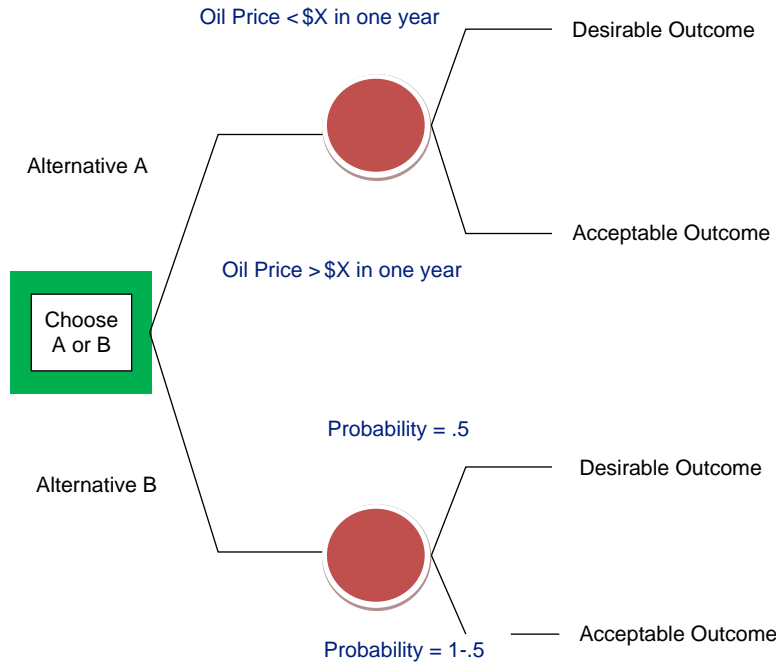

FIGURE 7.3.2 Representation of the assessment process. The expert(s) are asked to specify a future price level \$X that makes them indifferent—unable to choose—between alternatives A or B. Note that if the price of the commodity is less than X, the decision-maker who chooses alternative A will receive a desirable outcome. On the other hand, if the decision maker selects alternative B, there is a 50/50 chance of the desirable outcome.

methodologically assessed, fractiles. For example, the price of oil in mid-April, 2016 may be estimated using the following assessed fractiles:

The assessed fractiles shown in Table 7.3.2 may be interpreted as follows. The hypothetical expert who might have provided the judgments about the future price of WTI crude oil in mid-April, 2016 shown in Table 7.3.1 believe that

$$\text{Pr}(\text{Price} \leq 35) = 0.05 \quad (7.3.5a)$$

$$\text{Pr}(\text{Price} \leq 57.27) = 0.5 \quad (7.3.5b)$$

$$\text{Pr}(\text{Price} \leq 90) = 0.95 \quad (7.3.5c)$$

where “Pr” denotes “Probability”. Note that, if this were an actual assessment, the expert is also providing a 90% confidence interval for the future price:

$$\text{Pr}(35 \leq \text{Price} \leq 90) = 0.9 \quad (7.3.6)$$

We may write the three assessments as pairs, viz

$$(0.35, 0.05) \quad (7.3.7a)$$

$$(57.27, 0.5) \quad (7.3.7b)$$

$$(90, 0.95) \quad (7.3.7c)$$

Figure 7.3.3 contains a graphical presentation of the cumulative distribution derived from the example price

FIGURE 7.3.3 Graphical presentation of two WTI price assessments. Note that the second cumulative probability distribution assessment (Cumul 2, in red) has two more assessed points than the first (Cumul1, in blue). Also note that the probability of the price in April, 2016 being less than \$150 is less than 1.

assessment. Note that there are two cumulative distributions, one for the example data in Table 7.3.2 and one for an assessment (Cumul2) that featured two additional fractile assessments: (45, 0.25) and (82, 0.75).

Assessed cumulative distributions may be used, cautiously, for price estimations in April 2016. For example, suppose that a minimum price of \$70 in April 2016 is

TABLE 7.3.2 An Example of Three Assessed Distribution Fractiles for the Price of WTI Crude Oil in Mid-April 2016.

Fractile	April 2016 Estimate
0.05	35
0.5	57.27*
0.95	90

*indicates the futures price for April 2016 delivery on the NYMEX exchange as of 3 April 2015 (www.cmegroup.com). The futures price is a reasonable initial estimate of the median future spot estimate price—the price that is in the center of the distribution with regard to mass—for the distribution because the futures market is efficient and most WTI crude futures traders can be considered to be experts at synthesizing all available information [5]. Thus the futures price is an equilibrium, expert evaluation of the expected future price of the asset at the time the price was observed.

required for consideration of a potential development venture. From the first cumulative distribution,

$$Pr_1(\text{Price} \geq 70) = 1 - 0.69 = 0.31 \quad (7.3.8)$$

where the subscript denotes the cumulative distribution serving as the basis for the estimate, and

$$Pr_2(\text{Price} \geq 70) = 1 - 0.63 = 0.37 \quad (7.3.9)$$

The differences in these estimates are explained by the extra two assessed data points that characterize the second assessment of the same price variable. If the assessment was done carefully and correctly, the extra information leads to a slightly more confident assessment of the chance—still well under the median estimate of .5—that the WTI spot price will be greater than \$70 in mid-April 2016.

7.3.7 Risk Estimation and Modeling Using Data

In many drilling decision situations, historical data for the variable under consideration may be available, sometimes in large quantities. The presence of historical data does not eliminate the need for expert judgment and, perhaps, an assessment process. Data should never be ignored, and the assessment process can be used to provide updated estimates that enable expert judgment to be considered in addition to the distribution estimate(s) provided by data [12].

For example, the distribution depicted in Figure 7.3.4 is based on historical WTI daily price data available from the US Energy Information Agency (<http://www.eia.gov/dnav/pet/hist/LeafHandler.ashx?n=PET&s=RWTC&f=D>).

When using historical price data to evaluate a future spot-price distribution, it is often preferable to think about future prices in terms of percentage differences from current (or past) price or prices. This is because the distribution for (in this case, annual) changes is easier to model and also easier to use to forecast the price distribution for the future date.

Annual percentage changes (AC) can be computed on a daily basis as follows:

$$AC_t = \frac{\text{Price}_t}{\text{Price}_{t-1\text{year}}} - 1 \quad (7.3.10)$$

where t is any day in the price sequence. The price at that time is compared with the price one year before (usually this will be around 250 business days before) to generate the annual change as of that day. We can compute this measure for as many days as we have preceding-year data.

For the WTI data from eia.gov, a histogram of annual prices changes (also known as returns in a financial context)

FIGURE 7.3.4 Annual WTI price changes, observed daily, from January 1987 to March 2015. Note that while this histogram of the probability distribution appears to have a single major peak at around -0.02, the distribution is not symmetric, and the normal distribution should not be used to represent these data.

from January, 1987 through March, 2015 is shown in Figure 7.3.4.

The average annual WTI price change over this period was 7.2%, and the median change was 11%. The maximum price drop was 68% (−68%), and the maximum day-to-one-year change was 165%.

The 5% fractile—the annual change that was smaller than 95% of the changes—is −36%, and the 95% fractile is 73%. Using these data, along with the median of 7.2% and the spot price of 49.14 (<http://www.oil-price.net/>), results in a cumulative distribution estimate of (31.24, 0.05), (52.7, 0.5), and (85.04, 0.95) [7].

Figure 7.3.5 shows the new estimates superimposed on the example assessments in Figure 7.3.4.

At this point, the expert(s) can be consulted once again. This should be done in the context of the influence diagrams above—given the data in Table 7.3.3 below, what is the best estimate of the WTI price distribution going forward?

The example data-driven assessed values are consistently lower than the subjectively assessed price fractiles. This may indicate an expert that believes that the future will be different from the summary of the past as presented in the data. It should also be noted that the data summarize 28 years of prices, and a subset of those data may be more appropriate to generate the data-driven fractile values.

The output of a process such as the one demonstrated in this section should be the same: a probability distribution for the variable—in this case, the spot price of WTI crude in April, 2016. Note that the example above is in the context of estimation of the WTI price for one period in the future.

7.3.8 Multiple Variable Quantitative Risk Assessment

Influence diagrams, such as the more-general diagram shown above in Figure 7.3.1, can also be used to help develop comprehensive models of multi-factor risks, such as

TABLE 7.3.3 Summary of the Three Point Example WTI Future Price Assessment (Cumul 1), the Five-Point Assessment (Cumul 2), and the Data-Driven 3 Point Assessment (Data)*

Fractile	Probabilities		
	Cumul 1	Cumul 2	Cumul 3
0	0	0	0
31.24			0.05
35	0.05	0.05	
40		0.25	
52.7			0.5
57.27	0.5	0.5	
82		0.75	
85.04			0.95
90	0.95	0.95	
200	1.00	1.00	1.00

*These data are presented graphically above in Figure 7.3.6. Note that an absolute upper bound of \$200/barrel for the WTI price in April 2016 was used in this example.

cost. An example of a five-factor (A-D) total cost influence diagram is shown below in Figure 7.3.6.

Risks A–D in Figure 7.3.6 should be carefully identified and defined as before with the general diagram. Once the decision has been made to develop discrete distributions for each cost component, the next step is to assess specific outcomes and associated probabilities for each activity, and to combine these assessments in a single cost probability distribution [13].

The number of outcomes to consider for each activity is a decision that the modeler must make. If there are two out-

FIGURE 7.3.5 The two assessed April 2016 distributions and the data-driven distribution estimate (labeled “Data”). Note that the second cumulative assessment should be considered the most conservative of the 3, but these example assessed cumulative distributions are very similar.

FIGURE 7.3.6 Hypothetical example diagram showing drilling-cost risks as sequences with feedback loops to show cost dependencies between cost categories. Letters A–D can be seen to represent unique identified costs, such as Site Preparation, Drilling, Produced Water, and Completion. Note that cost events in activity C can impact costs in its predecessor—perhaps by forcing a do-over in the predecessor activity because of a negative event in a successor.

comes modeled for each activity, this will result in $2^4 = 16$ total cost outcomes in the model; three outcomes modeled for each activity will result in $3^4 = 81$ total outcomes and so on. Outcomes may come from data, subjective expert judgment, or—preferably—both. Risky cost outcomes may be assessed as either a list of (exhaustive) discrete cost outcomes or they may be assessed as a continuous probability distribution for each cost factor.

Assessing continuous distributions for any risk factor involves two critical steps:

- Picking a distribution function
- Picking parameters for the distribution

Too often modelers select a normal distribution as the appropriate distribution function, and then estimate the mean and variance (the distribution parameters) from existing data. This may be problematic for two reasons:

- The normal distribution is not appropriate because the cost data are not symmetric and/or because extreme cost events are more likely than would be expected given a normal-distribution model.
- Parameters chosen based on historical data may be irrelevant for the current decision situation.

A wide variety of continuous distributions exist for modeling of cost and other distributions. An excellent, flexible candidate is the beta general distribution. However, assessing the parameters for this 4-parameter distribution must be done with great care. Further, unlike the normal distribution, the distribution resulting from combinations of beta general distributions is often difficult to specify without the use of simulation.

On the other hand, discrete outcomes are associated with a discrete probability for each outcome. As noted above, the sum of the set of probabilities for outcomes associated with each risk factor must be one.

In the discrete-risk (in this example, cost) model case, probabilities for each outcome should be carefully assessed

using a variation of the assessment method presented above or a similar, proven assessment technique. Probabilities should be assessed for individual, factor-specific outcomes when those outcomes are independent of outcomes from other cost factors. Conditional probabilities should be carefully assessed for dependent activities, such as cost-factors B and C in Figure 7.3.4.

A conditional probability is generally written (in the context of the example in Figure 7.3.6) as $\Pr(C|B)$, which may be read as the “probability of cost C given predecessor cost B.” If risks B and C are independent, then $\Pr(C|B) = \Pr(C)$.

For example, suppose two outcomes and associated probabilities for each of the four risk factors in Figure 7.3.4 are assessed. Define these as A^+ and A^- as the better and worse cost outcome for cost A, with similar definitions for two assessed cost outcomes for factors B–D. Probabilities are defined as $\Pr(A^+)$ and $\Pr(A^-)$, with $\Pr(A^+) + \Pr(A^-) = 1$.

This would result in a total drilling cost distribution with 16 outcomes and associated probabilities. The best outcome, which we can call Outcome 1 (O_1) is:

$$O_1 = A^+ + B^+ + C^+ + D^+ \quad (7.3.11)$$

with probability

$$\Pr(O_1) = \Pr(D^+|A^+, B^+, C^+) \Pr(C^+|A^+, B^+) \Pr(B^+|A^+) \Pr(A^+) \quad (7.3.12)$$

which reflects conditional cost probabilities given the level of all predecessors for each factor. In the unlikely event that all cost events are independent, then

$$\Pr(O_1) = \Pr(A^+) \Pr(B^+) \Pr(C^+) \Pr(D^+) \quad (7.3.13)$$

Similarly, for the worst outcome O_{16} ,

$$O_{16} = A^- + B^- + C^- + D^- \quad (7.3.14)$$

and

$$\Pr(O_{16}) = \Pr(D^-|A^-, B^-, C^-) \Pr(C^-|A^-, B^-) \Pr(B^-|A^-) \Pr(A^-) \quad (7.3.15)$$

and so on for all other outcomes, which will all feature combinations of + and—cost levels for the four factors.

Once this process is complete, a distribution with 16 outcomes and associated probabilities will be assessed. To reiterate, an assessment methodology such as the technique presented earlier in this chapter should be used, and conditional probabilities should be carefully assessed. An experienced assessment subject(s)—one(s) who understand probability and may have been through an assessment process in the past—is preferred for generation of these discrete probabilities.

The mean of the distribution—the expected cost—can be computed as

$$E(\text{Cost}) = \sum_{i=1}^{16} O_i \Pr(O_i) \quad (7.3.16)$$

and the variance may be computed as

$$\text{Variance}(\text{Cost}) = \sum_{i=1}^{16} \Pr(O_i) [O_i E(\text{Cost})]^2 \quad (7.3.17)$$

The variance (or its square root, the standard deviation) is an often used measure of risk. However, the variance should be interpreted in the context of the expected value, as variance numbers by themselves can be difficult to interpret in a meaningful way.

7.3.9 Using Assessed Risks in Evaluation of Drilling Alternatives

Developed probability distributions can be used in proforma capital investment evaluation models where simulation is used to determine probability distributions for output variables of interest.

Use of quantitative risk assessments for multiple future dates may involve the somewhat-cumbersome task of development of multiple distributions. This may require multiple individual distribution assessments. On the other hand, this may be accomplished by shortening the timeframe for a single assessment. For example, a cash-flow analysis done on a quarterly basis can be done by assessing a price distribution for quarterly price *changes* instead of the price itself. Then the quarterly change (return) distribution may be used in the cash-flow analysis.

The key is to match the risk assessment with the timeframe needed in the cash-flow analysis model. On the other hand, single-period assessments, such as is described above, may be incorporated into a decision tree via use of the Pearson–Tukey method for transforming a continuous probability model into a theoretically acceptable discrete model that can be easily included in the decision tree [14].

7.3.10 Conclusion

A risk analysis is only as good as the process used to develop it. For a major, risky, drilling investment decision, the risk analysis process should be the responsibility of one or more people who have the ability to solicit inputs from subject-matter experts and other parties critical to the eventual success of the project.

Inclusion of all key inputs in a methodologically sound way, such as the techniques summarized in this chapter, increases the likelihood of a sound, requisite model that can be used in the allocation of scarce financial resources and physical firm assets. Drilling decision situations are well-suited to risk analysis and use of the quantitative

assessments in decision making provided the risk modeling is done carefully [15].

7.4 PETROLEUM ECONOMIC EVALUATION EXAMPLE

Ronald M. Brimhall and Peter Anselmo

7.4.1 Application of Net Present Value Analysis to Determine Reserves and Value for a Single, Multi-Well Project

Net present value and related calculations determine value of petroleum properties, quantities of petroleum commodities and corresponding economic life. Quantities of producible oil and gas up to the economic live quantify reserves. Nearly all economic valuations of petroleum assets are based solely on decline curve analyses without consideration of material balance parameters and their effects on

reservoir pressures and declining rates and their effects on value.

Annual oil prices were estimated using the method and two-scenario 40-quarter model presented earlier in this chapter, and all financial results presented here are based on that implementation. Annual prices were computed as the average of four consecutive quarters, and prices for years 11 and on were equated to the simulated 10-year price. Note that, because of the stochastic nature of the price model and the fact that each simulated price path is unique, values for key financial variables are presented as expected values instead of point estimates [1].

Net present value analysis of the asset evaluated as an example, *Gusher 7-III-B Asset*, results in an Expected NPV (E(NPV)) at 10 years of \$4.81 million, at 20 years of \$19.95 million, an expected economic limit of 17.4 years with an E(NPV) of \$19.89 million. The expected internal rate of return E(IRR) at 10 years is 16%, it is 18.4% for a project held for 17 years, and if the investment is held for 20 years the annualized E(IRR) is 18.3%.

According to the example Management Guidelines for screening assets, IRR is unacceptable ($< 25\%$), net present value is acceptable ($> \$10,000,000$) if the asset is held for the expected lifetime of 17 years or for 20 years.

If management decides invest in this asset, engineering is advised to develop a plan to reduce costs at beginning of operations and to consider selling the asset after the 10th year.

7.4.2 Introduction to Net Present Value and Simulation Modeling for Project Evaluation

This section is concerned with presentation of the results of a spreadsheet model for an example 40-well development project. The objective is illustration of how to combine property and economic factors in order to develop an analysis whose results might be useful to management in evaluation of individual properties and/or other alternatives.

The key is specification of costs (outflows) and benefits (inflows) that are due to a project. Only outflows and inflows that are (projected to be) directly attributable to a development project should be considered. Costs and benefits are almost always going to be directly related to physical characteristics of the property in question combined with company (expertise, financial capacity, cost control) and market (commodity price) factors.

This section is concerned with specification of the links between physical factors such as production rates for oil and water and company factors such as costs and market factors such as prices. We present an example development alternative and show the process of generating data that can be used in decision making.

An important caveat is that an evaluation model is only as good as its inputs and the way(s) those inputs are connected to produce projections in the form of model outputs. The modeler/analyst should always be specific about assumptions and other factors that contributed to the development of the model. In that spirit, we note the following:

1. All factors were initially treated as constants. Decline rates, produced water levels, and other production factors are modeled with state-of-the art techniques.
2. Oil (but not gas) prices are modeled using a geometric Brownian motion with Mean Reversion model as described in Section 7.2. This was the only non-constant price that was modeled, as this is intended as an example.
3. The only downstream decision alternative evaluated is the abandonment (through sale or other means) time for the project. We considered 10-, 17-, and 20-year lengths for the project.
4. Benefits from abandonment, such as sale of the property and/or equipment salvage, are not considered.
5. Depreciation is not considered in the cash flow model. This is associated with leasing of capital equipment or use of already-depreciated equipment owned by the development company.

Item 3 in the above list has to do with the notion of real options, which may be thought of as the ability—but not the requirement—to change the project after it has begun. Selling of ownership shares, shutting in of some wells, increasing the number of wells, and/or abandoning the project are all examples of real downstream options associated with a major development project.

A more comprehensive analysis would involve input from company personnel with regard to feasible downstream decision options to include in a capital allocation analysis. Inclusion of the option to pursue additional downstream alternatives, often when key uncertainties have been resolved, will often increase the time-0 valuation of an investment project.

7.4.3 Evaluating Petroleum Properties

The goals of petroleum economic (property) evaluation are five-fold:

1. What are the reserves and how would a rational observer classify them?
2. How much are the identified reserves worth in present value?
3. Can the company (management) afford the cost and meet an acceptable rate of return?
4. What outside influences effect our decisions to invest?

5. Choices of investment opportunity will be constrained by management's ability to invest from limited funds. Management will always be faced with limited funds and choices.

Reserves and value are inter-related and cannot be evaluated separately. Reserves effects value and values effect reserves—as in “one hand washes the other.” A petroleum property with higher quantity of producible petroleum that may be may not be the most profitable or have the greatest potential for profit. Conversely, a petroleum property with a lower quantity of reserves may be the more profitable (greatest return on investment). Who or what then, decides profitability? Therein is the rub.

The short answer is “management” and the guidelines that have been established for minimum standards to gage the company's measure of profitability. The long answer to deciding profitability is related to the collection of rules, regulations, guidelines, management philosophy, technical parameters, size and shape of reservoir with all the complexities and distributions of stratigraphy, sedimentation, porosities, thicknesses of layers; original oil, water and gas in place; flow characteristics and fluid properties; production method(s), environmental constraints, etc. for the property, or properties, under consideration. The evaluation of reserves and profitability may be limited to one property or, as is the usual case, may encompass several properties.

After taking into account all the relevant geological, engineering, environmental, and economical variables, do we invest in an asset, or perhaps a collection of assets? How much money do we have, or have from outside investors, what is the cost of money (capital), and can we afford required investments? What are the risks associated with relevant parameters that are known within some limits of certainty? What are the risks in product prices for which oil and gas may be sold? What are environmental costs for water disposal and reclamation?

The decision outcomes are then based on models depending on guidelines established by “management,” with inputs from technical staff, and constraints imposed by “investors.”

7.4.3.1 Property Valuation Methodology

The first element of oil property evaluation is this: A monetary value in the future will be worth less than the same monetary value today [1]. A million dollars in 2032 will be worth less (Net Present Value ~\$150,000 @ 20 years and 10% discount rate) than a million dollars (\$1,000,000) today. Another way of looking at time value of money is this: A purchase for \$150,000.00, at the As of Date will cost \$1,000,000.00 in 2032—at least on paper.

The second element: The procedure and methodology are not linear, in other words the method involves starting the analysis with volumetric, material balance and decline

curve calculations based on known (analogy), or assumed reservoir and fluid properties and the evaluator must be prepared to re-do the calculations as new information is developed.

Third element: Reserves are amounts of oil and gas that may be produced economically (meaning present value income greater than present value costs) with specified technology. If applied technology changed, then produced quantities (reserves) and NPV will change. What may be considered economical for one company may not be considered economical for another. What is considered economical at the “As of Date” may not be economical at some date in the future.

Fourth element is reservoir pressure correlated with fluid production and water influx. This allows the engineer to assess production history or production in the future with material balance and operational reservoir pressures—most important precursor to decline curve analyses. Sole reliance decline curves analyses may be the only recourse, but may not always give the better information for management to base investment decisions. The best results are expected from factors that are “known” from property and technical records and from production history. Unfortunately, this may not always be possible, and certain assumptions may be necessary. Why? Many important factors are not known because of poor practices on the part of operators in keeping records. So what do we do? Live with our assumptions and, if possible, apply risk assessments as described in another section of this chapter.

A complete evaluation of a petroleum asset will include the following analyses:

1. Gathering data
2. Geological parameters and fundamental controls
3. Log and core data
4. Fluid properties
5. Reservoir volumetrics for oil, gas and water
6. Original in-place volumes of oil, gas and water
7. Production history that includes volumes of all fluids produced and reservoir pressures
8. Material Balance calculations with relevant water influx determinations
9. Decline curve analyses for the appropriate reservoir
10. Economic parameters
11. Spread sheet formats easily are adapted for calculating all relevant parameters that define the evaluation
12. “Management” guidelines for investment
13. Reporting results

In practice, especially where a large number of assets are included in one package, a detailed analysis, as suggested above, would not be done because of time and economic constraints. Usually, economic evaluations are based on decline curve analyses only with minimal consideration given to volumetrics and material balances as they describe

reservoir performance. Reservoir performance and economic performance are closely inter-related.

What is the significance of volumetric and material balance calculations? The answer is to obtain a suitable answer to NPV issues. These engineering tools allow checking results from decline curve analyses to assure the proper fit with the controlling parameters that effect production. Reservoir pressure history and corresponding recoveries depend on what happens between anticipated well performance and corresponding reservoir response. In many cases, decline rates are determined by the methods of “by-guess and by-golly” (i.e., analogy and experience). The seller will naturally pick a somewhat arbitrary low rate of decline, whereas the buyer will pick a somewhat high decline rate. The low decline rate makes the calculated (Read “on paper”.) present value high—benefiting the seller by higher present value—on paper. The higher decline rate makes the calculated present value low—benefiting the buyer in lower costs of investment—on paper.

Results on paper do not represent the ultimate reality of investment and production, nor do they represent ultimate agreement between buyer and seller. Results on paper give rational values of cash flows and present values to aid in making investment decisions after the negotiation phase.

Most investment decisions are related to answering three fundamental questions. Do we buy? Do we sell? And what is a mutually agreeable price?

The example presented in this chapter demonstrates the basic steps in completing a net present value analysis for investment opportunity.

7.4.3.2 Spreadsheet Format

Spreadsheet formats are one of the most useful tools developed for many useful calculations, especially in solving problems in engineering [2]. Net present value problems (NPV) in association with geological and reservoir engineering considerations are most easily solved with spread sheets. Commercial spread sheet programs offer petroleum industry methodologies that rapidly solve multiple-asset properties solutions to NPV based on decline curve analyses. Most cases do not allow for incorporation of volumetrics and material balance considerations. This is not bad. Many good, and profitable, business decisions have been made based solely on decline curves. Many difficult NPV analyses could be better understood by utilizing volumetrics, material balance and fluid property calculations that include reservoir pressures. Predictions of reservoir pressures are important to determination economic limits and points in future when changes in means of production must be made for maximum recovery, and perhaps maximum NPV. Reservoir pressures, as functions of production history, offer an invaluable aid in determining economic limits,

and consequently, quantities of reserves and classifications of reserves.

What is expected as major outcomes from NPV analyses? Spreadsheets should be setup to determine the following by using iterative methods where necessary.

1. General Input Data: Beginning data requirements needed to accomplish . . .
2. Static Fluid Volumes: Original in Place
 - Oil, including solution gas
 - Water
 - Free gas
3. Factors that control water influx based on hydrogeological considerations. Ground water flow analyses extend well beyond the area of the reservoir!
4. Material balance considerations, including gas compressibility determinations
5. Well performance
6. Net Present Value and Internal Rate of Return at Base interest rate (say 10%)
7. Net Present Value, rate of return and Internal Rate of Return at interest rates other than base rate. May include 0.15 to 0.3 in 0.05 increments.
8. Management guidelines as prerequisites to decision making (To buy? To sell?)
9. Cash flow summary sheet(s)

Evaluators should consider items 1–8 as technical input to 9, the cash flow summary sheet(s). Decisions will be made on the cash flow summaries.

7.4.4 Example Property Evaluation

Introduction: This example illustrates the fundamental steps required to complete an economic evaluation of one petroleum asset. Petroleum assets contain certain common features, but all are decidedly different from each other. Thus, expertise and creativity must be applied to develop NPV analysis for each case. [This example is hypothetical and is the result of 60 years of experience. Any resemblance to an actual petroleum asset is purely coincidental.]

7.4.4.1 NPV Analysis: Gusher 7-III-B Asset

The Gusher 7-III-B Asset reservoir and production facilities consists of an existing field with wells and production facilities in place, but *no production history*. The field is classified as a proved undeveloped (PUD) because of its proximity to fields with similar reservoirs, fluid contents and distributions and production methods in proximity. Every facility needed for production is in place prior to any production actually taking place. (*Yes this is abnormal and somewhat unrealistic, but is a good starting place to demonstrate the methodology.*) By analogy and by geological

drilling and completion records, it is known the reservoir has a free gas cap, is associated with an active water drive, and production declines are more nearly hyperbolic in nature than exponential or parabolic.

Principle actors in this scenario are Seller—Gofer Broke, LLC and Prospective purchaser—“Buyer”. Asset is identified as Gusher 7-III-B Asset, Location: New Dorado Field, Oz-ee County (Any State). The reservoir is called By-Name Only.

7.4.4.2 General Input Data

Complete table of general input data, upon which all calculations will depend for the example NPV analysis (Table 7.4.1):

The field has an aerial extent of 2400 acres and 25 wells have been drilled, completed and equipped for production. As of 1/1/2012, the *As of Data* for which all time and time-value calculations are taken, the initial reservoir pressure is 2300 psi at 0’ msl. The nominal surface elevation is 4786 feet and mid-point elevation of average perforations is 0’ msl.

Some, but not all input data may come from information related to producing fields within a “reasonable” distance from the Gusher 7-III-B Asset. For this case, decline analyses suggest decline is more nearly hyperbolic with initial decline of 0.1 and decline exponent 0.6. Water production rate

Geological parameters and fundamental controls: The example asset is located in a geologic structural basin

		Water compressibility/(vol/vol/psia)	0.0000036
		Reservoir and Aquifer Rock Comp. vol/vol/psia	0.0000036

encompassing some 1500 square miles in a Rocky Mountain state. The topography is uplands with surface elevations ranging from 4000 feet to in excess of 8000 feet. Drainage in is general southwestward to the confluence of major rivers. The field is located near central to the structural basin. The aquifer is subject to near constant recharge at, or near, the outer boundary.

Log and core data: Major reservoir descriptors include structural high, sandstone and shale stratigraphy in the gas cap, oil zone and base water. Porosities range from 8% to 28% (22% average) in the oil zone and from 5% to 20% (15% average) in the gas cap. The aquifer, bottom and edge water drive porosities average 15%. Water saturations average 44% in the oil zone and 30% in the gas cap. The aquifer is assumed to be 100% water saturated and contains 5,000,000 acre-ft of water.

Fluid Properties: The properties of fluids most necessary for reservoir studies are formation volume factors (B_o , B_g , B_w , R_s , z ; compressibilities of formation rocks and water; amounts of N_2 , H_2S , and CO_2 ; and average reservoir pressures, all as functions of time. The time factor on fluid properties and pressures impacts production of reservoir fluids and, consequently, NPV. It may be argued that fluid properties measured in laboratories on bottom-hole samples of oil, water and gas are better than fluid properties obtained from correlations based on API gravities and bottom-hole temperatures. There is some merit to this contention, but rarely are lab measurements available in sufficient quantity to assist in the analysis. Therefore, correlations based on reservoir temperatures from logs, on gravity measurements from surface samples, minimal composition determinations and gas/oil ratios from production data. Therefore, the use of correlations for fluid properties may be the only recourse to getting recommendations to management.

Spread sheets should be programmed to estimate fluid properties using correlations from McCain [3].

7.4.4.3 Static Fluid Volumes: Original in Place Fluids

The significance for calculating original oil, gas and water in place is to form the basis for accuracy and reliability of final results. Usually original volumes of fluids may be estimated with a level of accuracy sufficient to use a standard for gauging reliability of other parameters in the analysis. Now understand, more reliability doesn't necessarily equate with true values. There is inherent inaccuracy in volumetrics because volumetric data is not perfect, nor will it be interpreted with perfection, but under the hand of experienced geologist and engineers the volumetrics form the basis for checking results of material balance values and corresponding reservoir pressures as function of times; and, checks and balances on production figures and reservoir

pressures. This will lead to better determinations of fluid volume factors—which effect fluid material balance and, also one would think this leads to “better” NPVs.

7.4.4.4 Reservoir Volumetrics for Oil, Gas and Water

Equations for reservoir volumetrics form the basis for methodologies programmed into spread sheet tools [4].

$$\begin{aligned} & \text{Total OOIP / stb for reservoir in n layers} \\ & = \sum_{i=1}^n \frac{7758A_i h_i f_i (1 - S_{wi} - S_{gi}) [\text{#bbls}]}{B_{oi} [\text{#bbls/stb}]} \quad (7.4.1) \end{aligned}$$

Similarly, for gas reservoirs in n layers:

$$\text{Total OGIP / MMSCF} = \sum_{i=1}^n \frac{1.546A_i h_i f_i (1 - S_{wi} - S_{oi}) \bar{p}}{z_i (460 + T (^{\circ}\text{F}))} \quad (7.4.2)$$

From the data presented above, the initial volumetric calculations for Gusher 7-III-B Asset are:

Original Oil in Place	196,000,000 Stbo
Original Gas in Place	96 Bscf
Original Water in Place	198,000,000 Stbw
Original Reservoir Pressure	2300

The data above and in Table 7.4.2 represent not only original fluids resources in place in the reservoir, OOIP, OGIP, and OWIP as they exist prior to the analysis, but also volumes of water produced and injected and water influx; volumes of oil produced as determined by decline methods and material balance calculations; volumes of gas produced. Fluid balance represents the change from original in-place fluids to the fluid content near the economic limit. Gas remaining is greater than gas originally because production is primarily from oil zone and free gas remaining in the reservoir because of relative permeability effects.

Oil in place value of 196,000,000 stbo is the standard to which material balance calculations will be compared to determine incremental volumes of fluids produced and corresponding reservoir pressures. The volumetrics are considered correct. Iterative calculation methods are incorporated in to the spread sheets. Reservoir/well performance, which forms the basis for NPV calculations, is shown below:

Volumetric calculations indicate reservoir and gas cap pore volume is 537,600,000 reservoir barrels. Original oil in place (OOIP) is 196 mm stbo; original gas-cap gas in place (OGIP) is 96 Bscf. Total water in place, oil zone, bottom water and gas cap, is 198.1 stbw. If we take volumetric recovery factors (Oil: 15%, Gas: 75%) at face value, without considering effects of water influx, time value of money, economic limits, proper decline in rates with time, etc., total oil reserves would be 29 mm stbo, gas reserves 57 Bscf.

TABLE 7.4.2 Fluid Volumes and Balances

7.4.4.5 Production and Production Decline

Production of oil, gas and water are calculated using conventional decline curve analysis [5,6]

7.4.4.6 Water Influx

Factors that control water influx are based on hydrogeological considerations and require study of the reservoir and environs well beyond the immediate map boundaries of New Dorado Field (Table 7.4.3):

Water influx depends on rate of pressure decline in the reservoir. Therefore, pressures determined from material balance are input to influx calculations (Figure 7.4.1, Page 44). Influx is re-input to material balance and pressures are re-determined [7].

7.4.4.7 Material Balance

For a control volume, such as a petroleum reservoir and associated gas and water, the material balance between original quantities of fluids in place and produced fluids and fluids remaining in place post a production period may be represented by

$$\begin{aligned} \Sigma (\text{Changes in Quantities of Fluids in Storage}) \\ = \Sigma (\text{Fluid inflows}) - \Sigma (\text{Fluids Produced}) \end{aligned} \quad (7.4.3)$$

TABLE 7.4.3 Aquifer Properties

Initial Reservoir Pressure PiR	2300.00

 \end{aligned}$$

General Material Balance Equation (Craft, B.C; Hawkins, M.: Terry, R.M.: Applied Petroleum Engineering, 2nd Ed, Prentice Hall, 1991, p 62, Eqn 2.7)

All parameters in the material balance equation are functions of pressure, so iterating the material balance equation on original oil in place and pressure and then comparing results with a relevant and known standard would be a method to determine reservoir pressure [8]. The relevant standard chosen for this example is Original Oil in Place. Forecasted pressures and production characteristics are shown in the graph in Figure 7.4.2.

7.4.4.8 Well Performance

Well performance is determined based on comparing bottom-hole flowing pressure (P_{wf}) with average reservoir pressures (P_j). The pressure differential $P_j - P_{wf}$ must be sufficient to maintain the quantities of production established for decline analyses for the period studied.

Calculated bottom-hole flowing pressures are based on well testing equation for transient conditions in “closed”

drainage area. The closed area effect is due to well interference from open reservoir. Skin and non-Darcy flow effects are considered along with well interference [9] and effects of total flow for oil, gas, water, q_t , and total fluid mobility λ_t :

Bottom-hole flowing pressure is determined by the following:

$$\begin{aligned}
 P_j - P_{wf} = 162.5 \left(\frac{q(t)}{\lambda_t h} \right) * \left[\log_{10} \frac{1688 f_{c_t} r_w^2}{\lambda_t} \right] \\
 + 141.2 \left(\frac{q_t S}{\lambda_t h} \right) + 141.2 \left(\frac{q_t^2 D}{\lambda_t h} \right) \quad (7.4.5)
 \end{aligned}$$

$$\lambda_t = \frac{k_{eo}}{\mu_o} + \frac{k_{eg}}{\mu_g} + \frac{k_{ew}}{\mu_w} \quad (7.4.6)$$

$q(t)$ = Total production of oil, water, gas from Material Balance calculations.

$$P_{wf} = P_{j \text{ from Mat Bal}} - (P_j - P_{wf}) \quad (7.4.7)$$

Well performance for Gusher 7-III-B Asset is shown in Figure 7.4.2. Pressure differential is shown relative to forecast rates for oil, water, gas and water influx. As illustrated, P_{wf} is sufficient to maintain back pressure on the perforations at 0’ msl well past the economic limit. *This suggests an increase in production rate may be warranted.*

FIGURE 7.4.2 Forecasted pressures and production characteristics.

7.4.4.9 Net Present Value (NPV)

All efforts at geological and reservoir studies and the data generated lead to here: What is the property worth? The answer is in the application of the following concepts [10]:

Net present value (NPV(i,n) for a future cash flow =

$$(7.4.8)$$

[Net Sales to Working Interest - Total Costs to Working Interest] * (Single Payment Present Worth Factor (i,n))

$$NPV(i,n) = \left[\sum_{j=n} \text{Sales} - \sum_{j=n} \text{Costs} \right] (SPPWF(i, n))$$

(7.4.9)

$$NPV(i,n) = \left[\sum_{j=n} \text{Sales} - \sum_{j=n} \text{Costs} \right] \left[\frac{1}{(1 + i)^n} \right]$$

(7.4.10)

i = Discount rate, n = time step or year.

Net Present Value remains a widely-accepted and implemented capital project decision criterion. Note that sales and costs are likely to be unpredictable with complete precision. Because of the complexity of field-development models such as in this example, Monte Carlo Simulation is a way to assess the impacts of the riskiness modeled probabilistically in models of critical risky factors in the cash-flow statement.

Monte Carlo Simulation output is typically in the form of a probability distribution summarizing the values gener-

ated for variables such as NPV and IRR. An example of a histogram for NPV for a 10-year project is shown below in Figure 7.4.3.

Similar distributions can be generated from simulated values for 17- and 20-year project windows. All three project length NPV distributions are shown below in Figure 7.4.4.

Note that these NPV distributions, while unimodal (single-peaked), are not normal distributions. Inferences about measures such as the probability of a negative NPV should be made from the data. Making inferences from an actual distribution involves finding a distribution function that best fits the data (this will not be a normal distribution) and then selecting the best set of parameters—given the data—for that function. Only then can non-data-driven inferences about the NPV distribution in question be made.

7.4.5 Return on Investment and Internal Rate of Return

Guidelines that have been established for minimum standards to gage the company’s measure of profitability are varied and depend on individual company goals and operational constraints. The most common minimum standard, and most elementary, are Return on Investment (ROI) [11] and Internal Rate of Return (IRR) [12].

FIGURE 7.4.3 NPV distribution for a 10-year project generated from 1000 simulation runs. The expected NPV is about \$4.81 million, and the probability of a negative NPV is 0.38. The latter point means that 380 of the 1000 observed, simulated NPV values were negative.

FIGURE 7.4.4 NPV distributions for the example project for 10-, 17-, and 20-year project lifetimes.

7.4.5.1 Internal Rate of Return (IRR)

The internal rate of return (IRR) is another measure of profitability that defines a relationship between revenues and sales and may be one of the indicators used by management for investment purposes. Internal rate of return is an interest rate that will cause a present value series of costs to equal the sum of present value for a series of revenues.

In other words, an investment equal to present value of costs that earns a rate of return, the IRR that makes present value revenues equal costs.

Interest rates, other than base rate (0.15 to 0.3 in 0.05 increments) may be included to give some measure of risks.

Mathematically, IRR, may be represented by:

$$\text{If } [PVC(i_1, n) - PVR(xi_2, n) = 0], \text{ IRR is the unknown interest, } xi_2. \tag{7.4.11}$$

Example: Series of Costs and Revenues by year (Table 7.4.4).

The internal rate of return (IRR) can also be generated at each simulation iteration by merely calculating (as mentioned below, using the canned function in Excel) the IRR

TABLE 7.4.4 Example Cost and Revenues

20 Years IRR			
	20.00	l[(Whole \$ Cost)*sppwf(n,i)]	r[(Whole \$ Revenue)*sppwf(n,r)]

11	12/29/2022	56691085.85	
12	12/29/2023	52750433.06	
13	12/28/2024	49230308.36	
14	12/28/2025	46071385.48	
15	12/28/2026	43224595.12	
16	12/28/2027	40649048.57	
17	12/27/2028	38310438.88	
18	12/27/2029	36179797.26	
19	12/27/2030	34232517.09	
20	12/27/2031	32447581.24	

For this example, the IRR is 18.7%. The method of calculation is, by nature, iterative. (XIRR(values,dates,guess))

FIGURE 7.4.5 Simulation data 10-year-project IRR distribution. Note that a substantial portion of the distribution is left of the 0.148 (~15%) level.

for each sample price path.⁶ Similar data-driven inferences may be made; in this case, the probability that the IRR is less than some required rate of return, such as the 15% discount rate used in this example.

Figure 7.4.5 consists of a histogram of the IRR data computed for a 10-year project-ownership window. Note that the probability that the IRR for a 10-year project is less than 15% is substantial. The probability that the IRR for a project is less than the discount/hurdle rate should be the same (or nearly the same depending on the number of simulation runs conducted) as the probability that the NPV of a project is less than 0. This is because of the fundamental relationship between NPV and IRR—if $NPV \leq 0$ then the IRR for that particular cash flow stream is less than/equal to/greater than the discount rate for the project.

Figures 7.4.5 and 7.4.6 contain single 10-year IRR distribution (Figure 7.4.5) and all three IRR distributions (Figure 7.4.6). These distributions are, like the NPV distributions, based on simulation data and any inferences should be made from the data unless a proper distribution-fitting procedure is followed for the simulation data.

If a sufficient number of simulation iterations are carried out (in this spreadsheet-simulation example, 1000 runs were done. This is a minimum number in order to use

the simulation data in project and alternative evaluations), then information about key measures—expected values, probabilities of the realized value being less (greater) than or equal to a cutoff value—can be used in project and alternative evaluations.

Overall expected values and probabilities of negative NPVs are presented below in Table 7.4.5.

The key relationship between cumulative NPV, incremental NPV, and annual expected oil production is shown in Figure 7.4.7. Note that the incremental NPV curve is non-monotonic. This is because this curve represents one set of NPVs from one (out of a total of 1000) simulated price path.

7.4.5.2 Return on Investment (ROI)

Generically ROI may be defined as, “What is the gain in value of an investment as compared with expenses”. ROI is related to both NPV and IRR, and analysts should take care to represent ROI based on undiscounted (close to IRR) or discounted (close to NPV) data. The ROIs presented for this example are for discounted data.

Mathematically, ROI is represented by ratio of sum of present value revenues to sum of present value expenses. In equation form:

$$ROI = \frac{\Sigma(\text{Present Value Revenues})}{\Sigma(\text{Present Value Costs})} \quad (7.4.12)$$

For profitability, $ROI > 1.0$

6. It is important to remember that the IRR is computed from *undiscounted* future cash flows.

FIGURE 7.4.6 IRR distributions for all 3 project-length scenarios. Note that, as was the case for the NPV distributions, the 17 and 20-year distributions are very close and to the right of the 10-year IRR distribution.

TABLE 7.4.5 Summary of Simulation Results for Gusher Asset 7-III-B. Project years refers to the number of years before the project is abandoned or sold (no value was assumed for this in this analysis), E(NPV) is the expected value of the simulated NPV distribution, Pr (NPV < 0) is the probability that the actual NPV will be less than 0 given the discount rate, and E(IRR) denotes the expected IRR. Annual discount rate used: 15%

Project Years	E(NPV)	Pr(NPV < 0)	E(IRR)
10	4.81×10^6	0.38	0.1598
17	1.99×10^7	0.148	0.1845
20	1.95×10^7	0.164	0.183

Another representation

$$ROI = \frac{\Sigma(\text{Present Value Revenues})}{\Sigma(\text{Present Value Costs})} - 1 \quad (7.4.13)$$

A ROI value greater than zero represents profit (Σ (Present Value Revenues) greater than Σ (Present Value Costs)).

An Example: At the calculated economic limit, an investment has cumulative present value revenues of \$2,500,000.00 and sum present value costs of

\$200,000,000.00; the corresponding ROI is 0.25. In other words, ROI is 25%.

Table 7.4.6 contains ROI numbers based on cumulative cost and benefit present values for the three ownership-length scenarios in this example at the 15% discount rate.

These data indicate that the ROI distributions are similar to the NPV and IRR distributions—the standard deviations increase with project life and the three distributions are all rightward-skewed.

The values of all of these financial and technical indicators will be compared with managements guidelines to help determine if this asset meets all expectations for investment.

7.4.5.3 Project Useful Life

In the abstract to this subchapter, we note that the expected economic lifetime of this project is 17.4 years. This is also a simulation-generated expected value that is computed as follows for each iteration of the simulation:

1. Run the simulation, which in this example consists of a simulated price path and all calculations based on that price path
2. Track individual annual NPVs—the discounted sum of benefits less costs for each year. For a project such as the one shown in this example, the first-year cost should always be negative because the initial capital investment

FIGURE 7.4.7 Incremental and Cumulative NPV and Annual Oil Production.

TABLE 7.4.6 ROI Data for the Three Project Life Scenarios

Project Years	E(ROI)	Standard Deviation	Skewness
10	0.016	0.061	0.212
17	0.064	0.076	0.482
20	0.063	0.078	0.513

is considered in the first year of the model. After that in projects such as this one⁷, the annual net NPVs should eventually become positive. These numbers should be tracked until a negative annual NPV occurs.

3. The useful life is measured, on an annual basis, as the project year preceding the first observed downstream negative annual NPV.

In a 1000-run simulation, as was conducted for this report, 1000 useful-life variables will be collected. In this case, 17.4 was the average of all observed useful-life numbers.

7.4.6 Management Guidelines as Prerequisites to Decision Making

Systems of policies are established by management that provide guidelines for proper investment decisions. Each

company will establish their own guidelines and how they are used. Some rules may be rigid, other may be flexible. For purposes of this handbook, Return on Investment (ROI), Internal Rate of Return (IRR), and Net Present Value (NPV) measured against cost of capital will be used.

Management for “Buyer” has established these first-cut policies:

Minimum Discounted ROI is 10% at the economic limit for the asset,

Minimum IRR is 15%. Less risky investments that return less than 20% ROI will be considered. In this case, the required IRR and the discount rate (also known as hurdle rate and, sometimes, the cost of capital) are the same.

Minimum NPV at 10 years must exceed \$5,000,000.00.

The procedure, after NPVs, ROIs and IRRs are determined, is to compare calculated values with the guidelines. Properties and assets for which the calculated values are less than the guideline values may not be considered further and other prospective assets will be evaluated for investment.

In this case, management would accept the project based on IRR and NPV criteria, and reject the project based on the ROI criterion. Care must be taken in setting multi-faceted objectives such as these because they are interrelated.

The reader will note that a NPV threshold that is greater than 0 (rather than the generally-accepted threshold of 0) is stated in the example. The stated NPV implies a higher IRR threshold than is stated in the example, and is also inconsistent with the stated ROI. In fact, the above three example goals are inconsistent, and part of the analysts job may be to help management develop consistent financial measures for project evaluation.

7. Not all projects will have this structure. Some capital projects require substantial downstream investment, which can cause alternating signs on annual NPVs.

7.4.7 Cash Flow Summary Sheet(s)

The basis for the cash flow calculation of NPV is:

Net present value (NPV(i,n) for a future cash flow =

[Net Sales to Working Interest - Total Costs to Working Interest] * (Single Payment Present Worth Factor (i,n))

(7.4.14)

$$\text{NPV}(i,n) = \left[\sum_{j=n} \text{Sales} - \sum_{j=n} \text{Costs} \right] (\text{SPPWF}(i, n))$$

(7.4.15)

$$\text{NPV}(i,n) = \left[\sum_{j=n} \text{Sales} - \sum_{j=n} \text{Costs} \right] \left[\frac{1}{(1+i)^n} \right]$$

(7.4.16)

i = Discount rate, n = time step or year.

Total sales minus total costs at each increment of time discounted to the “As of Date” determines NPV for that “time step.” Summing gives the total NPV.

Cash flow summary sheets contain nearly all the technical information upon which decisions may be based on investments between alternatives, etc. The major components of complete summaries include:

1. As of Date for the analyses and asset description (names, location, etc.)
2. Statements regarding resources OOIP, OGIP, OWIP, quantity and percent resources remaining.
3. Quantity of reserves and classification
4. Commodity prices on the “As of Date”
5. Summary of NPV and ROI at various rates related to cost of capital
6. Summary of major factors in the cash flow analysis as functions of time. Usually this is the major area of the summary and will include:
 - A section related to income that includes
 - Gross production Oil, Water, Gas
 - Net production to working interests(WI) Oil, Water, Gas
 - Net commodity sales to WI (\$) Oil, Gas, “Other”.
 - Total Sales/Revenues Net to WI

And a section related to Total Costs that includes

- Net Total Production Taxes
- Net Total Lease Operating Expenses
- Total Operating Expenses

And Cash Flow Before Federal Income Tax (BIFT)

- Net Operating Revenues (Total Sales/Revenues Net to WI—Total Operating Expenses)
- Capital Costs
- Incremental BIFT Cash Flow

- Discounted Incremental BIFT Cash Flow (Incr. NPV)
- Cumulative BIFT Cash Flow (NPV as function of date)

7. Date of forecasted economic limit

8. Net Present Value at the economic limit.

The cash flow summary sheet for Gofer Broke’s *Gusher 7-II-B Asset* is shown below with the eight major sections highlighted (Table 7.4.7, Page 52).

7.4.7.1 Major Conclusions from the Summary Sheet (Table 7.4.8, Page 53)

Tables 7.4.7 and 7.4.7 are illustrations of a spreadsheet model of a drilling cash-flow analysis. Details about the spreadsheets are available from the first author of this section.

7.4.8 Discussion of Results

Once a financial commitment is made to a development project such as the example presented here, owners will generally be interested in periodically valuing their property. Spreadsheet evaluation models are an excellent tool for this, particularly if key risks are appropriately modeled and included in the analysis.

The results generated by integrating an oil-price simulation model (only) into the spreadsheet model provide an example of key decision-making measures that are assessed for a series of price paths for one 10-year price scenario. Other scenarios could also be assessed, and baseline (for investment) scenarios could be developed. That is, price (and cost and other) scenarios could be generated that resulted in NPV and other measures that were close to or below minimum cutoff values. This would enable decision makers to understand multi-factor conditions under which an investment of this magnitude would be acceptable—or not.

Changes in commodity prices will alter computed reserves and present value dramatically. In the example case, if oil prices decrease by 50% (for example, oil market prices \$104.59 at 1/1/2012 changed to \$52.00 at 1/1/15 because of national and world conditions), NPV at the economic “limit date” 1/1/2031 becomes negative. What is the value of the project then? In this type of situation, where commodity prices devalue an ongoing project, decision makers would have to evaluate different alternatives—such as keep operating, sell, find partners, close the field—based on an evaluation model such as the one presented here. The key would be to generate reasonable models for the important factors, and this should be done via an iterative process involving both modeling and business experts.

TABLE 7.4.8 Conclusion Summaries

"As of Date"	1/1/2012	
Run Date	5/16/2015	
Name	Gusher 7-III-B Asset w/ Field Facilities in Place.	
Field	New Dorado	
Location	Oz-ee County	
Reservoir ID	By-Name-Only	1
Operator - WI	Gofer Broke, LLC	
Operator Interests		
Working Interest	Revenue Interest	Date
1.00000	0.75000	1/1/2012
IRR	30.00%	

1. Asset identifiers

Gross Resources			
	Original	Remaining	%Remaining
Oil/MStbo	196,000	196,000	100.0%
Gas/Bscf	100	100	100.0%
Water/MStbw	198,000	198,000	100.0%

2. Quantities of oil, gas and water Resources originally in place prior to initial development.

WI Reserves			
Original	Remaining	%Remaining	Classification
22,000,000	22,000,000	100.0%	PUD

3. Identification of reserves: working interest only.

Commodity Prices	
Initial	Ending
104.59	104.59
2.89	2.89

4. Commodity prices used. In this example, Constant prices are shown. In the analysis presented here, the Geometric Brownian Motion with Mean Reversion oil price model was used along with constant prices for gas.

Discount Factor	NPV/BFIT/MM\$	Time/Yrs	ROI
10.00%	\$ 231.2	20	0.72
15.00%	\$ 171.1	20	0.52
20.00%	\$ 115.6	20	0.40
25.00%	\$ 74.7	20	0.28
30.00%	\$ 43.5	20	0.18

5. Summary of NPV's and ROI at 20 years from "As of Date" for different discount factors (Cost of Capital/Inflation Rate). The asset loses 25% in NPV and the ROI changes by -30% if cost of capital changes from 10% to 15%.

6. Summary of major factors in the cash flow analysis as functions of time. Usually this is the major area of the summary.

Units, Dimensions and Conversion Factors

The system of dimensions and units used in mechanics and related engineering disciplines are based on Newton's second law of motion, which is force equals mass multiplied by acceleration, or

$$F = m a \quad (\text{A.1})$$

The above equation can be used with any consistent systems of units.

Over the past four decades there has been a great deal of effort to try to make the English unit system have a methodology of practical use that works like the methodology of practical use of the International System of Units (or SI metric). This involved the creation of "new" artificial terms like lb_f and lb_m (and even N_f and N_m) together with g and g_c to adjust equations to one or the other system of units. The objective of this exercise was make the two unit systems "easier" to use. This did not happen. In fact, the exercise allowed scientists and engineers to avoid learning the two systems of units properly. In essence, the exercise that created these artificial units and their associated terms was unnecessary. To properly understand how to use the two systems of units it is only necessary to practice the two systems of units side by side with a simple dynamics problem. The two systems of units are used in exactly the same manner.

In the English unit system, scientists and engineers define a pound of force as the force required to accelerate one slug of mass at the rate of one foot per second per second. One slug of mass has a weight of approximately 32.2 lb when acted upon by the acceleration of gravity present at the surface of the earth. Thus, using Equation A-1 in the English units is

$$1 \text{ lb} = (1 \text{ slug}) (1 \text{ ft./s}^2)$$

Using the above it can be found that

$$1 \text{ slug} = 1 \frac{\text{lb} - \text{s}^2}{\text{ft.}}$$

In SI metric, engineers define a Newton of force as the force required to accelerate on kilogram of mass at the rate of one meter per second per second. Thus, Equation A.1

in the SI metric is

$$1 \text{ N} = (1 \text{ kg}) (1 \text{ m/s}^2)$$

Using the above, it can be found that

$$1 \text{ kg} = 1 \frac{\text{N} - \text{sec}^2}{\text{m}}$$

The mass units in both systems are made up of force, length, and time units. The mass unit of either system cannot be measured directly. On the surface of the earth it is necessary to measure the mutual attraction force between the mass and the mass of the earth (this force is called weight). Then knowing the acceleration of gravity on earth, that force can be converted to the mass unit. The mass units in both systems are not independent units. They are made up of pounds, feet, and seconds in the English unit system and N, m, and sec in the SI metric system.

The English system of units is called a *gravitational system* since it denotes any mass by its weight (i.e., lb). Weight is a specially named force that is the mutual attraction force between an object mass and the mass of the earth. The SI metric system is called an absolute system since it denotes any mass by its mass unit (i.e., kg). Except for this distinction between the weight of an object and the mass of an object, the two systems are used in exactly the same manner in making practical calculations. Both require the measurement of the weight before the mass unit can be determined. We list mass in the SI metric system to define an object and we list weight in the English unit system to define an object. In the English unit system, we simply need to divide the weight by the acceleration of gravity to determine the object mass. To determine the weight of an object in the SI metric system we simply need to multiply the mass by the acceleration of gravity.

The two systems can be used in all science and engineering calculations. However, often one system is preferred over another in most problem types (e.g., the SI metric system is usually preferred for dynamics problems and the English system of units is usually preferred for strength of materials problems).

This handbook avoids the use of these artificial terms and uses these two systems of units in a consistent manner as described below.

2 Appendix

TABLE A.1 Basic Definitions of the English Unit System

Force	1 lb = 1 slug-ft./s ²
Area	1 acre = 43,560 ft. ²
Energy	1 Btu = 778 ft.-lb
Flowrate	1 cfs = 448.83 gpm
Length	1 ft. = 12 in.
	1 yd = 3 ft.
	1 statute mile = 5280 ft.
	1 nautical mile = 6000 ft.
Mass	1 slug = 1 lb-s ² /ft.
Power	1 hp = 550 ft.-lb/s = 0.708 Btu/sec
Velocity	1 mph = 1.467 ft./s
	1 knot = 1.689 ft./s = 1.152 mph
Volume	1 ft. ³ = 7.48 U.S. gal
	1 U.S. gal = 231 in. ³ = 0.1337 ft. ³ (8.34 lb of water)
	1 British imperial gal = 1.2 U. S. gal (10 lb of water)
Weight	1 U.S. (short) ton = 2000 lb
	1 British (long) ton = 2240 lb

TABLE A.2 Basic Definitions of the SI Metric System

Force	1 N = 1 kg-m/s ²
Area	1 Hectare (ha) = 10 ⁴ m ² = 100 m square
Energy (or work)	1 Joule (J) = 1 N-m
Flowrate	m ³ /s = 60,000 l pm
Length	1 cm = 10 mm
	1 m = 100 cm
	1 km = 1000 m
Mass	1 kg = 1000 g
	1 metric ton = 1000 kg
Power	1 Watt = 1 N-m/s
Velocity	1 kph = 1000 m/hr = 0.277 m/s
Volume	1 m ³ = 1000 L
	1 L = 10 ³ cm

TABLE A.3 Basic Quantities in English and SI Metric

	English Unit	SI Unit
Acceleration of gravity	32.2 ft./s ²	9.81 m/s ²
Density of water (at 39.4°F or 4°C)	1.94 slug/ft. ³	1000 kg/m ³
Specific weight of fresh water	62.4 lb/ft. ³	9810 N/m ³
Standard sea level atmospheric pressure		
API (at 60°F)	14.696 psia	
ASME (at 68°F)	14.7 pisa	
UK (at 60°F)	30.00 in. of Hg	
Continental Europe (at 15°C)	750 mm of Hg	

TABLE A.4 Other Important English and SI Metric Conversions

Engineering gas constant R	
English	$R = 53.36 \text{ ft.-lb/lb-}^\circ\text{R}$
Metric	$R = 29.28 \text{ N-m/N-K}$
Energy	
English	$1 \text{ ft.-lb} = 1 \text{ lb-ft.}$
Metric	$1 \text{ N-m} = 1 \text{ joule(J)}$
Heat	
English	$1 \text{ Btu} = 252 \text{ cal}$ (heat required to raise 1.0 lb of water 1.0°R)
Metric	$1 \text{ cal} = 4.187 \text{ J}$ (heat required to raise 1.0 g of water 1.0 K)
Temperature	
English	$^\circ\text{R} = 459.67^\circ + ^\circ\text{F}$
Metric	$\text{K} = 273.15 + ^\circ\text{C}$
Pressure	
English	$1 \text{ lb/ft.}^2 = 144 \text{ psi}$
Metric	$1 \text{ Pascal (Pa)} = \text{N/m}^2$
Power	
English	$1 \text{ horsepower} = 550 \text{ ft.-lb/s}$
Metric	$1 \text{ watt (W)} = 1 \text{ J/s}$ (or 1 N-m/sec)
Absolute viscosity	
English	$1 \text{ lb-s/ft.}^2 = 47.88 \text{ N-s/m}^2$
Metric	$1 \text{ Poise (P)} = 10^{-1} \text{ N-s/N}^2$
Kinematic viscosity	
English	$1 \text{ ft.}^2/\text{s} = 0.0929 \text{ m}^2/\text{s}$
Metric	$1 \text{ Stroke (St)} = 10^{-4} \text{ m}^2/\text{s}$

TABLE A.5 Commonly Used Prefixes for SI Metric Units

Factor by Which Unit is Multiplied	Prefix	Symbol
10^{12}	tera	T
10^9	giga	G
10^6	mega	M
10^3	kilo	k
10^2	hecto	h
10	deka	da
10^{-1}	deci	d
10^{-2}	centi	c
10^{-3}	milli	m
10^{-6}	micro	μ
10^{-9}	nano	n

year (tropical)	second (s)	3.155 693	E + 07

¹Since 1893 the U.S. basis of length measurement has been derived from metric standards. In 1959 a small refinement was made in the definition of the yard to resolve discrepancies both in this country and abroad, which changed its length from 3600/3937 m to 0.9144 m exactly. This resulted in the new value being shorter by two parts in a million. At the same time it was decided that any data in feet derived from and published as a result of geodetic surveys within the U.S. would remain with the old standard (1 ft. = 1200/3937 m) until further decision. This foot is named the U.S. survey foot. As a result, all U.S. land measurements in U.S. customary units will relate to the meter by the old standard. All the conversion factors in these tables for units referenced to this footnote are based on the U.S. survey foot, rather than the international foot. Conversion factors for the land measure given below may be determined from the following relationships:

1 league = 3 miles (exactly)
 1 rod = 16 1/2 ft. (exactly)
 1 chain = 66 ft. (exactly)
 1 section = 1 sq mile
 1 township = 36 sq miles

²This value was adopted in 1956. Some of the older International Tables use the value 1.055 04 E + 03. The exact conversion factor is 1.055 055 852 62* E + 03.

³This sometimes is called the moment of inertia of a plane section about a specified axis.

⁴The exact conversion factor is 1.638 706 4*E – 05.

⁵Not the same as reservoir "perm."

⁶Not the same dimensions as "millidarcy-foot."

TABLE A.7 Conversion Factors for the Vara *

Location	Value of Vara in Inches	Conversion Factor, Varas to Meters	
Argentina, Paraguay	34.12	8.666	E – 01
Cadiz, Chile, Peru	33.37	8.476	E – 01

STANDARD HANDBOOK OF PETROLEUM AND NATURAL GAS ENGINEERING, THIRD EDITION

BY WILLIAM C. LYONS, GARY J. PLISGA, AND MICHAEL D. LORENZ

Standard Handbook of Petroleum and Natural Gas Engineering, Third Edition, provides you with the best, state-of-the-art coverage for every aspect of petroleum and natural gas engineering. With thousands of illustrations and more than 1,600 information-packed pages, this handbook is the most comprehensive source for the newest developments, advances, and procedures in the oil and gas industry. Written by dozens of leading industry experts and academics, the book provides the best source of petroleum engineering information available. New to this edition are materials covering everything from drilling and production to the economics of the oil patch. Updated sections include underbalanced drilling, integrated reservoir management, and environmental health and safety. The sections on natural gas have been updated with new sections on natural gas liquefaction processing, natural gas distribution, and transport. Additionally, there are updated and new sections on offshore equipment and operations, subsea connection systems, production control systems, and subsea control systems. A classic for over 65 years, *Standard Handbook of Petroleum and Natural Gas Engineering, Third Edition* is a one-stop training tool for any new petroleum engineer or industry veteran looking for a daily practical reference.

Key Features

- Presents new and updated sections in drilling, production, and subsea
- Covers all calculations, tables, and equations for every day petroleum and natural gas engineers
- Features new sections on today's unconventional resources and reservoirs, particularly fractured reservoirs and shale reservoirs, horizontal drilling and completions, and hydraulic fracturing

About the Editors

William C. Lyons, PhD, PE (retired), holds nine patents in industrial drilling and has been responsible for the development of several important innovations in drilling and production technology. Dr. Lyons was a Professor in Petroleum Engineering and in Mechanical Engineering at the New Mexico Institute of Mining and Technology for 30 years. He also served two one-year tours as a Distinguished Visiting Professor in Mechanical Engineering at the U.S. Air Force Academy in Colorado Springs during his academic career. Since retiring from teaching, Dr. Lyons was most currently a Technical Learning Advisor with Chevron's Clear Leader Center in Houston, TX.

Gary J. Plisga, BS (retired) started his 35 year career in the petroleum industry in 1969 with Standard of Ohio (SOHIO) as a production engineer and later in managerial positions. SOHIO was merged with BP USA in the early 1980s where he held several production engineering and operations management positions. He is currently retired from active consulting and is living in Katy, TX.

Michael D. Lorenz, BS is an experienced oil industry professional with more than 30 years completions and workover experience. He has had the benefit of working in a wide variety of settings through his career including both service companies and operators. His specialties are the analysis of existing reservoir conditions and providing optimal completion engineering designs and/or workover operations. Mr. Lorenz is presently carrying out engineering duties in the Deepwater Group of Chevron USA. Mr. Lorenz lives in Houston, TX.
