The specific displacement per revolution of the rotor is equal to the cross-sectional area of the fluid multiplied by the distance the fluid advances. The specific displacement s (in.³) is

$$s = n_r n_s t_r A \quad (4.12.36)$$

Where A is the fluid cross-sectional area (in.²). The fluid cross-sectional area is approximately

$$A \approx 2n_e e_r^2 (n_r^2 - 1) \quad (4.12.37)$$

where e_r is the rotor rotation eccentricity (in.). The special case of a 1:2 lobe profile motor has a fluid cross-sectional area of

$$A \approx 2e_r d_r \quad (4.12.38)$$

where d_r is the reference diameter of the motor (in.). The reference diameter is

$$d_r = 2e_r n_s \quad (4.12.39)$$

For the 1:2 lobe profile motor, the reference diameter is approximately equal to the diameter of the rotor shaft.

FIGURE 4.12.12 Downhole positive displacement motor (*Courtesy of Archer Directional*).

The instantaneous torque of the positive displacement motor M (ft-lb) is

$$M = 0.0133 s \Delta p \eta \quad (4.12.40)$$

where Δp = differential pressure loss through the motor in psi

η = total efficiency of the motor. The 1:2 lobe profile motors have efficiencies around 0.80. The higher lobe profile motors have efficiencies that are lower (i.e., of the order of 0.70 or less)

The instantaneous speed of the positive displacement motor N (rpm) is

$$N = \frac{231.016q}{s} \quad (4.12.41)$$

where q is the circulation flowrate (gal/min).

The positive displacement motor horsepower HP (hp) for any speed is

$$HP = \frac{q\Delta p}{1,714} \eta \quad (4.12.42)$$

The number of positive displacement motor chambers n_c is

$$n_c = \frac{L}{t_s} - (n_s - 1) \quad (4.12.43)$$

where L is the length of the actual motor section (in.).

The maximum torque M_{\max} will be at the maximum differential pressure Δp_{\max} , which is

$$M_{\max} = 0.133s\Delta p_{\max}\eta \quad (4.12.44)$$

The maximum horse power HP_{\max} will also be at the maximum differential pressure Δp_{\max} , which is

$$HP_{\max} = \frac{q\Delta p_{\max}}{1,714} \eta \quad (4.12.45)$$

It should be noted that the positive displacement motor performance parameters are independent of the drilling mud weight. Thus, these performance parameters will vary with motor design values and the circulation flowrate.

If the above performance parameters for a positive displacement motor design are known for a given circulation flowrate (denoted as 1), the performance parameters for the new circulation flowrate (denoted as 2) can be found by the following relationships:

Torque

$$M_2 = M_1 \quad (4.12.46)$$

Speed

$$N_2 = \left(\frac{q_2}{q_1} \right) N_1 \quad (4.12.47)$$

Power

$$HP_2 = \left(\frac{q_2}{q_1} \right) HP_1 \quad (4.12.48)$$

FIGURE 4.12.14 Positive displacement motor, 6 3/4-in. outside diameter, 1:2 lobe profile, 400 gal/min, differential pressure limit 580 psi (Courtesy of Baker Hughes Co.).

Table 4.12.6 gives the performance characteristics for various circulation flowrates for the 1:2 lobe profile 6 3/4-in. outside diameter positive displacement motor. Figure 4.12.14 shows the performance of the 1:2 lobe profile positive displacement motor at a circulation flowrate of 400 gal/min.

Table 4.12.7 gives the performance characteristics for various circulation flowrates for the 5:6 lobe profile, 6 3/4-in. outside diameter positive displacement motor. Figure 4.12.15 shows the performance of the 5:6 lobe profile positive displacement motor at a circulation flow rate of 400 gal/min.

The positive displacement motor whose performance characteristics are given in Table 4.12.6 is a 1:2 lobe profile motor. This lobe profile design is usually used for deviation control operations. The 1:2 lobe profile design yields a downhole motor with high rotary speeds and low torque. Such a combination is very desirable for the directional

driller. The low torque minimizes the compensation that must be made in course planning which must be made for the reaction torque in the lower part of the drill string. This reactive torque when severe can create difficulties in deviation control planning. The tradeoff is, however, that higher speed reduces the bit life, especially roller rock bit life.

The positive displacement motor whose performance characteristics are given in Table 4.12.7 is a 5:6 lobe profile motor. This lobe profile design is usually used for

straight hole drilling with roller rock bits, or for deviation control operations where high torque polycrystalline diamond compact bit or diamond bits are used for deviation control operations.

Example 4.12.3

A 6³/₄-in. outside diameter positive displacement motor of a 1:2 lobe profile design (where performance data are given in Table 4.12.4) has rotor eccentricity of 0.60 in., a reference diameter (rotor shaft diameter) of 2.48 in. and a rotor pitch of 38.0 in. If the pressure drop across the motor is determined to be 500 psi at a circulation flowrate of 350 gal/min with 12.0 lb/gal, find the torque, rotational speed and the horsepower of the motor.

Torque

Equation 4.12.37 gives the fluid cross-sectional area of the motor, which is

$$A = 2(0.6)(2.48) = 2.98 \text{ in.}^2 \tag{4.12.49}$$

Equation 4.12.37 gives the specific displacement of the motor, which is

$$s = (1)(2)(38.0)(2.98) = 226.5 \text{ in.}^3 \tag{4.12.50}$$

The torque is obtained from Equation 4.12.40, assuming an efficiency of 0.80 for the 1:2 lobe profile motor. This is

$$M = 0.0133(226.5)(500)(0.80) = 1205 \text{ ft-lb} \quad (4.12.51)$$

Speed

The rotation speed is obtained from Equation 4.12.41. This is

$$N = \frac{231.016(350)}{226.5} = 357 \text{ rpm} \quad (4.12.52)$$

Horsepower

The horsepower the motor produces is obtained from Equation 4.12.42. This is

$$HP = \frac{350(500)}{1714}(0.80) = 82 \quad (4.12.53)$$

Planning for a positive displacement motor run and actually drilling with such a motor is easier than with a turbine motor. This is mainly due to the fact that when a positive displacement motor is being operated, the operator can know the operating torque and rotation speed via surface

data. The standpipe pressure will yield the pressure drop through the motor, thus the torque. The circulation flowrate will yield the rotational speed.

Example 4.12.4

A 6 3/4-in. outside diameter positive displacement motor (whose performance data are given in Tables 4.12.6 and 4.12.7) is to be used for a deviation control direction drill operation. The motor will use an 8 1/2-in. diameter roller rock bit for the drilling operation. The directional run is to take place at a depth of 10,600 ft (measured depth). The rock formation to be drilled is classified as medium, and it is anticipated that 30 ft/hr will be the maximum possible drilling rate. The mud weight is to be 11.6 lb/gal. The drilling rig has a National Supply Company duplex mud pump Model E-700 available. The details of this pump are given in Table 4.12.8 (also see the section titled “Mud Pumps”). Because this is a deviation control run, the 1:2 lobe profile positive displacement motor will be used since it has the lowest torque for a given circulation flowrate (see Table 4.12.6). Determine the appropriate circulation flowrate to be used for the roller rock bit, positive displacement motor combination and the appropriate liner size to be used in the duplex pump. Also, prepare the positive

FIGURE 4.12.16 Hydraulic thrust and indicated weight balance for positive displacement motor (Courtesy of Smith International, Inc.).

displacement motor performance graph for the chosen circulation flowrate. Determine the bit nozzle sizes.

Bit Pressure Loss

It is necessary to choose the bit pressure loss such that the thrust load created in combination with the weight on bit will yield an on-bottom load on the motor thrust bearings, which is less than the maximum allowable load for the bearings. Since this is a deviation control run and, therefore, the motor will be drilling only a relatively short time and distance, the motor thrust bearings will be operated at their maximum rated load for on-bottom operation. Figure 4.12.16 shows that maximum allowable motor thrust bearing load is about 6,000 lb. To have the maximum weight on bit, the maximum recommended bit pressure loss of 500 psi will be used. This will give maximum weight on bit of about 12,000 lb. The higher bit pressure loss will, of course, give the higher cutting face cleaning via jetting force (relative to the lower recommended bit pressure losses).

Total Pressure Loss

Since bit life is not an issue in a short deviation control motor run operation, it is desirable to operate the positive displacement motor at as high a power level as possible during the run. The motor has a maximum pressure loss with which it can operate. This is 580 psi (see Table 4.12.6). It will be assumed that the motor will be operated at the 580 psi pressure loss in order to maximum the torque output of the motor. To obtain the highest horsepower for the motor, the highest circulation flowrate possible while operating within the constraints of the surface mud pump should be obtained. To obtain this highest possible, or optimal, circulation flowrate, the total pressure losses for the circulation system must be obtained for various

circulation flowrates. These total pressure losses tabulated in the lower row of Table 4.12.9 represent the surface standpipe pressure when operating at the various circulation flowrates.

Pump Limitations

Table 4.12.8 shows there are six possible liner sizes that can be used on the Model E-700 mud pump. Each liner size must be considered to obtain the optimum circulation flowrate and a appropriate liner size. The maximum pressure available for each liner size will be reduced by a safety factor of 0.90. The maximum volumetric flowrate available for each liner size will also be reduced by a volumetric efficiency factor of 0.80 and an additional safety factor of 0.90. Thus, from Table 4.12.8, the allowable maximum pressures and allowable maximum volumetric flowrates will be those shown in Figures 4.12.17 through 4.12.22 which are the liner sizes 5 3/4, 6, 6 1/2 and 7 in., respectively. Plotted on each of these figures are the total pressure losses for the various circulation flowrates considered. The horizontal straight line on each figure is the allowable maximum pressure for the particular liner size. The vertical straight line is the allowable maximum volumetric flowrate for the particular liner size. Only circulation flowrates that are in the lower left quadrant of the figures are practical. The highest circulation flowrate (which produces the highest positive displacement motor horsepower) is found in figure 4.12.19, the 6 1/4-in. liner. The optimal circulation flow rate is 348 gal/min.

Positive Displacement Motor Performance

Using the positive displacement motor performance data in Table 4.12.6 and the scaling relationship in

TABLE 4.12.9 Drillstring Component Pressure Losses at Various Flowrates for Example 4.12.4

Components	Pressure (psi)			
	200 gpm	300 gpm	400 gpm	500 gpm

PDM	580	580	580	580
Drill Bit	500	500	500	500
Drill Collar Annulus	11	25	45	70
Drill Pipe Annulus	32	72	128	200
Total Pressure Loss	1288	1546	1909	2375

FIGURE 4.12.17 A 5 3/4-in. liner, total pressure loss vs. flowrate, Example 4.12.4 (Courtesy of Baker Hughes Co.).

FIGURE 4.12.19 A 6 1/4-in. liner, total pressure loss vs. flowrate, Example 4.12.4 (Courtesy of Baker Hughes Co.).

FIGURE 4.12.18 A 6-in. liner, total pressure loss vs. flowrate, Example 4.12.4 (Courtesy of Baker Hughes Co.).

Equations 4.12.46 through 4.12.48, the performance graph for the positive displacement motor operating with a circulation flowrate of 348 gal/min can be prepared. This is given in Figure 4.12.23.

Bit Nozzle Sizes

The pressure loss through the bit must be 500 psi with a circulation flowrate of 348 gal/min with 11.6-lb/gal mud weight. The pressure loss through a roller rock bit with

three nozzles is (see the section titled “Drilling Bits and Downholes Tools”)

$$\Delta p_b = \frac{q^2 \bar{\gamma}_m}{7430 C^2 d^4} \tag{4.12.54}$$

where C = nozzle coefficient (usually taken to be 0.95)

d_e = hydraulic equivalent diameter in in.

Therefore, Equation 4.12.54 is

$$500 = \frac{(348)^2 (11.6)}{7,430 (0.98)^2 d_e^4} \tag{4.12.55}$$

which yields

$$d_e = 0.8045 \text{ in.} \tag{4.12.56}$$

The hydraulic equivalent diameter is related to the actual nozzle diameters by

$$d_e = [ad_1^2 + bd_2^2 + cd_3^2]^{1/2} \tag{4.12.57}$$

where a = number of nozzles with diameter d₁

b = number of nozzles with diameter d₂

c = number of nozzles with diameter d₃

d₁, d₂ and d₃ = three separate nozzle diameters in in.

Nozzle diameters are usually in 32nds of an inch. Thus, if the bit has three nozzles with 15/32 of an inch diameter, then

$$d_e = [(3)(0.4688)^2]^{1/2} = 0.8120 \text{ in.} \tag{4.12.58}$$

FIGURE 4.12.20 A 6½-in. liner, total pressure loss vs. flowrate, Example 4.12.4 (Courtesy of Baker Hughes Co.).

FIGURE 4.12.22 A 7-in. liner, total pressure loss vs. flowrate, Example 4.12.4 (Courtesy of Baker Hughes Co.).

FIGURE 4.12.21 A 6¾-in. liner, total pressure loss vs. flowrate, Example 4.12.4 (Courtesy of Baker Hughes Co.).

The above hydraulic equivalent diameter is close enough to the one obtained with Equation 4.12.54. Therefore, the bit should have three $\frac{5}{32}$ -in. diameter nozzles.

4.12.4 Down the Hole Air Hammers

4.12.4.1 Design

There are two basic designs for the downhole air hammer. One design uses a flow path of the compressed air through a control rod (or feed tube) down the center hammer piston (or through passages in the piston) and then through the ham-

mer bit. The other design uses a flow path through a housing annulus passage (around the piston) and then through the hammer bit. Figure 4.12.24 shows a schematic of a typical control rod flow design downhole air hammer. The hammer action of the piston on the top of the drill bit shank provides an impact force that is transmitted down the shank to the bit studs, which, in turn, crush the rock at the rock face. In shallow boreholes where there is little annulus back pressure, the piston impacts the top of the bit shank at a rate of from about 600 to 1,700 strikes per minute (depending on volumetric flow rate of gas). However, in deep boreholes where the annulus back pressure is usually high, impacts can be as low as 100 to 300 strikes per minute. This unique air drilling device requires that the drill string with the air hammer be rotated so that the drill bit studs impact over the entire rock face. In this manner an entire layer of the rock face can be destroyed and the drill bit advanced.

Figure 4.12.24 shows the air hammer suspended from a drill string lifted off the bottom (the shoulder of the bit is not in contact with the shoulder of the driver sub). In this position, compressed air flows through the pin connection at the top of the hammer to the bit without actuating the piston action (i.e., to blow the borehole clean). When the hammer is placed on the bottom of the borehole and weight placed on the hammer, the bit shank will be pushed up inside the hammer housing until the bit shoulder is in contact with the shoulder of the driver sub. This action aligns one of the piston ports (of one of the flow passage through the piston) with one of the control rod windows. This allows the compressed air to flow to the space below the piston which in turn forces the piston upward in the hammer housing. During this upward stroke of the piston, no air passes through the bit shank to the rock face. In essence, rock

FIGURE 4.12.23 Positive displacement motor, 6-in. outside diameter, 1:2 lobe profile, 348 gal/min, differential pressure limit 580 psi, Example 4.12.4 (Courtesy of Baker Hughes Co.).

cuttings transport is suspended during this upward stroke of the piston.

When the piston reaches the top of its stroke, another one of the piston ports aligns with one of the control rod windows and supplies compressed air to the open space above the piston. This air flow forces the piston downward until it impacts the top of the bit shank. At the same instant the air flows to the space above the piston, the foot valve at the bottom of the control rod opens and air inside the drill string is exhausted through the control rod, bit shank, and the bit orifices to the rock face. This compressed air exhaust entrains the rock cuttings created by the drill bit for transport up the annulus to the surface. This impact force on the bit allows the rotary action of the drill bit to be very effective in destroying rock at the rock face. This in turn allows the air hammer to drill with low WOB. Typically for a $6\frac{3}{4}$ inch outside diameter air hammer drilling with a $7\frac{7}{8}$ inch air hammer bit, the WOB can be as low as 1,500 lb. Downhole air hammers must have an oil type lubricant injected into the injected air during the drilling operation. This lubricant is needed to lubricate the piston surfaces as it moves in the hammer housing. Air hammers are used exclusively for vertical drilling operations.

This piston cycle is repeated as the drill string (and thus the drill bit) is rotated and in this manner continuous layers of rock on the rock face are crushed and the cuttings removed. The air flow through the air hammer is not continuous. When the piston is being lifted in the hammer,

air is not being exhausted through the drill bit. For example, at a piston impact rate of 600 strikes per minute the air is shut down for about 0.050 seconds per cycle. This is so short a time that the air flow rate through the annulus can be assumed as a continuous flow.

Downhole air hammers are available in housing outside diameters from 3 inches to 16 inches. The 3 inch housing outside diameter hammer can drill a borehole as small as $3\frac{5}{8}$ inches. The 16 inch housing outside diameter hammer can drill a boreholes from $17\frac{1}{2}$ inches to 33 inches. For shallow drilling operations, conventional air hammer bits are adequate. For deep drilling operations (usually oil and gas recovery wells), higher quality oil field air hammer drill bits are required.

There are a variety of manufacturers of downhole air hammers. These manufacturers use several different designs for their respective products. The air hammer utilizes very little power in moving the piston inside the hammer housing. For example, a typical $6\frac{3}{4}$ inch outside diameter air hammer with a 77 lb piston operating at about 600 strikes per minute, will use less than 2 horsepower driving the piston. This is a very small amount of power relative to the total needed for the actual rotary drilling operation. Thus, it is clear that the vast majority of the power to the drill string is provided by the rotary table. Therefore, any pressure loss (i.e., energy loss) due to the piston lifting effort can usually be ignored. The major pressure loss in the flow through an air hammer is due to the flow energy

FIGURE 4.12.24 Schematic cutaway of a typical air hammer (Courtesy of Diamond Air Drilling Services, Inc.).

losses from the constrictions in the flow path when the air is allowed to exit the hammer (on the down stroke of the piston). All air hammer designs have internal flow constrictions. These flow constrictions can be used to model the flow losses through the hammer. In most designs these constrictions can be approximately represented by a set of internal orifice diameters in the flow passages to the drill bit. These internal orifices are usually the ports (and associated

channels) through the piston and the orifice at the open foot valve.

4.12.4.2 Operations Hammer Selection

With such a vast array of hammers on the market it is quite a task to pick the best hammer for your application. Some

manufacturers may have up to six different hammers to drill the same size hole. Why so many? Read on!

Size of Hammer

Generally, try to choose a hammer size nearest to the intended hole size. The bigger the hammer diameter, the bigger the piston diameter, the bigger the performance. [Figure 4.12.25](#) shows how rapidly performance drops when using an oversize bit on a small hammer, [Figure 4.12.26](#) shows how performance can be better maintained by going to a bigger hammer. Not only this, a bigger hammer allows a bigger bit shank, better energy transfer resulting in greater strength and lower stresses—more reliability and lower cost per foot. The only reasons hammer selection should not be based entirely on hole size is because of flexibility and capital cost of other hammers. Special hammer sizes such as 5.5 or 11 inch hammers are often used in such situations to maintain performance without sacrificing flexibility.

Hammer Air Consumption

The amount of air available from the air compressor will affect the choice of hammer. Generally, it is best to select a hammer nearest the maximum operating conditions of the compressor. The higher the hammer operating pressure, the better the performance. However, just like your car engine, the manufacturer's ingenuity and technology will play a

part in the efficiency and performance of the hammer under different conditions.

Some manufacturers offer low volume (LV) or Mizer hammers. These are usually variations of standard hammers and may contain different pistons, piston cases and/or rigid valves. Another approach by manufacturers is to change the internal port timing and volumes by substituting one part to adjust air consumption characteristics. Apart from the advantage of fewer stocked parts, this gives much greater flexibility and greater opportunity to optimize drilling for different rigs and drilling conditions. The following graphs show performance curves for three typical hammers plotted from manufacturer's data. For example, take three typical cases and show how to estimate operating pressure for each and make a hammer selection.

Case 1: 750SCFM X 250 PSI Compressor

[Figure 4.12.27](#) shows that the compressor produces more air than any of the hammers can use. Hammer 1 is the nearest to the maximum operating conditions of the compressor and will give the best performance. Hammer 2 or 3 will work of course, and could rely on the compressor unloader to control the excess air of the compressor (not a desirable situation with a piston compressor). There are two other reasons why Hammer 2 or 3 should be considered: (1) the lower air consumption will result in lower air velocity and less erosion on the bit and the hammer, and (2) as a means of reducing power requirements and fuel.

Expected performance index:

Hammer 1	190%
Hammer 2	104%
Hammer 3	100%

Case 2: 450 SCFM X 250 PSI

From a performance aspect, Hammer 3 can be expected to give a far better performance and hold around 220 psi when drilling. The user, for operational reasons, prefers to operate at around 180–200 psi with this specification we would select hammer 2 or possible 3 ([Figure 4.12.28](#)).

FIGURE 4.12.25 Poor Hammer/Bit Ratio. (Courtesy of DrillMaster.).

FIGURE 4.12.26 Correct Hammer/Bit Ratio. (Courtesy of DrillMaster.).

FIGURE 4.12.27 Case 1: 750 SCFM X 250 PSI Compressor. (Courtesy of DrillMaster.).

Expected performance index:

- Hammer 1 190%
- Hammer 2 142%
- Hammer 3 100%

Case 3: 825 SCFM X 350 PSI

According to Figure 4.12.29, Hammer 3 would not use all the air the compressor can produce causing the compressor to partially unload. Hammer 2 on the other hand needs more air than the compressor can make so it will only operate at 320 psi. On paper, both of these hammers could be expected to have the same performance. However, experience dictates that compressors rarely deliver the amount of air to the hammer that is claimed by the stickers on the side, Leaks at drill joints, altitude, blocked intake filters, oil scavenge system, even the weather will effect the air delivery. Knowing this, and the fact that the amount of air might be as little as 660 SCFM, Hammer 3 would be the right choice.

Expected performance index:

- Hammer 1 100%
- Hammer 2 118%
- Hammer 3 136%

Heavy Duty Hammers

These hammers are slightly bigger on the outside diameter to permit more wear allowance. Some manufacturers refer to them as “half inch bigger hammers,” for example 6.5 inch hammers. In fact, these may not be true 6.5 inch hammers, but the heavy duty hammers with the same internal parts.

Deep Hole Hammers

These hammers are specifically designed to maintain performance where high back pressures are encountered such at high volumes of ground water or very deep holes. Back pressure greatly reduces the impact velocity of the piston eventually causing the piston to cycle but not drill or

FIGURE 4.12.29 Case 3: 825 SCFM X 350 PSI Compressor. (Courtesy of DrillMaster.).

“wash out”. These hammers have a special piston design incorporating a very large bottom volume to reduce the compression ration making them less sensitive to back pressure. DTH hammers are not as efficient as normal drilling because of the extra piston mass and air consumption. A standard hammer can be made to work in high back pressure applications by boosting the air pressure thereby increasing air consumption and improving flushing.

Hammer Characteristics

Every hammer model has its own characteristics, dependent mostly on design and operating pressure. Two values used to describe these characteristics are blow energy and blow frequency (Blows/Minute). How does this effect performance? In basic terms, percussive hammers with a light-blow energy and a high blow frequency drill well in soft, broken formations where a hard-hitting, high-blow energy hammer will bury itself. In hard rock conditions, without a hard-hitting, high-blow energy hammer, power is insufficient to break rock. Great care must be taken when comparing two hammers on the basis of blow energy and blow frequency. Values measure in test beds or calculated may bear no resemblance to balies gained from drilling in actual rock conditions. To make matters more confusing, the bit face configuration and condition of the carbides play a big part in how efficiently energy is transferred to the rock for maximum penetration rates. Use the figures to select a hammer based on air consumption. This will play the biggest part in performance. Hammer and bit characteristics will effect performance, but trial and error is really the only sure way to find out if the performance can be improved.

FIGURE 4.12.28 Case 2: 450 SCFM X 250 PSI Compressor. (Courtesy of DrillMaster.).

4.12.5 Rotary Steerable Systems

To change the wellbore trajectory with steerable motors, the drilling rotation is paused in a position where the bend of

the motor points in the direction of the desired trajectory. This mode is known as the sliding mode. Sliding creates higher frictional forces on the drillstring, and sometimes to the point that no axial weight is available to overcome the drag of the drillstring against the wellbore, and for that reason, drilling is not possible.

To overcome this limitation, in the early 1990s rotary steerable systems (RSSs) were developed. RSS allows continuous rotation of the drillstring while steering the bit. This reduces drag, improves ROP, decreases the risk of sticking, and achieves superior hole cleaning. RSSs can be categorized by their steering mode, “push the bit” and “point the bit”.

4.12.5.1 Push the Bit RSS

Push the bit RSS (Figure 4.12.30) operates by applying a side force against the formation in the drilled bore. This can be done with synchronously actuating pads, or by a constant offset force on a geostationary assembly.

4.12.5.2 Point the Bit RSS

Point the bit RSS, illustrated in Figure 4.12.31, uses the same principle employed in the bent-housing motors. And it causes the direction of the bit to change relative to the rest of the tool by bending the main shaft running through it. This system requires some kind of non-rotating housing

FIGURE 4.12.30 Push the bit RSS (courtesy of Schlumberger [14]).

or reference housing in order to create this deflection within the shaft.

4.12.5.3 Hybrid Push and Point the Bit RSS

Recently hybrid push and point the bit technology has been developed [14] incrementing the capability to achieve high dogleg severities (DLSs) while reaching ROPs typical of rotary steerable systems. In this RSS, the internal pads push against the inside of the steering sleeve. This articulated sleeve then pivots on the universal joint to point the bit in the desired direction (Figure 4.12.32).

4.13 SELECTION OF DRILLING PRACTICES

Section reviewed by Thomas Carter and John Lofton

The objective of optimizing drilling practices is to safely deliver a product capable of the highest production capacity in a cost-effective manner. Throughout all phases of well planning and construction, the following ideas must be considered: health, safety, and environment (HSE), production capability, and drilling optimization. These criteria are requisite to delivering a successful drilling outcome. Several choices are normally available to achieve the required outcomes for each criterion, but fewer options, perhaps only one, may be viable to meet the needs of all three.

In today’s environment, HSE requirements play an equal role in the planning and implementation of drilling plans. Significant planning is required to protect operating personnel, retain licenses to operate, control costs, and coexist with the environment. Accidents are costly, more so than the up-front costs to mitigate the risk to people, property, and environment.

Production capacity, both rate and volume, are affected by decisions made during planning and construction phases. Proper selection of various cost control options can minimize the negative influences that some of these measures can have on production. Analyzing potential gains in capacity associated with incremental risk and investment is part of the optimization process.

Optimization requires understanding, prioritization, and implementation of the practices most appropriate for the specific well being drilled to accomplish the stated objectives. You must solve potential problems that remove limits or lessen their impact on the outcome. The right answer for one circumstance (e.g., well design, geographical area, hole size) is possibly the wrong answer in another circumstance. Problem solving must be approached with the overall objective in mind while understanding the causes and effects and the relative magnitudes of these effects. No matter how well the planning process is conducted, adjustment in real time is expected and will be required. The parameters of drilling operations parameters must be optimized. Noticing, understanding, and adapting to observed trends will yield significant value to the outcome. Real-time ability to respond to problems during drilling will minimize their impact and not allow these problems to cause other problems, which are often substantially more costly to solve. The days of characterizing drilling practices as simply operational parameters such as weight on bit (WOB), revolutions per minute (rpm), and flow rate are long gone. Drilling optimization is a multivariant analysis that requires diligent effort, but the challenge is rewarding personally and financially.

4.13.1 Health, Safety and Environment

An effective HSE program is characterized by no injury to people, no loss of property, and no harm to the environment. Great HSE performance is an indication of great leadership. It is much more than statistics, although measurements are necessary to facilitate performance improvement. HSE must be considered a core responsibility for all business participants, operators, contractors, and service companies and be accepted by all individuals on a personal basis. It is imperative that all parties are committed from the top management down throughout their organizations.

The main reasons companies in the current era support strong HSE programs include humanitarian reasons (i.e., not hurting people), legal or regulatory requirements, the company's public image, employee morale, and economic reasons (i.e., loss of business or the cost of poor HSE performance).

The modern era of HSE management for oil field operations began with the Piper Alpha disaster in the North Sea, where 167 men lost their lives in one incident. The subsequent investigation, conducted and published by Lord Cullen, contained the framework of HSE management embodied in much subsequent legislation and regulation [1]. This was the birth of safety cases for oil field facilities, including offshore MODU drilling rigs.

One of the key recommendations was that companies should have *safety management systems* (SMSs) that control a company's operations from top to bottom. The systems

were recommended to include the elements of ISO 9001 (a standard for management of quality in organizations) and include elements such as management responsibility and commitment, design control, documentation and procedures, process control, control of nonconformance, corrective actions, internal auditing, and training. All the elements of a safety management system are not directly applicable to drilling optimization and are therefore not addressed here. Examples include emergency response plans and oil spill response procedures that companies should have in place as part of their normal procedures.

Generally, each drilling department should have a set of operating guidelines that control the drilling work processes. The operating guidelines are a subset of the SMSs, and the documents may vary from multivolume sets at the major oil companies to much smaller documents for smaller companies. The drilling engineer is responsible for ensuring that all his work complies with these guidance instructions. Variations from these procedures usually will require a higher level of management approval.

The three components of HSE-related drilling issues that are normally considered during drilling operations are discussed separately in the following sections.

4.13.1.1 Health

Health issues related to drilling operations can include industrial hygiene issues related to onsite conditions and may include exposures to drilling fluid components such as oil-base mud fumes and skin contact, highly toxic completion brines, or oils, gas, and toxic materials such as hydrogen sulfide originating from the well. Naturally occurring radioactive materials (NORM) can also be encountered during workover operations, and metals such as mercury are encountered periodically in gas streams and may be found in production separators. An optimized drilling program includes careful consideration of the health impact on employees and workers at any well site.

4.13.1.2 Safety

The general safety culture adapted in the current era was derived from the Du Pont manufacturing culture and adapted to oil field operations when the company purchased Conoco. Du Pont was originally in the dynamite manufacturing business, and serious accidents in the past strongly motivated management to adopt a "best practice" approach to safety management. The primary concept is that *all accidents are preventable*. Accidents do not just happen, and with work, resources, and management commitment, accidents can be minimized or eliminated. In most all oil companies and service companies, management personnel leave no doubt that they are committed to providing a safe working environment. A poor safety record leads to the suffering of injured employees, the financial impact of

lawsuits, and the loss of business and shareholder support. It is not unusual for service companies to be removed from approved bidding lists if the safety performance is not up to the company's requirements. The second concept generally accepted is that *safety (or HSE) must be considered equally with production and profits* in the decision-making process. "Safety first" is not plausible. If we wanted to only be safe, we would never leave the comfort of our homes in the first place. Safety must be considered as an equal to other factors in the decision-making process to ensure that all jobs meet the company's safety goals.

Safety management is an engineering profession unto itself, with many disciplines and areas of coverage. For the drilling engineer or drilling foreman, safety at the well site is accomplished through sound engineering, formal safety reviews (as appropriate), contracting of reputable firms with strong safety cultures, and appropriate training of all personnel.

Operational risks for drilling operations can vary from simple, shallow onshore jobs to extremely complex offshore operations in remote hostile areas that can be extremely expensive and carry significant risk. Consequently, a "fit for purpose" approach must be considered for the safety management of each operation. A simple onshore job may rely completely on the drilling contract and include relatively simple tools such as a toolbox safety discussion and daily safety meeting. At the other end of the scale, in large offshore production platforms with simultaneous operation of wells and drilling in a remote or hostile area, a large amount of safety engineering may be required. Tools may include a full safety case preparation and hazard and operability (HAZOP) studies [2]. A HAZOP study is an examination procedure. Its purpose is to identify all possible deviations from the way in which a design is expected to work and to identify all the hazards associated with these deviations. When deviations arise that result in hazards, actions are generated that require design engineers to review and suggest solutions to remove the hazard or reduce its risk to an acceptable level. These solutions are reviewed and accepted by the HAZOP team before implementation. HAZOP techniques have been adopted by many countries and are required to provide assurance of safe operations.

It should be understood by all operation personnel that 96% of all accidents are related to unsafe behaviors and that only 4% of accidents are caused by unsafe conditions. Most drilling contractors have adopted policies that focus on encouraging safe behaviors.

4.13.1.3 Environment

Dramatic changes in environmental impact management have occurred continually from the earliest days of the oil field. Common practice in the early days was to produce oil into open pits for storage. Today's best practices

include serious management and minimization of all waste streams. Development of projects today may require full environmental impact assessments (EIA) before approval. The first legal requirement in the United States for an EIA was imposed on the Trans-Alaska oil pipeline, which was delayed for years and experienced cost overruns from an initial estimate of \$900 million to a final installed cost of \$9 billion. Today, most of the East and West coastlines of the United States and Florida are off limits for drilling because of environmental concerns. The Exxon Valdez incident will not leave the collective public memory any time soon and is an example of the negative impact to the environment from oil and gas operations.

Most companies have management systems in place for environmental management of their operations. Drilling personnel are responsible for planning and conducting operations to ensure optimization and compliance.

4.13.2 Production Capacity

Production capacity requires investment. Performance measures of optimization may include one or several of the following: days to pay out, cash flow, profit, finding cost (cost per barrel oil equivalent), and return on investment (ROI). The idea of *diminishing returns* plays a key role in the decision-making process. Delivering rate and reservoir volume carry associated cost and risks. Fundamental to drilling practices optimization is understanding how specific cause-and-effect relationships influence this objective.

Key issues affecting production capability, which therefore must receive a high priority when planning the drilling phase, include permeability (K) and porosity (Φ) of the zone of interest (ZOI). Formation damage resulting from poor planning may be permanent or very costly to correct. The right equipment, resources, knowledge, and skills are prerequisites for optimization.

Several key issues may establish constraints on the drilling program, narrowing choices for the drilling plan. For example, mud types and properties and exposure time to the ZOI may be critical. A special "drill-in" fluid (i.e., drilling mud that can minimize formation damage) may be required. The time and cost to change the drilling mud is deemed high value for achieving the final production capacity versus cost objective. Another example is the determination of the optimum hole and tubular sizes. Hole and tubular sizes must be optimized based on expected initial production (e.g., rate, fluid type, pressure), availability, potential future remediation, and consideration of how production may change throughout the life of the well. The geology and pore pressures determine the number of casing strings required to arrive at the ZOI, and the expected production rate will determine the size of production string that the drilling department must be deliver to the company. In some cases, exploration wells will be designed as expendable and

will never be produced. All of these factors influence the spectrum of possible casing plans and potential costs, and they will require evaluation.

Using a “cradle to grave” approach to well design considers the drilling phases and looks at all aspects of the well’s life, from initial production through permanent abandonment [3]. Close association is required between the multiple departments (e.g., geology, asset management, drilling, completion, production) of the oil company and the service provider representatives. Communicating and sharing their respective areas of expertise and requirements with the others is paramount to optimization of the outcome.

New technologies can significantly enhance production capacity when properly applied and should not be forgotten. Underbalanced drilling (UBD), expandable sand screens (ESS), expandable drilling liners (EDL), coiled-tubing drilling (CTD), hole enlarging devices (e.g., bi-center drill bits, hole openers), casing drilling, and fiberoptic “intelligent” completions are a few examples.

4.13.3 Well Planning and Implementation

4.13.3.1 Optimum Well Planning

Drilling optimization requires detailed engineering in all aspects of well planning, drilling implementation, and post-run evaluation (Figure 4.13.1) [4–6]. Effective well planning optimizes the boundaries, constraints, learning, nonproductive time, and limits and uses new technologies as well as tried and true methods. Use of *decision support packages*, which document the reasoning behind the decision-making, is key to shared learning and continuous improvement processes. It is critical to anticipate potential difficulties, to understand their consequences, and to be prepared with contingency plans. Post-run evaluation is required to capture learning. Many of the processes used are the same as used during the well planning phase, but are conducted using new data from the recent drilling events.

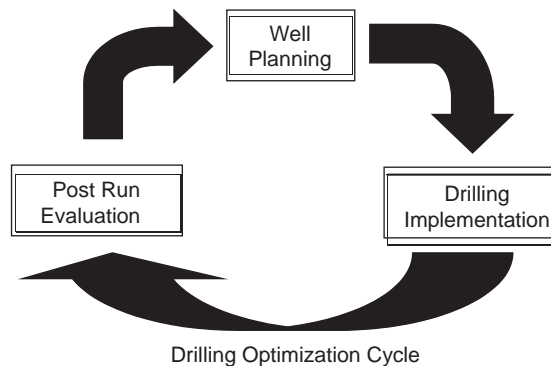

FIGURE 4.13.1 Drilling Optimization Cycle.

Depending on the phase of planning and whether you are the operator or a service provider, some constraints will be out of your control to alter or influence (e.g., casing point selection, casing sizes, mud weights, mud types, directional plan, drilling approach such as BHA types or new technology use). There is significant value in being able to identify alternate possibilities for improvement over current methods, but well planning must consider future availability of products and services for possible well interventions. When presented properly to the groups affected by the change, it is possible to learn why it is not feasible or to alter the plan to cause improvement. Engineers must understand and identify the correct applications for technologies to reduce costs and increase effectiveness. A correct application understands the tradeoffs of risk versus reward and costs versus benefits.

Boundaries

Boundaries are related to the “rules of the game” established by the company or companies involved. Boundaries are criteria established by management as “required outcomes or processes” and may relate to behaviors, costs, time, safety, and production targets.

Constraints

Constraints during drilling may be preplanned trip points for logs, cores, casing, and BHA or bit changes. Equipment, information, human resource knowledge, skills and availability, mud changeover, and dropping balls for downhole tools are examples of constraints on the plan and its implementation.

The Learning Curve

Optimization’s progress can be tracked using learning curves that chart the performance measures deemed most effective for the situation and then applying this knowledge to subsequent wells (see Figure 4.13.1). Learning curves provide a graphic approach to displaying the outcomes. Incremental learning produces an exponential curve slope. Step changes may be caused by radically new approaches or unexpected trouble. With understanding and planning, the step change will more likely be in a positive direction, imparting huge savings for this and future wells. The curve slope defines the optimization rate.

The learning curve can be used to demonstrate the overall big picture or a small component that affects the overall outcome. In either case, the curve measures the rate of change of the parameter you choose, typically the “performance measures” established by you and your team. Each performance measure is typically plotted against time, perhaps the chronological order of wells drilled as shown in Figure 4.13.2.

FIGURE 4.13.2 Learning Curves.

Cost Estimating

One of the most common and critical requests of drilling engineers is to provide accurate cost estimates, or *authority for expenditures* (AFE). The key is to use a systematic and repeatable approach that takes into account all aspects of the client's objectives. These objectives must be clearly defined throughout the organization before beginning the optimization and estimating process. Accurate estimating is essential to maximizing a company's resources. Overestimating a project's cost can tie up capital that could be used elsewhere, and underestimating can create budget shortfalls affecting overall economics.

Integrated Software Packages

With the complexity of today's wells, it is advantageous to use integrated software packages to help design all aspects of the well. Examples of these programs include

- Casing design
- Torque and drag
- Directional planning
- Hydraulics
- Cementing
- Well control

Decision Support Packages

Decision support packages document the reasoning behind the decisions that are made, allowing other people to understand the basis for the decisions. When future well requirements change, a decision trail is available that easily identifies when new choices may be needed and beneficial.

Performance Measures

Common drilling optimization performance measures are cost per foot of hole drilled, cost per foot per casing interval, trouble time, trouble cost, and AFEs versus actual costs [6].

Systems Approach

Drilling requires the use of many separate pieces of equipment, but they must function as one system. The borehole should be included in the system thinking. The benefit is time reduction, safety improvement, and production increases as the result of less nonproductive time and faster drilling. For example, when an expected average rate of penetration (ROP) and a maximum instantaneous ROP have been identified, it is possible to ensure that the tools and borehole will be able to support that as a plan. Bit capabilities must be matched to the rpm, life, and formation. Downhole motors must provide the desired rpm and power at the flow rate being programmed. Pumps must be able to provide the flow rate and pressure as planned [7].

Nonproductive Time

Preventing trouble events is paramount to achieving cost control and is arguably the most important key to drilling a cost-effective, safe well. Troubles are "flat line" time, a terminology emanating from the days versus depth curve when zero depth is being accomplished for a period of days, creating a horizontal line on the graph. Primary problems invariably cause more serious associated problems. For example, surge pressures can cause lost circulation. Excessive mud weight can cause differential sticking, stuck

pipe, loss of hole, and sidetracking. Wellbore instability can cause catastrophic loss of entire hole sections. Key seating and pipe washouts can cause stuck pipe and a fishing job.

When a trouble event leads to a fishing job, “fishing economics” should be performed. This can help eliminate emotional decisions that lead to overspending. Several factors should be taken in to account when determining whether to continue fishing or whether to start in the first place. The most important of these are replacement or lost-in-hole cost of tools and equipment, historical success rates (if known), and spread rate cost of daily operations. These can be used to determine a risk-weighted value of fishing versus the option to sidetrack.

Operational inefficiencies are situations for which better planning and implementation could have saved time and money. Sayings such as “makin’ hole” and “turnin’ to the right” are heard regularly in the drilling business. These phases relate the concept of *maximizing progress*. Inefficiencies which hinder progress include

- Poor communications
- No contingency plans and “waiting on orders” (WOO)
- Trips
- Tool failure
- Improper WOB and rpm (magnitude and consistency)
- Mud properties that may unnecessarily reduce ROP (spurt loss, water loss and drilled solids)
- Surface pump capacities, pressure and rate (suboptimum liner selection and too small pumps, pipe, drill collars)
- Poor matching of BHA components (hydraulics, life, rpm, and data acquisition rates)

Limits

Each well to be drilled must have a plan. The plan is a baseline expectation for performance (e.g., rotating hours, number of trips, tangibles cost). The baseline can be taken from the learning curves of the best experience that characterizes the well to be drilled. The baseline may be a widely varying estimate for an exploration well or a highly refined measure in a developed field. Optimization requires identifying and improving on the limits that play the largest role in reducing progress for the well being planned. Common limits include

1. Hole Size. Hole size in the range of $7\frac{7}{8} - 8\frac{1}{2}$ in. is commonly agreed to be the most efficient and cost-effective hole size to drill, considering numerous criteria, including hole cleaning, rock volume drilled, downhole tool life, bit life, cuttings handling, and drill string handling. Actual hole sizes drilled are typically determined by the size of production tubing required, the required number of casing points, contingency strings, and standard casing decision trees. Company standardization programs for casing, tubing, and bits may limit available choices.

- 2. Bit Life.** Measures of bit life vary depending on bit type and application. Roller cones in soft to medium-soft rock often use KREVs (i.e., total revolutions, stated in thousands of revolutions). This measure fails to consider the effect of WOB on bearing wear, but soft formations typically use medium to high rpm and low WOB; therefore, this measure has become most common. Roller cones in medium to hard rock often use a multiplication of WOB and total revolutions, referred to as the WR or WN number, depending on bit vender. Roller cone bits smaller than $7\frac{7}{8}$ in. suffer significant reduction in bearing life, tooth life, tooth size, and ROP. PDC bits, impregnated bits, natural diamond bits, and TSP bits typically measure in terms of bit hours and KREVs. Life of all bits is severely reduced by vibration. Erosion can wear bit teeth or the bit face that holds the cutters, effectively reducing bit life.
- 3. Hole Cleaning.** Annular velocity (AV) rules of thumb have been used to suggest hole-cleaning capacity, but each of several factors, including mud properties, rock properties, hole angle, and drill string rotation, must be considered. Directional drilling with steerable systems require “sliding” (not rotating) the drill string during the orienting stage; hole cleaning can suffer drastically at hole angles greater than 50. Hole cleaning in large-diameter holes, even if vertical, is difficult merely because of the fast drilling formations and commonly low AV.
- 4. Rock Properties.** It is fundamental to understand formation type, hardness, and characteristics as they relate to drilling and production. From a drilling perspective, breaking down and transporting rock (i.e., hole cleaning) is required. Drilling mechanics must be matched to the rock mechanics. Bit companies can be supplied with electric logs and associated data so that drill bit types and operating parameters can be recommended that will match the rock mechanics. Facilitating maximum production capacity is given a higher priority through the production zones. This means drilling gage holes, minimizing formation damage (e.g., clean mud, less exposure time), and facilitating effective cement jobs.
- 5. Weight on Bit.** WOB must be sufficient to overcome the rock strength, but excessive WOB reduces life through increased bit cutting structure and bearing wear rate (for roller cone bits). WOB can be expressed in terms of weight per inch of bit diameter. The actual range used depends on the “family” of bit selected and, to some extent, the rpm used. *Families* are defined as natural diamond, PDC, TSP (thermally stable polycrystalline), impregnated, mill tooth, and insert.
- 6. Revolutions per Minute (rpm).** Certain ranges of rpm have proved to be prudent for bits, tools, drill strings, and the borehole. Faster rpm normally increases ROP, but life of the product or downhole assembly may be

severely reduced if rpm is arbitrarily increased too high. A too-low rpm can yield slower than effective ROP and may provide insufficient hole cleaning and hole pack off, especially in high-angle wells.

7. **Equivalent Circulating Density (ECD).** ECDs become critical when drilling in a soft formation environment where the fracture gradient is not much larger than the pore pressure. Controlling ROP, reducing pumping flow rate, drill pipe OD, and connection OD may all be considered or needed to safely drill the interval.
8. **Hydraulic System.** The rig equipment (e.g., pumps, liners, engines or motors, drill string, BHA) may be a given. In this case, optimizing the drilling plan based on its available capabilities will be required. However, if you can demonstrate or predict an improved outcome that would justify any incremental costs, then you will have accomplished additional optimization. The pumps cannot provide their rated horsepower if the engines providing power to the pumps possess inadequate mechanical horsepower. Engines must be down rated for efficiency. Changing pump liners is a simple cost-effective way to optimize the hydraulic system. Optimization involves several products and services and the personnel representatives. This increases the difficulty to achieve an optimized parameter selection that is best as a system.

New Technologies

Positive step changes reflected in the learning curve are often the result of effective implementation of new technologies:

1. **Underbalanced Drilling.** UBD is implemented predominantly to maximize the production capacity variable of the well's optimization by minimizing formation damage during the drilling process. Operationally, the pressure of the borehole fluid column is reduced to less than the pressure in the ZOI. ROP is also substantially increased. Often, coiled tubing is used to reduce the tripping and connection time and mitigate safety issues of "snubbing" joints of pipe.
2. **Surface Stack Blowout Preventer (BOP).** The use of a surface stack BOP configurations in floating drilling is performed by suspending the BOP stack above the waterline and using high-pressure risers (typically 13 $\frac{3}{8}$ in. casing) as a conduit to the sea floor. This method, generally used in benign and moderate environments, has saved considerable time and money in water depths to 6,000 ft [8].
3. **Expandable Drilling Liners.** EDLs can be used for several situations. Future advances may allow setting numerous casing strings in succession, all of the exact same internal diameter. The potential as a step change

technology for optimizing drilling costs and mitigating risks is phenomenal.

4. **Rig Instrumentation.** The efficient and effective application of weight to the bit and the control of downhole vibration play a key role in drilling efficiency. Excessive WOB applied can cause axial vibration, causing destructive torsional vibrations. Casing handling systems and top drives are effective tools.
5. **Real-Time Drilling Parameter Optimization.** Downhole and surface vibration detection equipment allows for immediate mitigation. Knowing actual downhole WOB can provide the necessary information to perform improved drill-off tests [9].
6. **Bit Selection Processes.** Most bit vendors are able to use the electric log data (Sonic, Gamma Ray, Resistivity as a minimum) and associated offset information to improve the selection of bit cutting structures. Formation type, hardness, and characteristics are evaluated and matched to the application needs as an optimization process [10, 11].

4.13.4 Drilling Implementation

Most of the well drilling cost is time dependent rather than product cost dependent. Time is often the biggest influence. Rigs, boats, many tools, and personnel costs are charged as a function of time. Drilling mud is also discussed in terms of cost per day due to daily maintenance costs. The sum of the daily time-based costs is referred to as the operation's *spread rate*. In floater operations, the rig rate is the big influence. As spread rate increases, it becomes easier to economically justify higher-priced products that will save time. These may include more expensive bits, downhole turbines, rotary steerable systems, or a standard steerable system versus steering tools. The potential rewards of new technologies can be great.

4.13.4.1 Rate of Penetration

It is all about ROP, but how should we define ROP? Drilling optimization relies on minimizing total time. It is understood that we must be safe and must not damage production capacity. Our discussion focuses on drilling processes from spud to TD [12]. First consider each casing interval and then identify any subinterval where a substantially different drilling process would be beneficial or required (e.g., due to formation drillability or pressure changes, hole angle, mud type) and any planned events that would cause a trip. Where trips are required, an automatic opportunity is presented to change the drilling assembly and drilling approach or to replace the current tools with new ones if tool life may not be sufficient to reach the next planned trip point.

Alternatively, perhaps a planned trip may be challenged and found to be unneeded.

Discussing drilling “time” implies that the time is used to accomplish an outcome (i.e., creating hole)—hence the concept and measure of ROP. There is more than one measure and definition of ROP. This can create misunderstandings, but there are needs for these various measures. ROP, as historically defined, includes the hours after a bit reaches bottomhole divided by the distance drilled until a decision is made to trip out of the hole. By this definition, ROP includes the time spent actually drilling rock plus any back reaming, taking surveys with the steerable system, and making connections. It does not include time tripping in and out of the hole or circulating before tripping out.

Overall ROP (sometimes referred to as *effective ROP*) reflects the time to drill an entire interval, start to finish, divided by the distance drilled. This measure includes all time from start to finish, the rotating time, and the nonproductive time, and it is of great importance to the drilling engineer and operator management. The interval may start at drill out and conclude with starting the trip out of the hole to run casing, or it may be a subinterval as defined in the planning stage.

Instantaneous ROP is the ROP being achieved at any point in time. This can be correlated to the bit features, operating parameters, mud type and properties, and formation to optimize choices for each of these parameters in the interval

in real time and in future wells. Instantaneous ROP can be studied over the length of each joint (or stand if using a top drive) to assess changes in ROP, usually as a function of hole cleaning. This concept can be taken one step further to compare the ROP of respective joints as drilling progresses to assess bit wear or look for formation changes.

4.13.4.2 Special Well Types

The boundaries, constraints, limits, risks, drilling practices, equipment selection, and costs change significantly, depending on the type of well to be drilled. Because the relative importance and effect of these variables also change, the optimization approach and prioritization become more specific to the particular well type. Common groupings are

- Extended reach drilling (ERD)
- Horizontal
- Deepwater

Extended Reach Drilling

An ERD well is typically defined as one in which the horizontal departure is at least twice its TVD. Be aware that this is two-dimensional thinking and does not account for complex well paths or a degree of difficulty based on the equipment. However, Figure 4.13.3 provides examples of TVD versus horizontal displacement for several groups

FIGURE 4.13.3 Examples of TVD versus horizontal displacement for several groups of drilled assets.

Colin Mason
Phil Hearn, Sept 00

FIGURE 4.13.4 Extended-Reach Drilling—Evolution in the 1990s.

of drilled assets. ERD wells are expensive and typically are pushing the envelope [13–16]. The “envelope” has been pushed over time, as shown in Figure 4.13.4. Requirements and drilling objectives become very critical. Drill strings are designed differently [17, 18], rig capacity may be pushed to the limit, hole cleaning processes and capabilities will be tested, dogleg severity and differential sticking take on heightened sensitivity, and casing wear is a distinct possibility. Rotation of the drill string is still a key component to accomplish hole cleaning. Rotary steerable systems have provided tremendous value and are allowing ERD wells to be drilled longer than ever before [19–25].

The key issues are torque, drag, and buckling; hole cleaning; ECDs; rig capability; survey accuracy and target definition; wellbore stability; differential sticking and stuck pipe; well control; casing wear; bit type; BHA type; logistics; and costs.

Horizontal Wells

Horizontal wells are defined according to the rate of build from vertical to horizontal. Choosing one well profile instead of another is based on numerous criteria, including the location of the production zone in relation to the well’s surface location, the length of horizontal lateral needed, minimizing cost for footage drilled, and maximizing value. Table 4.13.1 provides a summary of typical ranges of application of each of these technologies, although it seems that as soon as numbers are written, they become obsolete. Product and tool selection must be suited to and optimized for the respective footages, hours, hole angles, and rate of change of hole angles. Large-radius horizontal wells essentially use the same build rates to build the curve as ERD wells use. However, drill collar weight is placed high enough in the drill string so that the collars do not enter the curved build

section. In this way, the weight is most effective axially along the drill string, causing less hole drag. Buckling is still a significant planning need. Casing wear is a lesser concern. Mud systems for horizontal laterals normally possess very low low-end viscosity, which maximizes turbulence when pumping, but solids will fall out of solution when pumping stops. Rotation of the drill string is still a key component to accomplish hole cleaning. Laterals are aligned to drill across any expected fractures to add most effectively to the effective permeability [24].

Deepwater

Until as late as 10 years ago, anything off the continental shelf (500–600 ft) was considered deepwater. However, with recent advances in drilling, exploration, and production technologies, wells are being drilled and produced in depths of 10,000 ft of water. A generally accepted minimum depth of 1,000 ft is common today but will surely change along with the technology. Drilling costs are a major share of the total development cost. A deepwater well may also be an ERD or horizontal profile and therefore possess those sensitivities.

The key issues are rig-buoyed weight and variable deck load capacity; surface stack BOPs; shallow water flows; riser design; hole cleaning; mud temperature cooling; hydrates; low pore pressure; ability to predict pore pressure during planning and in real time; narrow range of pore pressure to fracture gradient; ECD control; wellbore stability; trouble cost; BHA type; logistics; and time cost sensitivity.

New technologies for reducing finding costs include dual density and gradient drilling, composite risers, expandable casing, casing drilling, hole-enlarging devices, and surface stack BOPs.

TABLE 4.13.1 Well Profiles

Well Type	Angle Build Rate (°/100 ft)	Feet Drilled to Turn 90°	Curve Radius (ft)	Maximum Lateral Length (ft)	Special Tools Required (?)
Long radius	2–8	1125–4500	1000–3000	8000	No
Medium radius	8–20	450–1125	700–1250	8000	No
Short radius	150–300	30–60	20–40	1000	Yes

4.13.4.3 Real Time Optimization Practices

Prudent use of real time information and outcomes during drilling facilitate improved optimization. Real-time decisions must be allowed versus the well plan. This does not, however, mean that all decision-making should be placed on one person.

Drilling Mud

Optimum mud properties control the borehole effectively but minimize the negative effect on instantaneous ROP. Water loss, spurt loss, and low-gravity solids (i.e., drilled solids) directly reduce instantaneous ROP.

Directional Drilling Techniques

Unnecessary “drilling on the line” (especially on ERD wells) that is dictated by the customer or desired by the directional driller will add unnecessary doglegs, hole drag, time and costs, and hole-cleaning problems to a well. Meaningful criteria specific to the particular well plan should be developed.

Evaluation of the Last Bit

Information can be applied to the next bit run if the formation and the application method are substantially similar for the upcoming need. Bit BHA for the next run may change.

4.13.4.4 Drill-off Tests

Drill-off tests establish the preferred operational parameters in an effort to optimize ROP and bit life. The objective is not necessarily to maximize ROP, because bit life may be severely shortened. The objective is to produce the highest ROP with an acceptable bit and bearing wear rate, if applicable. This is accomplished by using only the magnitudes of rpm and WOB that cause a reasonably sufficient increase in ROP to justify the bit wear that will be caused. New parameters are needed when the formation changes throughout the drilling interval. Sometimes, the ROP is very sensitive to the WOB, and it is important to keep the WOB replaced as it drills off.

Once the WOB and rpm constraints are understood for the downhole tools and possible drill string vibration, the process for performing a drill-off test is as follows:

- Select a WOB believed to be reasonable and then vary the rpm up to the maximum, identifying the lowest rpm that produced the highest ROP.
- Select a reasonable rpm and then vary the WOB through its range, identifying the lowest WOB that produced the highest ROP.

4.13.4.5 Downhole Vibration

The effects of downhole vibration can be disastrous, and recognition, mitigation, and planning for vibration can be critical for success. Drill string failure, downhole tool (DHT) failures, and bit destruction are possible. Less than catastrophic outcomes include reduction in ROP, bit, DHT, and drill string life. A formula for drill string harmonics rule of thumb was removed from the API RP7G recommendations during the 1998 revision because of the inability to accurately predict vibration occurrence. Vibration observed at the surface is not always a model of what is occurring downhole.

Mitigation is accomplished by modifying operational parameters or the drill string and BHA and bit type selection, individually or in combination (e.g., using a downhole motor or turbine). Rig instrumentation or real-time downhole vibration monitoring can be added to recognize drilling vibration. The first step of mitigation operationally involves increasing the rpm. If this does not stop the event, WOB can be lessened. The last choice is to stop and then restart drilling. Damage can be caused very quickly. Quick recognition and mitigation is imperative.

4.13.4.6 Trendology

Drilling must use trend analysis because changes during drilling (over time) tell stories that can and should be used to prevent nonproductive time and to optimize drilling practices. Tabular data or graphical representations can be used to assess the data. The following relationships are predictable, and any unexpected changes are indicators of possible problems.

Standpipe Pressure (SPP) versus Strokes Per Minute (SPM)

An unexpected change may be caused by pump liner failure, drill string and tool washouts, lost nozzles in drill bits, plugged tools, or downhole motor failure.

Torque and Drag

Torque and drag change during the operation. Tracking of these criteria can indicate the borehole condition and hole cleaning. The measurement criteria are pick-up and slack-off weights and free rotating torque. When plotted against time, unexpected and rapid changes are indicators of potential problems. High-angle wells, which typically involve higher daily spread rates and higher risks of occurrence are prime candidates for this level of effort, as are wells with expected hole stability problems.

ROP

Changes in ROP during a bit run should correlate to changes in formation properties (e.g., type, hardness, characteristics), mud properties, or operating parameters (e.g., WOB, rpm, flow rate). An increase in pore pressure can cause a safety incident or borehole instability.

Mud

The mud weight, spurt loss, water loss, and drilled solids all directly affect ROP, hole stability, hole washouts, and future cementing effectiveness.

4.13.5 Post-Run Evaluation

Continuous improvement demands understanding to what extent each variable influences the outcome and how to apply the knowledge. The post-run evaluation process completes the cycle shown in [Figure 4.13.1](#). This should be a continuous improvement cycle.

The data acquired from the well just drilled become the input data for subsequent well planning and drilling stages. These data have become useful information for achieving new learning and greater optimization.

The key criteria that affected the outcome should be the primary focus of evaluation. The data will be used in the specialized “tools” used by operator and service company engineers. End of well (EOW) summary reports are created as a method to communicate the lessons learned.

4.14 WELL PRESSURE CONTROL

Section reviewed by John Breidenthal

4.14.1 Introduction

Basically all formations penetrated during drilling are porous and permeable to some degree. Fluids contained in pore spaces are under pressure that is overbalanced by the drilling fluid pressure in the well bore. The borehole pressure is equal to the hydrostatic pressure plus the friction pressure loss in the annulus. If for some reason the borehole pressure falls below the formation fluid pressure, the formation fluids can enter the well. Such an event is known as a *kick*. This name is associated with a rather sudden flowrate increase observed at the surface.

A formation fluid influx (a kick) may result from one of the following reasons:

- abnormally high formation pressure is encountered
- lost circulation
- mud weight too low
- swabbing in during tripping operations
- not filling up the hole while pulling out the drillstring
- recirculating gas or oil cut mud.

4.14.2

A blowout is the loss of containment of an unwanted reservoir influx (kick). Blowouts can be either a surface blowout or an underground blowout. If a kick is not controlled properly, a blowout will occur. A blowout may develop for one or more of the following causes:

- improper application of well control procedures
- malfunction or even lack of adequate well control equipment

4.14.3 Surface Equipment

A formation gas or fluid kick can be efficiently and safely controlled if the proper equipment is installed at the surface. One of several possible arrangement of pressure control equipment is shown in [Figure 4.14.1](#). The blowout preventer (BOP) stack consists of a spherical preventer (i.e., Hydril) and ram type BOPs with blind rams in one and pipe rams in another with a drilling spool placed in the stack.

A spherical preventer contains a packing element that seals the space around the outside of the drill pipe. This preventer is not designed to shut off the well when the drill pipe is out of the hole. The spherical preventer allows stripping operations and some limited pipe rotation. Hydril Corporation, Shaffer, and other manufactures provide several models with differing packing element designs for specific types of service. The ram type preventer uses two concentric halves to close and seal around the pipe, called

pipe rams or blind rams, which seal against the opposing half when there is no pipe in the hole. Some pipe rams will only seal on a single size pipe; 5 in. pipe rams only seal around 5 in. drill pipe. There are also variable bore rams, which cover a specific size range such as 3½ in. to 5 in. that seal on any size pipe in their range.

Care must be taken before closing the blind rams. If pipe is in the hole and the blind rams are closed, the pipe may be damaged or cut. A special type of blind rams that will sever the pipe are called shear blind rams. These rams will seal against themselves when there is no pipe in the hole, or, in the case of pipe in the hole, the rams will first shear the pipe and then continue to close until they seal the well.

A drilling spool is the element of the BOP stack to which choke and kill lines are attached. The pressure rating of the drilling spool and its side outlets should be consistent with BOP stack. The kill line allows pumping mud into the annulus of the well in the case that is required. The choke line side is connected to a manifold to enable circulation of drilling and formation fluids out of the hole in a controlled manner.

A mud/gas separator is installed on the mud return line to remove any small amounts of entrained gas in the returning drilling fluids. Samples of gas are analyzed using the gas chromatograph.

If for some reason the well cannot be shut in, and thus prevents implementation of regular kick killing procedure, a diverter type stack is used rather, the BOP stack described above. The diverter stack is furnished with a blow-down line to allow the well to vent wellbore gas or fluids a safe distance away from the rig. [Figure 4.14.2](#) shows a diverter stack arrangement.

4.14.4 When and How to Close the Well

There are *possible* and *positive* kick indicators. The *possible* indicators include:

Real time:

1. ROP increase or decrease (drilling break)
2. Change in drilling parameters (torque and drag)
3. Decrease in circulating pressure with an increase in pump stroke rate
4. Logging While Drilling (LWD), Pressure While Drilling (PWD) and Measurement While Drilling (MWD)

Bottoms-up:

1. Increase in connection/trip/background gas (possible loss of ECD)
2. Changes in cuttings volume/size/shape
3. Changes in mud properties (gas cut mud, water cut mud, chlorides change)
4. Changes in flowline temperature
5. Cutting size and shape

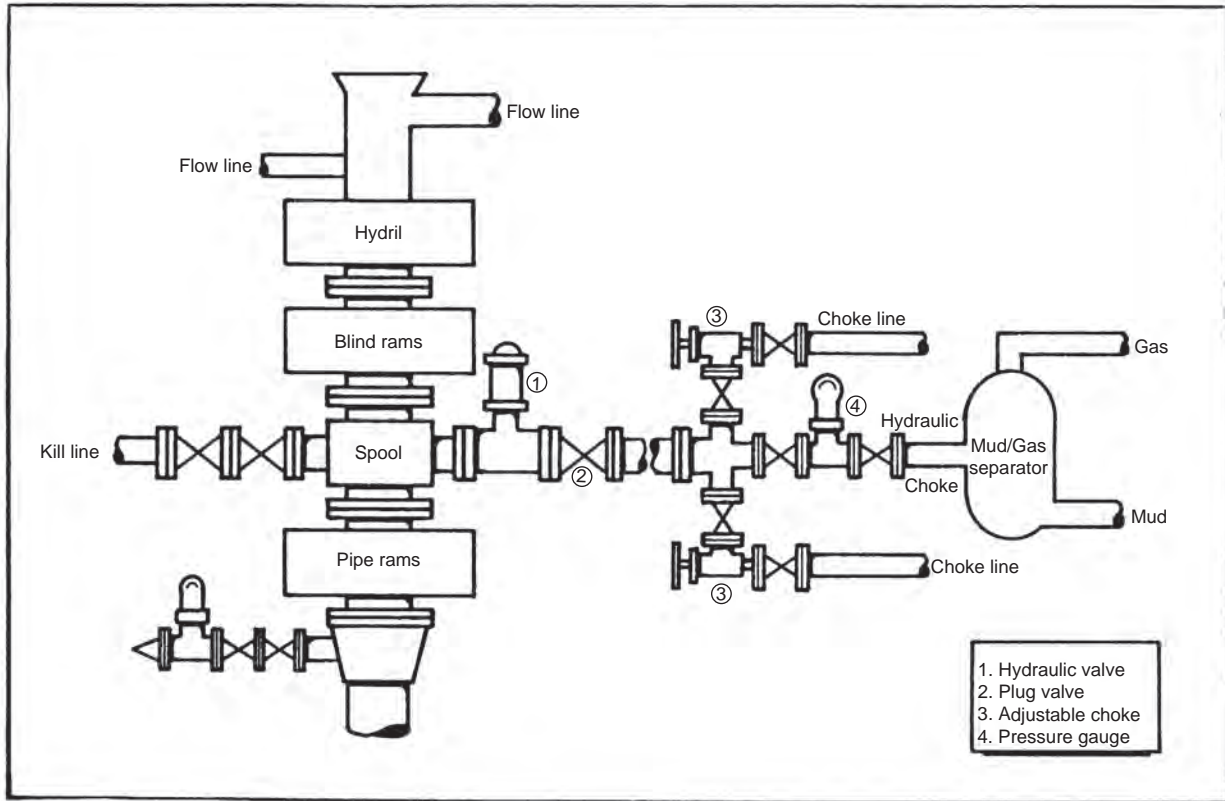

FIGURE 4.14.1 Pressure control equipment [2].

FIGURE 4.14.2 Driller’s method–Schematic diagram of drill pipe pressure vs. time.

For a possible kick indicator, at a minimum the well should be checked for flow. If flow is detected, the well should immediately be shut-in. The *positive* kick indicators are:

While drilling:

1. Increase in flow
2. Pit gain
3. Flow with the pumps off

While tripping:

1. Positive flow with pipe static
2. Trip log deviation:
 - Short fill ups tripping out
 - Excess pit gain tripping in

For a positive indicator the driller must immediately shut in the well. To shut in the well:

While drilling:

1. Space out (with respect to BOPE)
2. Shut down (stop pumping)
3. Shut in the well

While tripping:

1. Stab full opening safety valve (close same)
2. Space out (with respect to BOPE)
3. Shut-in

Note: Install IBOP and prepare to strip back to the bottom. It is recommended that a hard shut-in be employed when shutting in the well as follows:

4.14.5 Gas-Cut Mud

A gas-cut mud is a warning sign of possible formation fluid influx, although it is not necessarily a serious problem. Due to gas expandability, it usually gives the appearance of being more serious than it actually is.

The bottomhole hydrostatic head of gas-cut mud and the expected pit gain can be calculated from the following equations:

$$P_h = P_s + \frac{\gamma_s H}{(1 - a_s)} - \frac{P_s a_s}{(1 - a_s)} \ln \left(\frac{P_h}{P_s} \right) \quad (4.14.1)$$

$$V_p = \frac{A_n P_s a_s}{\bar{\gamma}_s} \ln \left(\frac{P_h}{P_s} \right) \quad (4.14.2)$$

where

$$\gamma_s = \frac{P_s M a_s}{z R T_{av}} + \gamma_m (1 - a_s) \quad (4.14.3)$$

where P_h = hydrostatic pressure of gas-cut mud in lb/ft^2 , abs

P_s = casing pressure at the surface in lb/ft^2 , abs

H = vertical hole depth with the gas-cut mud in ft

a_s = gas concentration in mud (ratio of gas to total fluid volume)

$\bar{\gamma}_s$ = gas-cut mud specific weight at surface in lb/ft^3

A_n = cross-sectional area of annulus in ft^2

γ_m = original mud specific weight in lb/ft^3

z = the average gas compressibility factor

M = gas molecular mass

T_{av} = the average fluid temperature in $^\circ\text{R}$

R = universal gas constant in $\text{lb} \cdot \text{ft}$

Example 4.14.1

Calculate the expected reduction in bottomhole pressure and pit gain for the data as given below:

Hole size = $9\frac{5}{8}$ in.

Hole depth = 10,000 ft

Drilling rate = 60 ft/hr

Original mud density = 10 lb/gal

Mud flowrate = 350 gal/min

Formation pore pressure gradient = 0.47 psi/ft

Porosity = 30%

Water saturation = 25%

Gas saturation = 75%

Gas specific gravity = 0.6 (air specific gravity is 1.0)

Surface temperature = 540°R

Temperature gradient = $0.01^\circ\text{F}/\text{ft}$

Solution

Gas volumetric rate entering the annulus

$$\begin{aligned} \dot{V} &= \frac{\pi(9.625)^2}{4 \times 144} \times 60 \times \frac{1}{60} \times 0.3 \times 0.75 \\ &= 0.1136 \text{ ft}^3/\text{min} = 0.85 \text{ gal}/\text{min} \end{aligned}$$

Gas volumetric flowrate at surface (at constant temperature) is

$$\dot{V} = \frac{0.85 \times 4700}{14.7} = 272.6 \text{ gal}/\text{min}$$

The surface pressure is assumed to be 14.7 psia. Gas concentration at surface is

$$a_s = \frac{272.6}{272.6 + 350} = 0.4378$$

Mud weight at surface (assume $z = 1.0$) is

$$\begin{aligned} \gamma_s &= \frac{14.7 \times 144 \times 0.6 \times 29 \times 0.4378}{1,544 \times 540} \\ &\quad + 10 \times 7.48(1 - 0.4378) \\ &= 42.07 \text{ lb}/\text{ft}^3, \text{ or } 5.62 \text{ lb}/\text{gal} \end{aligned}$$

Hydrostatic pressure of gas-cut mud is

$$\begin{aligned} P_h &= 14.7 + \frac{0.052 \times 5.62 \times 9,038}{(1 - 0.4378)} \\ &\quad - \frac{14.7 \times 0.4378}{1 - 0.4378} \ln \left(\frac{P_h}{14.7} \right) \end{aligned}$$

Solving the above yields

$$P_h = 4646 \text{ psia}$$

Hydrostatic head at the bottom of the hole is

$$P_{bh} = 0.052 \times 10(10,000 - 9,038) + 4,646 = 5,146 \text{ psia}$$

Since the hydrostatic pressure of the original mud is 5,214.7 psia, the reduction in the hydrostatic pressure is about 69 psi. Because the pore pressure at the vertical depth of 10,000 ft is 4,700 psi, the hydrostatic pressure of the gas-cut mud is sufficient to prevent any formation fluid kick into the hole.

4.14.6 The Closed Well

When a drillstring is in the hole, it is recommended that a non-ported float be installed above the bit. The non-ported float is a check valve (either flapper type or plunger type) that prevents fluids from entering the drillstring from the bit. With a non-ported float installed, any kick that enters the wellbore will exclusively be on the annular side. When the well is shut in, pressure will build up on the annular side and casing pressure increases. The rate of pressure buildup and time required for stabilization depend upon the formation fluid type, formation properties, initial differential pressure, and drilling fluid properties. Once the casing pressure has stabilized, the casing pressure should be noted as shut-in casing pressure (SICP). Since there is a float in the drillstring, the float must be “bumped” to record the shut-in drill pipe pressure (SIDPP). To do this, line the mud pump to the standpipe and pump as slow as possible down the drillstring while the well is shut in. Do so until an observable increase in casing pressure is seen (a positive indication that the float has opened) and stop pumping. Then note the drill pipe pressure and this is SIDPP. The type of reservoir influx has direct bearing the difference between SIDPP and SICP. For a given sized kick volume, V , the difference in pressures will be greatest for a gas kick, and followed by an oil kick and least for a saltwater kick. It should be understood that if a migrating gas bubble is in the well, the casing pressure will be increasing with time. Under certain conditions, this increasing pressure may even break down the formation at the casing shoe. Certain factors can mitigate this potential problems such as keeping any influx volume as small as possible, proper casing setting depths based on mud weight and worst case formation pore pressures or beginning the well control procedure (such as the Driller’s Method) expeditiously before the trapped pressure caused by migration reaches the point that would break down the formation.

Assuming the formation fluid does not enter the drillpipe, we know that the SIDPP plus the hydrostatic head of the drilling fluid inside the pipe equals the pressure of the kick fluid (formation pressure). The formation pressure is also equal to the SICP plus the hydrostatic head of the original mud, plus the hydrostatic head of the kick fluid in the annulus.

Thus

$$P_p = 0.052 \bar{\gamma}_m H + \text{SIDPP} \quad (4.14.4)$$

$$= 0.052 \bar{\gamma}_m (H - L) + 0.052 \bar{\gamma}_f L + \text{SICP} \quad (4.14.5)$$

where H = vertical hole depth in ft

$\bar{\gamma}_m$ = original mud specific weight in lb/gal

$\bar{\gamma}_f$ = formation fluid specific weight in lb/gal

L = vertical length of the kick in ft

p_p = formation pore pressure in psi

If the hole is vertical the kick length can be calculated as

$$L = \frac{V}{\text{VC}_{dc}} \quad (4.14.6)$$

or

$$L = L_{dc} = \frac{V - L_{dc} \text{VC}_{dc}}{\text{VC}_{dp}} \quad (4.14.7)$$

where V = pit gain in bbl

VC_{dc} = annulus volume capacity opposite the drill collars in bbl/ft

L_{dc} = length of drill collar in ft

VC_{dp} = annulus volume capacity opposite the drillpipe in bbl/ft

Equation 4.14.6 is applicable if the kick length is shorter than the drill collars while Equation 4.14.7 is used if the kick fluid column is longer than the drill collars.

From Equations 4.14.4 and 4.14.5 it is found that the required mud weight increase can be calculated from

$$\Delta \gamma_m = \frac{19.23 \times \text{SIDPP}}{H} \quad (4.14.8)$$

The formation fluid density can be obtained from

$$\bar{\gamma}_f = \bar{\gamma}_m - \frac{\text{SICP} - \text{SIDPP}}{0.052 H} \quad (4.14.9)$$

4.14.7 Kick Control Procedures

There are several techniques available for kick control (kick-killing procedures). In this section only three methods will be addressed.

1. *Driller’s method.* First the kick fluid is circulated out of the hole and then the drilling fluid density is raised up to the proper density (kill mud density) to replace the original mud. An alternate name for this procedure is the two circulation method.
2. *Engineer’s method.* The drilling fluid is weighted up to kill density while the formation fluid is being circulated out of the hole. Sometimes this technique is known as the *one circulation method*.
3. *Volumetric method.* This method is applied only if there is a migrating bubble AND if the well cannot be circulated with the drillstring near bottom, i.e., the bubble must be above the bottom of the string.

There are a number of instances where the well may not be circulated such as:

- pipe is off bottom
- no pipe in the hole
- pumps are inoperable drillstring is plugged

The guiding principle of all these techniques is that bottomhole pressure is held constant and slightly above the formation pressure at any stage of the process. To choose the most suitable technique one ought to consider (a) complexity of the method, (b) drilling crew experience and training, (c) maximum expected surface and borehole pressure and (d) time needed to reestablish pressure overbalance and resume normal drilling operations.

4.14.7.1 Driller's Method

Driller's Method

The Driller's method is based on maintaining a constant bottomhole (BHP).

Constant BHP well control method using two circulations:

First circulation *removes influx* with the original fluid.

Second circulation *kills the well* with kill fluid.

There are two basic rules for the Driller's method:

Rule No. 1: Anytime you start, stop, or change pump speed, maintain casing pressure constant (make sure casing pressure is correct).

Rule No. 2: At all other times, maintain the pressure constant on the side that has the constant fluid density

To initiate the first circulation, bring the pumps up to the slow circulating rate (between 2–5 BPM) pumping the original mud weight while maintaining a constant casing pressure by manipulation of the choke. Once the pumps are up to speed and pressures have stabilized, note the circulating drillpipe pressure (after subtracting any safety factor that has been established) and this is the Initial Circulating Pressure (ICP). This is an important pressure because the drill pipe pressure must be at or above this pressure as long as original mud weight is being pumped and the pump speed is constant. Continue pumping while maintaining this drill pipe pressure until all of the influx is removed from the well. Choke manipulation especially with gas passing through the choke will be required to accomplish this. Opening the choke will decrease BHP and closing the choke will have the opposite result. It is important to realize that after a choke adjustment is made, it will be seen immediately on the casing pressure gauge but there will be a lag time before the change is seen on the drill pipe side of the u-tube. [Figure 4.14.3](#) is a plot of casing pressure vs time during the first circulation.

Once the influx has been removed from the well there will be original mud on both the drillpipe and annulus sides of the well but the well is not dead. Kill mud weight must be circulated throughout the wellbore to kill the well. To calculate the required kill mud weight (KMW), use Equation [4.14.10](#).

$$\gamma_{\text{KMW}} = \gamma_{\text{M}} + \frac{\text{SIDPP}}{0.052\text{TVD}} \quad (4.14.10)$$

Where

γ_{KMW} = kill mud weight (lb/gal)

γ_{M} = original mud weight (lb/gal)

TVD = true vertical depth of kick formation (ft)

To conduct the second circulation, bring the pumps up to speed (2–5 BPM) pumping KWM while holding the casing pressure constant using the choke. Once the pumps are up to speed, continue to hold the casing pressure constant until the weighted mud reaches the bit (calculate strokes to the bit). At that point observe the drill pipe pressure and hold the drill pipe pressure constant until KWM reaches the surface. Shut down the pumps while holding casing pressure constant. At this point KWM should be everywhere in the wellbore and the shut in pressure should be only whatever safety factor was used during the circulation with the drill pipe and casing pressure being equal. The well should be dead at this point and the trapped pressure can be carefully bled off and the well confirmed dead.

4.14.7.2 Engineer's Method (Wait and Weight Method)

The Engineer's method is also known as the wait and weight method. Like the Driller's method, it is also a constant BHP technique that has advantages and disadvantages. One advantage is that in one circulation the influx can be removed and the well killed (the Driller's method requires two circulations). Another advantage is that when the open hole section is long, lower shoe pressures will be exerted during the circulation. A major disadvantage is that it is significantly more complex when the drillstring is tapered and/or is a non-vertical well.

The procedure is as follows:

1. Establish the initial *stabilized SICP*, then bump the float to obtain SIDPP
2. Calculate KMW
3. Bring pumps up to speed holding CP constant; record *ICP*, then shut down the pumps
4. Calculate SCR pressure; use it to calculate *FCP*.
5. Calculate strokes required to displace from pump to bit
6. Prepare circulating *drill pipe pressure schedule* (kill sheet)
7. When KMW is ready, change suction to KMW, then BPUTS and follow the DPP schedule until kill mud is at the bit
8. Maintain constant DP pressure (at FCP) until kill mud reaches the surface
9. Shut down pumps holding CP constant. Confirm that the well is dead

To calculate FCP,

$$\text{FCP} = \text{SCR} \left(\frac{\gamma_{\text{KMW}}}{\gamma_{\text{M}}} \right) \quad (4.14.11)$$

where FCP = Final circulating pressure (psi)
and

$$SCR = ICP - SIDPP \quad (4.14.12)$$

where SCR = slow circulating rate pressure (psi)
To prepare the drill pipe pressure schedule,

$$DP \text{ pressure/stroke} = (ICP - FSP) / \text{strokes to bit} \quad (4.14.13)$$

where DP pressure/stroke = change of drill pipe pressure per mud pump stroke. Figure 4.14.4 is a plot of drill pipe pressure for a vertical, non-tapered drill string. Figure 4.14.5 shows casing pressure during the circulation.

4.14.7.3 Volumetric

The volumetric method is another constant BHP method but should be used when there is a migrating gas bubble in a wellbore that cannot be circulated from bottom for any reason. There may or may not be pipe in the well. In essence, as the bubble migrates up the hole, by bleeding a calculated volume of mud from the well, the bubble is expanded in a controlled manner that maintains near constant BHP. The procedure is as follows:

1. Select safety factor (SF) and pressure increment (PI), and calculate mud increment (MI).
 - SF: dependent on MISICP (recommend 100 psi)
 - PI: pressure change for each step (recommend 100 psi)
 - MI: mud volume equivalent to PI

$$MI = \frac{PI \times ACF}{0.052 \times \gamma_M}$$

FIGURE 4.14.3 Driller's method—Schematic diagram of casing pressure vs. time. t_A = kick fluid out the top of the hole; t_B = kick fluid out of the hole; t_C = kill mud at the bottom of the hole; t_D = killing procedure completed.

where ACF = annular capacity factor (bbl/ft)

$$\gamma_M = \text{mud weight (lb/gal)}$$

2. Wait for CP to increase by SF + PI
3. Hold CP constant by bleeding small increments of mud at a time until MI is bled off.
4. Close choke and wait for CP to increase by PI.
5. Repeat steps 3 and 4 until:
 - a. Casing pressure stops increasing, or
 - b. Operations can revert to a preferred method, and influx is above the bit

4.14.8 Maximum Casing Pressure

Determination of the maximum expected casing pressure is required for selection of the kick control technique. If the driller's method is used for kick control, the maximum casing pressure $P_{c \text{ max}}$ (psi) is calculated assuming gas influx into the hole. This is

$$P_{c \text{ max}} = \frac{SIDPP}{2} + \left[\left(\frac{SIDPP}{2} \right)^2 + 0.052 \bar{\gamma}_m + \frac{P_p \Delta V_p T_2 z_2}{z_1 T_1 AV} \right]^{0.5} \quad (4.14.12)$$

where SIDPP = shut-in drillpipe pressure in psi

$\bar{\gamma}_m$ = original mud density specific weight in lb/gal

P_p = formation pressure

ΔV_p = pit gain in bbl

T_2 = gas temperature at surface in °R

T_1 = gas temperature at the bottom of the hole in °R

z_1 = gas compressibility factor at surface conditions
 z_2 = gas compressibility factor at the bottom of the hole
 AV = volume capacity of annulus in bbl/ft

Annular volume capacity = 0.13 bbl/ft
 Gas compressibility ratio $z_1/z_2 = 1.35$
 Gas temperature at the surface = 120°F
 Well-bore temperature gradient = 1.2°F/100 ft
 Surface temperature = 80°F

For the engineer's method the maximum expected casing pressure can be calculated from

$$p_{c \max} = 0.026(\bar{\gamma}_k - \bar{\gamma}_m)L_m + \left([0.026(\bar{\gamma}_k - \bar{\gamma}_m)L_m]^2 + 0.052 \bar{\gamma}_k \frac{p_p \Delta V_p z_2 T_2}{z_1 T_1 AV} \right)^{0.5} \quad (4.14.13)$$

where $\bar{\gamma}_k$ = kill mud density
 L_m = length of original mud in the annulus at the moment the bubble reaches the top of the hole

Example 4.14.3

Calculate the maximum expected casing pressure for the driller's and engineer's techniques of kick control for the data as below:

- Vertical hole depth = 12,500 ft
- Original mud weight = 12.0 lb/gal
- Shut-in drillpipe pressure = 260 psi
- Pit gain = 30 bbl
- Volume of mud inside the drillstring = 175 bbl

Solution

Required mud weight for killing the well is

$$\bar{\gamma}_k = 12 + \frac{260}{0.052 \times 12,500} + 0.5 = 12.9 \text{ lb/gal}$$

For trip margin, a 0.5 lb/gal was added arbitrarily. Bottom-hole temperature is

$$T_1 = 80 + 1.2 \times 125 = 230^\circ\text{F}$$

Formation pore pressure is

$$p_p = 260 + 0.052 \times 12 \times 12,500 = 8,060 \text{ psi}$$

For the driller's method

$$p_{c \max} = \frac{260}{2} + \left[\left(\frac{260}{2} \right)^2 + 0.052 \times 12 \frac{8,060 \times 30 \times 1.35 \times 580}{690 \times 0.13} \right]^{0.5} = 1,285 \text{ psi}$$

FIGURE 4.14.4 Engineer's method—drill pipe pressure vs. time.

FIGURE 4.14.5 Engineer's method—casing pressure vs. time; t_1 = kill mud at the bottom of the hole; t_2 = formation fluid reaches the choke; t_3 = kick fluid out of the hole; t_4 = pressure overbalance is restored.

For the engineer's method

$$p_{c \max} = 0.026(12.9 - 12.0) \frac{175}{0.13} + \left[(0.026 \times 0.9 \times 1,346.1)^2 + 0.052 \times 12.9 \frac{8,060 \times 30 \times 1.35 \times 580}{690 \times 0.13} \right]^{0.5} = 1,222 \text{ psi}$$

The engineer's method normally results in lower maximum surface pressure than the driller's method. For last field-type calculations, the following equation for the engineer's method can be used:

$$p_{c \max} = 200 \left(\frac{p_p \Delta V_p \bar{\gamma}_k}{AV} \right)^{0.5} \quad (4.14.14)$$

All symbols in Equation 4.14.14 are the same as those used above.

4.14.9 Maximum Borehole Pressure

When the top of the gas bubble just reaches the casing setting depth, the open part of the hole is exposed to the highest pressure. If this pressure is less than the formation fracture pressure, the kick can be circulated out of the hole safely without danger of an underground blowout.

If the driller's method is used, this maximum pressure p_{bm} can be obtained from

$$p_{bm}^2 - (p_p - 0.052 \times \bar{\gamma}_m \times H + 0.052 \bar{\gamma}_m D_1) p_{bm} - 0.052 \bar{\gamma}_m \frac{\Delta V_p p_p}{AV} = 0 \quad (4.14.15)$$

Example 4.14.4

The data for this example are the same as the data used in Example 4.14.3.

Casing setting depth = 9,200 ft

Formation fracturing pressure at casing shoe = 7,550 psi

It is required to determine whether or not the formation at the casing shoe will break down while circulating the kick out of the hole. The annulus volume capacity in an open hole is 0.046 bbl/ft.

Solution

Using Equation 4.14.15 we write

$$p_{bm}^2 - (8,060 - 0.052 \times 12 \times 12,500 + 0.052 \times 12 \times 7,550) p_{bm} - 0.052 \times 12 \times \frac{30 \times 8,060}{0.046} = 0$$

Solving the above equation yields $p_{bm} = 5,561$ psi. Since the maximum expected pressure in an open hole is less

than the formation fracture pressure, the kick can be safely circulated out of the hole.

4.14.10 Subsea Considerations

The preceding discussion has focused on blowout preventer systems that are above ground or above the water in the case of offshore equipment. However, for wells drilled using *subsea* blowout preventers additional variables must be factored in. Procedurally, the biggest difference between a surface stack and a subsea stack when circulating out a kick is that in the case of the subsea stack the choke line friction pressure must be compensated for. If it is not compensated for then the bottom hole pressure will not be held constant when using the Driller's method or the Engineer's method as it should be and instead will be increased by the amount of friction pressure in the choke line. Compensation means that the casing pressure should be reduced by the amount of choke line friction as the pumps are brought up to speed. The greater the water depth then the greater the choke line friction for a given mud system.

4.15 FISHING AND ABANDONMENT

Section reviewed by William Linn

A fish is a part of the drill string that separates from the upper remaining portion of the drill string while the drill string is in the well. This can result from the drill string failing mechanically, or from the lower portion of the drill string becoming stuck or otherwise becoming disconnected from drill string upper portion. Such an event will instigate an operation to free and retrieve the lower portion (or fish) from the well with a specialized string. Junk is usually described as small items of non-drillable metals that fall or are left behind in the borehole during the drilling, completion, or workover operations. These non-drillable items must be retrieved before operations can be continued [1–3]. The process of removing a fish or junk from the borehole is called *fishing*.

It is important to remove the fish or junk from the well as quickly as possible. The longer these items remain in a borehole, the more difficult these parts will be to retrieve. Further, if the fish or junk is in an open hole section of a

well the more problems there will be with borehole stability. There is an important tradeoff that must be considered during any fishing operation. Although the actual cost of a fishing operation is normally small compared to the cost of the drilling rig and other investments in support of the overall drilling operation, if a fish or junk cannot be removed from the borehole in a timely fashion, it may be necessary to sidetrack (directionally drill around the obstruction) or drill another borehole. Thus, the economics of the fishing operation and the other incurred costs at the well site must be carefully and continuously assessed while the fishing operation is underway. It is very important to know when to terminate the fishing operation and get on with the primary objective of drilling a well. Equation 4.15.1 can be used to determine the number of days that should be allowed for a fishing operation.

The number of days, D (days), is

$$D = \frac{V + C_s}{R_f + C_d} \quad (4.15.1)$$

where

V is the replacement value of the fish (dollars or other money),

C_s is the estimated cost of the sidetrack or the cost of restarting the well (dollars),

R_f is the cost per day of the fishing tool and services (dollars/day),

C_d is the cost per day of the drilling rig (and appropriate support) (dollars/day).

4.15.1 Causes and Prevention

There are a number of causes for fishing operations. Many of the problems that lead to fishing operations can be prevented by careful operational planning and being very watchful as drilling operations progress for indications of possible future borehole troubles [4]. The major causes of a fishing or junk retrieval operation are

1. *Differential Pressure Sticking.* It is estimated that the cost of stuck pipe in deep oil and gas wells can be approximately 25% of the overall budget. Therefore, a large portion of the fishing tools available were developed for the recovery of stuck pipe. This condition occurs when a portion of the drill string becomes stuck against wall of an open hole section of the borehole. This is due to smooth surface of the drill string (usually the drill collars) has become embedded in the filter cake on the wall. Differential sticking is possible in most borehole operations where drilling mud is being used as the circulation fluid. Underbalanced operations generally avoid this differential pressure sticking (see Section 4.9). Sticking occurs when the pressure exerted by the mud column is greater than the pressure of the formation fluids. Normally the drill string is differentially stuck when
 - A. The drill string cannot be rotated, raised or lowered, but circulating pressure is normal.
 - B. The drill collars are opposite a permeable formation.
 - C. Sticking was instantaneous when the pipe was stationary after drilling at a higher than normal penetration rate. In some cases a differentially stuck string or bottomhole assembly may be freed by reducing the mud weight.
 - a. This will reduce the differential pressure between the column of mud and the permeable zone. However, this procedure should not be used if well control is a problem.
2. *Under Gauge Borehole.* Mud filter cake can build excessively across a low pressure permeable formation when the circulation rate is low, water loss is very high, and there is an extended period between trips. Under these conditions, a drill string or logging tools can become stuck in the under gauge borehole and/or filter cake. Filter cake build up is usually slow and appears as drag on the multi-channel recorder, or as an under gauge hole on a caliper survey.
3. *Key seats.* Key seats develop where there is a sudden change in hole deviation or above a washout in a deviated hole. Doglegs above the drill collars are subject to erosion or wear by the drill pipe on the high side of the dogleg. Continuous rotation can slowly cut a groove into the dogleg forming what is known as a key seat. The drill pipe body and tool joints wear a groove in the formation approximately the same diameter as the tool joints. The wear is confined to a narrow groove, because high tension in the drill pipe prevents side ways movement. During a trip out of the hole, the BHA may be pulled into these grooves and the grooves may be too small to allow the BHA to pass through. In this situation no attempt should be made to jar the collars through a key seat. A possible solution to this problem would be to circulate and rotate the drill string and move the string in small increments up through the key seat. All tight spots (over pull and depth of the over pull) should be noted and recorded on the IADC daily report and the drilling recorder. A tight spot that occurs on two successive trips out of the hole with over pull on the second trip greater than the first, is an indication of a key seat forming. A key seat wiper or string reamer should be run on the third trip.
4. *Tapered hole.* Abrasive hole sections will tend to dull bits and thereby reduce bit and stabilizer gauge. Attempting to maximize the length of a bit run in an abrasive formation may prove to be a false economy since an under gauge hole will likely lead to a reaming operation. If the driller fails to ream a new bit to bottom

when this situation exists, the bit may jam in the under gauge hole. Proper grading and gauging of the old bit prior to running a new one will prevent this problem. Since this type of sticking usually occurs while tripping in the hole. In such situations, the string should be jarred up immediately. This will usually free the drill string. If jarring does not free the string, it will be necessary to make a back-off and wash over. Wash over procedures will be discussed below.

5. *Object along side the drill string.* Occasionally, an object such as a wrench, bolt, slip or tong part, or a hammer will fall into the hole along side the drill string. Except when the string can be pushed or pulled around the object or the object can be pushed into the wall of the hole, serious fishing problems can develop. This is especially true when the string gets jammed to one side of the hole in a cased hole. A visual check of all hand and other surface tools is required to see if anything is missing. Never leave the hole unprotected or leave loose objects lying around the rotary area. Jarring might free the string, if not, a short wash over is required using an internal spear to catch the string when it falls.
6. *Inadequate hole cleaning occurs as a result of*
 - A. A drill string washout above the bit.
 - B. Low circulation rate in a large hole with an unweighted mud system.
 - C. Sloughing shale.
 - D. Gravel bed in the shallow portion of the hole.
 - E. Partial returns.

Indications of sticking due to inadequate hole cleaning are:

- A. A significant change in the amount of returns across the shaker before sticking.
- B. A decrease in pump pressure or increase in pump strokes followed by an increase in drag while picking up on the pipe (a washout in the drill string).
- C. An increase in pump pressure and drag.
- D. The inability to circulate if the pipe sticks.
- E. Frequent bridges on trips.

Even with the challenging wells being drilled today the incident of parted strings occur less often than decades ago. Improved maintenance, inspection procedures, monitoring systems, materials and coatings are all contributing to a reduction in this fishing operations. The biggest challenge when fishing a parted string is in the interpretation of the condition of the top of the fish. A string may part due to any of the following reasons:

- a. A twist off after the drill string has become stuck.
- b. A washout.
- c. A back lash and subsequent unscrewing of the string.
- d. Junk wearing through a tubular.
- e. Metal fatigue in the string.

When working shallow without the benefit of a torque limit switch and if the string becomes stuck, the torque can build up very rapidly in the string and cause a twist off. If a work string is in poor condition a twist off can occur at any depth (with or without a torque limit switch). A twist off can be the most difficult type of fishing job due to the possible condition of the top of the fish. Turbulent flow of the circulating drilling fluid can damage a connection and cause a washout in the metal of the connection itself. If such a washout is not detected, the drill string can be weakened in the washed out area resulting in the failure of the string component. A washout in a tubular can in turn washout the formation. This would reduce the annular velocity in the washout area which in turn would diminish hole cleaning. Any time there is a drop in the standpipe pressure that cannot be explained, the string should be pulled immediately.

A string that alternately sticks then releases while drilling forward can result in a build up of torque which, when released, rotates the lower portion of the string at an accelerated rate. The inertia of the lower portion of the string can make the string back off. In a gauged area of the hole, the string could be screwed back together, but in a washed out area it will be necessary to run special tools to engage the fish. This can also occur off bottom while torque is in the string. Junk pushed into a soft formation can later damage tubulars rotating against the junk. It is always better to remove the junk than to push it to the side. Metal fatigue can cause a string to fail under normal operating parameters. Fatigue can be reduced by establishing the working life of string components and replacing them at the appropriate respective time intervals.

In general, parted strings are easier to fish than stuck pipe. However, if a fish is in an open hole, the likelihood of recovery a fish will diminishes with time. If a fish has a connection is facing up, a screw-in assembly with jars should be run. If the fish top cannot be screwed into, an overshot with a jarring assembly should be run. Different types of fishing and jarring assemblies are shown in [Figure 4.15.1](#). The condition of the bottom of the string pulled after a string parts should give an indication of the condition of the top of the fish and, thus, determine what tools should be used for the fishing job. The piece of fish pulled out of the hole should be a reverse mirror image of what the top of the fish looks like.

4.15.2 Pipe Recovery and Free Point

When a drill string or other tubular becomes stuck in a borehole it is very important that the depth where the pipe is stuck be determined. In most cases this can be accomplished via a simple calculation. The depth to where the drill string is free and where sticking commences is

FIGURE 4.15.1 Screw in Sub and Overshot Jarring Assemblies. (Courtesy Dailey Fishing Tools).

called the free point [2]. This free point can be calculated using measurements taken on the rig floor.

The length of the drill string from the surface to the free point is L_f . This will be less than the overall length of the drill string D . To obtain the L_f , the following procedure is used:

1. An upward force F_1 is applied to the top of the drill string via the drawworks. The force should be slightly greater than the total buoyant weight of the drill string. This ensures that the entire drill string is in tension.
2. With this tension on the drill string, a reference mark is made on the drill string exposed at the top of the string.

3. A greater upward force F_2 is then applied to the drill string. This causes the free portion of the drill string to elastically stretch by an amount ΔL . The stretch (or elastic displacement) is measured by the movement of the original reference mark. The magnitude of F_2 must be limited by the yield stress, or elastic limit stress of the specific pipe steel grade.

Knowing the stretch ΔL and the forces applied F_1 and F_2 , Hooke's law (see Section 2.3), the length to the free point is

$$L_f = EA \frac{\Delta L}{(F_2 - F_1)} \quad (4.15.2)$$

where

E is the Elastic Modulus (Young's Modulus) of steel (i.e., 29×10^6 psi, 200 GPa),

A is the cross-sectional area of the pipe body (ft², m²),

ΔL is the stretch distance (ft, m),

F_1 is the force to place the entire drill string in tension (lb, N),

F_2 is a force greater than F_1 but less than the force limited by the yield stress of the pipe grade (lb, N).

Example 4.15.1

A drill string API 3½ in., 13.3 lb/ft nominal weight, Grade E75 drill pipe is stuck in a 12,000 ft borehole. The driller places 150,000 lb of tension on the top of the drill string above the normal weight of the string and makes a mark on the string at top of the rotary table. The driller then increases the tension to 210,000 lb beyond the weight of the drill string. This later tension will give a maximum stress in the drill pipe body that is less than the 75,000 psi yield stress of Grade E75. The original mark on the drill string shows that the free portion of the drill string has stretched 4 ft due to the additional tension placed on the drill string by the drawworks.

The cross-sectional area of the drill pipe body is approximately

$$A = \frac{13.3}{490}$$

$$A = 0.0271 \text{ ft}^2$$

where the specific weight of steel is 490 lb/ft³. Equation 4.15.1 is

$$L_f = \frac{(29 \times 10^6)(144)(0.0271)(4.0)}{(210000 - 150000)}$$

$$L_f = 7805 \text{ ft}$$

There is a special downhole tool that can be used to determine the location where the drill string (or other

tubulars) is stuck. This is called a free point tool. Prior to using the free point tool must be calibrated in the free drill string (free pipe). This calibration is accomplished using an anchor system in the free string prior to normal operations being initiated. Once the tool is calibrated, the calibration should not be changed during the course of the operation. The free point tool is calibrated so that 100 units of movement is defined as completely free pipe. When the tool enters an increased cross-sectional area (increased wall thickness) such as Hevi-Wate drill pipe (HWDP), the scale will change so that 70 units of movement is accepted to be completely free pipe (the calibration of the free point tool has not changed). As the tool goes from HWDP into drill collars, there is another scale change. In the drill collars, 40 to 50 units of movement indicates completely free drill collars. A unit of movement in a free point application is a nondefined reference term.

There are four types of anchoring systems used in free point tools today. The oldest is the bow spring anchor. This design has been in use since 1941. The others are the permanent magnet anchoring system, the electromagnet anchoring system, and the motorized anchoring system. All free point tools measure movement between the two anchors (average about 17/1000 of 1 in. in movement). All free point tools read movement between the two anchors in the form of tension on the pipe, compression on the pipe, right hand torque on the pipe, and the newest tools, including the read left hand torque. It is critical that both torque and stretch readings be measured and compared. If the two readings differ, the torque reading is generally more reliable.

The interval between free pipe and stuck pipe is called the transition area. The interval is a length of the borehole. The length of the transition area is an important clue in helping to identify why the pipe is stuck. For example, in free pointing a stuck packer, the transition area would be extremely short if the pipe is free from the surface to the top of the packer. If the pipe were stuck due to fill on top of the packer, the transition area would be spread out over a longer interval. In an open hole a keyseat would result in a very short transition area while differential sticking would result in the transition area being spread out over a much longer interval. When parting the pipe it is important to leave some free pipe looking up (one or two joints of free pipe is recommended). Back-off at least 100 ft. below a casing seat or up inside the casing. Do not back-off in a washed out section or immediately below a drop in hole angle. Always make the back-off at the depth that will facilitate the best chance of future engagement to the fish.

4.15.3 Parting the Pipe

There are seven options to be considered prior to parting the pipe. These are chemical cut, jet cutter, internal mechanical cutter, outside mechanical cutter, multi-string cutter,

severing tool, and washover back-off safety joint/washover procedures.

There are five requirements for a back-off to be successful:

1. Free pipe: the connection to be backed off must be free.
2. Torque: the correct amount of left hand torque is required.
3. Weight: the connection being shot must be at neutral weight.
4. Shot placement: the shot must be fired across the connection.
5. Shot: use the proper size string shot/prima cord.

4.15.3.1 Chemical Cut

The first chemical cutter was developed by McCullough Tool Company and used in the field in 1957. The chemical cutter is lowered inside the pipe (that is to be cut) to a depth of one or two joints above the stuck point. A collar locator is used to correlate depths. Chemical cuts do not require that the pipe be torqued up. This affords a safer operation and is recommended in bad strings of pipe. Sometimes pipe will rotate freely, even though it cannot be pulled from the hole. This makes it impossible to back off the pipe. The chemical cutter utilizes heat energy to make a smooth cut without flare or distortion to the OD or ID of the pipe. It will not damage the outer string of casing or tubing making for easy engagement of the pipe being cut.

4.15.3.2 Jet Cutter

The shaped explosive charges using parabolic geometry were developed after World War I to penetrate thick steel armor. This shaped charge was adapted to fit in casing or tubing and became production jet perforating charges that replaced the earlier bullet perforators. Further improvements in the technology allowed the shaped charge concept to be used in a 360° circle design that can be used to completely sever a steel tube. Advantages of the jet cutter are that the jet cutter does not have mechanical slips to set so the condition of the tubular being cut, or what the ID is coated with, has little bearing on the operation of the cutting. Jet cutters are shorter in length than a chemical cutter and greater size ranges are available. The disadvantage of a jet cutter is that the pipe being cut will be deformed and must be dressed off before fishing. Also, adjacent strings could be damaged.

4.15.3.3 Internal Mechanical Cutter

The mechanical cutter usually cannot compete with cutters that can be run on wire line due to the cost of trip time. An internal mechanical cutter is shown in [Figure 4.15.2](#). However, if large OD tubulars are being cut a mechanical

FIGURE 4.15.2 Type "C" Internal Mechanical Cutter. (Courtesy Weatherford International).

cutter can be cost effective due to the high cost of large OD chemical and jet cutters. Also a mechanical cutter can be run in conjunction with a spear which allows cutting and retrieving in a single trip. The mechanical cutter is an option that will have merit in several situations. These are shallow depth cuts, large OD tubular cuts, the need to cut and retrieve in a single trip, and in well conditions too adverse for wireline conveyed cutters. The mechanical cutter is lowered into the hole on a tubular string to the point where the cut is to be made. At this point, right hand rotation will allow the friction assembly to unscrew from the mandrel and a gradual lowering of the tool permits the cone to be driven through the slips thereby anchoring the tool in the pipe. As the slips firmly engage, the wedge block

forces the knives outward. This action is continued until the pipe is cut. With the cut complete the pipe is raised, the slips disengage, the knives retracted and the friction assembly returns automatically to the running in position. A unique feature of this tool is the automatic nut which allows the resetting and disengaging of the tool frequently without coming out of the hole.

4.15.3.4 Outside Mechanical Cutter

Figure 4.15.3 shows an external mechanical cutter. Washing over the stuck pipe is done with washover pipe and a rotary shoe slightly larger than the cutter to make a gauge run. When washing over the desired section is completed, the washover pipe is pulled out of the hole and the rotary shoe is replaced with the cutter. The cutter and washpipe are then lowered over the stuck pipe. To operate, the cutter is slowly raised until the dog assembly engages the joint. The string is then lowered slightly to reduce excess pressure on the knives as the cut is started. Rotating the cutter to the right starts the cut. A slight upward pull and slow uniform rotation is maintained while the cut is being made. When the cut is completed, the string is raised, bringing with it the cut off section of pipe which is held in the cutter and washpipe. At the surface the cut off section is stripped out of the washpipe and the process is repeated.

4.15.3.5 Multi-String Cutter

Figure 4.15.4 shows a multi-string cutting assembly. The multi-string cutter is lowered into the hole on a working string. This cutting assembly is used for cutting multiple string of casing cemented together. There are three or four bladed cutter designs and both are hydraulically actuated. The tool is run to the desired depth and rotation is begun. As hydraulic pressure increases the knives are forced into the cutting position and the cut is made. In making the multiple cut, a series of different length knives are used in succession, each enlarging the window cut by the previous set. The tool is easily retracted by easing the hydraulic pressure and picking up on the string. Knives can be quickly exchanged from the rig floor. A well stabilized cutter will do a better downhole cutting job. A space out assembly is required on floating rigs so that the cutter can be accurately repositioned after each knife change. In making single or multiple cuts in large pipe (20 in.) or larger, a replaceable blade stabilizer is used since cutter stabilization is most important for efficient cutting action. On floating rigs, a marine swivel also must be used to stabilize the cutting depth and land properly in the wellhead.

4.15.3.6 Severing Tool-Open Hole Only

The severing tool is an option for parting pipe, drill collars, casing or other tubing. This tool is so powerful it will often

FIGURE 4.15.3 Type "A" Outside Mechanical Cutter. (Courtesy Weatherford International).

eliminate many fishing options. The 3 in. OD severing tool is rated to sever up to an 11 in. OD drill collar. The explosive material in a severing tool is C-4. If attempting to sever anything other than drill collars, it is recommended that the charge be placed in a tool joint or coupling. The severing tool needs metal mass in order to shatter the drill collar (or other thick walled tubular). If the tool is fired in the pipe body or casing the severing tool may balloon and rail split

FIGURE 4.15.4 Multi-String Cutting Assembly. (Courtesy Weatherford International).

the pipe wall rather than part it. When the severing tool is fired across a connection on drill pipe or casing, even if the pipe does not part, the connection is usually damaged enough so that the pipe can be pulled into.

4.15.3.7 Washover Back-off Safety Joint/Washover Procedures

The washover back-off safety joint is used to cross the wash pipe back to the jarring assembly and allow for washing over, screwing into a fish, and making a string shot back off in one trip. Should the washpipe become stuck, the washover safety joint provides a means to back off at the top of the washpipe with considerably less torque than is required to back off the work string. Due to the high risk of sticking the washpipe, a washover safety joint should be used any time a washover assembly is run in open hole. A fish can be screwed into with the washover safety joint, but several factors should be considered before this is done.

A washover assembly is shown in Figure 4.15.5. A typical washover assembly should consist of the following tools from the bottom up:

- A rotary shoe
- Washpipe
- Washover safety joint
- Bumper jars
- Oil jars
- Drill collars

FIGURE 4.15.5 Washover Assembly. (Courtesy Weatherford International).

- Accelerator jar
- Drill pipe or work string

A jarring assembly should always be run with washpipe in case the washpipe becomes stuck. The washover assembly is run into the hole to within 10 ft to the top of the fish. Circulation is established and the washpipe is lowered slowly over the top of the fish. The free portion of the fish standing above the stuck point acts as a guide for the washpipe. Once over the fish, free torque, circulating pressure and all other parameters should be recorded. Use rotary speeds of 40 to 50 rpm in soft formations and higher rotary speeds for harder formation. As with all milling applications, the surface speed should be calculated to insure the correct carbide dressed shoe feed rate. For crushed carbide the recommended feed rate is 150 to 200 surface feet per minute. During this operation, torque and

circulating pressure should be closely monitored. The OD of the washpipe in relation to the hole circumference makes sticking the washpipe a real possibility. The string should not be allowed to be static for any period of time. If the torque becomes too great, it is necessary to come out of the hole and lay down about half of the washpipe. If the hole is crooked and the location of the back off was poorly chosen, the top of the fish may be laying under a bend. Shorting of the washpipe may allow it to conform to the curvature of the hole more easily.

When the entire length of the washpipe had washed over the fish, the washpipe can be pulled from the hole and a jarring assembly run back to recover the fish. Special tools exist that allow the washing over, screwing in, and recovering of the fish in one trip. Use of these tools is very dependent on hole conditions and require a seasoned fishing tool operator. If the fish has been engaged but will not pull, a back-off should be made and the washover operation repeated to recover another section of the fish.

When a fish has been washed over and recovered in one trip, the fish must be stripped out of the washpipe. This can be a long and difficult operation. The drill pipe and part of the fishing string is pulled, broken out and set back until the washpipe is in the rotary table and the slips are set around it. The washpipe safety joint with the fish attached is then broken out and raised a few feet. A split slip holder or bowl is then screwed into the threads on the top of the washpipe and split slips are set around the fish to hold it. The fish is stripped out of the washpipe with the elevators. The washpipe can be pulled to change the rotary shoe if necessary. The whole washover process is repeated until all of the fish is recovered. When the last section of the fish is retrieved, the fish is stripped until the bit or stabilizer is near the bottom of the rotary shoe. The fish and washpipe must be pulled, suspended and broken out together. This double stripping job takes about one hour per 100 ft of washpipe. There are tools such as the drill collar spear that can be used to lower the fish and suspend it in the bottom joint of washpipe so that the washpipe can be pulled first, saving a double stripping job.

4.15.4 Jars, Bumper Subs and Intensifiers

Jars, Bumper Subs and Intensifiers are basic components in a fishing assembly. Improved design, new materials, and sophisticated computer programs for jar placement are continually improving jar overall jar performance. The fishing bumper sub is engineered to withstand sustained bumping loads and displacements during fishing, drilling, and workover operations. These tools are designed to permit a 10 to 60 in. vertical strokes downward. The stroke is always available in the tool, whether rotating or not, but the ease of the stroke may be affected by friction within the bumper sub itself. The lubricated bumper sub is better suited

for high or sustained circulating pressures. In all bumper subs, an adequate striking surface (to produce impact) must be provided at the limits of the free movement of the sub mechanism. Specially designed splines, torque keys, or torque slippers provide a source of continuous torque transmission. In addition the bores permit full circulation at all times.

By providing an immediate bumping action these tools can help to free drill pipe, drill collars, bits and other tools that have become stuck, lodged or keyseated. To achieve a good impact with a bumper sub, the drill string stretch must be utilized to provide the speed for the impact. This requires dropping the drill or working string until the jar is approximately 50% closed; the string is stopped abruptly at the surface and the downward momentum continues down, supplying the impact. This is a delicate operation and requires a little practice. Another function of the bumper sub is to release engaging tools and provide a "soft touch" when attempting to get over the top of a fish. Whenever a releasing type of fishing tool is to be used, a bumper sub should be run just above it to aid in its release.

The fishing jar is a straight pull operated jar that employs elementary principles of hydraulics and mechanics. Fishing jars can be mechanically or hydraulically actuated. Hydraulic fishing jars are most common. Hydraulic jars require no setting or adjustments before going in the hole, or after the fish has been engaged. The intensity of the jarring blow may be controlled within a wide range of impact load applied by the amount of over pull applied to the string before the jar is tripped. As pull is applied to the jar, oil is forced from one side of the inner body to the other through some type of orifice slots that will meter volume of fluid into storage chambers. This allows for ample time to pull the required stretch in the string.

To minimize the dulling effect on a grapple, hydraulic oil jars should be closed or reset using only sufficient weight to overcome friction in the inner body. During resetting, oil is forced in the opposite direction, unimpeded from one cavity to the other. Some jars require that the resetting be done slowly to optimize the life of the jar. It is possible to jar with torque in the string though it is not recommended. In most cases, the friction created by the torque will slow down the upward movement, reducing the impact loads. When used in fishing operations, an oil jar should be installed below a string of drill collars. For maximum effectiveness, a jar intensifier should be used in the string.

4.15.4.1 Drill Collars in a Jarring Assembly

In a jarring assembly, drill collars provide the mass to deliver the impact. The drill collars can be compared to the weight of head of a conventional hammer. A light hammerhead can deliver a fast impact blow, but the lack of mass reduces inertia, which means the impact is quickly

diminished. A heavy hammerhead delivers a slow impact blow, and the high mass increases inertia, increasing the effectiveness of the impact. Too many drill collars can have the same effect as too-heavy a hammerhead. Just as a hammer could be too heavy to swing, the friction produced between the borehole wall and a long string of drill collars could diminish the impact force at the fish.

4.15.4.2 Fluid Accelerator or Intensifier

During conventional jarring operations with either mechanical or hydraulic jars, the intensity of the blow struck is a function of, and proportional to the accelerated movement of the drill string above the jar. This accelerated movement will often be diminished by friction between the string and the wall of the hole. In such cases much of the energy will be lost. Also, at very shallow depths, lack of stretch in the running string causes significant loss in the effectiveness of the acceleration.

The intensifier provides the means to store the required energy immediately above the jar and drill collars. This is done to effectively offset the friction loss of stretch or drag on the string. An important secondary contribution of the intensifier is the use of its contained hydraulic fluid or gas to cushion the shock of the string as it rebounds after each jarring stroke. This reduces the tendency to cause shock damage to the tool and string. Use of the intensifier allows fewer drill collars to be used in specific cases than would otherwise be possible. This is particularly true at shallow operating depths where excessive numbers of drill collars are sometimes used to produce great mass in place of available stretch. However, the use of too many drill collars can be damaging to the tools and the string. The stretch created when over-pulling the drill string provides the energy required to actuate the fishing jar. Because of this energy, oil jars will work without intensifiers but less effectively. Illustrations of Jars, Bumper Subs and Intensifiers are shown in [Figure 4.15.6](#).

4.15.5 Attachment Devices

An attachment or engaging device provides a means to reconnect to the equipment (fish) left in a wall. Engaging devices should have as many as possible of the following features:

1. There should be a means to release the engaging tool from the fish.
2. Full and positive circulation through the fish should be possible.
3. There should be an unobstructed ID that will allow wire line access to the fish.
4. The device should have the highest tensile and torsion yield possible.
5. The device should be able to withstand up and down jarring impact.
6. The tool should allow the application of torque through the work string and into the fish when applying overpull or set down weight or when the engaging tool is at the neutral weight.

In open hole, the preferred method of engaging a fish is screwing in the with a screw in sub, joint of drill pipe, or a drill collar. This will meet all of the above requirements as well as providing the simplest and most fail safe means of solid engagement. Once screwed back together, the screw in point will have as high or higher mechanical properties as the fish below it. Screwing in will allow pump pressures equal to that of the string to be applied to the fish. Other than the jars, the ID of the string will not have changed after screwing in.

Screwing in is the preferred when down jars will be used due to the releasing mechanism of most engaging tools. Most engaging tools require over pull to maintain a good bite on the fish, which makes it very difficult to work torque down to the fish. The only drawback to screwing in is that a wire line string shot back-off becomes the surest method of backing off at the screw in point.

4.15.5.1 Cutlip Screw-in Sub

When a fish is partially buried in the wall or partially behind a ledge or even against the high side of the hole, a cut lip sub can be used to pull the connection over to align with the screw-in the assembly. Due to the cutting of the threaded area, this sub is not API approved. If a fish is in a gauged section of a hole in medium to hard rock formations, with low borehole deviation ($\sim 5^\circ$ or less), a joint of drill pipe, or a drill collar may be used to screw into the fish. A cutlip screw-in sub is shown in [Figure 4.15.7](#).

4.15.5.2 Skirted Screw-in Assembly

A skirted screw-in assembly gives an operator all the hole sweeping advantages of an overshot with the strength, torque and circulating ability of a screw-in sub. The skirt can be of an OD that will not allow the skirted assembly to pass the fish. The cut lip makes it possible to pull the fish inside the skirt.

Skirted assemblies are most often made up from a washpipe triple connection bushing and a blank rotary shoe. The shoe can then be cut into the desired shape, cut lip or wallhook. A Weatherford skirted cutlip screw-in assembly is shown in [Figure 4.15.8](#).

4.15.5.3 External Engaging Devices

The second choice for engaging a fish is with an external catch device (when it meets the strength requirements). An external engaging device usually will not restrict the

FIGURE 4.15.6 Jars, Bumper Subs and Intensifiers. (Courtesy Weatherford International).

ID of the fishing assembly, thus, leaving wireline options open and allowing full circulation. An external catch device can also be of sufficient OD to eliminate the possibility of passing the fish.

4.15.5.4 Series 150 Releasing and Circulating Overshot

The most-popular external catch device is the Series 150 releasing and circulating overshot. The tool was invented

over 60 years ago and has not changed from the original design. This overshot provides the strongest means available to externally engage, pack off, and pull a fish when screwing in is not possible. Its basic simplicity, rugged construction, and availability make this tool the standard for all external catch fishing tools.

The Series 150 is designed to engage, pack off, and grapple (and retrieve) a specific size of tubing, pipe, coupling, tool joint, drill collar or smooth OD tool. Through the installation of the proper parts, these tools may be adapted

FIGURE 4.15.7 Cutlip Screw in Sub. (Courtesy Weatherford International).

to engage and pack off a wide range of diameters for each overshot size. Series 150 overshots are available in Full Strength or Slim Hole types. The overshot consists of three outside components: the top sub, bowl and guide. The basic overshot may be addressed with either of two sets of internal parts, depending on whether the fish to be retrieved is near the maximum catch size for the particular overshot. If the fish diameter is near the maximum retrieval for the overshot, a spiral grapple spiral grapple control, and type A packer are used. If the fish is a tubing collar, a type D collar pack-off assembly will be used. If the fish diameter is below the maximum retrieval size (by approximately $\frac{1}{2}$ in.), then basket grapple and mill control packer are used. Both the spiral and basket grapple are the engaging mechanism. The spiral control and basket grapple control locks the torque in the grapple but still allows the grapple to move up and down inside the bowl.

The bowl of the overshot is designed with a helical tapered spiral section within its inside diameter. The gripping mechanism (the grapple) is fitted into this section. When an upward pull is exerted against a fish, a contraction strain is spread evenly over a long section of the fish. The catch range is from $\frac{1}{32}$ to $\frac{1}{16}$ in. above and below the specified catch range. The overshot is engaged by slacking off over the fish, then a straight pull will engage the overshot. As long as there is an over pull, either right

or left hand torque may be applied. To release the Bowen overshot, the string is bumped or jarred down on to break the freeze between the overshot bowl and the grapple. Once the freeze has been broken, rotation to the right while slowly picking up on the string will walk the grapple off the fish. A Series 150 releasing and circulating overshot is shown in [Figure 4.15.9](#).

[Tables 4.15.1](#) and [4.15.2](#) give specific restrictions for overshot sizes in openhole and cased hole environments, respectively.

4.15.5.5 High-Pressure Pack-Off

The mill control and Type A packers used with the overshot have a limited pressure rating. If high pressures will be required or there are well control concerns, it is advisable to run a high pressure pack-off. The pack-off is run directly above the overshot bowl. Chevron packing is used for sealing. This type of assembly can be used as a permanent tubing patch. The pack-off is good for approximately 5,000 psi.

4.15.5.6 Oversize Cutlip Guide

The oversize guide is used when the fish OD in relation to the hole ID makes it possible for the overshot to bypass the fish. The oversize guide may be used to better utilize inventory by keeping a smaller selection of overshots. But care should be taken not to sacrifice strength to do this. An oversize cutlip guide is shown in [Figure 4.15.10](#).

4.15.5.7 Wallhook Guide

The wallhook guide is used with a bent joint of pipe or hydraulic knuckle joint to sweep a washed out section of hole when a fish cannot be pulled into the overshot with a standard cutlip guide. The assembly is made up so the lip of the wallhook has the maximum possible reach. Once the overshot has passed the top of the fish, the string is slowly rotated until torque indicates the wallhook is made up to the fish. The string is then elevated until the torque is lost. The fish should be in a position that it can be engaged by slacking off on the overshot. A wallhook guide is shown in [Figure 4.15.10](#).

4.15.5.8 Hollow Mill Container and Hollow Mill

The hollow mill container with a hollow mill insert is used to dress off the top of a fish that has been damaged. This device is used to engage the fish in one trip. This accessory is most often used when a fish top is flared after a jet cut or in the event a twist off has occurred. This assembly is run directly below the overshot bowl. A hollow mill container and hollow mill device is shown in [Figure 4.15.10](#).

FIGURE 4.15.8 Skirted Cutlip Screw in Assembly. (Courtesy Weatherford International).

4.15.5.9 Bowen Series 70 Short Catch Overshot

Series 70 short catch overshots are specifically designed to engage the exposed portion of a fish too short to be caught with a conventional overshots. The short catch overshot consists of a top sub, a bowl, a basket grapple and a basket grapple control. The grapple is inserted in the top end of the overshot and is positioned at the extreme lowered end of the bowl. Spiral grapples, mill control packers and Type A packers cannot be used with a short catch overshot. A Series 70 short catch overshot is shown in Figure 4.15.11.

4.15.5.10 Internal Engaging Devices

If the fish must be engaged internally, releasable spears are used. Spears restrict the ID of the fishing assembly. There is no pack off system built into the tool but certain accessories may be used to accomplish circulation. The Itco Type Bowen releasing spear is designed to assure positive

engagement with a fish. Built to withstand severe jarring and pulling strains, it engages the fish over a large area without damage to the fish. If the fish cannot be pulled, the spear may be released. The Itco type Bowen releasing spear consists of a mandrel, grapple, and a locking ring and nut. The mandrel may be a shoulder type or flush type. The flexible one-piece grapple has an internal helix which mates with the helix on the mandrel. The tang of the grapple rests against a stop on the mandrel when the spear is in the engaged position. A Bowen Itco releasing spear is shown in Figure 4.15.12.

4.15.5.11 Box Taps and Taper Taps

Box taps are used to engage the outside diameter of a fish, usually in a situation where conventional releasing overshots would not be a feasible option. They are designed to tap threads into the steel tubing (or other steel downhole tools) so that the fish can be retrieved. Standard box taps are made with an integral guide on the lower end to insure

FIGURE 4.15.9 Series "150" Releasing and Circulating Overshot. (Courtesy Weatherford International).

proper engagement to the fish even when the fish is not centralized in the hole.

Taper taps are used to engage the inside of a fish where conventional releasing spears would not be feasible. Like the box tap, the taper tap is designed to cut threads where no threads existed. Standard taps are machined from high quality heat treated steel, with buttress type threads that are carbide for hardness. They can be ordered with right or left hand wickers. Box and taper taps can be used to fish tubulars, packers, or other types of downhole equipment that cannot be fished by conventional means. They have the widest catch range of any fishing tool. Since all taps are nonreleasable, a safety joint should always be run just above them. A box tap and taper tap are shown in Figure 4.15.13.

4.15.6 Fishing For Junk

Junk is all that other devices that may fall into the hole or become detached in the hole that are not tubulars. The type of junk retrieval device to be used in the fishing operation will depend on the properties of the junk (to be milled up or recovered). There are many tools designed to recover junk, and often an operational practice preference will determine which tool is used.

4.15.6.1 Poor Boy Junk Basket

One of the simplest fishing tools is the poor boy junk basket. It is run in the hole, circulation established, then the tool is slowly rotated down over the fish. If the basket is nearly hole size, its finger like catchers will gather junk toward the

center of hole. When weight is applied the basket will bend inward to trap the junk inside. It is most effective for a small solid mass lying loose on bottom, such as a single bit cone. A poor boy junk basket is shown in [Figure 4.15.14](#).

4.15.6.2 Boot Basket

A boot basket is run just above a bit or mill to collect a variety of small pieces of junk. The boot basket design traps junk by producing a sudden decrease in annular velocity when cuttings (with entrained junk) pass the larger OD of the boot and reach the smaller OD of the mandrel and top connection. A boot basket is shown in [Figure 4.15.14](#).

4.15.6.3 Core Type Junk Basket

The core-type junk basket is used to retrieve junk such as bit cones that may or may not be embedded in the wall or bottom of the rock formation. A milling shoe is made up on the bottom of the tool. After it is run nearly to bottom, the mud is circulated at reduced pressure and the tool is slowly rotated and lowered to make contact with the junk. Weight is gradually increased on the shoe as it cuts away the edges of the junk and the formation. The junk is forced into the barrel and a short core is cut. Rotation and circulation are stopped, torque is released from the drill string, and the working string is raised to break the core. Catchers inside the basket hold the core and the junk as it is tripped out of the hole. A core type junk basket is shown in [Figure 4.15.14](#).

4.15.6.4 Jet Powered Junk Baskets and Reverse Circulating Junk Baskets

One of the most common types of junk baskets is the venturi jet basket. The basket is run into the hole and fluid is circulated to clean all cuttings and debris off the junk. A ball is then dropped down the pipe and seated in a valve to produce reverse circulation. The circulating fluid is then jetted outward and downward against the full circumference of the hole where it is deflected in a manner that directs all annular flow below this point into the shoe. Along with drilling fluid (mud), small pieces of junk are sucked up into the barrel where pieces are caught by catcher fingers. A reverse circulating junk basket is shown in [Figure 4.15.14](#).

4.15.6.5 Hydrostatic Junk Baskets

The hydrostatic junk basket derives its actuating forces from circulating fluid pressure differential. The tool and drill string are lowered into the hole nearly empty of fluid. Once on bottom with the junk basket over the junk, application of weight on the string (downward) trips a

valve allowing drilling fluids under great hydrostatic pressure to enter the empty drill string carrying debris (junk) with it. The effect is the same as lowering an empty straw, its top covered with a finger, into a glass of water. When the finger is removed, water rushes into the straw. The hydrostatic junk retriever can be opened and closed many times before being removed from the hole.

4.15.6.6 Milling Tools

Junk mills are designed to mill bit cones, reamer blades, or any other junk which may obstruct the wellbore. Many milling tools are fabricated for a specific milling operation. Some mills are manufactured from a solid piece of AISI 4140 heat-treated steel. Others are fabricated by welding the blades and stabilizer pads on to a simple tubular body. Although these tools are quite simple in appearance, the junk mill requires thought and experience to obtain the desired junk removal results. These tools should be designed to be versatile and to withstand spudding, heavy weights, and fast rotation. Factors that affect milling rates and the design of the mill are the type of fish, being milled, the stability of the fish, and its hardness.

4.15.6.7 Mill Designs

The concave design centers the mill over the fish and is less likely to sidetrack. The cone buster junk mill is a very popular type of mill. It is used to mill loose junk, or dress off the top of a fish. The Type P mill is a very aggressive mill. It has a large throat (rather than smaller water courses). The bladed junk mill is used to mill up packers and will cut faster through sand, cement or fill. String mills are used to enlarge windows in a whipstock operation, or to mill out a collapsed casing. Tapered mills are used to dress liner tops, smooth out perforations, and are sometimes run with pilot mills to stabilize and keep the casing clear. Pilot mills are used to mill up casing, drill pipe or liners. They perform better if the fish is stabilized (to reduce vibration and chatter). Pilot milling should be treated as a machining process. Shock subs are usually run directly above the mill to reduce vibration. A section mill is used to cut windows in the casing to facilitate a sidetrack operation. They can also be used to mill out internal casing patches or to cut pipe. Junk, string, taper, pilot, and section mills are shown in [Figure 4.15.15](#).

4.15.6.8 Impression Block

One method that is sometimes used to access the condition of the top of the fish is to run an Impression block. A typical impression block consists of a block of lead that is molded

FIGURE 4.15.14 Poor Boy, Boot, Core Type and Reverse Circulating Junk Baskets. (Courtesy Weatherford International).

FIGURE 4.15.15 Junk, String, Taper, Pilot and Section Mills. (Courtesy Weatherford International).

into a circular steel body. The block is made up on drill collars and run into the hole until it just above the fish. Circulation is started to wash all fill off the top of the fish so that a good impression can be obtained. The block is lowered gently to touch the fish and weight is applied. The top of the fish indents the bottom of the soft lead, leaving an impression that can be examined and measured at the surface.

4.15.6.9 Fishing Magnets

Ferrous metallic junk can often be retrieved using a fishing magnet that is made up to the bottom of a working string. This tool is a powerful permanent magnet that has ports for circulation and a nonmagnetic brass sleeve housing to prevent junk from clinging to the side of the magnet. A fishing magnet is lowered into the hole with circulation to wash cuttings off the top of the fish. A cut lip skirt on the bottom helps to rake the junk into the face of the magnet for engagement and also prevents the junk from being knocked off while pulling out of the hole. Do not run excessive weight on a fishing magnet; it is not a drilling tool.

4.15.6.10 Junk Shot

When a large or oddly shaped piece of junk is in the wellbore and it cannot be retrieved using regular junk baskets, a junk shot may be used to break piece into smaller pieces. This junk shot tool contains a shaped charge. This tool must be run on collars and drill pipe to keep the force of its explosion directed downhole (at the junk). The tool is lowered to just above the junk and circulation is established to wash all fill off the junk. When the shaped charge is fired, its downward-directed blow breaks up the junk so that it can be finished with more conventional means.

4.15.7 Abandonment

Well abandonment is a process to permanently shut-in a previously producing well in a safe and environmentally responsible way. This process is applied to both land and offshore wells. Obviously, offshore wells are the most complicated to permanently abandon. To abandon a well the casing is generally cut below the mud line. In the United States and its territorial waters, the depth below the mud line is defined in U.S. Federal Government regulations [6]. Other countries and regions of the world often use similar but different regulation sources. This type of operation was at one time the hardest perform. But with today's new recovery systems and new casing cutting technologies NPT has been greatly reduced, saving the operators thousands of dollars in rig time. Some companies have advanced wellhead recovery systems available on the market. An example of such tool systems is the Weatherford M.O.S.T.

Tool System that cuts and retrieves the casing, wellhead, and the temporary guide base in a single trip. These advanced systems when used with a downhole mud motor for cutting can eliminate wellhead damage and confirm cuts without tripping pipe. There are two different types of tools; the deepwater version, and the standard version. The deepwater versions utilize a mud motor and can be used at all water depths and water currents. The standard version has three options for cutting the casing; rotary table, top drive, or a mud motor. When using the rotary table or top drive for cutting a marine swivel must be used. The rotary table or top drive options of cutting the pipe are used primarily for shallow water operations (less than 2,000 ft and water currents less than 3 knots). Using the standard version with a mud motor increases cutting efficiencies (all water depths and water currents). The deepwater and standard versions (using a marine swivel) are shown in [Figures 4.15.16](#) and [4.15.17](#), respectively.

4.15.8 Wirelines

Wirelines are utilized in a variety of operations in drilling and completions and production operations. During exploration and development drilling operations wireline logging operations, retrieval of bottomhole samples, and placement and retrieval of downhole tools are vital to the assessment of new reservoirs and the continued operation of producing reservoirs. Thus, the subject of wirelines is an important issue in a number sections and subsections throughout this handbook. However, in order not to repeat this subject in the other sections and subsections where wirelines are an important subject, the wireline subject has been concentrated for convenience in this Fishing and Abandonment section.

4.15.8.1 Wireline Construction

There are two basic categories of wirelines. All wirelines are anchored at one end at the surface with a wireline head that can be mounted on the drilling rig floor or on some other auxiliary equipment (e.g., logging truck bed) at the operational site. The free end of the wireline carries a load of some type of downhole tool (a deadload or tool for providing a downhole actuating force).

The first category of wirelines are made up of simple armored cables of various diameters and strengths that have no electrical conductor lines integrated into the overall construction. These wirelines are used to carry loads (e.g., special downhole tools) or otherwise provide actuating forces inside the wellbore. The second category of wirelines are an integrated construction with armored cables (for load carrying) surrounding a variety of electrical conductor lines.

FIGURE 4.15.16 Deepwater MOST Tool. (Courtesy of Weatherford International.).

FIGURE 4.15.17 Tool with Marine Swivel. (Courtesy Weatherford International.).

The standard load carrying armored cables are special galvanized improved plow steel wires. The wires of the standard cables are coated with zinc. The tensile strength of each wire used in the standard cables are in the range of 270,000 to 300,000 psi. These standard load carrying cables are not recommended for operations in H_2S and CO_2 environments.

For operations in H_2S and CO_2 it is necessary to use load carrying armored cables constructed of stainless steel wires. Stainless steel wires have tensile strengths that are

slightly below those of the standard wires discussed above (e.g., range of 240,000 to 270,000 psi). Thus, armored cables constructed with stainless steel are rated at slightly lower breaking strengths than the standard armored cables discussed above. Usually H_2S and CO_2 are accompanied by higher downhole temperatures. Higher operating borehole temperatures will result in decreased breaking strength for all armored cables.

All mechanical properties are for room temperature conditions.

4.15.8.2 Electrical Conductors

Most wireline manufactures rate their conductors cables at DC rather than AC. Rating a conductor cables for maximum AC voltage presents difficulties. AC voltage ratings are dependent on frequency and actual wave shape. Such an AC voltage can be characterized by an equivalent DC voltage that will provide the same amount of heating. In many applications, AC power is transmitted as alternating voltages and currents in a sine or cosine wave variation in time. Also, 60 hertz is a common power frequency. If this is the method of transmission, then a 707-volt sine wave has 1000 volts peak voltage. Therefore, a 707-volt average voltage at a frequency of 60 hertz would correspond to 1000 volts DC. At higher frequencies there can be more stress on the dielectric due to heating. Generally, the higher the frequency, the lower the breakdown voltage.

All electrical data for resistance and capacitance are nominal values and have been corrected to 20°C.

Proper selection of armored cable materials and conductor insulation materials can allow wirelines to operate up to temperature of 600°F (316°C).

4.15.8.3 Simple Armored Wirelines

This category of wirelines is composed of a variety of armored wirelines that are used in numerous downhole, rig site and/or wellhead operations. These wirelines vary in diameters from $\frac{3}{16}$ in. (4.80 mm) to as high as $\frac{9}{16}$ in. (14.30 mm).

Table 4.15.3 gives the typical construction, dimensions, and mechanical properties for sand lines.

Table 4.15.4 gives the typical construction, dimensions, and mechanical properties for Swablines.

Table 4.15.5 gives the typical construction, dimensions, and mechanical properties of a variety of utility wirelines used in wellhead operations.

Most manufactures of wirelines will construct specially designed armored wirelines for unique downhole operations.

4.15.8.4 Armored Wirelines with Electrical Conductors

This category of wirelines is composed of a variety of armored wirelines that surround electrical conductors.

Table 4.15.6 shows the $\frac{1}{10}$ ths of an inch (2.54 mm) diameter monconductor wireline. The table gives typical construction, dimensions, mechanical properties, and electrical properties.

Table 4.15.7 shows the $\frac{7}{32}$ ths of an inch (5.69 mm) diameter three-conductor wireline. The table gives typical construction, dimensions, mechanical properties, and electrical properties.

Table 4.15.8 shows the $\frac{5}{16}$ th of an inch (8.62 mm) diameter seven-conductor wireline. The table gives typical construction, dimensions, mechanical properties, and electrical properties.

Table 4.15.8 shows the $\frac{3}{16}$ ths of an inch (4.80 mm) diameter four-conductor wireline. The table gives typical

The armor wires are high tensile, galvanized extra improved plow steel (GEEIPS), and coated with anti-corrosion compound for protection during shipping and storing. Wires are preformed and cables are post tensioned.

Core assembly – Conductors are bound with conductive tape and voids are filled with conductive paste and string.

Conductors are "Water Blocked" to reduce water and gas migration. Conductor resistance is measured at 68° F.

The temperature rating assumes a normal gradient for both temperature and weight.

Center conductor construction is 7 × 0.0100". The typical capacitance is decreased by approximately 5 to 10% in comparison to the outer conductors.

construction, dimensions, mechanical properties, and electrical properties.

Most manufactures of wirelines will construct specially designed armored electrical conductor wirelines for unique downhole operations.

4.15.8.5 Wireline Operating and Breaking Strengths

During field operations the line tensions should be no greater than one half of the wireline breaking strength. This will insure that no permanent damage is done to the wireline.

In the tables above the breaking strength for each wireline is given. For stainless steel armored cables or other special construction the manufacturer should be consulted for breaking strength.

4.15.8.6 Wireline Stretching

Many field operations using wirelines requires that the wireline stretch be determined. One common need is the necessity of determine the true depth of the particular logging tool in the well. The true depth can be determined by adding the amount of cable stretch ΔL to the measured wireline length L in the well. The amount of wireline stretch is determined from

$$\Delta L = \left(\frac{KL}{2} \right) [(T + W_t) - 2T_m] \quad (4.15.3)$$

where

L is the length of wireline in the well (in units of 1,000 ft)

T is the surface tension (in units of 1,000 lb)

W_t is the effective weight (in the well fluid) of any downhole tool on the free end of the wireline (in units of 1,000 lb)

T_m is the marked cable tension (usually 1,000 lb)

K is the elastic stretch coefficient (ft/1,000 ft/1,000 lb)

Example 4.15.2

Determine the stretch of 10,000 ft of a monoconductor 7H32RZ wireline with a 300=lb tool (weight in drilling mud used). The stretch coefficient is 1.8 ft/kft/klb. The wireline has been marked 1000 lb tension. The wirelines tension measured at the surface is 5000 lbs. Using Equation 4.15.3,

$$\Delta L = \left[\frac{1.8(10.0)}{2} \right] [(5.0 + 0.3) - 2(1.0)]$$

$$\Delta L = 29.7 \text{ ft}$$

Thus, the true depth as measured by wireline would be 10,000 ft + 29.7 ft = 10,029.7 ft.

4.16 CASING AND CASING STRING DESIGN

Section reviewed by Phil Pattillo and Steve Morey

4.16.1 Types of Casing

Based on the primary function of the casing string, there are five types of casing to be distinguished.

Drive or Jet Casing

The stovepipe is usually driven to sufficient depth (15–60 ft) to protect loose surface formation and to enable circulation of the drilling fluid. This pipe is sometimes cemented in predrilled holes.

Conductor Casing

This string acts as a guide for the remaining casing strings into the hole. The purpose of the conductor string is also to cover unconsolidated formations and to seal off overpressured formations. The conductor string is the first string that is always cemented to the top and equipped with casing head and blowout prevention (BOP) equipment.

Surface Casing

Surface casing is set deeply enough to protect the borehole from caving-in in loose formations frequently encountered at shallow depths, and protects freshwater sands from contamination while subsequently drilling a deeper hole. In case the conductor string has not been set, the surface casing is fitted with casing head and BOP.

Intermediate Casing

Also called protection string, this string is usually set in the transition zone before abnormally high formation pressure is encountered, to protect weak formations or to case off loss-of-circulation zones. Depending upon geological conditions, the well may contain two or even three intermediate strings.

Production Casing

Production Casing (oil string) is the string through which the well is produced.

Intermediate or production casing can be set as a liner. A liner extends from the bottom of the hole upward to a point 150–250 ft above the lower end of the previous casing string.

Casing Program Design

Casing program design is accomplished by two steps. In the first step, the casing sizes and corresponding bit sizes are determined. In the second step, the setting depths of the individual casing strings are evaluated.

Before starting the casing program design, the designer should know the following basic information:

- purpose of the well (exploratory or development);
- geological cross-sections that contain the type of formations, expected hole problems, pore and formation fracture pressure, number and depth of water, oil, gas horizons;
- available rock bits, reamer shoes and casing sizes;
- load capacity of derrick and mast if the type of rig has already been selected.

Before starting the design, the production casing size and depth of the well are established by the petroleum engineer in cooperation with a geologist, so that the hole size (rock bit diameter) for the casing may be selected. Regarding the diameter of the hole, sufficient clearance beyond the coupling outside diameter should be provided to allow for mud cake and for a good cementing job. Field experience shows that the casing clearance should range from about 1.0 in. to 3.5 in. Larger casing sizes require greater diametric clearance.

Once the hole size for the production string has been selected, the smallest casing through which a bit to drill that hole will pass is determined. The bit diameter should be slightly less (0.05 in.) than the casing drift diameter. After choosing casing with appropriate drift diameter, a suitable coupling diameter for this casing may be found. Next, the appropriate size of the confining hole for this casing and its corresponding bit can be determined and the procedure repeated.

Example 4.16.1

The production string for a certain well is 5-in. casing. Determine casing and corresponding bit sizes for the intermediate, surface and conductor strings. Take casing data and bit sizes from [Table 4.16.1](#).

Solution

For the production hole, select a 6 3/4-in. rock bit. Therefore, the casing clearance = $6.75 - 5.563 = 1.187$ in.

For the intermediate string, select a 7 5/8-in. casing, ignoring that wall thicknesses that corresponds to drift diameters of 6.640 or smaller. For the 7 5/8-in. intermediate string, use a 9 7/8-in. bit. The casing clearance = $9.875 - 8.5 = 1.375$ in.

For the surface string, select a 10 3/4-in. casing. Note that only wall thicknesses corresponding to drift diameters of 10.038 and 9.894-in. can be used. For the 10 3/4-in. casing, use a 14 3/4-in. bit, so the casing clearance = $14.75 - 11.75 = 3.0$ in.

For conductor string, select 16 in. casing; the bit size will then be at least 20 in. and the casing clearance = $20 - 17 = 3$ in.

Having defined bit and casing string sizes, the setting depths of the individual strings should be determined.

The operation of setting is governed by the principle according to which casing should be placed as deep as possible. However, the designer must remember to ensure the safety of the drilling crew from a possible blowout, and to maintain the hole stability, well completion aspects (formation damage) and state regulations.

In general, casing should be set

- where drilling fluid could contaminate freshwater that might be used for drinking or other household purposes;
- where unstable formations are likely to cave or slough into the borehole;
- where loss of circulation may result in blowout;
- where drilling fluid may severely damage the production horizon.

A graphical method of casing setting depth determination can be used. The method is based on the principle that the borehole pressure should always be greater than pore pressure and less than fracture pressure. (Drilling with borehole pressures lower than pore pressure requires the use of under-balanced drilling technologies not covered in this chapter.) These limits may be adjusted to allow for low pressure (swab) and high pressure (surge) transients caused by drilling assembly or casing movement in the wellbore.

For practical purposes, a safety margin for reasonable kick conditions should be imposed. Even when the borehole pressure is adjusted correctly, problems may arise from contact between the drilling fluid and the formation. Depending on the drilling fluid and formation, the more time spent drilling in open hole, the greater the possibility of formation caving or sloughing into the borehole. Formation instability may lead to expensive work in the borehole, which influences the time and cost of the drilling operation. To reduce this problem, special treatment drilling fluids might be used, but these special drilling fluids are expensive. Therefore, the casing and drilling fluid programs depend on each other, and solving the issue of correct casing setting depth evaluation is a rather complicated optimization problem.

Example 4.16.2

Suppose that in some area the expected formation pressure gradient is 0.65 psi/ft and formation fracture pressure gradient is 0.85 psi/ft. A gas-bearing formation is expected at a depth of 15,000 ft. Assume that a gas kick occurs that, to be removed from the hole, induces a surface pressure of 2,000 psi. The first intermediate casing is set at a depth of 7,200 ft. Determine the setting depth for the second intermediate casing string if required in given conditions. Assume drilling fluid pressure gradient = 0.65 psi/ft.

Solution

The formation fracture pressure line is

$$P_f = (0.85)(D)$$

The borehole pressure line is

$$P_{bh} = 2,000 + (0.65)(D)$$

So

$$(0.85)(D) = 2,000 + (0.65)(D)$$

$$D = \frac{2,000}{0.2} = 10,000 \text{ ft.}$$

The second intermediate casing string is required and must be set at a depth of 10,000 ft.

4.16.2 Product Data

The following information is based on API Specification 5CT, Ninth Edition, July 2011, including Errata, September 2012 and API Specification 5CRA, First Edition, February 2010.

4.16.2.1 Process of Manufacture

Product is defined as pipe, coupling, coupling stock, coupling material, coupling blank, or accessory material. All products shall be made to a fine grain practice which is steel that contains one or more grain refining elements intended to result in the steel having a fine austenitic grain size.

API Spec 5CT pipe shall be made by the seamless or electric weld process as defined by API Spec 5CT Tables C/E.3. API Spec 5CRA product shall be made by the seamless process. Pup joints may be made from pipe, coupling stock, coupling material, accessory material, mechanical tube or bar stock. Coupling stock, coupling material and accessory material shall be made by the seamless process.

Seamless product is a wrought steel product made without a weld seam, it is manufactured by hot-working steel and if necessary by subsequently cold-working or heat treating or a combination of these operations to produce the desired shape, dimensions and properties.

Electric welded pipe is pipe having one longitudinal seam formed by electric resistance or electric induction welding, without the addition of filler metal. The edges to

be welded are mechanically pressed together and the heat for the welding is generated by the resistance to flow of the electric current. The weld seam shall be heat treated or processed so that no untempered Martensite remains.

Details concerning heat treatment, straightening, and traceability can be found in API Spec 5CT/5CRA Clause 6.

4.16.2.2 Material Requirements**4.16.2.2.1 Chemistry**

The chemistry requirements for all grades are defined in API Spec 5CT Tables C/E.4 and API Spec 5CRA Tables A/C.2 and 28.

4.16.2.2.2 Tensile Requirements

The tensile requirements, based on longitudinal test specimens, for all API grades are defined in API Spec 5CT Tables C/E.5 or API Spec 5CRA Tables A/C.3 and 27.

Yield Strength: the tensile stress at which plastic yield of the material has commenced.

Tensile Strength: the maximum tensile stress the material is capable of sustaining, the rupture or fracture stress.

Elongation: the percent increase in the gauge length of the specimen subjected to the tensile stress.

4.16.2.2.3 Charpy V-notch Requirements

The Charpy V-notch test is a high strain-rate test that determines the amount of energy absorbed by the material during fracture. The absorbed energy is a measure of the material notch toughness.

4.16.2.2.4 Hardness Requirements

The hardness test measures the material resistance to deformation from a specific load. API uses both the Rockwell C (HRC) and Brinell (HRB) test methods. The hardness limits for API grades are defined in API Spec 5CT Tables C/E.5 or API Spec 5CRA Tables A/C.3 and 27.

4.16.2.2.5 Grain Size/Microstructure Requirements

Grades C90, T95 and C110 have maximum specified grain sizes in API Spec 5CT. CRA materials have specific microstructure requirements specified in API Spec 5CRA.

Additional details for chemical composition, tensile properties, Charpy v-notch, hardness, grain size and microstructure can be found in API Spec 5CT/5CRA Clause 7.

4.16.2.3 Dimensions, masses, tolerances

Pipe shall be supplied in the sizes and wall thicknesses defined in API 5CT Tables C/E.23-26, API Spec 5CRA Tables A/C.15, or other sizes and wall thicknesses agreed

to by the purchaser and manufacturer. Coupling stock, coupling material and accessory material shall be supplied as specified on the purchase agreement or in the case of coupling material, the manufacturer's internal requirements.

Outside Diameter: the API tolerance for pipe is: ± 0.031 in. for sizes $< 4 \frac{1}{2}$ in., -0.5% , $+1.0\%$ for size $\geq 4 \frac{1}{2}$ ".

Wall thickness: the API wall thickness tolerance is -12.5% of the specified wall thickness; however the acceptance criterion is that 87.5% of the specified wall thickness shall remain after removing any imperfections.

Mass: the API tolerance for single lengths of pipe is: -3.5% , $+6.5\%$. The plain end mass of any product is calculated by:

$$W_{pe} = k_m K_{wpe} (D - t) t$$

where

W_{pe}	is the plain end mass per unit length
D	is the specified outside diameter
t	is the specified wall thickness
k_m	is the mass correction factor, 1.000 for carbon steel, 0.989 for martensitic chromium steel. For austenitic and austenitic Ni-based alloys the correction factor must be supplied by the manufacturer.
K_{wpe}	is the mass per unit length conversion factor, 10.69 for USC units, 0.0246615 for SI units

Additional calculations for other pipe configurations are defined in API TR 5C3 Clause 11.

Inside Diameter: the inside diameter is governed by the outside diameter and mass tolerances, there is no specified tolerance and there is no measurement requirement.

Drift Diameter: the drift mandrel requirements are defined in API 5CT Tables C/E.28 & 29, API Spec 5CRA Tables A/C.18, or as specified on the purchase agreement.

Length: the API range length requirements are defined in API 5CT Tables C/E.27 or API Spec 5CRA Tables A/C.16.

Additional details for dimensions, masses and tolerances can be found in API Spec 5CT/5CRA Clause 8.

4.16.2.4 Inspection and Testing

The manufacturer is required to deliver product that conforms to the requirements of API Spec 5CT/5CRA; to do this the manufacturer must determine and document the proper calibration and verification frequency of all test equipment to meet this requirement.

API Spec 5CT Clause 10 and API Spec 5CRA Clause 9 provide details concerning lot definition, testing and

inspection frequencies, retest requirements (in the case of a failure), and NDE (Non-destructive examination) requirements.

4.16.2.5 Marking and Documentation

All product manufactured to API Spec 5CT/5CRA requirements shall be marked and color coded in accordance with API Spec 5CT/5CRA Clause 11. All products shall be fully documented in accordance with API Spec 5CT/5CRA Clause 12.

4.16.2.6 Thread Protectors

Internal (box thread) and external (pin thread) thread protectors that meet the requirements of API Spec 5CT Annex I shall be applied to threaded connections unless otherwise specified on the purchase agreement. Connections and thread protectors are not addressed in API Spec 5CRA; however the requirements of API Spec 5CT should apply.

Additional details for thread protectors can be found in API Spec 5CT Clause 12.

4.16.3 Elements of Threads

Threaded connections are complicated mechanisms consisting of elements that must interact in prescribed fashion to perform a useful function. Each of these elements of a thread may be gauged individually as described in API RP 5B1, 5th Edition, October 1999. The thread elements are defined as

1. *Thread height or depth.* The thread height or depth is the distance between the thread crest and the thread root normal to the axis of the thread.
2. *Lead.* For pipe thread inspection purposes, lead is defined as the distance from a point on a thread to a corresponding point on the adjacent thread measured parallel to the thread axis.
3. *Taper.* Taper is the change of diameter of a thread expressed in in./ft of thread length.

4.16.3.1 Round Threads

The purpose of round top (crest) and round bottom (root) is

- A. To improve the resistance of the threads to galling in make-up.
- B. To provide a controlled clearance between make-up thread crest and root for foreign particles or contaminants.
- C. To make the crest less susceptible to harmful damage from minor scratches or dents. If sufficient interference is applied during makeup, the leak path through the connection should be through the annular clearance between mated crest and roots. Proper thread compound is necessary to promote leak resistance.

4.16.3.2 Buttress Threads

Buttress threads are designed to resist high axial tension or compression loading in addition to offering resistance to leakage.

The 3° load flank offers resistance to disengagement under high axial tension loading, while the 10° stab flank offers resistance to high axial compression loading. In any event, leak resistance is again promoted with use of proper thread compound and/or thread coating agents.

4.16.3.3 Extreme-Line Casing (Integral Connection)

Extreme-line casing in all sizes uses a modified acme type thread having a 12° included angle between stab and load flanks, and all threads have crests and roots flat and parallel to the pipe axis. For all sizes, the threads are not intended to be leak resistant when made up. Threads are used purely as a mechanical means to hold the joint members together during axial tension loading. The connection uses upset pipe ends for pin and box members that are an integral part of the pipe body. Axial compression load resistance is primarily offered by external shouldering to the connection on makeup.

Leak resistance is obtained on makeup by interference of a metal-to-metal seal between a long radius curved seal surface on the pin member engaging a conical metal seal surface on the box member.

Thread compound is used primarily as an antigalling or antiseizure agent.

4.16.4 Minimum Performance Properties of Product

4.16.4.1 Collapse Resistance

Four collapse formulas, applicable to different ranges of yield strength and diameter:thickness ratio, are used to determine minimum tube collapse resistance.

Yield Strength Collapse Pressure Formula

The yield strength collapse pressure is not a true collapse pressure but rather the external pressure P_{yp} that generates minimum yield stress Y_p on the inside of the wall of a tube as calculated by

$$P_{yp} = 2Y_p \left[\frac{(D/t) - 1}{(D/t)^2} \right] \quad (4.16.1)$$

The applicable D/t ratios for yield strength collapse pressure are shown in [Table 4.16.2](#).

Plastic Collapse Pressure Formula

The minimum collapse pressure for the plastic range of collapse is calculated by

$$P_p = Y_p \left[\frac{A}{D/t} - B \right] - C \quad (4.16.2)$$

The formula for minimum plastic collapse pressure is applicable for D/t values as shown in [Table 4.16.2](#). The factors A, B and C are given in [Table 4.16.3](#).

Transition Collapse Pressure Formula

The minimum collapse pressure for the plastic to elastic transition zone P_T is calculated by

$$P_T = Y_p \left[\frac{F}{D/t} - G \right] \quad (4.16.3)$$

The applicable D/t range and factors F and G for the transition collapse pressure formula are shown in [Tables 4.16.2](#) and [4.16.3](#), respectively.

Elastic Collapse Pressure Formula

The minimum collapse pressure for the elastic range of collapse is calculated by

$$P_E = \frac{46.95 \times 10^6}{(D/t)(D/t) - 1} \quad (4.16.4)$$

The applicable D/t ratios for elastic collapse pressure are shown in [Table 4.16.2](#).

Collapse Pressure under Axial Stress

The collapse pressure in the presence of axial stress is calculated by replacing Y_p in formulas (1)-(4) with Y_{pa} , where

$$Y_{pa} = Y_p \left[\sqrt{1 - 0.75(S_A/Y_p)^2} \right] - 0.5(S_A/Y_p) \quad (4.16.5)$$

Equation [4.16.5](#) is not applicable to the elastic collapse formula.

Symbols in Equations [4.16.1](#) to [4.16.5](#) are as follows:

D = specified outside diameter in in.

t = specified wall thickness in in.

Y_p = minimum yield strength of pipe in psi

P_{Yp} = minimum yield strength collapse pressure in psi

P_p = minimum plastic collapse pressure in psi

P_T = minimum transition collapse pressure in psi

P_E = minimum elastic collapse pressure in psi

Y_{pa} = yield strength in presence of axial tension

S_A = axial tension stress in psi

4.16.4.2 Internal Yield Pressure for Pipe

Minimum internal yield pressure for pipe is calculated from Equation [4.16.6](#). The factor 0.875 appearing in the formula allows for minimum wall thickness.

$$P_i = 0.875 \left[\frac{2Y_p t}{D} \right] \quad (4.16.6)$$

$$F_Y = 0.7854(D^2 - d^2)Y_p \quad (4.16.7)$$

where

- P_i = minimum internal yield pressure in psi
- Y_p = minimum yield strength in psi
- t = specified wall thickness in in.
- D = specified outside diameter in inches.

where

- F_Y = pipe body yield strength in lb
- Y_p = minimum yield strength in psi
- D = specified outside diameter in in.
- d = inside diameter in in.

4.16.4.3 Pipe Body Yield Strength

Pipe body yield strength is the axial load required to yield the pipe. It is taken as the product of the cross sectional area and the specified minimum yield strength for the particular grade of pipe. Values for pipe body yield strength are calculated by means of the following formula:

Note: Many recent, computer oriented treatments of yield include the additional combined effects of internal and external pressure, bending and torsion on pipe body yield.

4.16.4.4 Connection Joint Strength

Caution: API casing connection joint strengths are based on parting, or complete failure of the joint, whereas many

designers use a connection joint strength design factor based on yield of the connection.

Round Thread Casing Joint Strength

Round thread casing joint strength is calculated from formulas 4.16.8 and 4.16.9. The lesser of the values obtained from the two formulas governs. Formulas 4.16.9 and 4.16.10 apply both to short and long threads and couplings. Formula 4.16.8 is for minimum strength of a joint failing by fracture, and formula 4.16.9 for minimum strength of a joint failing by thread jumpout or pullout.

The fracture strength is

$$P_j = 0.95 A_{jp} U_p \quad (4.16.8)$$

The pullout strength is

$$P_j = 0.95 A_{jp} L \left[\frac{0.74 D^{-0.59} U_p}{0.5 L + 0.14 D} + \frac{Y_p}{L + 0.14 D} \right] \quad (4.16.9)$$

where

P_j = joint strength in lb

A_{jp} = cross-sectional area of the pipe wall under the last perfect thread in in.²

= $0.7854(D - 0.1425)^2 - d^2$ for eight round threads

D = specified outside diameter of pipe in in.

d = inside diameter of pipe in in.

L = engaged thread length in in.

= $L_4 - M$ for nominal makeup, API Spec 5B

Y_p = minimum yield strength of pipe in psi

U_p = minimum ultimate strength of pipe in psi

Buttress Thread Casing Joint Strength

Buttress thread casing joint strength is calculated from formulas 4.16.10 and 4.16.11. The lesser of the values obtained from the two formulas governs.

Pipe thread strength is

$$P_j = 0.95 A_p U_p [1.008 - 0.0396(1.083 - Y_p/U_p)D] \quad (4.16.10)$$

Casing thread strength is

$$P_j = 0.95 A_c U_c \quad (4.16.11)$$

where

P_j = joint strength in lb

Y_p = minimum yield strength of pipe in lb

U_p = minimum tensile strength of pipe in psi

U_c = minimum tensile strength of coupling in psi

A_p = cross-sectional area of plain end pipe in in.²

= $0.7854(D^2 - d^2)$

A_c = cross-sectional area of coupling in in.²

= $0.7854(W^2 - d_i^2)$

D = outside diameter of pipe in in.

W = outside diameter of coupling in in.

d = inside diameter of pipe in in.

d_i = diameter of the root of the coupling thread at the end of the pipe in the powertight position

Extreme-line Casing Joint Strength

Extreme-line casing joint strength is calculated from

$$P_j = A_{cr} U_p \quad (4.16.12)$$

where

- P_j = joint strength in lb
 A_{cr} = critical section area of box, pin or pipe,
 whichever is least, in in.²
 (see API Bulletin 5C3)
 U_p = specified minimum tensile strength in psi
 (Table 4.16.3)

4.16.5 Design Consideration

Solving the problem of casing string design for a known type and size of casing string relies on selection of the most economical grades and weights of casing that will withstand, without failure, the loads to which the casing will be subjected throughout the life of the well.

There are various established methods of designing a technically satisfactory casing string. The differences between these methods rely on different design models, different values of the design factors and different sequences of calculations. There are no commonly accepted methods of string design nor accepted values for the design factors.

In general, the following loads must be considered: tension, collapse, burst and compression. The reasonably worst working conditions ought to be assumed.

Collapse

The casing must be designed against collapse to withstand the hydrostatic pressure of the fluid behind the casing at any depth, decreased by anticipated pressure inside the casing at the corresponding level. Usually, the maximum collapse pressure to be imposed on the casing is the hydrostatic pressure of the heaviest mud used to drill to the depth of the casing string, acting on an empty string. Depending upon the design model, it is recommended to use a design factor of 1.0 to 1.2. For example, if it is known that casing will never be empty inside, this fact should be considered for collapse pressure evaluation and selection of the magnitude of safety factor.

Burst

Casing must be designed to resist expected burst pressure at any depth. In burst pressure consideration, there exist different design models depending upon the type of casing string.

Conductor Casing

It is assumed that the external pressure for conductor casing is zero. In any case, the maximum expected internal pressure cannot be greater than fracture pressure at the open hole below the conductor casing shoe, usually the first formation below the casing shoe. If this pressure is not known (exploratory drilling), the burst pressure of gas equivalent to 0.9 or 1.0 psi/ft can be assumed. Hydrostatic head due to gas is neglected. For example, if the setting

depth of a conductor string is 1,100 ft, then the maximum expected burst pressure is even along the string and equal to $(1,100)(1.0) = 1,100$ psi; safety factor = 1.1 to 1.15.

4.16.5.1 Surface and Intermediate Casing

It is suggested to evaluate the burst load based on the internal pressure expected, reduced by the external pressure of the drilling fluid outside the string. Internal pressure is based on the expected bottomhole pressure of the next string with the hole being evacuated from drilling fluid up to a minimum of 50%. In exploratory wells, a reasonable assumption of expected formation pore pressure gradient is required.

Example 4.16.3

Evaluate an expected burst pressure acting on a surface casing string in exploratory drilling if the setting depth of the next string is 11,000 ft.

Solution

Step 1. Internal pressure in the borehole. Because the next string is set at 11,000 ft, the formation pore pressure gradient is assumed to be 0.65 psi/ft. Thus, the bottomhole pressure (at a depth of 11,000 ft) is $(11,000)(0.65) = 7,150$ psi. Assume 50% evacuation; thus, $(11,000)(0.5) = 5,500$ ft.

Note: It is assumed that below 5,500 ft, the hole is filled with mud, which exerts a pressure gradient of 0.65 psi/ft. The hole above 5,500 ft is filled with gas, the weight of which is ignored.

The internal pressure at a depth of 5,500 ft is $(5,500)(0.65) = 3,575$ psi. Since the weight of gas is ignored for this type of string, the internal pressure at the top of the hole is also 3,575 psi.

Step 2. External pressure. It is assumed that there is drilling fluid with specific gravity of 1.2 outside the casing. Thus, the external pressure at surface = 0.0 psi and at 5,000 ft is $(5,000)(1.2)(8.34)(0.052) \cong 2,600$ psi.

Step 3. Burst load (P_b). The burst pressure is equal to internal pressure reduced by the external pressure of the drilling fluid outside the casing. Therefore,

$$\text{at surface: } P_b = 3,575 - 0.0 = 3,573 \text{ psi}$$

$$\text{at 5,000 ft: } P_b = 3,575 - 2,600 = 987 \text{ psi}$$

The burst pressure line equation is as below:

$$P_b = 3,575 - 0.52(D) \text{ (psi)}$$

$$D = \text{depth at the hole (ft) (from 0 to 5,000 ft)}$$

Note: For practical purposes, a graphic solution is advisable.

4.16.5.2 Production Casing

In exploratory drilling, it is assumed that internal pressure acting on the casing is reduced by external saltwater pressure

Steel grade	Unit mass (lb/ft)	Cross-sectional area (in.)	Collapse resistance	Burst resistance	Joint strength (10 ³ lb)	Pipe body yield (10 ³ lb)
N-80	26.0	7.548	5,410	7,240	519	604
N-80	29.0	8.451	7,020	8,160	597	676
N-80	32.0	9.315	8,600	9,060	672	745

gradient of about 0.5 psi/ft. Internal pressure is based on expected gas pressure gradient and the anticipated pore pressure of the target reservoir. For long strings, the weight of gas is not ignored.

4.16.5.3 Tension Load

The maximum tensile load acting on the casing string is often considered to be the static weight of the casing as measured in air.

Casing must be designed to satisfy these equations:

$$P_j = (W)(N_j) \quad (4.16.13)$$

$$P_y = (W)(N_p) \quad (4.16.14)$$

where

P_j = casing joint strength in lb

P_y = pipe body strength in lb

W = weight (mass) of casing suspended below the cross-section under consideration in lb

N_j = design factor for joint

N_p = design factor for pipe body

Design factors (N_j , N_p) of 1.6 to 2.0, are used and should be applied to the minimum joint tensile strength and the minimum pipe body yield strength respectively. The design factor for the pipe body may be lower as it is based on yield.

4.16.5.4 Compression Load

Under certain conditions, casing can be subjected to compression, such as if the weight of the inner strings (conductor or surface casing string) is transferred to the outer string or if a portion of the casing weight is slacked off on the bottom of the hole. This load may result in casing failure and, therefore, must also be considered.

An example is offered on the following pages of the design procedure to be followed in designing a combination string.

Example 4.16.4

Design a combination casing string if data are as below:

Type of well: exploration well

Type of casing: production for testing purposes

Casing setting depth: 12,000 ft

Casing size: 7 in.

Design model:

Collapse: Assumed external fluid pressure gradient of 0.52 psi/ft and casing empty inside. Design factor for collapse = 1.0. Reduction of collapse pressure resistance due to axial load is ignored (This calculation is too complex for a hand design).

Burst: Assumed external pressure gradient of salt-water = 0.465 psi/ft and formation pore (gas) pressure gradient = 0.65 psi/ft. Gas weight is neglected. Design factor = 1.1.

Tension: Casing suspended at the surface in air. Design factor = 1.6.

Compression: Casing not subjected to compression load.

The selected coupling should be long round thread. The available casing grade is N-80 and unit masses as given above.

Solution

Part 1. Consider collapse pressure and tension load.

Step 1. Determine the lightest weight of casing to resist collapse pressure for a setting depth of 12,000 ft. Because the maximum collapse pressure is $(12,000)(0.52) = 6,240$ psi, select N-80, 29-lb/ft casing with collapse resistance of 7,020 psi. (Note: assumed design factor for collapse = 1.0.) This is Section 1.

Step 2. The next section (above section 1) is to consist of the next lighter casing, i.e., N-80, 26-lb/ft. This is Section 2. Neglecting the effect of the axial load due to the weight of Section 1 suspended below it, the setting depth of Section 2 is

$$D'_2 = \frac{5,410}{(1.0)(0.52)} = 10,403 \text{ ft}$$

Then, the length and weight of Section 1 is

$$L_1 = 12,000 - 10,403 = 1,597 \text{ ft and}$$

$$W_1 = 46,313 \text{ lb}$$

(Note: If the next lighter casing were available, then Steps 2 must be repeated for this casing and that would be Section 3, etc.).

The maximum length of Section 2 is limited by coupling load capacity and is calculated below:

$$L_{2\max} = \frac{519,000 - (46,313)(1.6)}{(1.6)(26)} = 10,695 \text{ ft}$$

which is greater than its setting depth (10,403 ft). Section 2 extends to the top of the hole. (Note: If Section 2 would not cover the entire length of the hole, then the next stronger casing should be applied. That would be Section 3. The setting depth of Section 3 is governed by joint strength, not by collapse pressure.)

Part 2. Check casing string on burst pressure obtained in Part 1 and make necessary corrections.

Step 1. Determine external pressure.

At top: 0.0 psi

At bottom: $(12,000)(0.465) = 5,580$ psi.

Step 2. Determine internal pressure

At bottom: $(12,000)(0.65) = 7,800$ psi.

At top: 7,800 psi (weight of gas is ignored).

Step 3. Determine burst pressure.

At top: 7,800 psi.

At bottom: $7,800 - 5,580 = 2,220$ psi.

Burst pressure line equation is

$$P_b = 7,800 - \frac{7,800 - 2,220}{12,000}(D)$$

$$= 7,800 - (0.456)(D)$$

D = hole depth in ft

Graphical solution is presented in [Figure 4.16.1](#).

Step 4. It is apparent that Section 1 is capable of withstanding the expected burst pressure.

Step 5. Section 2 can withstand the expected burst pressure up to the depth calculated below:

$$\frac{7,240}{1.1} = 7,800 - (0.456)(D)$$

$$D = \frac{7,800 - 6,581}{0.456} = 2,673 \text{ ft}$$

Therefore, the length and weight of Section 2 is

$$10,403 - 2,673 = 7,730 \text{ ft}$$

$$W_2 = (7,730)(26) = 200,980 \text{ lb}$$

To cover the upper part of the hole (2,673 ft), stronger casing must be used.

Step 6. Take the next stronger casing, i.e., N-80, 29 lb/ft with burst pressure resistance of $(8,160)/(1.1) = 7,418$ psi.

This is Section 3. This casing can be used up to the hole depth of

$$7,418 = 7,800 - (0.456)(D)$$

$$D = \frac{7,800 - 7,418}{0.456} = 837 \text{ ft}$$

Then, the length and weight of Section 3 is $2,673 - 837 = 1,836$ ft

$$W_3 = (1,836)(29) = 53,244 \text{ lb}$$

To cover the remaining 837 ft of the hole, stronger casing must be used.

Step 7. The next stronger casing is N-80, 32 lb/ft with burst pressure resistance of $(9,060)/(1.1) = 8,236$ psi. This is Section 4.

N-80, 32 lb/ft casing is strong enough to cover the remaining part of the hole (Note: $8,236 \text{ psi} > 7,800 \text{ psi}$). Therefore, the length and weight of Section 4 is $837 - 0.0 = 837$ ft and $W_4 = 26,784$ lb.

Part 3. Check casing string on tension obtained in Part 2 and, if necessary, make corrections to satisfy the required magnitude of safety factor.

Step 1. Maximum length of Section 3 due to its joint strength is

$$L_3 = \frac{597,000 - (1.6)(62,015 + 186,888)}{(1.6)(29)} = 4,283 \text{ ft}$$

Since the length of Section 3 is 1,836, the safety factor is even greater than required.

Step 2. Maximum length of Section 4 due to its joint strength is

$$L_4 = \frac{672,000 - (1.6)(46,313 + 200,980 + 26,784)}{(1.6)(32)} = 4,560 \text{ ft}$$

Because L_4 is greater than the length obtained in Part 2 (837), it may be concluded that the requirements for tension are satisfied.

A summary of the results obtained is presented in the table above and in [Figure 4.16.2](#).

4.16.6 Running and Pulling Pipe

API recommended practice 5C1 contains detailed information for: preparation, inspection, drift checking, stabbing, make-up, lowering, landing and recovery (pulling) of pipe (casing and tubing).

FIGURE 4.16.1 Graphical representation of burst load determination.

Section no.	Setting depth(ft)	Length	Weight (lb)	Grade	Unit weight	Coupling
4	837	837	26,784	N-80	32	Long with round thread
3	2,673	1,836	53,244	N-80	29	Long with round thread
2	10,403	7,730	200,980	N-80	26	Long with round thread
1	12,000	1,597	46,313	N-80	29	Long with round thread

4.16.6.1 Preparation and Inspection Before Running

4.1.1. New casing is delivered free of injurious defects as defined in API Specification 5CT and within the practical limits of the inspection procedures therein prescribed. One should:

- a. Familiarize himself with inspection practices specified in the standards and employed by the respective mills.
- b. Thoroughly evaluate any nondestructive inspection to be used on API tubular goods to assure that the inspection does in fact correctly locate

FIGURE 4.16.2 Schematic diagram of combination casing string.

and differentiate defects from other variables that can be and frequently are sources of misleading “defect” signals with such inspection methods.

- 4.1.2. All casing, whether new, used, or reconditioned, should always be handled with thread protectors in place. Casing should be handled at all times on racks or on wooden or metal surfaces free of rocks, sand, or dirt other than normal drilling mud. When lengths of casing are inadvertently dragged in the dirt, the threads should be recleaned and serviced again as outlined in 4.1.7.
- 4.1.3. Slip elevators are recommended for long strings. Both spider and elevator slips should be clean and sharp and should fit properly. Slips should be extra long for heavy casing strings. The spider must be level.

Note: Slip and tong marks are injurious. Every possible effort should be made to keep such damage

at a minimum by using proper up-to-date equipment.

- 4.1.4. If collar-pull elevators are used, the bearing surface should be carefully inspected for (a) uneven wear that may produce a side lift on the coupling with danger of jumping it off, and (b) uniform distribution of the load when applied over the bearing face of the coupling.
- 4.1.5. Spider and elevator slips should be examined and watched to see that all lower together.

4.17 WELL CEMENTING

Section reviewed by Deryck Williams, Cory Arceneaux, Robert Martin, Steven Riedinger, Ksenia Eliseeva, and Craig Gardner

4.17.1 Introduction

Cementing the casing and liner cementing (denoted as *primary cementing*) are the most important operations in the development of an oil and gas well. The drilling group is usually responsible for cementing the casing and the liner. The quality of these cementing operations will affect the success of follow-on drilling, completion, production and workover efforts in the well [1–4].

In addition to primary cementing of the casing and liner, there are other important well cementing operations. These are *squeeze cementing* and *plug cementing*. Such operations are often called *secondary* or *remedial cementing* [2].

Well cementing materials vary from basic Portland cement used in civil engineering construction of all types, to highly sophisticated special-purpose resin-based or latex cements. The purpose of all of these cementing materials is to provide the well driller with a fluid state slurry of cement, water and additives that can be pumped to specific locations within the well. Once the slurry has reached its intended location in the well and a setup time has elapsed, the slurry material can become a nearly impermeable, durable solid material capable of bonding to rock and steel casing.

The most widely used cements for well cementing are the Portland-type cements. The civil engineering construction industry uses Portland cement and water slurries in conjunction with clean rock aggregate to form concrete. The composite material formed by the addition of rock aggregate forms a solid material that has a compressive strength that is significantly higher than the solid formed by the solidified cement and water slurry alone. The rock of the aggregate usually has a very high compressive strength (of the order of 5,000 to 20,000 psi). The cement itself will have a compressive strength of about 1,000 to 3,000 psi. Therefore, the rock of the aggregate forms a solid material that has a very high compressive strength of the order of 5,000 to 2,000 psi (345 to 1830 bar). Therefore, the rock aggregate together with the matrix of solid cement can form a high-strength composite concrete with compressive strengths of the order of 4,000 to 15,000 (276 to 1035 bar).

The well drilling industry does not generally use aggregate with the cement except for silica flour and Ottawa sand. This is mainly due to the tight spacing within a well that precludes the passage of the larger particles of aggregate through the system. Thus, the well drilling industry refers to this material as simply cement. The slurry pumped to wells is usually a slurry of cement and water with appropriate additives [1].

4.17.2 Chemistry of Cements

Cement is made of calcareous and argillaceous rock materials that are usually obtained from quarries. The process of making cement requires that these raw rock materials be ground, mixed and subjected to high temperatures.

The calcareous materials contain calcium carbonate or calcium oxide. Typical raw calcareous materials are as follows:

Limestone. This is sedimentary rock that is formed by the accumulation of organic marine life remains (shells or coral). Its main component is calcium carbonate.

Cement rock. This is a sedimentary rock that has a similar composition as the industrially produced cement.

Chalk. This is a soft limestone composed mainly of marine shells.

Marl. This is loose or crumbly deposit that contains a substantial amount of calcium carbonate.

Alkali waste. This is a secondary source and is often obtained from the waste of chemical plants. Such material will contain calcium oxide and/or calcium carbonate.

The argillaceous materials contain clay or clay minerals. Typical raw argillaceous materials are as follows:

Clay. This material is found at the surface of the earth and often is the major component of soils. The material is plastic when wetted, but becomes hard and brittle when dried and heated. It is composed mainly of hydrous aluminum silicates as well as other minerals.

Shale. This sedimentary rock is formed by the consolidation of clay, mud and silt. It contains substantial amounts of hydrous aluminum silicates.

Slate. A dense fine-grained metamorphic rock containing mainly clay minerals. Slate is obtained from metamorphic shale.

Ash. This is a secondary source and is the by-product of coal combustion. It contains silicates.

There are two processes used to manufacture cements: the dry process and the wet process. The dry process is the least expensive of the two, but is the more difficult to control.

In the dry process the limestone and clay materials are crushed and stored in separate bins and their composition analyzed. After the composition is known, the contents of the bins are blended to achieve the desired ultimate cement characteristics. The blend is ground to a mesh size of 100–200. This small mesh size maximizes the contact between individual particles.

In the wet process the clay minerals are crushed and slurried with water to allow pebbles and other rock particles

to settle out. The limestone is also crushed and slurried. Both materials are stored in separate bins and analyzed. Once the desired ultimate composition is determined, the slurry blend is ground and then partially dried out.

After the blends have been prepared (either in the dry or wet process), these materials are fed at a uniform rate into a long rotary kiln. The materials are gradually heated to a liquid state. At temperatures up to about 1,600°F the free water evaporates, the clay minerals dehydroxylate and crystallize, and CaCO_3 decomposes. At temperatures up to about 1600°F (870°C) the CaCO_3 and CaO react with aluminosilicates and the materials become liquids. Heating is continued to as high as 2800°F (1540°C).

When the kiln material is cooled it forms into crystallized clinkers. These are rather large irregular pieces of the solidified cement material. These clinkers are ground and a small amount of gypsum is added (usually about 1.5 to 3%). The gypsum prevents flash setting of the cement and also controls free CaO . This final cement product is sampled, analyzed and stored. The actual commercial cement is usually a blend of several different cements. This blending ensures a consistent product.

There are four chemical compounds that are identified as being the active components of cements.

Tricalcium aluminate ($3\text{CaO} \bullet \text{Al}_2\text{O}_3$) hydrates rapidly and contributes most to heat of hydration. This compound does not contribute greatly to the final strength of the set cement, but it sets rapidly and plays an important role in the early strength development. This setting time can be controlled by the addition of gypsum. The final hydrated product of tricalcium aluminate is readily attacked by sulfate waters. High-sulfate-resistant (HSR) cements have only a 3% or less content of this compound. High early strength cements have up to 15% of this compound.

Tricalcium silicate ($3\text{CaO} \bullet \text{SiO}_2$) is the major contributor to strength at all stages, but particularly during early stages of curing (up to 28 days). The average tricalcium silicate content is from 40% to maximum of 67%. The retarded cements will contain from 40% to 45%. The high early strength cements will contain 60% to 67%.

Dicalcium silicate ($2\text{CaO} \bullet \text{SiO}_2$) is very important in the final strength of the cement. This compound hydrates very slowly. The average dicalcium silicate content is 25% to 35%.

Tetracalcium aluminoferrite ($4\text{CaO} \bullet \text{Al}_2\text{O}_3 \bullet \text{FeO}_3$) has little effect on the physical properties of the cement. For high-sulfate-resistant (HSR) cements, API specifications require that the sum of the tetracalcium aluminoferrite content plus twice the tricalcium aluminate may not exceed a maximum of 24%.

In addition to the four compounds discussed above, the final Portland cement may contain gypsum, alkali sulfates,

magnesia, free lime and other components. These do not significantly affect the properties of the set cement, but they can influence rates of hydration, resistance to chemical attack and slurry properties.

When the water is added to the final dry cement material, the hydration of the cement begins immediately. The water is combined chemically with the cement material to eventually form a new immobile solid. As the cement hydrates, it will bond to the surrounding surfaces. This cement bonding is complex and depends on the type of surface to be cemented. Cement bonds to rock by a process of crystal growth. Cement bonds to the outside of a casing by filling in the pit spaces in the casing body [4].

4.17.3 Cementing Principles

There are two basic oil well cementing activities: primary cementing and secondary cementing.

The purposes of primary cementing are the following:

1. Support vertical and radial loads applied to casing
2. Isolate porous formations from producing zone formations
3. Exclude unwanted subsurface fluids from the producing interval
4. Protect casing from corrosion
5. Resist chemical deterioration of cement
6. Confine abnormal formation pressures

When applied to the various casing or liner strings used in oil well completions, the specific purposes of each string are as follows:

- Conductor casing string is cemented to prevent the drilling fluid from escaping and circulating outside the casing.
- Surface casing string must be cemented to protect freshwater formations near the surface and provide a structural connection between the casing and the subsurface competent rock formations. This subsurface structural connection will allow the blowout preventor to be affixed to the top of this casing to prevent high-pressure fluids from being vented to the surface. Further, this structural connection will give support for deeper run casing or liner strings.
- Intermediate casing strings are cemented to seal off abnormal pressure formations and cover both incompetent formations, which could cave or slough, and lost circulation formations.
- Production casing string is cemented to prevent the produced fluids from migrating to nonproducing formations and to exclude other fluids from the producing interval.

Cementing operations are carried out with surface equipment specially designed to carry out the primary

FIGURE 4.17.1 Recirculating blender [2].

and secondary cementing operations in oil wells. The key element in any well cementing operation is the recirculating blender (Figure 4.17.1). The recirculating blender has replaced the older jet mixing hopper. The blender provides a constant cement slurry specific weight that could never be achieved by the older equipment. A very careful control of the slurry weight is critical to a successful cementing operation. The recirculating blender is connected to a cement pump that in turn pumps the cement at low circulation rates (and high pressures if necessary) to the cementing head at

FIGURE 4.17.3 Cementing head [2].

the top of the casing string (see Figures 4.17.2 and 4.17.3 and Ref. [3]).

The proper amount of water must be mixed with the dry cement product to ensure only sufficient water for hydration of the cement. Excess water above that needed for hydration will reduce the final strength of the set cement and leave voids in the cement column that are filled with unset liquid. Insufficient water for proper hydration will leave a slurry too viscous to pump.

FIGURE 4.17.2 Blender, pump truck, cementing head and subsurface equipment [2].

The cement is usually dry mixed with the additives that are usually added for a particular cementing application. Often this mixing of additives is carried out at the service company central location. Depending on the application of the well cement, there are a variety of additives that can be used to design the cement slurry characteristics. These are accelerators, retarders, dispersants, extenders, weighting agents, gels, foamers and fluid-loss additives. With these additives the cement slurry and ultimately the set cement can be designed for the particular cementing operation. It is necessary that the engineer in charge of the well carry out the necessary engineering design of the slurries to be used in the well. In addition, the engineer should ensure that the work is carried out in accordance to the design specifications. This critical activity should not be left to the service company technicians.

4.17.4 Standardization and Properties of Cements

The American Petroleum Institute (API) has six classes of well cements. These are as follows [5]:

Class A: Intended for use from surface to 6,000 ft (1,830 m) depth, when special properties are not required. Available only in ordinary type (similar to ASTM C 150, Type I¹).

Class B: Intended for use from surface to 6,000 ft (1,830 m) depth, when conditions require moderate to high sulfate resistance. Available in both moderate (similar to ASTM C 150, Type II) and high-sulfate-resistant types.

Class C: Intended for use from surface to 6,000 ft (1,830 m) depth, when conditions require high early strength. Available in ordinary and moderate (similar to ASTM C 150, Type III) and high-sulfate-resistant types.

Class D: Intended for use from 6,000 to 10,000 ft (1,830 to 3,050 m) depth, under conditions of moderately high temperatures and pressures. Available in both moderate and high-sulfate-resistant types.

Class G, H: Intended for use as a basic well cement from surface to 8,000 ft (2,440 m) depth as manufactured, and can be used with accelerators and retarders to cover a wide range of well depths and temperatures. No additions other than calcium sulfate or water, or both, shall be interground or blended with the clinker during manufacture of Class H well cement. Available in moderate and high-(tentative) sulfate-resistant types.

The ASTM specifications provide for five types of Portland cements: Types I, II, III, IV and V; they are manufactured for use at atmospheric conditions [6]. The API Classes A, B and C correspond to ASTM Types I, II and III, respectively. The API Classes D, E, F, G, H and J are cements manufactured for use in deep wells and to be subject to a wide range of pressures and temperatures. These classes have no corresponding ASTM types.

Sulfate resistance is an extremely important property of well cements. Sulfate minerals are abundant in some underground formation waters that can come into contact with set cement. The sulfate chemicals, which include magnesium and sodium sulfates, react with the lime in the set cement to form magnesium hydroxide, sodium hydroxide and calcium sulfate. The calcium sulfate reacts with the tricalcium aluminate components of cement to form sulfoaluminate, which causes expansion and ultimately disintegrates to the set cement. To increase the resistance of a cement to sulfate attack, the amount of tricalcium aluminate and free lime in the cement should be decreased. Alternatively, the amount of pozzolanic material can be increased in the cement to obtain a similar resistance. The designations of ordinary sulfate resistance, moderate sulfate resistance and high sulfate resistance in the cement classes above indicate decreasing amounts of tricalcium aluminate.

Table 4.17.1 gives the basic properties of the various classes of the dry API cements [5].

1. American Society for Testing and Materials (ASTM).

TABLE 4.17.1 Properties of the Various Classes of API Cements

Cement Class	A	B	C	D	G	H
Specific Gravity	3.14	3.14	3.14	3.16	3.16	3.16
Surface Area (cm ² /gm)	1500	1600	2200	1200	1400	1200
Weight Per Sack, lb	94	94	94	94	94	94
Bulk Volume, ft ³ /sk	1	1	1	1	1	1
Absolute Volume, gal/sk	3.59	3.59	3.55	3.57	3.62	3.57

4.17.5 Properties of Cement Slurry and Set Cement

In well engineering and applications, cement must be dealt with in both its slurry form and in its set form. At the surface the cement must be mixed and then pumped with surface pumping equipment through tubulars to a designated location in the well. After the cement has set, its structure must support the various static and dynamic loads placed on the well tubulars.

4.17.5.1 Density, Specific Weight, and Specific Gravity

Density: The term “density” is the mass per unit volume. In the System International (SI), this is kg/m^3 , or kg/l , g/cm^3 . In the British Imperial System (BIS) and United States Customary System (USCS), the mechanical properties of a fluid are not published in mass per unit volume units (the BIS and USCS are basically the same). In the USCS, the mass per unit volume must be calculated from the published weight per unit volume (this latter term is denoted as specific weight). For decades the oil and gas industry in the West has used the term “density” as a form of an oil field slang for the USCS weight per unit volume published fluid mechanical properties usually published as lb/ft^3 , or lb/gal (the latter also written as ppg). The weight per unit volume of freshwater is 62.4 lb/ft^3 or 8.34 lb/gal . To obtain the USCS density terms (equivalent to the SI density terms) from the published specific weight values, both terms must be divided by the USCS acceleration of gravity constant, namely 32.2 ft/s^2 . This would give density values of

$$\rho_{\text{fw}} = \frac{\gamma_{\text{fw}}}{g} = \frac{62.4}{32.2} = 1.94 \frac{\text{lb} - \text{s}^2}{\text{ft}^4} = 1.94 \frac{\text{slug}}{\text{ft}^3}$$

or

$$\rho_{\text{fw}} = \frac{\gamma_{\text{fw}}}{g} = \frac{8.34}{32.2} = 0.258 \frac{\text{lb} - \text{s}^2}{\text{ft} - \text{gal}} = 0.258 \frac{\text{slug}}{\text{gal}}$$

Who knows what the slug is? Well of course most people don't know what the slug is because it is not used often in engineering practice. Basically, the slug is the USCS equivalent to the SI kilogram. The USCS slug is

$$1 \text{ slug} = 1 \frac{\text{lb} - \text{s}^2}{\text{ft}}$$

Likewise, the SI kilogram is

$$1 \text{ kg} = 1 \frac{\text{N} - \text{s}^2}{\text{m}}$$

where the N is the Newton which is force unit which is equivalent to the lb force unit in the USCS (the conversion

is $4.445 \text{ N} = 1 \text{ lb}$). As the slug is not often written in the technical literature, the kilogram is very rarely written in the terms its basic terms of

$$\frac{\text{N} - \text{s}^2}{\text{m}}$$

Specific Weight: Since the SI mechanical properties of a fluid are listed in density units, these density terms must be used to calculate the specific weight so that practical engineering calculations can be made. Therefore, the density of freshwater can be written in SI units as 1000 kg/m^3 , or 1 kg/l . To carry these calculations out, we must **multiply** these density terms by the SI acceleration of gravity constant, namely 9.81 m/s^2 . This would give the specific weight values of

$$\gamma_{\text{fw}} = \rho_{\text{fw}} g = 1000(9.81) = 9810 \frac{\text{N}}{\text{m}^3}$$

or

$$\gamma_{\text{fw}} = \rho_{\text{fw}} g = 1(9.81) = 9.810 \frac{\text{N}}{\text{l}}$$

Note that currently there is a new oil field slang term being used. This is CW for “cement weight” (or MW for “mud weight”). These new slang terms are replacing the use of the old slang term of “density” particularly in the areas where the USCS is used. These terms are more scientifically correct since they refer to specific weight values.

Specific Gravity: The above is a complicated units situation especially for engineers who may have worked in one part of the world where either the SI or the USCS was being used and later are assigned to work in another part of the world where the other unit system dominates. Fortunately, instead of dealing with such complicated units situations, the specific gravity of a fluid can be determined from either the published SI density data or the published USCS specific weight data. The specific gravity term can be defined as

$$\begin{aligned} \text{Specific gravity} &= \frac{\text{Density of a fluid}}{\text{Density of freshwater}} \\ &= \frac{\text{Specific weight of a fluid}}{\text{Specific weight of freshwater}} \end{aligned}$$

For example, if an engineer from Germany is working temporarily for his operating company at drilling location in the Gulf Coast region of the US and wants to convert his SI density calculation result for a new cement slurry to a USCS specific weight value for service company staff working at the location, his calculation result for the new cement slurry is 1.88 kg/l . Therefore, the specific gravity of this new cement slurry is

$$\text{Specific gravity} = \frac{1.88}{1.00} = 1.88$$

Therefore, the new cement slurry specific weight is

$$\text{Specific weight} = 1.88(8.34) = 15.7 \frac{\text{lb}}{\text{gal}}$$

or

$$\text{Specific weight} = 1.88(62.4) = 117.3 \frac{\text{lb}}{\text{ft}^3}$$

Specific weight is one of the most important properties of a cement slurry. A neat cement slurry is a combination of only cement and water. The specific weight of a neat cement slurry is defined by the amount of water used with the dry cement. The specific weight range for a particular class of cement is, therefore, limited by the minimum and maximum water-to-cement ratios permissible by API standards.

The minimum amount of water for any class of cement is defined as that amount of water that can be used in the slurry with the dry cement that will still produce a neat slurry with a consistency that is below 30 Bearden units of

consistency.² Note that the minimum water content defined in this manner is much greater than the stoichiometric minimum for cement hydration and setting.

The maximum amount of water for any class of cement is usually defined as the ratio that results in the cement particles remaining in suspension until the initial set of the slurry has taken place. If more than the maximum amount of water is used, then the cement particles will settle in such a manner that there will be pockets of free water within the set cement column.

Table 4.17.2 gives the API recommended optimum water-to-cement ratios and the resulting neat slurry specific weight (lb/gal) and specific volume, or yield (ft³/sack) for the various classes of API cements [2].

Table 4.17.3 gives the maximum and minimum water-to-cement ratios and the resulting neat slurry specific weight and specific volume, or yield for three classes of API cement.

The specific weight of a cement slurry $\bar{\gamma}$ (lb/gal) is

$$\bar{\gamma} = \frac{\text{Cement (lb)} + \text{Water (lb)} + \text{Additive (lb)}}{\text{Cement (gal)} + \text{Water (gal)} + \text{Additive (gal)}} \tag{4.17.1}$$

2. This was formally referred to as poise.

TABLE 4.17.2 Properties of Neat Cement Slurries for Various Classes of API Cements

API Class	API Rec'd Water (gal/sk)	API Rec'd Water (gal/sk)	API Rec'd Water (gal/sk)	Percent of Mixing Water
A (Portland)	5.20	15.6	1.18	46
B (Portland)	5.20	15.6	1.18	46
C (High Early)	6.32	14.8	1.32	56
D (Retarded)	4.29	16.46	1.05	38
G (Basic)	4.97	15.8	1.15	44
H (Basic)	4.29	16.46	1.05	38

TABLE 4.17.3 Maximum and Minimum Water-to-Cement Ratios for API Classes A, C and E Neat Cement Slurries

API Class	Maximum Water			Minimum Water		
	Water (gal/sk)	Weight (lb/gal)	Volume (ft ³ /sk)	Water (gal/sk)	Weight (pb/gal)	Volume (ft ³ /sk)
A	5.5	15.39	1.22	3.90	16.89	1.00
C	7.9	13.92	1.53	6.32	14.80	1.32

The volumes above are absolute volumes. For example, a 94-lb sack of cement contains 1 ft³ of bulk cement powder, yet the actual or absolute space occupied by the cement particles is only 0.48 ft³.

For dealing with other powdered materials that are additives to cement slurries, the absolute volume must be used. The absolute volume (gal) is

$$\text{Absolute value (gal)} = \frac{\text{Additive material (lb)}}{(8.34 \text{ lb/gal})(\text{S.G. of material})} \quad (4.17.2)$$

The volume of slurry that results from 1 sack of cement additives is defined as the yield. The yield (ft³/sack) is

$$\text{Yield} = \frac{\text{Cement (gal)} + \text{Water (gal)} + \text{Additives (gal)}}{7.48 \text{ gal/ft}^3} \quad (4.17.3)$$

where the cement, water and additives are those associated with 1 sack of cement, or 94 lb of cement.

Example 4.17.1

Calculate the specific weight and yield for a neat slurry of Class A cement using the maximum permissible water-to-cement ratio.

Table 4.17.3 gives the maximum water-to-cement ratio for Class A cement as 5.5 gal/sack. Thus using the absolute volume for Class A cement from Table 4.17.1 as 3.59 gal/sack, Equation 4.17.1 is

$$\begin{aligned} \bar{\gamma} &= \frac{94 + 5.5(8.34)}{3.59 + 5.5} \\ &= 15.39 \text{ lb/gal} \end{aligned}$$

The yield determined from Equation 4.17.3 is

$$\begin{aligned} \text{Yield} &= \frac{3.59 + 5.5}{7.48} \\ &= 1.22 \text{ ft}^3/\text{sack} \end{aligned}$$

It is often necessary to decrease the specific weight of a cement slurry to avoid fracturing weak formations during cementing operations. There are basically two methods for accomplishing lower specific weights. These are

1. Adding clay or chemical silicate type extenders together with their required extra water.
2. Adding large quantities of pozzolan, ceramic microspheres or nitrogen. These materials lighten the slurry because they have lower specific gravities than the cement.

It also may be necessary to increase the specific weight of a cement slurry, particularly when cementing through high-pressure formations. There are basically two methods for accomplishing higher specific weights. These are

1. Using the minimum permissible water-to-cement ratio for the particular cement class and adding dispersants to increase the fluidity of the slurry.
2. Adding high-specific-gravity materials to the slurry together with optimal or slightly reduced (but not necessarily the minimum) water-to-cement ratio for the particular cement class.

4.17.5.2 Thickening Time

It is important that the thickening time to be known prior to using the slurry in a cementing operation. When water is added to dry cement and its additives, a chemical reaction begins that results in an increase in slurry viscosity. This viscosity increases over time, which will vary in accordance with the class of cement used, the additives placed in the dry cement prior to mixing with water and the temperature and confining pressure in the location where the cement slurry is placed. When the viscosity becomes too high, the slurry is no longer pumpable. Thus, if the slurry has not been placed in its proper location within the well prior to the cement slurry becoming unpumpable, the well and the surface equipment would be seriously damaged.

Thickening time T_t (hr) is defined as the time required for the cement slurry to reach the limit of 100 Bearden units of consistency.³ This thickening time must be considerably longer than the time necessary to carry out the actual cementing operation. This can be accomplished by choosing the class of cement that has a sufficiently long thickening time, or placing the appropriate additives in the slurry that will retard the slurry chemical reaction and lengthen the thickening time.

It is necessary that an accurate estimate of the total time be for the actual operation. A safety factor should be added to this estimate. Usually this safety factor is from 30 min (for shallow operations) to as long as 2 hr (for deep complex operations).

The cementing operation time T_o (hr) is the time required for the cement slurry to be placed in the well:

$$T_o = T_m + T_d + T_p + T_s \quad (4.17.4)$$

where T_m = time required to mix the dry cement (and additives) with water in hr

T_d = the time required to displace the cement slurry (that was pumped to the well as mixing took place) by mud or water from inside the casing in hr

T_p = plug release time in hr

T_s = the safety factor of 0.5 to 2 hr

3. 70 Bearden units of consistency is considered to be maximum pumpable viscosity.

The mixing time T_m is

$$T_m = \frac{\text{Volume of dry cement}}{\text{Mixing rate}}$$

$$= \frac{V_c(\text{sacks})}{\text{Mixing rate (sack/min)}(60)} \quad (4.17.5)$$

where V_c is the dry volume of cement (sacks).

The displacement time T_d is

$$T_d = \frac{\text{Volume of fluid required to displace top plug}}{\text{Displacement rate}}$$

$$= \frac{\text{Volume (ft}^3\text{)}}{\text{Displacement rate (ft}^3\text{/min)}(60)} \quad (4.17.6)$$

The cement slurry chosen must have a thickening time that is greater than the estimated time obtained for the actual cementing operation using Equation 4.17.4. Thus, $T_t > T_o$.

Figure 4.17.4 gives a relationship between well depth and cementing operation time and the specifications for the various cement classes. This figure can be used to approximate cementing operation time.

The cement slurry thickening time can be increased or decreased by adding special chemicals to the dry cement prior to mixing with water. Retarders are added to increase the thickening time and thus increase the time when the cement slurry sets. Some common retarders are organic compounds such as lignosulphonate, cellulose derivatives, sugar derivatives and synthetics. Accelerators are added to decrease the thickening time and thus decrease the time when the cement slurry sets. Accelerators are often used when it is required to have the cement obtain an early compressive strength, usually of the order of 500 psi (35 bar). Early setting cement slurries are used to cement surface casing strings or directional drilling plugs where waiting-on-cementing (WOC) must be kept to a minimum.

FIGURE 4.17.4 Well depth and cementing time relationships [5]. *Specified maximum thickening time—120 minutes.

The most common accelerators are calcium chloride to a lesser extent sodium chloride.

In general the thickening time for all neat cement slurries of all classes of cement will decrease significantly with increasing well environment temperature and/or confining pressure. Thus it is very important that the well extreme temperatures and confining pressures be defined for a particular cementing operation before the cement slurry is designed. Once the well temperature and pressure conditions are known, either from offset wells or from actual well logs during the drilling operation, and the estimated cementing operation time is known, the cement slurry with the required thickening time can be designed. After the initial cement slurry design has been made it is usually necessary to carry out laboratory tests to verify that the actual cement batch mix used will give the required thickening time (and other characteristics needed). Such tests are usually carried out by the cementing service company laboratory using the operator's specifications.

Example 4.17.2

Calculate the minimum thickening time required for a primary cementing operation to cement a long intermediate casing string. The intermediate casing string is a $9\frac{5}{8}$ -in., 53.5-lb/ft casing set in a $12\frac{1}{2}$ -in. hole. The string is 12,000 ft in length from the top of the float collar to the surface. The cementing operation will require 1,200 sacks of Class H cement. The single cementing truck has a mixing capacity of 25 sacks per minute. The rig duplex mud pump has an 18-in. stroke (2.5 in. rod) and $6\frac{1}{2}$ -in. liners and will be operated at 50 strokes per minute with a 90% volumetric efficiency. The plug release time is estimated to be about 15 min.

The mixing time is obtained from Equation 4.17.5. This is

$$T_m = \frac{1,200}{25(60)} \\ = 0.80 \text{ hr}$$

The inside diameter of $9\frac{5}{8}$ -in., 53.50-lb/ft casing is 8.535 in. (see Section titled Fishing Operations). The internal capacity per unit length of casing is

$$\text{Casing internal capacity} = \frac{\pi (8.535)^2}{4 \cdot 12} \\ = 0.3973 \text{ ft}^3/\text{ft}$$

Thus the total internal capacity of the casing is

$$\text{Total volume} = 12,000(0.3973) \\ = 4,768 \text{ ft}^3$$

The volume capacity of the mud pump per stroke q ($\text{ft}^3/\text{stroke}$) (see section titled "Mud Pumps") is

$$q = \left\{ 2 \left[\frac{\pi}{4} (6.5)^2 \right] (18.0) \right. \\ \left. + 2 \left[\frac{\pi}{4} (6.5)^2 - \frac{\pi}{4} (2.5)^2 \right] (18.0) \right\} \frac{(0.90)}{(12)^3} \\ = 1.1523 \text{ ft}^3/\text{stroke}$$

The displacement time is obtained from Equation 4.17.6. This is

$$T_d = \frac{4,768}{50(1.1523)(60)} \\ = 1.38 \text{ hr}$$

The plug release time is

$$T_p = \frac{15}{60} \\ = 0.25 \text{ hr}$$

Using a safety factor of 1 hr, the cementing operation time is obtained from Equation 4.17.4. This is

$$T_o = 0.80 + 1.38 + 0.25 + 1.00 \\ = 3.43 \text{ hr}$$

Thus the minimum thickening time for the cement slurry to be used this cementing operation is

$$T_t = 3.43 \text{ hr}$$

or 3 hr and 26 min.

4.17.5.3 Strength of Set Cement

A properly designed cement slurry will set after it has been placed in its appropriate location within the well. Cement strength is the strength the set cement has obtained. This usually refers to compressive strength, but can also refer to tensile strength. Cement having a compressive strength of 500 psi (35 bar) is considered adequate for most well applications.

The compressive strength of set cement is dependent upon the water-to-cement ratio used in the slurry, curing time, the temperature during curing, the confining pressure during curing and the additives in the cement. As part of the cement design procedures, samples of the cement slurry to be used in the cementing operation are cured and compression strength tested and often shear bond strength tested. These tests are usually carried out by the cementing company laboratory at the request of the operator.

In the compression test, four or five sample cubes of the slurry are allowed to cure for a specified period of time. The cement cubes are placed in a compression testing machine and the compressive strength of each sample cube

obtained experimentally. The average value of the samples is obtained and reported as the compressive strength of the set cement.

In the shear bond strength test, the cement slurry is allowed to cure in the annulus of two concentric steel cylinders. After curing the force to break the bond between the set cement and one of the cylinders (usually the inner one) is obtained experimentally. The shear force, F_s (lb), which can be supported on the inner cylinder, or by the casing, is [4]

$$F_s = 0.969 \sigma_c dl \quad (4.17.7)$$

where σ_c = compressive strength of cement in psi
 d = outside of the casing in in.
 l = length of the cement column in in.

Table 4.17.4 shows the influence of curing time, temperature and confining pressure on the compressive strength of Class H cement [3]. Also shown is the effect of the calcium chloride accelerator. In general, for the ranges of temperature and other values considered, the compressive strength increases with increasing curing time, temperature, confining pressure and the amount of calcium chloride accelerator. In general, the other classes of cement follow the same trend in compressive strength versus curing time, temperature and confining pressure.

At curing temperatures of about 230°F (93°C) or greater, the compressive strength of nearly all classes of cement cured under pressure will decrease. This decrease in compressive strength is often denoted as strength retrogression. An increase in cement permeability accompanies this decrease in strength. This strength retrogression problem can be solved by adding from 30 to 50% (by weight) of silica flour or silica sand to the cement slurry. This silica additive prevents the strength retrogression and the corresponding increase in permeability of the cement.

Table 4.17.5 shows the effect of silica flour on the compressive strength of Class G cement cured at 700°F (371°C).

Example 4.17.3

For Example 2, determine the total weight that can be supported by the set cement bonded to the 9⁵/₈-in. casing. Assume the cement slurry yield is 1.05 ft³/sack (see Table 4.17.2) and there are 120 ft of casing below the float collar. A compressive strength of 500 psi is to be used.

The total volume of the cement slurry to be pumped to the well is

$$\begin{aligned} \text{Volume of slurry} &= 1,200(1.05) \\ &= 1,260 \text{ ft}^3 \end{aligned}$$

TABLE 4.17.4 Influence of Time and Temperature on the Compressive Strength of API Class H Cement [3]

Curing Time (hours)	Calcium Chloride (percent)	Compressive Strength (psi) at Curing Temperature and Pressure of			
		95°F 800 psi	110°F 1,600 psi	140°F 3,000 psi	170°F 3,000 psi
6	0	100	350	1,270	1,950
8		500	1,200	2,500	4,000
12		1,090	1,980	3,125	4,700
24		3,000	4,050	5,500	6,700
6	1	900	1,460	2,320	2,500
8	1	1,600	1,950	2,900	4,100
12	1	2,200	2,970	3,440	4,450
24	1	4,100	5,100	6,500	7,000
6	2	1,100	1,700	2,650	2,990
8	2	1,850	2,600	3,600	4,370
12	2	2,420	3,380	3,900	5,530
24	2	4,700	5,600	6,850	7,400

TABLE 4.17.5 Effect of Silica Flour on the Compressive Strength of Class G Cement Cured at Pressure

Curing Time (days)	Silica Flour (percent)	Compressive Strength (psi), 1 Day at 130°F, All Remaining Days at 700°F
1	0	3525
2		988
4		1012
8		1000
1	40	2670
2		3612
4		3188
8		4588

The volume of slurry that is pumped to the annulus between the open borehole and the outside of the casing is

$$\begin{aligned}\text{Volume of annulus} &= 1,260 - (0.3973)(120) \\ &= 1,212 \text{ ft}^3\end{aligned}$$

The height in the annulus to where the casing is cemented to the borehole well and casing is

$$\begin{aligned}h &= \frac{1,212}{\pi/4[(12.5/12)^2 - (9.625/12)^2]} \\ &= 3,493 \text{ ft}\end{aligned}$$

The total weight that can be supported is calculated from Equation 4.17.7. This is

$$\begin{aligned}F_s &= 0.969(500)(9.625)(3,493)(12) \\ &= 195.5 \times 10^6 \text{ lb}\end{aligned}$$

4.17.6 Cement Additives

There are many chemical additives that can be used to alter the basic properties of the neat cement slurry and its resulting set cement. These additives are to alter the cement so that it is more appropriate to the surface cementing equipment and the subsurface environment.

Additives can be subdivided into six functional groups that are [7–9]:

1. Specific weight control
2. Thickening and setting time control
3. Loss of circulation control
4. Filtration control

5. Viscosity control
6. Special problems control

4.17.6.1 Specific Weight Control

As in drilling mud design, the cement slurry must have a specific weight that is high enough to prevent high pore pressure formation fluids from flowing into the well. But also the specific weight must not be so high as to cause fracturing of the weaker exposed formations. In general, the specific weight of the neat cement slurry of any of the various API classes of cement are so high that most exposed formations will fracture. Thus, it is necessary to lower the specific weight of nearly all cement slurries. The slurry specific weight can be reduced by using a higher water-to-cement ratio. But this can only be accomplished within the limits for maximum and minimum water-to-cement ratios set by API standards (see Table 4.17.3). The reduction in specific weight is normally accomplished by adding low-specific-gravity solids to the slurry. Table 4.17.6 gives the specific gravity properties of a number of the low-specific-gravity solids that are used to reduce the specific weight of cement slurries.

The most common low-specific-gravity solids used to reduce cement slurry specific weight are bentonite, diatomaceous earth, solid hydrocarbons, expanded perlite and pozzolan. It may not be possible to reduce the cement slurry specific weight enough with the above low-specific-weight materials when very weak formations are exposed. In such cases nitrogen is used to aerate the mud column above the cement slurry to assist in further decreasing the hydrostatic pressure.

Nearly all materials that are added to a cement slurry require the addition of additional water to the slurry. Table 4.17.7 gives the additional requirements for the various cement additives [7].

Bentonite. Bentonite without an organic polymer can be used as an additive to cement slurries. The addition of bentonite requires the use of additional water, thereby, further reducing the specific weight of the slurry (Table 4.17.7). Bentonite is usually dry blended with the dry cement prior to mixing with water. High percentages of bentonite in cement will significantly reduce compressive strength and thickening time. Also, high percentages of bentonite increase permeability and lower the resistance of cement to sulfate attack. At temperatures above 230°F (93°C), the bentonite additive promotes, retrogression of strength in cements with time. Bentonite has been used in 25% by weight of cement. Such high concentrations are not recommended. In general, the bentonite additive makes a poor well cement.

Diatomaceous Earth. Diatomaceous earth has a lower specific gravity than bentonite. Like bentonite this additive

also requires additional water to be added to the slurry. This additive will affect the slurry properties similar to the addition of bentonite. However, it will not increase the viscosity as bentonite will do. Diatomaceous earth concentrations as high as 40% by weight of cement have been used. This additive is more expensive than bentonite.

Solid Hydrocarbons. Gilsonite (an asphaltite) and coal are used as very-low-specific-gravity solids additives. These additives do not require a great deal of water to be added to the slurry when they are used.

Expanded Perlite. Expanded perlite requires a great deal of water to be added to the slurry when it is used to reduce

the specific weight of a slurry. Often perlite as an additive is used in a blend of additives such as perlite with volcanic glass fines, or with pozzolanic materials, or with bentonite. Without bentonite the perlite tends to separate and float in the upper part of the slurry.

Pozzolan. Diatomaceous earth is a type of pozzolan. Pozzolan refers to a finely ground pumice or fly ash that is marketed as a cement additive under that name. The specific gravity of pozzolans is slightly less than the specific gravity of cement. The water requirements for this additive are about the same as for cements. Only a slight reduction in specific weight of a slurry can be realized by using these additives. The cost of pozzolans is very low.

Where very high formations pore pressure are present the specific weight of the cement slurry can be increased by using the minimum water-to-cement ratio and/or by adding high-specific-gravity materials to the slurry. The most common high-specific-gravity solids used to increase cement slurry specific weight are hematite, ilmenite, barite and sand. Table 4.17.6 gives the specific gravity properties of a number of these high-specific-gravity additives.

Hematite. This additive can be used to increase the specific weight of a cement slurry to as high as 19 lb/gal. This is an iron oxide ore with a specific gravity of about 5.02. Hematite requires the addition of some water when it is used as an additive. Hematite has minimal effect on thickening time and compressive strength of the cement.

Ilmenite. This additive has a specific gravity of about 4.67. It is a mineral composed of iron, titanium and oxygen. It requires no additional water to be added to the slurry; thus, it can yield slurry specific weights as high as the hematite additive. Ilmenite also has mineral effect on thickening time and compressive strength of the cement.

Barite. This mineral additive requires much more water to be added to the cement slurry than does hematite. This large amount of added water required will decrease the compressive strength of the cement. This additive can be used to increase the specific weight of a cement slurry to as high as 19 lb/gal.

Sand. Ottawa sand has a low specific gravity of about 2.63. But since no additional water is required when using this

additive, it is possible to use sand to increase the cement slurry specific weight. The sand has little effect on the pumpability of the cement slurry. When set the cement will form a very hard surface. Sand used as an additive can be used to increase the specific weight of a cement slurry to as high as 18 lb/gal.

Example 4.17.4

A specific weight of 12.8 lb/gal is required for a Class A cement slurry. It is decided that the cement be mixed with bentonite to reduce the specific weight of the slurry. Determine the weight of bentonite that should be dry blended with each sack of cement. Determine the yield of the cement slurry. Determine the volume (gal) of water needed for each sack of cement.

The weight of bentonite to be blended is found by using Equation 4.17.1. Taking the appropriate data from Tables 4.17.1, 4.17.2, 4.17.6 and 4.17.7 and letting x be the unknown weight of bentonite per sack of cement, Equation 4.17.1 is

$$12.8 = \frac{94 + x + 8.34(5.20 + 0.692x)}{\left(\frac{94}{3.14(8.34)} + \frac{x}{2.65(8.34)} + 5.20 + 0.692x\right)}$$

Solving the above for x gives

$$x = 9.35 \text{ lb}$$

Thus, 9.35 lb of bentonite will need to be added for each sack of Class A cement used.

The yield can be determined from Equation 4.17.3. This is

$$\text{Yield} = \frac{\frac{94}{3.14(8.34)} + \frac{9.35}{2.65(8.34)} + 5.20 + 0.692(9.35)}{7.48}$$

$$= 2.10 \text{ ft}^3/\text{sack}$$

The volume of water needed is

$$\text{Volume of water} = 5.20 + 0.692(9.35)$$

$$= 11.69 \text{ gal/sack}$$

Example 4.17.5

A specific weight of 18.2 lb/gal is required for a Class H cement slurry. It is decided that the cement be mixed with hematite to increase the specific weight of the slurry. Determine the weight of hematite that should be dry blended with each sack of cement. Determine the yield of the cement slurry. Determine the volume (gal) of water needed for each sack of cement.

The weight of hematite to be blended is found by using Equation 4.17.1. Taking the appropriate data from Tables 4.17.1, 4.17.2, 4.17.6 and 4.17.7 and letting x be the unknown weight of hematite per sack of cement, Equation 4.17.1 is

$$18.2 = \frac{94 + x + 8.34(4.29 + 0.0036x)}{\frac{94}{3.14(8.34)} + \frac{x}{5.02(8.34)} + (4.29 + 0.0036x)}$$

Solving the above for x gives

$$x = 25.8 \text{ lb}$$

Thus, 25.8 lb of hematite will need to be added for each sack of Class H cement used.

The yield can be determined from Equation 4.17.3. This is

$$\text{Yield} = \frac{\frac{94}{3.14(8.34)} + \frac{25.8}{5.07(8.34)} + 4.29 + 0.0036(25.8)}{7.48}$$

$$= 1.15 \text{ ft}^3/\text{sack}$$

The volume of water needed is

$$\text{Volume of water} = 4.29 + 0.0036(25.8)$$

$$= 4.38 \text{ gal/sack}$$

Example 4.17.6

A specific weight of 17.1 lb/gal is required for a Class H cement slurry. It is decided that the cement be mixed with sand in order to increase the specific weight of the slurry.

Determine the weight of sand that should be added with each sack of cement. Determine the yield of the cement slurry. Determine the volume (gal) of water needed for each sack of cement.

The weight of sand to be added is found by using Equation 4.17.1. Taking the appropriate data from Tables 4.17.1, 4.17.2, 4.17.6, and 4.17.7 and letting x be the unknown weight of sand per sack of cement, Equation 4.17.1 is

$$17.1 = \frac{94 + x + 8.34(4.29)}{\frac{94}{3.14(8.34)} + \frac{x}{2.63(8.34)} + 4.29}$$

Solving the above for x gives

$$x = 31.7 \text{ lb}$$

Thus, 31.7 lb of sand will need to be added for each sack of Class H cement used.

The yield can be determined from Equation 4.17.3. This is

$$\text{Yield} = \frac{\frac{94}{3.14(8.34)} + \frac{31.7}{2.63(8.34)} + 4.29}{7.48} = 1.25 \text{ ft}^3/\text{sack}$$

Since no additional water is needed when using sand as the additive, the volume of water needed is

$$\text{Volume of water} = 4.29 \text{ gal/sack}$$

4.17.6.2 Thickening Setting Time Control

It is often necessary to either accelerate, or retard the thickening and setting time of a cement slurry.

For example, when cementing a casing string run to shallow depth or when setting a directional drilling kick-off plug, it is necessary to accelerate the cement hydration so that the waiting period will be minimized. The most commonly used cement hydration accelerators are calcium chloride, sodium chloride, a hemihydrate form of gypsum and sodium silicate.

Calcium Chloride. This accelerator may be used in concentrations up to 4% (by weight of mixing water) in well having bottomhole temperatures less than 125°F. This additive is usually available in an anhydrous grade (96% calcium chloride). Under pressure curing conditions calcium chloride tends to improve compressive strength and significantly reduce thickening and setting time more than 4-5% BWOC of CaCl₂ may cause the slurry to flash set.

Sodium Chloride. This additive will act as an accelerator when used in cements containing no bentonite and when in concentrations of about 5% (by weight of mixing water). In concentrations above 5% the effectiveness of sodium chloride as an accelerator is reduced. This additive should be used in wells with bottom-hole temperatures less than

160°F. Saturated sodium chloride solutions act as a retarder. Such saturated sodium chloride solutions are used with cement slurries that are to be used to cement through formations that are sensitive to freshwater. However, potassium chloride is far more effective in inhibiting shale hydration. In general, up to a 5% concentration, sodium chloride will improve compressive strength while reducing thickening and setting time.

Gypsum. Special grades of gypsum hemihydrate cement are blended with Portland cement to produce a cement with reduced thickening and setting time for low-temperature applications. Such cement blends should be used in wells with bottomhole temperatures less than 140°F (regular-temperature grade) or 180°F (high-temperature grade). There is a significant additional water requirement for the addition of gypsum (see Table 4.17.7). When very rapid thickening and setting times are required for low-temperature conditions (i.e., primary cementing of a shallow casing string or a shallow kick-off plug), a special blend is sometimes used.

Sodium Silicate. When diatomaceous earth is used with the cement slurry, sodium silicate is used as the accelerator. It can be used in concentrations up to 7% by weight.

When it is necessary to cement casing or line strings set at great depths, additives are often used in the design of the cement slurry to retard the thickening and setting time. Usually such retarding additives are organic compounds. These materials are also referred to as thinners or dispersants. Calcium lignosulfonate is one of the most commonly used cement retarders. It is very effective at increasing thickening and setting time in cement slurries at very low concentrations (of the order of 1% by weight or less). It is necessary to add an organic acid to the calcium lignosulfonate when high-temperature conditions are encountered.

Calcium-sodium lignosulfonate is a better retarding additive when high concentrations of bentonite are to be used in the design of the cement slurry.

Also sodium tetraborate (borax) and carborymethyl hydroxyethyl cellulose are used as retarding additives.

4.17.6.3 Filtration Control

Filtration control additives are added to cement slurries for the same reason that they are added to drilling muds. However, untreated cement slurries have much greater filtration rates than untreated drilling muds. It is this important to limit the loss of water filtrate from a slurry to a permeable formation. This is necessary for several reasons:

- Minimize hydration of formations containing water sensitive formations
- Limit the increase in slurry viscosity as cement is placed in the well

- Prevent annular bridges
- Allow for sufficient water to be available for cement hydration

Examples of filtration control additives are latex, bentonite with a dispersant and other various organic compounds and polymers.

4.17.6.4 Viscosity Control

The viscosity of the cement slurry will affect the pumping requirements for the slurry and frictional pressure gradient within the well. The viscosity must be kept low enough to ensure that the cement slurry can be pumped to the well during the entire cementing operation period. High viscosity will result in high-pressure gradients that could allow formation fractures.

Examples of commonly used viscosity control additives are calcium lignosulfonate, sodium chloride and some long-chain polymers. These additives also act as accelerators or retarders so care must be taken in designing the cement slurry with these materials.

4.17.6.5 Special Problems Control

There are some special problems in the design of cement slurries for which additives have been developed. These are

- Gel strength additives for the preparation of spacers (usually fragile gel additives).
- Silica flour is used to form a stronger and less permeable cement, especially for high-temperature applications.
- Hydrazine is used to control corrosion of the casing.
- Radioactive tracers are used to assist in assessing where the cement has been placed.
- Gas-bubble-producing compounds to slowly create gas bubbles in the cement as the slurry sets and hardens. It is felt that such a cement will have less tendency to leak formation gas.
- Paraformaldehyde and sodium chromate that counteract organic contaminants left in the well from drilling operations.
- Fibrous materials such as nylon are added to increase strength, in particular, resistance to impact loads.

4.17.7 Primary Cementing

The cementing of casing or liner string is carried out so that producible oil and gas, or saltwater will not escape from the producing formation to another formation, or pollute freshwater sands at shallower depth.

The running of long casing strings and liner strings to great depths and successfully cementing these strings required careful engineering design and planning.

4.17.7.1 Normal Single-Stage Casing Cementing

It is often necessary to circulate the drilling mud in the hole prior to running the casing string. This is to assure that all the cutting and any borehole wall prices have been removed. However, the longer a borehole remains open, the more problems will occur with the well.

Prior to running the casing string into the well the mill varnish should be removed from the outer surface of the casing. The removal of the mill varnish is necessary to ensure that the cement will bond to the steel surface.

The casing string is run into the well with a guide shoe (Figure 4.17.5) or float shoe (Figure 4.17.6). Figure 4.17.4 illustrates a regular pattern guide shoe with a wireline re-entry bevel and no internal components to drill.

Figures 4.17.7 and 4.17.8 show two typical float collars. Figure 4.17.7 is a plunger style float collar and Figure 4.17.8 is a flapper float collar. Most modern float equipment is PDC drillable and constructed of composites and cement. Typically a float shoe and a float collar with both be run on one string to provide a redundant check valve capability.

Centralizers are placed along the length of the casing string in a spacing of between 2 per casing joint to 1 every 4 joints. The spacing of centralizer placement varies dependent on casing to hole size combination, fluid rheology, and well profile and is usually determined using centralizer placement software. Centralizers ensure that the

FIGURE 4.17.5 Regular pattern guide shoe [2]. (Courtesy of Weatherford International Limited.).

FIGURE 4.17.6 Swirl guide shoe [2]. (Courtesy of Weatherford International Limited.).

FIGURE 4.17.7 Ball float collar [2]. (Courtesy of Weatherford International Limited.).

FIGURE 4.17.8 Flapper float collar [2]. (Courtesy of Weatherford International Limited.).

FIGURE 4.17.9 Scratcher [2]. (Courtesy of Weatherford International Limited.).

casing is nearly centered in the borehole, thus allowing a more uniform distribution of cement slurry flow around the casing. This nearly uniform flow around the casing is necessary to remove the drilling mud in the annulus and provide an effective seal.

Figure 4.17.9 shows a typical rigid centralizer and 4.17.10 shows a typical bow spring centralizer. Bow spring

FIGURE 4.17.10 Centralizer [2]. (Courtesy of Weatherford International Limited.)

centralizers are generally run when casing is being run through a restricted bore hole, into under reamed sections, or into washed out zones. Rigid centralizers perform best when the well internal diameter is constant.

The casing string is lowered into the drilling mud in the well using the rig drawworks and elevators. The displaced drilling mud flows to the mud tanks and is stored there for later use. Once the entire casing string is in place in the borehole, the casing string is left hanging in the elevators through the cementing operation. This allows the casing string to be reciprocated (moved up and down) and possibly rotated as the cement is placed in the annulus. This movement assists the removal of the drilling mud.

While the casing string is hanging in the elevators a cementing head is made up to the upper end of the string (see Figure 4.17.3). The cementing head is then connected with flow liners that come from the pump truck (see Figure 4.17.2). The blender mixes the dry cement and additives with water. The high-pressure, low-volume triplex cement

pump on the pump truck pumps the cement slurry to the cementing head. Usually a preflush or spacer is initially pumped ahead of the cement slurry. This spacer (usually about 20 bbl or 3.2 m³) is used to assist in removing the drilling mud from the annular space between the outside of the casing and the borehole wall.

Figure 4.17.11 gives a series of schematics that show how the spacer and cement slurry displace drilling mud in the well. Two wiper plugs are usually used to separate the spacer and the cement slurry from the drilling mud in the well. The cementing head has two retainer valves that hold the two flexible rubber wiper plugs with two separate plug-release pins (Figure 4.17.11a). When the spacer and the cement slurry are to be pumped to the inside of the casing through the cementing head, the bottom plug-release pin is removed. This releases the bottom wiper plug into the initial portion of the spacer flow to the well (see Figure 4.17.11b). This bottom wiper plug keeps the drilling mud from contaminating the spacer and the cement slurry while they pass through the inside of the casing. When all the cement slurry has passed through the cementing head, the top plug-release pin is removed releasing the top wiper plug into the flow to the well. At this point in the cementing operation the cement pump begins to pump drilling mud through the cementing head to the well (see Figure 4.17.11a).

When the bottom wiper plug reached the float collar a diaphragm is burst at 200 to 400 psi (14 to 28 bar). Typically this pressure event is not witnessed at surface due to the

FIGURE 4.17.11 Single-stage cementing: (a) circulating mud; (b) pumping spacer and slurry; (c) and (d) displacing; (e) end of job. ●, plug-releasing pin in; ○, plug releasing pin out (Courtesy of Schlumberger).

density difference between the cement and the drilling mud. This specific weight differential is almost always large enough to rupture the diaphragm. Once the diaphragm is broken, the flow continues into the annulus between the casing and the borehole wall (see Figure 4.17.11d). The spacer and the cement slurry displace the drilling mud below the float collar and the drilling mud in the annulus. The spacer is designed to efficiently displace nearly all the drilling mud in the annulus prior to the cement slurry entering the annulus.

When the top wiper plug reached the float collar, the pump pressure rises sharply. This wiper plug does not have a diaphragm and, therefore, no further flow into the well can take place. At this point in the cementing operation the cement pump is usually shut down and the pressure released on the cementing head. The back-flow valve in the float collar stops the heavier cement slurry from flowing back into the inside of the casing string (see Figure 4.17.11e). The volume of spacer and cement slurry is calculated to allow the cement slurry to either completely fill the annulus, or to fill the annulus to a height sufficient to accomplish the objectives of the casing and cementing operation.

Usually a lighter drilling mud is used to follow the heavy cement slurry. In this way the casing is under compression from a higher differential pressure on the outside of the casing. Thus when the cement sets and drilling or production operations continues, the casing will always have an elastic load on the cement-casing interface. This elastic load is considered essential for maintenance of the cement-casing bond and to keep leakage between the cement and casing (i.e., the microannulus) from occurring.

Since the early 1960s there has been a great deal of discussion regarding the desirability of using a low viscosity cement slurry to improve the removal of drilling mud from the annulus [2, 3]. More recent studies have shown that low viscosity slurries do not necessarily provide effective removal of drilling mud in the annulus. In fact, there is strong evidence that spacers and slurries should have a higher gel strength and a higher specific weight than the mud that is being displaced [9]. Figure 4.17.12 gives the annular residual drilling mud removal efficiency as a function of differential gel strength and differential specific weight between the drilling mud and the spacer. The most successful spacer is an initial portion of the cement slurry that will give about 200 ft of annulus and that has a higher gel strength and a higher specific weight than the drilling mud it is to displace. The cement slurry spacer should have a gel strength that is about 10 to 15 lb/100 ft² greater and a specific weight that is about 2 to 4 lb/gal greater than the drilling mud to be displaced.

It makes no sense to use a water or a drilling mud spacer. If such spacers are used, the follow-on normal cement slurry will be just as unsuccessful at removing the water or the

FIGURE 4.17.12 Spacer gel and specific weight relationships [8].

drilling mud of the spacer as it would at removing drilling mud if no spacer were used.

The basic steps for the planning and execution of a successful cementing operation are:

1. Condition the well and the drilling mud prior to pulling the drill pipe. Typically at least one hole volume is circulated to remove cutting and debris.
2. Centralize the casing using a placement program.
3. Determine the specific weight and gel strength of drilling mud to be displaced.
4. Estimate the approximate cementing operation time.
5. Run a preflush spacer compatible with the mud and cement.
6. Select the most appropriate API class of cement that meets the depth, temperature, sulfate resistance and other well limitations. Select the cement class that has a natural thickening time that most nearly meets the cementing operation time requirement, or that will require only small amounts of retarding additives.
7. Design the cement slurry and its initial spacer to have the appropriate gel strength and specific weight. Have the cementing service company run laboratory tests on the cement slurry blend selected. These tests should be run at the anticipated bottomhole temperature and pressure. These tests should be carried out to verify thickening time, specific weight, gel strength (of spacer) and compressive strength.
8. Reciprocate or rotate the casing or liner while conditioning the hole and during the cementing operations. The combination of rotation and reciprocation is widely considered to provide the best results. Rotation

is more effective than reciprocation if only one of the two options can be employed. Special cementing hardware may be required to rotate casing.

9. The fluid mechanics should be modeled to provide the optimum pump rates during displacement.
10. The mixed cement slurry should be closely monitored with high-quality continuous specific weight monitoring and recording equipment as the slurry is pumped to the well.
11. When the cementing operation is completed, bleed off internal pressure inside the casing and leave valve open on cementing head.

Example 4.17.7

A 7-in., N-80, 29-lb/ft casing string is to be run in a 13,900-ft borehole. The casing string is to be 13,890 ft in length. Thus the guide shoe will be held about 10 ft from the bottom of the hole during cementing. The float collar is to be 90 ft from the bottom of the casing string. The borehole is cased with $9\frac{5}{8}$ -in., 32.30-lb/ft casing to 11,451 ft of depth. The open hole below the casing shoe of the $9\frac{5}{8}$ -in. casing is $8\frac{1}{2}$ in diameter. The 7-in. casing string is to be cemented to the top of the borehole. Class E cement with 20% silica flour is to be used from the bottom of the hole to a height of 1,250 ft from the bottom of the borehole. Class G cement with at least 10% silica flour is to be used from 1,250 ft from the bottom to the top of the borehole. The drilling mud in the borehole has a specific weight of 12.2 lb/gal and an initial gel strength of 15 lb/100 ft². A space sufficient to give 200 ft of length in the open-hole section will be used. An excess factor of 1.2 will be applied to the Class G cement slurry volume.

1. Determine the specific weight and gel strength for the spacer.
2. Determine the number of cement sacks for each class of cement to be used.
3. Determine the volume of water to be used.
4. Determine the cementing operation time and thus the minimum thickening time. Assume a cement mixing rate of 25 sacks/min. Also assume an annular displacement rate no greater than 90 ft/min while the spacer is moving through the open-hole section and a flowrate of 300 gal/min thereafter. A safety factor of 1.0 hr is to be used.
5. Determine the pressure differential prior to bumping the plug.
6. Determine the total mud returns during the cementing operation.

The basic properties of Class E and Class G cements are given in Table 4.17.1 and 4.17.2.

1. The drilling mud has a specific weight of 12.2 lb/gal and an initial gel strength of 15 lb/100 ft². Thus from

Figure 4.17.12 it will be desirable to have a cement slurry spacer with a specific weight of at least 15.2 lb/gal and an initial gel strength of about 20 lb/100 ft².

The spacer will be designed with Class G cement. Taking the appropriate data from Tables 4.17.6 and 4.17.7, the weight of silica flour to be used is

$$0.10(94) = 9.4 \text{ lb/sack}$$

Equation 4.17.1 becomes

$$\begin{aligned}\bar{\gamma} &= \frac{94 + 9.4 + 8.34[4.97 + 0.0456(9.4)]}{\frac{94}{3.14(8.34)} + \frac{9.4}{2.63(5.34)} + 4.97 + 0.0456(9.4)} \\ &= 16.4 \text{ lb/gal}\end{aligned}$$

Thus the spacer will be designed to have a specific weight of 16.4 lb/gal and sufficient fragile gel additive to have an initial gel strength of about 20 lb/100 ft².

2. The spacer must have a volume sufficient to give 200 ft of length in the open-hole section. The annular capacity of the open hole is

$$\frac{\pi}{4} \left[\left(\frac{8.5}{12} \right)^2 - \left(\frac{7.0}{12} \right)^2 \right] = 0.1268 \text{ ft}^3/\text{ft}$$

Equation 4.17.3 gives the yield of the spacer as

$$\text{Yield} = \frac{3.59 + 0.4286 + 4.97 + 0.4286}{7.48} = 1.21 \text{ ft}^3/\text{sack}$$

Thus the number of sacks to give that will be 200 ft in length in the open-hole section is

$$\text{Sacks} = \frac{0.1268(200)}{1.21} = 20.96$$

The above is rounded off to the next highest sack, or 21 sacks.

The volume of Class G cement is the sum of the spacer volume, annular volume in the cased portion of the borehole and the applicable annular volume in the open-hole section of the borehole. The annular capacity of the cased portion of the borehole is

$$\frac{\pi}{4} \left[\left(\frac{9.001}{12} \right)^2 - \left(\frac{7.0}{12} \right)^2 \right] = 0.1746 \text{ ft}^3/\text{ft}$$

Thus the volume of Class G cement slurry to be used to cement the well (excluding spacer, but considering the excess factor) is

$$\begin{aligned}\text{Volume} &= [(2,449 - 1,250)(0.1268) + 11,451(0.1746)]1.2 \\ &= 2,581.66 \text{ ft}^3\end{aligned}$$

The total number of Class G sacks of cement needed, including the spacer volume, is

$$\text{Total sacks} = \frac{2,581.66}{1.21} + 21 = 2,134 + 21 \approx 2,155$$

The volume of Class E cement is

$$\begin{aligned} \text{Volume} &= \frac{\pi}{4} \left(\frac{8.5}{12} \right)^2 (10) + \frac{\pi}{4} \left(\frac{6.184}{12} \right)^2 90 \\ &\quad + (1,250 - 10)(0.1268) \\ &= 3.94 + 18.77 + 157.23 = 179.94 \text{ ft}^3 \end{aligned}$$

The specific weight of the Class E cement is determined from Equation 4.17.1. The weight of silica flour to be added is

$$0.20(94) = 18.8 \text{ lb}$$

Equation 4.17.1 is

$$\begin{aligned} \bar{\gamma} &= \frac{94 + 18.8 + 8.34[4.29 + 0.0456(18.8)]}{94 + \frac{18.8}{3.14(8.34)} + 4.29 + 0.0456(18.8)} \\ &= 16.2 \text{ lb/gal} \end{aligned}$$

Equation 4.17.3 is

$$\text{Yield} = \frac{3.59 + 0.8571 + 4.29 + 0.8573}{7.48} = 1.28 \text{ ft}^3/\text{sack}$$

The total number of Class E sacks of cement needed are

$$\text{Total sacks} = \frac{179.94}{1.28} \approx 141$$

3. The volume of water to be used in the cementing operation is

$$\begin{aligned} \text{Volume} &= 2,155(4.97 + 0.4286) + 141(4.29 + 0.8573) \\ &\approx 11,634 + 726 \\ &\approx 12,360 \text{ gal} \end{aligned}$$

or about 295 bbl.

4. The total cementing operation time is somewhat complicated since it is desired to reduce the rate of flow when the spacer passes through the open hole section of the well. The mixing time is

$$T_m = \frac{2,155 + 141}{25(60)} = 1.53 \text{ hr}$$

During this time the volume of cement slurry pumped to the casing string is

$$\begin{aligned} \text{Volume pumped} &= 2,155(1.21) + 141(1.28) \\ &= 2,788.1 \text{ ft}^3 \end{aligned}$$

The internal volume of the casing string above the float collar is

$$\begin{aligned} \text{Internal volume} &= 13,800(0.2086) \\ &= 2,878.7 \text{ ft}^3 \end{aligned}$$

Therefore, the mud pumps are used to fill the remainder of the casing string at a rate of 300 gal/min. Thus, the additional time T_1 to get the bottom plug to the float collar is

$$T_1 = \frac{2,878.7 - 2,788.1}{\left(\frac{300}{7.48} \right) (60)} = 0.04 \text{ hr}$$

The time to release the plug is

$$\begin{aligned} T_p &= 15/60 \\ &= 0.25 \text{ hr} \end{aligned}$$

From the time the plug is released the pumping rate is reduced to 85.4 gal/min, which gives a velocity of 90 ft/min in the openhole section of the annulus. The time for the spacer to pass through the open-hole section T_2 (including the 90 ft of internal volume of the casing below the float collar and the 10 ft of open hole below the casing string guide shoe) is

$$T_2 = \frac{3.94 + 18.77 + (2,449 - 10)(0.1268)}{\left(\frac{85.4}{7.48} \right) (60)} = 0.49 \text{ hr}$$

After this time period, the rate of pumping to the well can be returned to 300 gal/min rate.

Equation 4.17.4 becomes

$$\begin{aligned} T_0 &= 1.53 + 0.04 + 0.25 + 0.49 \\ &\quad + \frac{2,878.7 - 91 - 332}{\left(\frac{300}{7.48} \right) (60)} + 1.0 = 4.33 \text{ hr} \end{aligned}$$

Therefore, the thickening time for the cement slurries to be used must be greater than 4.33 hr.

5. The pressure differential prior to the top plug reaching the float collar is

$$\begin{aligned} p &= \frac{122.7}{144} (13,900 - 1,250) + \frac{121.2}{144} (1,250 - 90 - 10) \\ &\quad - \frac{91.3}{144} (13,900 - 90 - 10) \\ &= 2997 \text{ psi} \end{aligned}$$

6. The total volume of the mud returns will be

$$\begin{aligned} \text{Mud volume} &= \text{Total volume well without steel} \\ &\quad - \text{Steel volume} \\ &= \frac{(8.5)^2}{4 \cdot 12} (13,900 - 11,451) \\ &\quad + \frac{(9.001)^2}{4 \cdot 12} (11,451) - \frac{29.0}{490} (13,890) \\ &= 5,203 \text{ ft}^3 \text{ or about } 927 \text{ bbl} \end{aligned}$$

4.17.7.2 Large-Diameter Casing Cementing

Often when large-diameter casing strings are to be cemented, an alternate method to cementing through inside diameter of the casing is used. This alternative method requires that the inner string of drillpipe be placed inside the large-diameter casing string. The drillpipe string is centralized within the casing and a special stab-in unit is made up to the bottom of the drillpipe string. After the drillpipe string is run into the well through the casing, the special unit on the bottom of the drillpipe string is stabbed into the stab-in cementing collar located a joint or two above the casing string guide shoe, or the unit is stabbed into a stab-in cementing shoe (a combination of the stab-in cementing collar and the guide shoe). Figure 4.17.13 shows the schematic of a large-diameter casing with the inner drillpipe string used for cementing [4]. Figure 4.17.14 shows the stab-in cementing shoe and a stab-in cementing collar. Also shown is a flexible latch-in plug used to follow the cement slurry. Once the stab-in unit of the drillpipe string is seated in the stab-in cementing shoe or cementing

FIGURE 4.17.13 Cementing of large-diameter casing with an inner drillpipe string (courtesy of Dowell Schlumberger).

collar, a special circulating head is made up to the top of the drillstring. Circulation is established through the circulating head to the drillpipe and up the annular space between the casing and the borehole wall. The stab-in unit may be locked into the cementing collar. The collar will act as a back-flow valve [3]. After the cement slurry has been run, the drillpipe string can be unlocked and withdrawn from the casing.

The advantages of cementing large diameter casing using an inner drillpipe string are:

- Avoids excessive mud contaminations of the cement slurry with drilling mud prior to reaching the annulus
- Allows cement slurry to be added if wash out zones are excessive (avoids top-up job)

When cementing large-diameter casing loss of circulation can occur. The solution to such problems is to recement down the annulus. This technique of cementing is denoted as a top-up job. This type of cementing can be accomplished by running small-diameter tubing called “spaghetti” into the annulus space from the surface. Under these conditions usually low-specific-weight cement is used so that the formations will not fracture.

The hook load after a cementing operation (but prior to the cement setting) is important to know, particularly when large-diameter casings are to be cemented. Figure 4.17.15 shows the schematic of a casing string with the cement slurry height shown. Prior to the cement slurry setting the hook load $V_h(\text{lb})$ will be

$$V_h = w_c \left\{ 1 - \left[\left(\frac{\gamma_c}{\gamma_s} \right) \frac{h}{1} + \left(\frac{\gamma_m}{\gamma_s} \right) \left(\frac{1-h}{1} \right) \right] \right\} 1 - A_i [(\gamma_c - \gamma_m)h] \quad (4.17.8)$$

where w_c = unit weight of the casing in lb/ft

γ_c = specific weight of the cement slurry in lb/ft³

γ_m = specific weight of the drilling mud in lb/ft³

γ_s = specific weight of the steel, which is 490 lb/ft³

l = length of the casing in ft

h = height the cement slurry is placed in the annular in ft

A_i = internal cross-sectional diameter of the casing in ft²

Equation 4.17.8 is valid for a back-flow valve at the bottom of the casing string such as a float collar. It is also valid for a back-flow valve located at the top of the casing string.

FIGURE 4.17.14 Stab-in unit, stab-in cementing shoe, stab-in cementing collar, and flexible latch-in plug [2].

Example 4.17.8

A large-diameter casing is to be cemented to the top in a 2,021-ft borehole. The casing string is 2,000 ft long and has ball float shoe at the bottom of the cement slurry. The borehole is 26 in. in diameter. The casing is to be 20 in., J-55, 94 lb/ft. The drilling mud in the borehole prior to running the casing has a specific weight of 10.0 lb/gal. The cement slurry is to have a specific weight of 17.0 lb/gal. The conventional cementing operation will be utilized, i.e., cementing through the inside of the casing. Determine the hook load after the cementing operation has been completed.

The hook load may be determined from Equation 4.17.8. This is

$$\begin{aligned}
 V_u &= 94.00 \left\{ 1 + \left[\left(\frac{127.3}{490.00} \right) \frac{2,000}{2,000} + \left(\frac{75.0}{490.0} \right) \frac{0}{2,000} \right] \right\} \\
 &\quad 2,000 - \frac{\pi}{4} \left(\frac{19.124}{12} \right)^2 [(127.3 - 75.0)2,000] \\
 &= -69,557 \text{ lb}
 \end{aligned}$$

This answer means that the casing and its contained drilling mud will float when the cementing operation is completed and the back-flow valve is actuated. Thus the casing should be secured down at the well head prior to initiating the cementing operation.

It should be noted that if this cementing operation were to be carried out using an inner drillpipe string to place the cement in the annulus, the above force of buoyancy would be reduced by the buoyed weight of the drillpipe. However, unless very heavy drillpipe were used, the casing and drillpipe would still float on the cement slurry.

As the cement slurry sets the hook load will decrease from its value just after the cementing operation. If the cement slurry sets up to the height (freeze point) indicated in Figure 4.17.14, and if the casing has been landed as cemented, then the hook load V_h will be approximately

$$V_h = W_c \left(1 - \frac{\gamma_m}{\gamma_s} \right) (1 - h) \tag{4.17.9}$$

Example 4.17.9

A 5½-in., J-55, 17.00-lb/ft casing string 16,100 ft in length is to be run into a 16,115-ft deep well. The float collar is 30 ft from the bottom of the casing string. The drilling mud in the well has a specific weight of 12.0 lb/gal. The casing string is to be cemented to a height of 4,355 ft above the bottom of the borehole with a cement slurry having a specific weight of 16.4 lb/gal.

1. Determine the approximate hook load prior to the cementing operation.
2. Determine the approximate hook load just after the cement slurry has been run.

FIGURE 4.17.15 Schematic of casing after a cementing operation.

3. Determine the approximate hook load after the cement has set.

1. The hook load prior to the cementing operation should read approximately

$$V_h = 17.00 \left(1 - \frac{89.9}{490.0} \right) 16,100 = 223,540 \text{ lb}$$

2. The hook load just after the cementing operation can be approximated by Equation 4.17.8. This is

$$\begin{aligned} V_h &= 17.00 \left\{ 1 - \left[\left(\frac{122.7}{490.0} \right) \frac{4,340}{16,100} + \left(\frac{89.9}{490.0} \right) \right. \right. \\ &\quad \left. \left. \times \left(\frac{16,100 - 4,340}{16,100} \right) \right] \right\} 16,100 \\ &\quad - \frac{\pi}{4} \left(\frac{4.892}{12} \right)^2 [(122.7 - 89.8)4,340] \\ &= 199,943 \text{ lb} \end{aligned}$$

3. The hook load after the cement has set can be approximated by Equation 4.17.9. This is

$$V_h = 17.00 \left(1 - \frac{89.8}{490.0} \right) (16,100 - 4,340) = 163,282 \text{ lb}$$

4.17.7.3 Multistage Casing Cementing

Multistage casing cementing is used to cement long casing strings. The reasons that multistage cementing techniques are necessary are as follows:

- Reduce the pumping pressure of the cement pumping equipment
- Reduce the hydrostatic pressure on weak formations to prevent fracture
- Selected formations can be cemented
- Entire length of a long casing string may be cemented
- Casing shoe of the previous casing string may be effectively cemented to the new casing string
- Reduces cement contamination

There are methods for carrying out multistage cementing. These are

1. Regular two-stage cementing
2. Continuous two-stage cementing
3. Regular three-stage cementing

Regular two-stage cementing requires the use of stage cementing collar and plugs in addition to the conventional casing cementing equipment. The stage cementing collar is placed in the casing string at near the mid point, or at a position in the casing string where the upper cementing of the casing is to take place. Figure 4.17.16 shows a schematic of a regular two-stage casing cementing operation. The stage cementing collar is a special collar with ports to the annulus that can be opened and closed (sealed off) by pressure operated sleeves (see Figure 4.17.16).

The first stage of cementing (the lower section of the annulus) is carried out similar to a conventional single-stage casing cementing operation. The exception is that a wiper plug is generally not run in the casing prior to the spacer and the cement slurry.⁴ During the pumping of the spacer and cement slurry for the lower section of the annulus, the ports on the stage cementing collar are closed. After the appropriate volume of spacer and cement slurry has been pumped to the well (lower section) the first stage plug is released. This plug is pumped to its position on the float collar at the bottom of the casing string with drilling mud or completion fluid as the displacement fluid. This first plug is designed to pass through the stage cementing collar without actuating it. When the first plug is landed on the float collar,

4. A wiper plug may be accommodated with special equipment [2].

FIGURE 4.17.16 Regular two-stage cementing [2].

there is a pressure rise at the pump. This plug seals the float collar such that further flow throughout the collar cannot take place.

After the first-stage cementing operation has been carried out the opening bomb can be dropped and allowed to fall by gravity to the lower seal of the stage cementing collar. This can be done immediately after the first-stage cementing has taken place, or at some later time when the cement slurry in the lower section of the well has had time to set. In the later case great care must be taken that the first-stage cement slurry has not risen in the annulus to a height above the stage cementing collar. Once the opening bomb is seated, pump pressure is applied that allows hydraulic force to be applied to the lower sleeve of the stage cementing collar. This force shears the lower sleeve retaining pins and exposes the ports to the annulus.

Once the ports are opened the well is circulated until the appropriate drilling mud or other fluid is in the well. The second-stage cementing slurry is mixed and pumped to the well (again without a wiper plug separating the spacer from the drilling mud). This cement slurry passes through the stage cementing float ports to the upper section of the annulus. The closing plug is released at the end of the second-stage cement slurry and is displaced to the stage cementing collar with drilling mud or other fluid. The closing plug seats on the upper sleeve of the stage cementing collar. A pressure of about 1,500 psi causes the retaining pins in the upper sleeve to shear thus forcing the sleeve downward to close the ports in the stage cementing collar.

Continuous two-stage cementing is an operation that requires that the cement slurry be mixed and displaced to the

lower and upper sections of the annulus in sequence without stopping to wait for an opening bomb to actuate the stage cementing collar. In this operation the first-stage cement slurry is pumped to the well and a wiper plug released behind it (Figure 4.17.17). Displacing the wiper plug is a volume of drilling mud or completion fluid that will displace the cement slurry out of the casing and fill the inside of the casing string from the float collar at the bottom of the casing string to a height of the stage cementing collar. A bypass insert allows fluid to pass through the wiper plug and float collar after the plug is landed. The opening plug is pumped immediately behind the volume of drilling mud. Immediately behind the opening plug is the second-stage spacer and cement slurry. The opening plug sits on the lower sleeve of the stage cementing collar, opening the ports to the

annulus. At the end of the second-stage cement slurry the closing plug is run. This plug sits on the upper sleeve of the stage cementing collar and with hydraulic pressure, closing the ports in the stage cementing collar.

Three-stage cementing is carried out using the same procedure as the regular two-stage cementing operation discussed above. In this case, however, two-stage cementing collars are placed at appropriate locations in the casing string above the float collar. Each stage of cementing is carried out in sequence, the lower annulus section cemented first, the middle annulus section next and the top annulus section last. Each stage of cement can be allowed to set, but great care must be taken in not allowing the lower stage of cement to rise above the stage cementing collar of the next stage above.

FIGURE 4.17.17 Continuous two-stage cementing [2].

4.17.7.4 Liner Cementing

A liner is a short string of casing that does not reach the surface. The liner is hung from the bottom of the previous casing string using a liner hanger that grips the bottom of the previous casing with a set of slips. Figure 4.17.18 shows typical liner types. The liner is run into the borehole on the drillpipe and the cementing operation for the liner is carried out through the same drillpipe. The placing of liners and their cementing operations are some of the most difficult operation in well drilling and completions. Great care must be taken in designing and planning these operations to ensure a seal between the liner and the previous casing.

Figure 4.17.19 shows a typical liner assembly. The liner assembly is made up with the following components:

Float shoe. The float shoe may be placed at the bottom of the liner. This component is a combination of a guide shoe and a float valve.

Landing collar. This is a short sub placed in the string to provide a seat for the casing string.

Liner. This is a string of casing used to case off the open hole without bringing the end of the string to the surface. Usually the liner overlaps the previous casing string (shoe) by about 200 to 500 ft. (60 to 150 m.).

Liner hanger. This special tool is installed on the top of the liner string. The top of the liner hanger makes up to the drillpipe on which the entire liner assembly is lowered

FIGURE 4.17.18 Liner types [2].

FIGURE 4.17.19 Liner assembly [2].

into the well. Liner hangers can be either mechanically or hydraulically actuated.

The liner hanger is the key element in the running of liners and the follow-on cementing operations. The liner hanger allows the liner to be hung from the bottom section of the previous casing. After the cementing operation the upper part of the liner hanger is retrievable, thus allowing

the residual cement above the liner hanger to be cleaned out of the annulus between the drillpipe and the previous casing (by reverse circulation) and the liner left in the well.

The casing joints of the liner are placed in the well in the normal manner. After the liner is at the desirable location in the well, the drillpipe is connected to the rig pumps and mud circulation carried out. This allows conditioning of the drilling mud in the well prior to the cementing operation and ensures that circulation is possible before the liner is hung and cemented.

The liner hanger is set (either mechanically or hydraulically) and the drillpipe with the upper part of the liner hanger (the setting tool) released. The drillpipe and the setting tool are raised to make sure that the setting tool and the drillpipe can be released from the lower part of the liner hanger and the liner. The drillpipe and the setting tool are lowered to make a tight seal with the lower portion of the liner hanger.

After these tests of the equipment have been made, a liner cementing head is made up to the drillpipe at the surface. Figure 4.17.20 shows the liner cementing head and the pump-down plug (or plugs). The pump-down plug is placed in the liner cementing head, but not released. The cement pump is connected to the liner cementing head and the spacer and cement slurry pumped to the head. The pump-down plug is released at the end of the cement slurry and separates the slurry from the drilling mud. Figure 4.17.21 shows the sequence of the liner cementing operation. The drilling mud displaces the pump-down plug to the liner hanger. As the pump-down plug passes through

FIGURE 4.17.20 Liner cementing head [2].

the liner hanger it latches into the liner wiper plug (see Figure 4.17.19). With increased surface pressure (1200 psi or 83 bar) by the pump, the liner wiper plug with the pump-down plug coupled to it are released from the liner hanger and begin to move downward. These two coupled plugs eventually seat on the landing or float collar. Another pressure rise indicates the cement is in place.

Once the spacer and the cement slurry have been successfully pumped to their location in the well, the drillpipe and setting tool are released from the lower part of the liner hanger. Also, the liner cementing head is removed from the drillpipe. The drillpipe and setting tool are raised slightly and the excess cement slurry reverse circulated from around the liner hanger area. These steps should be taken immediately after the completion of the cementing operation, otherwise the excess cement slurry between the drillpipe and the previous casing could set and cause later drilling and completions problems if the excess cement is too great. If reverse circulation is not planned, then the excess cement slurry that comes through the liner hanger to the annulus between the drillpipe and the previous casing must be kept to a minimum so that it can be easily drilled out after it sets.

The determination of the excess cement slurry should be carefully calculated: too little and the cement seal at the liner hanger is contaminated with drilling mud; too much and there are problems removing it.

4.17.8 Secondary Cementing

Secondary or remedial cementing refers to cementing operations that are intended to use cement as a means of maintaining or improving the well's operation. There are two general secondary cementing operations, squeeze cementing and plug cementing.

4.17.8.1 Squeeze Cementing

Squeeze cementing operations utilize the mechanical power of the cement pumps to force a cement slurry into the annular space behind a casing and/or into a formation for the following purposes:

- Repair a faulty primary cementing operation
- Stop loss of circulation in the open hole during drilling operations
- Reduce water-oil, water-gas and gas-oil ratios by selectively sealing certain fluid producing formations
- Seal abandoned or depleted formations
- Repair casing leaks such as joint leaks, split casing, parted casing or corroded casing
- Isolate a production zone by sealing off adjacent non-productive zones

FIGURE 4.17.21 Liner cementing [2].

There are numerous squeeze cementing placement methods that utilize many different special downhole tools. In general, the squeeze cementing operation forces the cement slurry into fractures under high pressure, or into casing perforations using low pressure. As a cement slurry is forced into rock fractures, or through casing perforations into the rock formations, the slurry loses part of its mix water. This leaves a filter cake of cement particles at the interface of the fluid and the permeable rock. As the filter cake builds up during the squeeze cementing operation, more channels into the formation are sealed and the pressure

increases. If the cement slurry is poorly designed for an intended squeeze cementing operation, the filter cake builds up too fast and the cement pump capability is reached before the cement slurry has penetrated sufficiently to accomplish its purpose. Thus the squeeze cementing operation slurry should be designed to match the characteristics of the rock formation to be squeeze cemented and the equipment to be used.

There are five important considerations regarding the cement slurry design for a squeeze cementing operation:

1. *Fluid loss control.* The slurry should be designed to match the formation to be squeezed. Low permeability formations should utilize slurries with 100–200 ml/30 min water losses. High Permeability formations should utilize slurries with 50–100 ml/30 min water losses.
2. *Slurry volume.* The cement slurry volume should be estimated prior to the squeeze operation. In general, high-pressure squeeze operations of high-permeability formations that have relatively low fracture strengths will require large volumes of slurry. Low-pressure squeeze operation through perforations will require low volumes.
3. *Thickening time.* High-pressure squeeze operations that pump large volumes in a rather short time period usually require accelerator additives. Low-pressure slow-pumping-rate squeeze operations usually require retarder additives.
4. *Dispersion.* Thick slurries will not flow well in narrow channels. Squeeze cement slurries should be designed to be thin and have low yield points. Dispersive agents should be added to these slurries.
5. *Compressive strength.* High compressive strength is not a necessary characteristic of squeeze cement slurries.

There are basically two squeeze cementing techniques used: the high-pressure squeeze operation and the low-pressure squeeze operation.

High-pressure squeeze cementing operations are utilized where the hydraulic pressure is used to make new channels in the rock formations (by fracturing the rock) and force the cement slurry into these channels.

Low-pressure squeeze cementing operations are utilized where the existing permeability structure is sufficient to allow the cement slurry to efficiently move in formation without making new fracture surfaces with the hydraulic pressure.

Hesitation method of applying pressure is applicable to both high and low-pressure squeeze cementing operations. This method of applying pressure (and thus volume) appears to be more effective than continuous pressure application. The hesitation method is the intermittent application of pressure, separated by a period of pressure leakoff caused by the loss of filtrate into the formation. The leakoff periods are short at the beginning of an operation but get longer as the operation progresses.

Figure 4.17.22 shows a typical squeeze cementing downhole schematic where a retrievable packer is used. The cement slurry is spotted adjacent to the perforations in the casing. The packer raise and set against the casing wall. Pressure is then applied to the drilling mud and cement slurry below the packer forcing the cement slurry into the perforation and into the rock formation or voids in the annulus behind the casing.

Figure 4.17.23 shows how a retrievable packer with a tail pipe can be used to precisely spot the cement slurry at the location of the perforations.

Figure 4.17.24 shows how a drillable cement retainer can be used to ensure that the cement slurry will be applied directly to the perforations.

Most squeeze cementing operations take place in cased sections of a well. However, open-hole packers can be used to carry out squeeze cement operations of thief zones during drilling operations.

FIGURE 4.17.22 Retrievable packer near perforations [2].

FIGURE 4.17.23 Retrievable packer with tail pipe [2].

FIGURE 4.17.25 Bradenhead squeeze [2].

FIGURE 4.17.24 Drillable cement retainer [2].

Another technique for carrying out a squeeze cementing operation is the Bradenhead technique. This technique can be used to squeeze a cement slurry in a cased hole or in an open hole. Figure 4.17.25 shows a schematic of the technique. Instead of using a downhole packer, the cement slurry is spotted by drillpipe (or tubing) adjacent to the perforations or a thief zone. After the drillpipe has been raised, the pipe rams are closed over the drillpipe and pump pressure applied to the drilling mud which in turn forces the cement slurry into the perforations or fractures.

The basic squeeze cementing operation procedures are as follows [2]:

1. Lower zones are isolated by a retrievable or drillable bridge plug.
2. Perforations are washed using a perforation wash tool or they are reopened by surging. If there is no danger of damaging the lower perforations, this operation can be carried out before running the bridge plug, which may be run in one trip with the packer.
3. The perforation wash tool is retrieved and the packer run in the hole with a work string, set at the desired depth and tested. An annular pressure test of 1,000 psi (69 bar) is usually sufficient. The packer is run with or without a tail pipe, depending on the operation to be performed. If cement is to be spotted in front of the perforations, a tail pipe that covers the length of the zone plus 10 to 15 ft (3 to 5 meters) must be run with the packer.
4. An injectivity test is performed using clean, solids-free water or brine. If a low fluid loss completion fluid is in the hole, it must be displaced from the perforations before starting the injecting. This test will give an idea of the permeability of the formation to the cement filtrate.
5. A spearhead or breakdown fluid followed by the cement slurry is circulated downhole with the packer by-pass open. This is done to avoid the squeezing of damaging fluids ahead of the slurry. A small amount of back pressure must be applied on the annulus to prevent the slurry fall caused by U tubing. If no tail pipe has been run, the packer by-pass must be closed 2 or 3 bbl (.25 to .33 m³) before the slurry reaches the packer. If the cement is to be spotted in front of the perforations, with the packer unset, circulation is stopped as soon

as the cement covers the desired zone, the tail pipe pulled out of the cement slurry and the packer set at the desired depth at which the packer is set must be carefully decided.

1. [] If tail pipe is run, the minimum distance between perforations and packer is limited to the length of the tail pipe. The packer must not be set too close to the perforations as pressure communication through the annulus above the packer might cause the casing to collapse. A safe setting depth must be decided on after seeing the logged quality of the cement bond. Casing conditions and possible cement contamination limit the maximum spacing between packer and treated zone.
6. Squeeze pressure is applied at the surface. If high-pressure squeezing is practiced, the formation is broken down and the cement slurry pumped into the fractures before the hesitation technique is applied. If low-pressure squeezing is desired, hesitation is started as soon as the packer is set.
7. Hesitation continues until no pressure leak-off is observed. A further test of about 500 psi (35 bar) over the final injection pressure will indicate the end of the injection process. Usually, well-cementing perforations will tolerate pressures above the formation fracture pressure, but the risk of fracturing is increased.
8. Pressure is released and returns are checked. If no returns are noticed, the packer by-pass is opened and excess cement reversed out. Washing off cement in front of perforations can be performed by releasing the packer and slowly lowering the work string during the reversing.

Plug Cementing

The major reasons for plug cementing are:

Abandonment. State regulations have rules on plugging and abandoning wells. Cement plugs are normally used for that purpose (see [Figure 4.17.26](#)).

Kick-off plug. Usually an Ottawa sand-cement plug is used to plug off a section of the borehole. This plug uses a hard surface to assist the kick-off procedure (see [Figure 4.17.27](#)).

Lost circulation. A cement plug can be placed adjacent to a zone of lost circulation in the hope that the cement slurry will penetrate and seal fractures (see [Figure 4.17.28](#)).

Openhole completions. Often in openhole completions it is necessary to shut off water flows, or to provide an anchor for testing tools, or other maintenance operations ([Figure 4.17.29](#)).

FIGURE 4.17.26 Abandonment plugs [2].

There are two methods for placing cement plugs.

1. *Balance plug method* is the most commonly used. The cement slurry is placed at the desired depth through the drillpipe or tubing run to that depth. A spacer is placed below and above the slurry plug to avoid contamination of the cement slurry with surrounding drilling mud and to assist in balancing the mud. There are a number of tools available in the market to assist in plug balancing. Most involve drill pipe darts that provide a means of separating fluids, wiping the pipe and provide an indication of the end of displacement.
2. *Dump bailing method* utilizes a bailing device that contains a measure volume of cement slurry. The bailer is run to the appropriate depth on a wireline and releases its load upon bumping the bottom or a permanent bridge plug set at the desired depth (see [Figure 4.17.30](#)).

Cement plugs fail for the following reasons:

FIGURE 4.17.27 Kickoff plug [2].

FIGURE 4.17.29 Openhole completions plug [2].

- Lack of hardness (kick-off plug)
- Contaminated cement slurry
- Placed at wrong depth
- Plug migrates from intended depth location due to lack of balancing control

When placing a plug in well the fluid column in the tubing or drillpipe must balance the fluid column in the annulus. If the fluid in the drillpipe is heaviest, then the fluid from the drillpipe (the slurry) will continue down and out the end of the drillpipe and then up into the annulus after pumping has stopped. If the fluid in the annulus is heaviest, then the fluid from the drillpipe will continue downward in the annulus after pumping. The two columns are balanced by using a spacer (or wash) above and below the cement slurry. Since the cement slurry usually has a higher specific weight than the annular fluid.

Example 4.17.10

Balance a 100-sack cement plug of Class C neat cement slurry when 15 bbl of water are to be run ahead of the slurry. The plug is to be run through 2-in., 4.716-lb/ft, EUE tubing. The depth of placement is 4,000 ft.

1. Determine the top of the plug.
2. Determine the volume of water to run behind cement slurry to balance the 15 bbl of water run ahead of the slurry.
3. Determine the volume of mud to pump to balance plug.

FIGURE 4.17.28 Lost circulation plug [2].

FIGURE 4.17.30 Dump bailer [2].

The annular volume per ft is $0.1997 \text{ ft}^3/\text{ft}$. The tubing volume per ft is $0.0217 \text{ ft}^3/\text{ft}$. The yield of a Class C neat cement slurry is $1.32 \text{ ft}^3/\text{sack}$ (see Table 4.17.2). Thus the volume of the cement slurry is

$$\text{Volume} = 1.32(100) = 132 \text{ ft}^3$$

1. The height H (ft) of the plug is

$$H = \frac{132}{0.1997 - 0.0217} = 742 \text{ ft}$$

Depth to top of plug D (ft) is

$$D = 4,000 - 742 = 3,258 \text{ ft.}$$

2. The amount of water to place behind the plug to balance the 15 bbl ahead of the cement slurry is

$$\text{Volume} = 15 \left(\frac{0.0217}{0.1997} \right) = 1.6 \text{ bbl}$$

3. The height h (ft) of trailing water in the tubing is

$$h = \frac{1.6(42)}{(0.0217)(7.48)} = 414 \text{ ft}$$

The volume of mud to pump to balance plug is

$$\text{Volume} = [4,000 - (742 + 414)] \frac{0.0217}{5.6146} = 11 \text{ bbl}$$

4.18 TUBING DESIGN

Section reviewed by Phil Pattillo, Steve Morey, and Alex Sas-Jaworsky

Tubing is pipe placed in the well to produce or inject fluids. The proper selection of size, grade and connection is important to the well completion program. Tubing must be designed to resist failure from axial and compressive forces, internal and external pressures, buckling and corrosion.

4.18.1 Selection of Wall Thickness and Grade of Tubing

Tubing design relies on the selection of the most economical steel grades and wall thicknesses (unit mass of tubing) that will withstand, without failure, the forces to which tubing will be exposed throughout the expected tubing life.

Tubing must be designed for:

- collapse;
- burst;
- tension;
- possibility of permanent corkscrewing;
- corrosion.

Tubing string design is much the same as for casing. For shallow and moderately deep holes, uniform strings are preferable; however, in deep wells, a tapered tubing can be desirable. A design factor for tension should be about 1.4-1.6. The collapse design factor must not be less than 1.0, assuming an annulus filled up with fluid and evacuated tubing. The design factor for burst should not be less than 1.1.

Two approaches can be used to handle tubing movement:

1. Provide seals of sufficient length.
2. Slack off enough weight of tubing to prevent movement.

4.18.2 Packers

A packer is simply a mechanical means of forming a seal between two strings of pipe or between the pipe and the open hole. This generated seal isolates the tubing from the casing or open hole, preventing vertical flow of fluids.

To qualify as a packer, a tool needs only a sealing means and a method of maintaining an opening through the middle. Typically, most packers available today incorporate the following components in their design.

Slips to anchor the packer in the casing or open hole

Cone to support the slips and create a wedge to enhance anchoring capability

Elastomer elements which expand to seal the area between the packer and the casing or open hole

Mandrel which maintains a consistent bore and typically has an ID compatible with the tubular used. Outer body components are supported by the mandrel.

Setting mechanism which initiates the setting sequence when desired during installation.

Typically, packers are identified by their classification (permanent or retrievable), application (production or service), and setting method (mechanical, hydraulic, hydrostatic or wireline).

Permanent packers do not have releasing mechanisms and are not retrievable from surface. When a permanent packer is set, the tubing can be removed from the well without releasing the packer. Permanent packers can only be removed by destroying their integrity through milling or drilling.

Retrievable packers are an integral part of the tubing string. The packer is set, released and pulled with the tubing string. The tubing string cannot be removed from the well bore without pulling the packer unless an on/off tool or similar mechanism is used with the packer.

Production packers are designed to meet general or specific well conditions and provide a long operational life in those conditions. They are manufactured from a variety of materials to meet operational life expectancy in different environments. Production packers are used for a number of reasons, which can be summarized into four categories, which are: protecting the casing string, maximum safety and control, energy conservation, and improve productivity.

4.18.2.1 Protecting the Casing

Since the casing string is cemented in the hole, it is considered permanent and non-replaceable. A string of replaceable tubing is normally run inside the casing to control and provide the conduit necessary to bring the producible fluids to the surface.

Damaged tubing is relatively easy to remedy as it can be pulled and replaced. Damage to the casing, on the other hand, creates a serious problem, which jeopardize the productivity of the well. Casing is difficult and expensive to repair.

Where a packer is not used, the casing is exposed to produced fluids, which are often corrosive. In order to maintain a controlled inhibited atmosphere, a packer is necessary to seal the bottom of the casing, which prevents the release of produced fluids into the tubing annulus.

The casing may also be exposed to pressure differentials high enough to cause casing damage. The tubing string normally has higher-pressure ratings than the casing. Using a packer to seal the tubing annulus above the productive zone will confine the high differentials to the tubing string.

4.18.2.2 Safety

A packer acts as a downhole blowout preventer or valve to provide maximum control of the formation at depth.

During completion operations, the packer can be used as a plug to completely shut off the production zone while work is being done up the hole, or during nipping up operations. High-pressure zones can be tested or produced without exposing the casing or wellhead equipment to unnecessary high pressures.

During producing operations, the packer confines high pressures to the tubing string where they are more easily controlled. Safety shut-in devices and other accessory equipment are often installed in the tubing for maximum control.

4.18.2.3 Energy Conservation

One of the primary reasons for using a smaller tubing string to produce the formation fluids is to maintain sufficient velocity to take full advantage of available energy. With high velocities, oil, water and gas are intermingled so that the gas energy is used, preventing the heavier water from falling back and killing the well.

When a packer is not used, gas tends to break out into the tubing annulus, accumulating at the top of the casing. This results in a loss of energy. A packer funnels all of the production into the tubing string, so all of the available gas energy is utilized to lift the fluid.

If two different zones are perforated, interflow between the zones results in a loss of energy for the more prolific zone. Formation damage and/or loss of hydrocarbon reserves can also result from this uncontrolled formation flow.

4.18.2.4 Improve Productivity

A packer allows the casing to be used as an energy storage area and/or conduit in artificial lift operations; such as, gas lift and hydraulic pumping.

Sealing between two zones allows both to be produced simultaneously with maximum control by using two strings of tubing.

In some cases, it is desirable to perforate a second zone for production at a later date. To keep this alternate zone isolated from the producing zone, a packer is set between the two. With the proper equipment, the zones can be switched without pulling the tubing string.

Service packers are used to perform specialized functions. When the function is completed, the packer is removed from the well. Service packers are commonly designed with higher differential pressure ratings than permanent packers, and are more likely to have their operational capabilities tested to the fullest extent. Service packers are commonly used to pressure test casing and repair if a leak exists; tem-

porarily suspend producing intervals; and protect the casing string from high pressures during hydraulic fracturing.

In a mechanical set application, tubing movement is used to create the force necessary to set the packer and energize the element.

In a hydraulic set application, a force is generated internally within the packer by applying fluid pressure against a plug to set the slips and energize the element.

In a hydrostatic set application, a setting force is generated by applying fluid pressure to both the inside and outside of the tubing to set the slips and energize the element.

For wireline set applications, an electric wireline pressure setting tool is used. An electric current ignites a powder charge to create a gas pressure within the setting tool. The gas pressure then acts on a hydraulic piston to create a force sufficient to set the packer slips, energize the element and shear the setting tool from the packer.

Choosing and successfully installing the best packer for a job depends on the proper evaluation and analysis of the forces that may act on the tubing and the packer during the lifetime of the installation. The effect of the forces can only be determined by an accurate force analysis. The installation can proceed with a high degree of confidence if no detrimental effects are shown during analysis. However, if analysis indicates that damage to the tubing or packer could occur, reassessment and revision of the installation procedures will reduce the risk of costly recovery.

The anticipated change in well conditions that may occur after the packer has been set must be analyzed to evaluate the forces affecting the packer and tubing string.

Temperature and pressure variations occur within the well throughout its lifecycle. Changes in these conditions can lead to a change in length of the tubing string or a change in force throughout the tubing string depending on the type of packer chosen and the packer to tubing configuration. The tubing will either lengthen or shorten when temperature, tubing pressure or annulus pressure is changed in the well. If the tubing is anchored, the change in force will occur at the packer as well as over the entire length of the tubing string. If the tubing is free to move, the tubing string will experience a net change in length.

During the service life of a well, tubing can experience various combinations of pressures and temperatures that result in tubing length changes. The four effects to consider are as follows:

1. piston effect;
2. helical buckling effect;
3. ballooning and reverse ballooning effect;
4. temperature change effect.

4.18.2.5 Piston Effect

The piston effect is the result of pressure changes, which occur inside the tubing string and annulus at the packer.

In retrievable packer installations, pressure changes that occur inside the tubing at the packer act on the difference in areas between the packer valve area (A_p) and the tubing ID area (A_i). Pressure changes that occur in the annulus act on the difference in areas between the packer valve area (A_p) and the tubing OD area (A_o).

In permanent packer installations, pressure changes that occur inside the tubing act on the difference in areas between the seal bore (packer valve, A_p) and the tubing ID area (A_i). Pressure changes that occur in the annulus act on the difference in areas between the seal bore (packer valve, A_p) and the tubing OD area (A_o).

The result of the piston effect is either an up or down force on the tubing at the packer. Upward forces are designated as negative (−) forces, and downward forces are designated as positive (+) forces.

In “anchored” installations (the tubing is not allowed to move), the piston effect leads to a change in force either upward (compression) or downward (tension) at the packer. Upward forces are designated as negative (−), and downward forces are designated as positive (+).

In “free” installations (the tubing-to-packer configuration allows movement of the tubing), the piston effect leads to a change in length either upward (shortening) or downward (lengthening) of the tubing string.

In retrievable packer installations where the tubing is attached to the packer via a coupling on the packer mandrel, the piston effect will always result in a force change on the packer. The resulting force change will either be a change in tubing compression, or a change in tubing tension unless an expansion joint is installed in the tubing string above the packer.

If the tubing pressure is greater than the annular pressure, the affected area is calculated on the knife seal OD. If the annular pressure is greater than the tubing pressure, the affected area is calculated on the knife seal ID.

When the packer and tubing string are installed in the well, the hydrostatic pressure in the well acts on the end area of the tubing string. This creates an upward, pressure-related effect, resulting in a reduction in the weight of the tubing string as well as a shortening of the overall length of the tubing string. This effect is known as force due to buoyancy or the buoyancy effect. Although the tubing is shortened as a result of the buoyancy effect, the packer-to-tubing relationship is not affected until the packer is set. Once the packer is set and the packer valve is closed, a change in pressure in either the tubing or the annulus will result in a change in the tubing force at the packer, and will affect the tubing-to-packer relation.

When calculating the piston effect, always consider the tubing-to-packer relation as “balanced” when the packer is set. Any changes in well condition that occur after the packer is set will affect the packer-to-tubing relation.

When calculating the force due to the piston effect, it is the change in pressure rather than the absolute pressure that is important. To determine this, both initial and final well conditions need to be known. The initial conditions are those that existed when the packer was set, or when the seal assembly was stung into the packer sealbore. Final conditions are those conditions that are to be expected during production, stimulation, or well work-overs [4].

Use the following formula to calculate piston force when no tubing movement is permitted:

$$\Delta F_1 = (A_p - A_i)\Delta P_i - (A_p - A_o)\Delta P_o \quad (4.18.1)$$

where

ΔF_1 = Force change due to Piston Effect, lbs.

A_p = Packer valve area, in²

A_o = Area of the tubing O.D., in²

A_i = Area of the tubing I.D., in²

ΔP_o = Change in the total annular pressure at the packer, psi

ΔP_i = Change in the total tubing pressure at the packer, psi

To calculate the length change due to the Piston Effect (ΔL_1), use this formula:

$$\Delta L_1 = \frac{LF_1}{-EA_s} \quad (4.18.2)$$

where

ΔL_1 = Length change due to Piston Effect, in.

L = Length of the tubing string, in.

F_1 = Force change due to Piston Effect, lbs.

E = Modulus of elasticity, 30×10^6 psi

A_s = Cross sectional area of the tubing, in²

4.18.2.6 Buckling Effect

The buckling effect is the most difficult of the four basic effects to understand. Tubing buckling will occur due to two different force distributions. One is the compressive force mechanically applied to the end of the tubing, and the other is a pressure effect that results in a force distribution on the OD and ID of the tubing.

A mechanically applied compressive force acting on the end area of the tubing will cause tubing to buckle. When compressive force is applied to a tubing string that is, essentially, relatively flexible, the tubing will bow outward or will buckle. For example, tubing that is standing in a derrick will buckle or bow outward due to its own weight.

The second force that will cause a tubing string to buckle is pressure. Pressure buckling will occur when the pressure inside a tubing string ($P_i A_i$) is greater than the pressure outside the tubing ($P_o A_o$).

Buckled tubing is defined as tubing that is bowed from its original straight condition. The tubing will buckle or bow outward until it contacts the casing wall at which point it will begin to coil. This coiling of the tubing is referred to as helical buckling. As long as the stresses that occur because of the buckling do not exceed the yield strength of the tubing, the tubing will return to its original shape when the force is removed. Should the stresses created due to the buckled condition of the tubing exceed the yield strength of the tubing, the tubing will not return to its original shape; it will become permanently corkscrewed.

Buckling will only shorten a tubing string. Pressure buckling will only exert a negligible change in force on a packer and will only occur if the final pressure within the tubing string is greater than the final pressure outside the tubing string.

It should be noted that pressure buckling can occur in a tubing string even if the tubing is in tension throughout its entire length. Although in tension and considered as being in a "straight" condition within the wellbore, the tubing string will buckle due to the effect of pressure on buckling.

Tubing buckling is most severe at the bottom of the tubing string where the pressure is the greatest. It lessens further up the hole until, normally, a point is reached where tubing buckling does not occur. This point is known as the neutral point. The tubing below the neutral point is buckled, while the tubing above remains straight.

The factors that have the most influence on the amount of tubing buckling that will occur are the radial clearance (r) between the tubing OD and the casing ID, the magnitude of the pressure differential from the tubing ID to the tubing OD, and the size of the packer valve. Because these factors have a direct effect on buckling, as any one of these factors increases, the length change due to buckling will increase.

Use this formula to calculate the length change due to buckling:

$$\Delta L_2 = \frac{r^2 A_p^2 (P_i - P_o)^2}{-8EI(W_s + W_i - W_o)} \quad (4.18.3)$$

where

ΔL_2 = Length change in inches due to buckling

r = radial clearance between the tubing and the casing, inches

A_p = Packer valve area, in.²

P_i = Total tubing pressure at the packer that will exist for the given conditions, psi

P_o = Total annulus pressure at the packer that will exist for the given conditions, psi

E = Modulus of elasticity, 30×10^6 psi for carbon steels

I = Moment of inertia of the tubing, in.⁴

$I = [(Tubing OD)^4 - (Tubing ID)^4] \times \pi \div 64$

W_s = Weight of the tubing, lbs./in.

W_i = Weight of the final fluid displaced in the tubing per unit length, psi

$W_i = (Tubing ID)^2 \times 0.0043 \times \text{Final tubing fluid wt., lbs./gal.}$

W_o = Weight of the final fluid displaced in the annulus per unit length, psi

$W_o = (Tubing ID)^2 \times 0.0043 \times \text{Final annulus fluid wt., lbs./gal.}$

Use this formula to determine length from packer to neutral point:

$$n = \frac{A_p(P_{i \text{ final}} - P_{o \text{ final}})}{(W_s + W_i - W_o)} \quad (4.18.4)$$

where

n = The distance from the Packer to the Neutral Point, in.

A_p = Packer valve area, in.²

$P_{i \text{ final}}$ = Total tubing pressure at the packer that will exist for the given conditions, psi.

$P_{o \text{ final}}$ = Total annulus pressure at the packer that will exist for the given conditions, psi.

W_s = Weight of the tubing, lbs./in.

W_i = Weight of the final fluid displaced in the tubing per unit length, psi

$W_i = (Tubing ID)^2 \times 0.0043 \times \text{Final tubing fluid wt., lbs./gal.}$

W_o = Weight of the final fluid displaced in the annulus per unit length, psi

$W_o = (Tubing ID)^2 \times 0.0043 \times \text{Final annulus fluid wt., lbs./gal.}$

Use this formula for Corrected Length Change due to Buckling if the neutral point is above the wellhead:

$$\Delta L'_2 = \Delta L_2 \times \frac{L}{n} \times [2 - L/n] \quad (4.18.5)$$

where

$\Delta L'_2$ = Length change due to buckling when neutral point is above wellhead, in.

ΔL_2 = Length change due to buckling, in.

L = Length of the tubing string, in.

n = The distance from the packer to the neutral point

4.18.2.7 Ballooning Effect

The third effect which must be considered in packer installations is the ballooning effect. Tubing ballooning occurs when pressure is applied to the inside of a tubing string.

As the tubing expands radially, the tubing string will shorten due to the Poisson's ratio effect if it is free to move. If the tubing is not free to move, the potential expansion will create a tension force on the packer. This shortening of the

tubing due to internal differential pressure is referred to as ballooning.

If the pressure differential exists on the outside of the tubing string, the tubing tries to contract radically and, it lengthens if it is free to move. If the tubing is not free to move, it will create a compressive force. This lengthening of the tubing string due to external pressure change is referred to as reverse ballooning.

The ballooning effect is directly proportional to the area over which the pressure is acting, and as a result, the effect of reverse ballooning is slightly greater than that of ballooning.

Unlike the piston and buckling effects, the ballooning effect occurs over the entire length of the tubing string. Ballooning effect calculations are based on changes in the average pressures inside and outside the tubing.

The average pressure is based on the half the sum of the surface pressure plus the pressure at the packer. Increasing the bottom hole pressure, by changing the fluid gradient would have half the effect of making the same change by applying added surface pressure.

Well conditions can affect the average pressure inside and outside the tubing: The effects due to ballooning and reverse ballooning are calculated together, then the net effect is expressed as either a positive force (ballooning), or a negative force (reverse ballooning), or change in length of the tubing string, depending on the tubing string's ability to move at the packer.

Pressure increases in the tubing tend to balloon the tubing, and will result in a shortening of the tubing string. Similarly, pressure increases in the casing cause the tubing diameter to contract, resulting in reverse ballooning, and an elongation of the string. As treating pressures increase, and depths become greater, the resultant changes in length can be considerable.

In considering the results of ballooning and reverse ballooning, two point of note are:

1. The pressure that is responsible for ballooning or reverse ballooning is the pressure change in the tubing and/or annulus, and from the conditions that prevailed when the well was completed. The fact that a differential pressure exists between tubing and casing does not necessarily mean that ballooning exists.
2. Pressure calculations are based on changes in the surface tubing or casing pressure (applied) and changes in fluid density (hydrostatic).

Use this formula to calculate the effects due to ballooning:

$$\Delta F_3 = -0.6[(\Delta P_{oa}A_o) - (\Delta P_{ia}A_i)] \quad (4.18.6)$$

where

ΔF_3 = Ballooning effect force change, lbs.

ΔP_{oa} = Change in average annulus pressure, psi.

A_o = Area of the tubing OD, in.²

ΔP_{ia} = Change in average tubing pressure, psi.

A_i = Area of the tubing ID, in.²

To calculate the length change (ΔL_3) due to the ballooning effect use this formula:

$$\Delta L_3 = \frac{2Lv}{E} \times \frac{(R^2 \Delta P_{oa}) - \Delta P_{ia}}{R^2 - 1} \quad (4.18.7)$$

where

ΔL_3 = Change in length (in.)

L = Length of the tubing string (in.)

v = Poisson's ratio: 0.3 for steel

E = Modulus of elasticity: 30×10^6 psi for steel

ΔP_{ia} = Change in average tubing pressure (psi)

ΔP_{oa} = Change in average annulus pressure (psi)

R^2 = Ratio of the tubing OD to the tubing ID (where

$R = OD \div ID$)

4.18.2.8 Temperature Effect

The last basic effect is the temperature effect. It is the only one of the four basic effects that is not pressure related: The length and force changes that occur are functions of a change in the average tubing temperature.

The basic principles of expansion and contraction apply when the average temperature of the tubing string is increased or decreased. When the average temperature of the tubing is decreased by injecting cool fluids, the tubing string will shorten in length if it is free to move. If the tubing string is not free to move, then a tension force will be created.

When the average temperature of the tubing string is increased either by injecting warm fluids, or by producing warm oil and/or gas, the tubing will lengthen, or elongate, if it is free to move. If the tubing is not free to move, a compressive force on the packer will result, caused by the increase in the average tubing temperature. In many packer installations, the temperature effect will be the largest of the four basic effects.

Because the temperature change in a tubing string occurs over the entire length of the tubing string, the change in average tubing temperature must be calculated to determine the resulting change in force or length.

To calculate the average temperature of the tubing the bottom hole temperature and the surface temperature must be known. The following formula is used to calculate the average tubing temperature:

Avg. tbg. temp. (°F)

$$= [(Surface \text{ temp. } (^\circ F) + Bottom \text{ hole temp. } (^\circ F)) \div 2] \quad (4.18.8)$$

If reliable temperature data is not available, it is strongly recommended that any and all assumptions made be conservative in nature to prevent possible equipment failure.

Use this formula to calculate the change in Force due to temperature effect when no tubing movement is permitted:

$$\Delta F_4 = -(207)(A_s)(\Delta T) \quad (4.18.9)$$

where

ΔF_4 = Force change due to temperature effect, lbs.

A_s = Tubing cross sectional area, in.²

ΔT = Change in average temperature, °F.

ΔT = Final average tubing temperature — Initial average tubing temperature

Use this formula to calculate change in tubing length due to temperature effect:

$$\Delta L_4 = (L)(\beta)(\Delta T) \quad (4.18.10)$$

where

ΔL_4 = Length change due to temperature effect, in.

L = Length of tubing string, in.

β = Coefficient of thermal expansion for steel, 0.0000069 in/in/°F

ΔT = Change in average temperature, °F.

4.18.2.9 Total Effect

The four basic effects plus any mechanically applied forces are used to determine the total effect of the tubing on the packer. The method used to determine the total effect at the packer depends on the type of packer being considered for the installation and the tubing-to-packer relation.

In packer installations that do not permit movement of the tubing, the degree and direction of the tubing force change expected (total effect) must be determined after considering the four basic effects independently, then collectively.

The total effect is then determined by adding together each basic effect and any mechanically applied effect and can be expressed mathematically.

Use this formula to calculate total length changes with slack off weight applied to packer:

$$\Delta L_{total 1} = \Delta L_1 + \Delta L_2 + \Delta L_3 + \Delta L_4 + \Delta L_s \quad (4.18.11)$$

where

$\Delta L_{total 1}$ = Total length change, in.

ΔL_1 = Length change of the tubing due to piston effect, in.

ΔL_2 = Length change of the tubing due to buckling effect, in.

ΔL_3 = Length change of the tubing due to ballooning effect, in.

ΔL_4 = Length change of the tubing due to temperature effect, in.

ΔL_s = Length change of the tubing due to slack off force, in.

Use this formula to calculate total length changes with tension applied to packer:

$$\Delta L_{total 1} = \Delta L_1 + \Delta L_2 + \Delta L_3 + \Delta L_4 + \Delta L_t \quad (4.18.12)$$

where

$\Delta L_{total 1}$ = Total length change, in.

ΔL_1 = Length change of the tubing due to piston effect, in.

ΔL_2 = Length change of the tubing due to buckling effect, in.

ΔL_3 = Length change of the tubing due to ballooning effect, in.

ΔL_4 = Length change of the tubing due to temperature effect, in.

ΔL_t = Length change of the tubing due to tension force, in.

When determining length changes of the tubing in an installation where the tubing is stung through the packer, there will always be a change (ΔL_{total}) in the total length of the tubing string if a change in pressure or temperature occurs, and this change must be calculated.

Example 4.18.1

Calculate the expected movement of tubing under conditions as specified below. Initially both tubing and annulus are filled with a crude of 30°API. Thereafter, the crude in the tubing is replaced by a 15-lb/gal cement slurry to perform a squeeze cementing operation. While the squeeze cementing job is performed, pressures $p_i = 5,000$ psi and $p_o = 1,000$ psi are applied at the surface on the tubing and annulus respectively.

Tubing: 2 7/8-in. 6.5 lb/ft

Casing: 7 in.; 32 lb/ft ($r = 1.61$ in.)

$A_o = 6.49$ in.², $A_i = 4.68$ in.², $A_s = 1.81$ in.²

Ratio of OD/ID of tubing, $R = 1.178$

$A_p = 8.30$ in.²

Length of tubing = 10,000 ft (120,000 in.)

Average change in temperature: -20 degF

Pressure drop due to flow is disregarded ($\delta = 0$)

Solution

Pressure changes are the following. At the surface the pressures are $\Delta p_i = 5,000$ psi and $\Delta p_o = 1,000$ psi. At the packer level, $\Delta P_i = 9,000$ psi and $\Delta P_o = 1,000$ psi. Liquid density changes are $\Delta \rho_i = 0.0332$ psi/in. and $\Delta \rho_o = 0.0$ psi/in. The unit weight of tubing is

$$\begin{aligned} W &= W_s + W_i - W_o \\ &= \frac{6.5}{12} + \frac{1.5 \times 4.68}{231} - \frac{0.876 \times 8.34 \times 6.49}{231} \\ &= 0.64 \text{ lb/in.} \end{aligned}$$

The moment of inertia is $I = 1.61 \text{ in.}^4$. The tubing movement due to piston effect is

$$\begin{aligned}\Delta L_1 &= \frac{120,000}{-30 \times 10^6 \times 1.81} \\ &\times [(8.3 - 4.68)9,000 - (8.3 - 6.49)1,000] \\ &= -68.0 \text{ in.}\end{aligned}$$

The tubing movement due to buckling effect is

$$\begin{aligned}\Delta L_2 &= \frac{(1.61)^2 \times (8.3)^2 (1,000 - 9,000)^2}{8 \times 30 \times 10^6 \times 1.61 \times 0.64} \\ &= -46.23 \text{ in.}\end{aligned}$$

The tubing movement due to ballooning effect is

$$\begin{aligned}L_3 &= \frac{0.3}{30 \times 10^6} \frac{0.0332 - 0}{1.178^2 - 1} (120,000)^2 - \frac{2 \times 0.3}{30 \times 10^6} \\ &\times \frac{5,000 - (1.178^2)1,000}{1.178^2 - 1} 120,000 = -34.69 \text{ in.}\end{aligned}$$

The temperature effect is

$$\Delta L_4 = -6.9 \times 10^{-6} \times 120,000 \times 20 = -16.56 \text{ in.}$$

The total expected tubing movement is

$$\Delta L_6 = \Delta L_1 + \Delta L_2 + \Delta L_3 + \Delta L_4 = -165.48 \text{ in.}$$

In a packer installation where the tubing is landed on the packer and the change in total length (ΔL_{total}) calculated is a downward movement (a positive value), the total length change will not occur due to the tubing being restrained from downward movement because of its landed configuration. The change in tubing length will result in a change in force (compressive) on the packer.

If the tubing is in a landed condition and the total change in length (ΔL_{total}) calculated is an upward movement (a negative value), the tubing is not restrained and is free to move upward.

If the tubing is latched to the packer, the total length change (ΔL_{total}) will be zero because the tubing is restrained from upward or downward movement and compressive or tension forces will result. In such instances the solutions for the tubing force and tubing-to-packer force are best left to computer software. Even a minor bit of complexity in the tubing configuration can render the solution trial-and-error.

When determining force changes in the tubing string in an installation where the tubing is stung through the packer, the tubing-to-packer force (F_p) will always equal zero because the tubing can never exert a force on the packer.

A sufficient amount of accurate data is important in the complete analysis. The validity of the results depends largely on the accuracy of the data used, and this should

weigh heavily on the final selection of the procedure, equipment to be used and the safety factor required.

The formulas used do not intentionally include any safety factor and the safety factor must be added. The magnitude of the safety factor should be based on the severity of the application and the validity of the data used.

4.18.2.10 Permanent Corkscrewing

To ensure that permanent corkscrewing will not occur, the following inequalities must be satisfied:

$$\left[3 \left(\frac{P_i - P_o}{R^2 - 1} \right)^2 + \left(\frac{P_i - R^2 P_o}{R^2 - 1} + \sigma_a \pm \sigma_b \right)^2 \right]^{0.5} \leq Y_m \quad (4.18.13)$$

$$\left[3 \left(\frac{R^2 (P_i - P_o)}{R^2 - 1} \right)^2 + \left(\frac{P_i - R^2 P_o}{R^2 - 1} + \sigma_a \pm \frac{\sigma_b}{R} \right)^2 \right]^{0.5} \leq Y_m \quad (4.18.14)$$

where

$$\sigma_a = \frac{\hat{F}_a}{A_s} \quad \text{and} \quad \sigma_b = \frac{D \times r}{4I} \hat{F}_f$$

All symbols in Equations 4.18.16 and 4.18.17 are as previously stated with the following additions.

\hat{F}_a = actual existing force at the lower end of the tubing in lb.

\hat{F}_f = effective force (axial force plus pressure terms) at the lower end of the tubing in lb

$$\hat{F}_f = \hat{F}_a - (P_i A_i - P_o A_o)$$

4.18.2.11 Coiled Tubing

Coiled tubing is a recent development in tubing technology. Coiled tubing is a continuous length of steel tubing with no joints. In general, the coiled tubing is fabricated to the length needed for a particular well application and rolled onto a reel for transport to a well site for placement in the well. The tubing can be butt-welded or continuously-milled as the tubing is placed on the roll. Coiled tubing is used in a variety of oil and gas well production, completions, and drilling operations. Like conventional tubing, coiled tubing is fabricated in a several material grades.

In the early 1960s, the development of continuous-length tubular products spooled onto a drum began to be used in well servicing operations and quickly grew in utility to expand into well completions and drilling operations. At the present time, coiled tubing is manufactured as a continuous-length "high frequency induction" welded product and maybe assembled where the flat skelp lengths of

TABLE 4.18.1 Tensile and Hardness Requirements for “As Manufactured” Coiled Tubing

Grade	Yield Strength		Ultimate Tensile Strength		Hardness HRC, Maximum	
	Minimum Psi	Maximum Psi	Minimum Psi	Maximum Psi	Weld	Body
CT-70	70,000	80,000	80,000	100,000	22.0	22.0
CT-80	80,000	90,000	88,000	105,000	22.0	22.0
CT-90	90,000	100,000	97,000	115,000	22.0	22.0
CT-100	100,000	—	108,000	125,000	28.0	28.0
CT-110	110,000	—	115,000	—	30.0	30.0

steel are plasma-arc welded together prior to milling or by butt-welding previously milled tubing segments together. At the present time, the commonly used coiled tubing material grades recognized by API Spec 5ST are shown in Table 4.18.1, along with projected minimum yield strength, ultimate tensile strength and maximum hardness values [1].

Based on the API-recommended performance calculation methodology, tables have been prepared for the sizes of coiled tubing typically used in the oil and gas industry today [4].

4.18.2.11.1 Coiled Tubing Surface Equipment

For a given material yield strength and specified OD size, the Yield Radius of Curvature (R_Y) defines the minimum bending radius (in inches) that the tube can be subjected to and still remain in the elastic state (Tables 4.18.2–4.18.15). The equation used to calculate yield radius of curvature is shown in Equation 4.18.15:

$$R_Y = \frac{E_s D_C}{Y_s 2} \quad (4.18.15)$$

where

- D_C = Specified coiled tube outside diameter, inches
- E_s = Modulus of elasticity of steel, psi
- Y_s = Specified minimum yield strength for steel, psi

For a given size of coiled tubing, the Reel Capacity ($L_{Spooled}$) describes the total amount of coiled tubing (in feet) which can be stored on a reel with specified core diameter, flange height and width dimensions as seen in Equations 4.18.16, 4.18.17, and 4.18.18:

$$N = \frac{\text{Flange Height (inch)} - \text{Freeboard (inch)}}{0.875} \quad (4.18.16)$$

$$M = \text{Drum Width (inch)} \times N \text{ (inch)} \quad (4.18.17)$$

$$L = 0.2618 \left(\frac{\text{Feet}}{\text{inch}} \right) \times M(\text{inch}^2) \left[\frac{(2 R_{REEL}(\text{inch}) + N(\text{inch}))}{D^2(\text{inch})} \right] \quad (4.18.18)$$

where

- Flange Height = Height from reel core to outer flange edge, inches
- Free Board = Height from outer CT layer to outer flange height, inches
- Drum Width = Width of reel between inside flange edges, inches
- R_{Reel} = Radius of reel core, inches
- D_C = Specified coiled tubing outside diameter, inches

The calculation to determine Coiled Tubing Inside Diameter (d_c) with specified dimensions is seen in Equation 4.18.19:

$$CT \ d_c = D_C - t_{nom} - t_{nom} \quad (4.18.19)$$

where

- D_C = Coiled tube outside diameter, inches
- t_{nom} = Specified wall thickness of coiled tube, inch

The calculation to determine cross-sectional area of the coiled tubing inside diameter with specified dimensions is seen in Equation 4.18.20:

$$\text{Area } d_c = 0.7854 d_c^2 \quad (4.18.20)$$

Tube body weight (Wpe) in lbs/ft is based on specified outside diameter and specified wall thickness dimensions of the tube.

TABLE 4.18.3 Coiled tubing performance properties for 1.250" OD (Courtesy of SAS Industries, Inc.)

WELL SERVICING GRADE COILED TUBING SPECIFICATIONS							CALCULATED PERFORMANCE PROPERTIES					COILED TUBING COLLAPSE PRESSURE CALCULATIONS				
Specified Tubing Size (Inches)	Specified Tubing Grade (API SST)	Tube Wall Thickness		Tubing D / tmin Ratio	Tube Inside Diameter (Inches)	Tube Body Weight (Lb / Ft)	Material Yield Strength (Psi)	Tube Body Yield Load Ly = 100% (Lbs.)	Internal Tube Pressure		Torsional Yield Strength (Lb - Ft)	0% Ovality Ly = 0% Differential (Psig)	2% Ovality Ly = 0% Differential (Psig)	2% Ovality Ly = 50% Differential (Psig)	5% Ovality Ly = 0% Differential (Psig)	5% Ovality Ly = 50% Differential (Psig)
		Specified Wall (Inch)	Minimum Wall (Inch)						Minimum Yield (Psi)	Test @ 80% (Psig)

The internal yield pressure and the hydrostatic test pressure are Barlow formula calculations using minimum wall thickness, specified minimum yield strength and specified outside diameter. The effect of axial loading on internal yield pressure is not included in this calculation.

The performance properties and hydrostatic test pressures apply to new tubing and do not take into account additional deformation, axial load, residual stresses or ovality caused by spooling or service cycling.

TABLE 4.18.6 Coiled tubing performance properties for 2.000" OD (Courtesy of SAS Industries, Inc.)

WELL SERVICING GRADE COILED TUBING SPECIFICATIONS							CALCULATED PERFORMANCE PROPERTIES					COILED TUBING COLLAPSE PRESSURE CALCULATIONS				
Specified Tubing Size (Inches)	Specified Tubing Grade (API SST)	Tube Wall Thickness		Tubing D / t _{min} Ratio	Tube Inside Diameter (Inches)	Tube Body Weight (Lb / Ft)	Material Yield Strength (Psi)	Tube Body Yield Load Ly = 100% (Lbs.)	Internal Tube Pressure		Torsional Yield Strength (Lb - Ft)	0% Ovality Ly = 0% Differential (Psig)	2% Ovality Ly = 0% Differential (Psig)	2% Ovality Ly = 50% Differential (Psig)	5% Ovality Ly = 0% Differential (Psig)	5% Ovality Ly = 50% Differential (Psig)
		Specified Wall (Inch)	Minimum Wall (Inch)						Minimum Yield (Psig)	Test @ 80% (Psig)

The calculated D/t_{min} Ratio is based on the specified outside diameter and minimum wall thickness of the coiled tubing size shown.

TABLE 4.18.7 Coiled tubing performance properties for 2.375" OD (Courtesy of SAS Industries, Inc.)

WELL SERVICING GRADE COILED TUBING SPECIFICATIONS							CALCULATED PERFORMANCE PROPERTIES					COILED TUBING COLLAPSE PRESSURE CALCULATIONS				
Specified Tubing Size (Inches)	Specified Tubing Grade (API 5ST)	Tube Wall Thickness		Tubing D / t min Ratio	Tube Inside Diameter (Inches)	Tube Body Weight (Lb / Ft)	Material Yield Strength (Psi)	Tube Body Yield Load Ly = 100% (Lbs.)	Internal Tube Pressure		Torsional Yield Strength (Lb - Ft)	0% Ovality Ly = 0% Differential (Psi)	2% Ovality Ly = 0% Differential (Psi)	2% Ovality Ly = 50% Differential (Psi)	5% Ovality Ly = 0% Differential (Psi)	5% Ovality Ly = 50% Differential (Psi)
		Specified Wall (Inch)	Minimum Wall (Inch)						Minimum Yield (Psi)	Test @ 80% (Psi)

The column headings "2% Ovality, Ly = 0%" and "5% Ovality, Ly = 0%" seen under Coiled Tubing Collapse Pressure Calculations represent the predicted collapse pressure for the respective oval tubing condition with zero applied axial tensile load (L = 0). The calculation methodology is seen in API RP 5C7.

The column headings "2% Ovality, Ly = 50%" and "5% Ovality, Ly = 50%" seen under Coiled Tubing Collapse Pressure Calculations represent the predicted collapse pressure for the respective oval tubing condition with an applied axial tensile load equal to 50% of the tube body yield load. The calculation methodology is seen in API RP 5C7.

TABLE 4.18.10 Coiled tubing performance properties for 3.250" OD (Courtesy of SAS Industries, Inc.)

WELL SERVICING GRADE COILED TUBING SPECIFICATIONS							CALCULATED PERFORMANCE PROPERTIES					COILED TUBING COLLAPSE PRESSURE CALCULATIONS				
Specified Tubing Size (Inches)	Specified Tubing Grade (API 5ST)	Tube Wall Thickness		Tubing D / tmin Ratio	Tube Inside Diameter (Inches)	Tube Body Weight (Lb / Ft)	Material Yield Strength (Psi)	Tube Body Yield Load Ly = 100% (Lbs.)	Internal Tube Pressure		Torsional Yield Strength (Lb - Ft)	0% Ovality Ly = 0% Differential (Psi)	2% Ovality Ly = 0% Differential (Psi)	2% Ovality Ly = 50% Differential (Psi)	5% Ovality Ly = 0% Differential (Psi)	5% Ovality Ly = 50% Differential (Psi)
		Specified Wall (Inch)	Minimum Wall (Inch)						Minimum Yield (Psi)	Test @ 80% (Psi)

With the exception of the "Test 80%" column under Calculated Performance Properties, the values represent the tube performance limits calculated with a safety factor of 1 (SF = 1.0). The limits for applied working pressures and working loads should incorporate all appropriate safety factors and take into account condition of the tube and serviceability issues.

TABLE 4.18.11 Coiled tubing performance properties for 3.500" OD (Courtesy of SAS Industries, Inc.)

WELL SERVICING GRADE COILED TUBING SPECIFICATIONS							CALCULATED PERFORMANCE PROPERTIES					COILED TUBING COLLAPSE PRESSURE CALCULATIONS				
Specified Tubing Size (Inches)	Specified Tubing Grade (API 5ST)	Tube Wall Thickness		Tubing D / tmin Ratio	Tube Inside Diameter (Inches)	Tube Body Weight (Lb / Ft)	Material Yield Strength (Psi)	Tube Body Yield Load Ly = 100% (Lbs.)	Internal Tube Pressure		Torsional Yield Strength (Lb - Ft)	0% Ovality Ly = 0% Differential (Psi)	2% Ovality Ly = 0% Differential (Psi)	2% Ovality Ly = 50% Differential (Psi)	5% Ovality Ly = 0% Differential (Psi)	5% Ovality Ly = 50% Differential (Psi)
		Specified Wall (Inch)	Minimum Wall (Inch)						Minimum Yield (Psi)	Test @ 80% (Psi)

TABLE 4.18.16 Tolerances for Specified Coiled Tube Wall Thicknesses

Wall Thickness(es) Below 0.110 inch	- 0.005 inch to + 0.010 inch
Wall Thickness(es) of 0.111 inch to 0.175 inch	- 0.008 inch to + 0.012 inch
Wall Thickness(es) of 0.176 inch to 0.250 inch	- 0.012 inch to + 0.012 inch
Wall Thickness(es) of 0.251 inch and greater	- 0.015 inch to + 0.015 inch

where

d_c = Coiled tube inside diameter, inches

The calculation to determine cross-sectional area of coiled tubing outside diameter with specified dimensions is seen in Equation 4.18.21:

$$\text{Area } D_C = 0.7854 D_C^2 \quad (4.18.21)$$

where

D_C = Coiled tube outside diameter, inches

As per API Spec 5ST, the wall thickness at any place within the coiled tubing string should not vary from the specified thickness, t_{nom} by more than the permissible tolerance seen in Table 4.18.16 [1]:

Plain-end weight (W_{PE}) is calculated using the theoretical density of the steel, the specified wall thickness, and specified outside diameter of the tube as seen in Equation 4.18.22 in units of lb/ft:

$$W_{PE} = 10.69(D_C - t_{nom})t_{nom} \quad (4.18.22)$$

where

D_C = Specified coiled tube outside diameter, inches

t_{nom} = Specified wall thickness for coiled tube, inch

Tube Capacity ($V_{capacity}$) is the unit volume of fluid contained inside of the coiled tubing and may be calculated as shown in Equation 4.18.23a or Equation 4.18.23b in units of “barrels per foot”.

$$V_{capacity} = 0.0009714 d_c^2 \quad (4.18.23a)$$

$$V_{capacity} = \frac{d_c^2}{1029.4} \quad (4.18.23b)$$

where

d_c = Specified coiled tube inside diameter, inches.

Body Displacement (V_{Body}) is the equivalent unit volume of fluid that will be displaced by the cross-sectional area of the coiled tubing body upon insertion into a filled well with both ends of the coiled tubing string open to the atmosphere and may be calculated as shown in Equation 4.18.24a or Equation 4.18.24b in units of “barrels per foot”.

$$V_{Body} = 0.0009714 (D_c^2 - d_c^2) \quad (4.18.24a)$$

$$V_{Body} = \frac{(D_c^2 - d_c^2)}{1029.4} \quad (4.18.24b)$$

where

D_C = Specified coiled tube outside diameter, inches

d_c = Specified coiled tube inside diameter, inches

Tube External Displacement (V_{Dis}) is the equivalent unit volume of fluid that will be displaced by insertion of a fluid-filled or closed-end string of coiled tubing into a fluid filled well and may be calculated as shown in 4.18.25a or Equation 4.18.25b in units of “barrels per foot”.

$$V_{Dis} = 0.0009714 D_C^2 \quad (4.18.25a)$$

$$V_{Dis} = \frac{D_C^2}{1029.4} \quad (4.18.25b)$$

where

D_C = Specified coiled tube outside diameter, inches

The term typically used to describe elliptically shaped tubing is “ovality” and may be calculated for new “as manufactured” or used coiled tubing with Equation 4.18.26.

$$\text{Ovality} = 2 \frac{(D_{max} - D_{min})}{(D_{max} + D_{min})} \quad (4.18.26)$$

where

D_{max} = Maximum measured coiled tube outside diameter, inches

D_{min} = Minimum measured coiled tube outside diameter, inches

The Tube Body Yield Load (L_Y) is defined as the axial tensile load (in the absence of pressures or torque) which produces a stress in the tube equal to the specified minimum

yield strength (Y_s) as shown in Equation 4.18.27 below in units of “pounds force”.

$$L_Y = 3.1416 (D_C - t_{min}) t_{min} Y_s \quad (4.18.27)$$

where

- D_C = Specified coiled tube outside diameter, inches
- t_{min} = Minimum allowable wall thickness for coiled tube, inch
- Y_s = Specified minimum yield strength for steel, psi

The Internal Yield Pressure (P_r) is defined as the internal pressure which produces a stress in the tubing equal to the specified minimum yield strength (Y_s), based on the specified outside diameter and the minimum wall thickness and is calculated using the Barlow Formula as shown in Equation 4.18.28 in units of “pounds per square inch” (psig).

$$P_r = \frac{2 Y_s t_{min}}{S_F D_C} \quad (4.18.28)$$

where

- S_F = Safety factor for pressure containment, fraction
- D_C = Specified coiled tube outside diameter, inches
- t_{min} = Minimum allowable wall thickness for coiled tube, inch
- Y_s = Specified minimum yield strength for steel, psi

Torsional Yield Strength (T_f) is defined as the torque required to yield the coiled tubing (in the absence of pressures or axial stress) and is calculated as shown in Equation 4.18.29 in units of “foot-pounds” (ft-lb).

$$T_f = \frac{Y_s [D_C^4 - (D_C - 2t_{min})^4]}{105.86 D_C} \quad (4.18.29)$$

where

- D_C = Specified coiled tube outside diameter, inches
- t_{min} = Minimum allowable wall thickness for coiled tube, inch
- Y_s = Specified minimum yield strength for steel, psi

4.18.2.11.2 Coiled Tubing Well Intervention

The Buoyancy Factor (BF) is obtained by taking the difference between steel density (65.51 ppg) and the given fluid

density (in ppg) and dividing by the density of steel (65.51 ppg). This similar fluids buoyancy factor is valid where the density of the fluid in the coiled tube segment is equal to the density of the fluid in the annulus.

$$\text{Buoyancy Factor} = \frac{65.51 \text{ ppg} - \gamma_1 \text{ ppg}}{65.51 \text{ ppg}} \quad (4.18.30)$$

where

- γ_1 = Specific weight of fluids within CT ID and annulus, ppg

A “similar fluid” coiled tube buoyancy calculation ($W_{\text{Buoy-s}}$) is seen as Equation 4.18.31, where the density of the fluid internal to the coiled tubing segment having a constant wall thickness is the same as the density of the fluid in the annulus, yielding a tube weight in “pounds” (lbs).

$$W_{\text{Buoy-s}} = L W_{pe} [1 - (0.01526 \gamma_f)] \quad (4.18.31)$$

where

- W_{PE} = Plain-end weight of the coiled tube segment, lbs
- γ_f = Specific weight of fluids within CT ID and annulus, ppg
- L = Length of CT segment deployed, feet

A “dissimilar fluid” coiled tube buoyancy calculation (W_{Buoy}) is seen as Equation 4.18.32, where the density of the fluid internal to the coiled tubing segment having a constant wall thickness is different from the density of the fluid in the annulus, yielding a tube weight in “pounds” (lbs).

$$W_{\text{Buoy}} = L \left[W_{PE} + \left(\frac{d_c^2 \gamma_{fi}}{24.51} \right) - \left(\frac{D_C^2 \gamma_{fo}}{24.51} \right) \right] \quad (4.18.32)$$

where

- W_{PE} = Plain-end weight of the coiled tube segment, lbs
- γ_{fi} = Specific weight of fluids within coiled tube inside diameter, ppg
- γ_{fo} = Specific weight of fluids within annulus, ppg
- L = Length of constant wall thickness CT segment deployed, feet
- D_C = Specified coiled tube outside diameter, inches
- d_c = Specified coiled tube inside diameter, inches

When entering a wellbore with a given amount of surface pressure, the amount of force required to overcome the pressure and initiate tubing movement into the borehole will be a function of the tube diameter. Because coiled tubing

operates as a closed system, the entire cross-sectional area of the tube body must be used to determine the upward force (F_{PACS}) acting against the tubing as in Equations 4.18.33 in units of “pounds force”.

$$F_{PACS} = 0.7854 P_{wh} D_C^2 \quad (4.18.33)$$

Where:

D_C = Specified coiled tube outside diameter, inches
 P_{wh} = Surface wellhead pressure, psig

The maximum width dimension of a collapsed tube (W_{Col}) may be calculated using Equation 4.18.34 where the original tube OD size and actual wall thickness dimensions are known.

$$W_{Col} = 0.95 \left[D_C + (0.5708 D_C) \left(1 - \frac{2t}{D_C} \right) \right] \quad (4.18.34)$$

where

D_C = Specified coiled tube outside diameter, inches
 t = Actual measured coiled tube wall thickness, inch

The calculation for determining cross-sectional area of the annular space between the “boundary” conduit and coiled tube outside diameter is seen in Equation 4.18.35:

$$\text{Annulus Area} = \left(\text{Conduit } d_b^2 - \text{CT } D_C^2 \right) \times 0.7854 \quad (4.18.35)$$

where

d_b = Internal diameter of boundary conduit, inches
 D_C = Specified coiled tube outside diameter, inches

The calculation for Fluid Flow Velocity (V_{CT}) in feet per second through the CT inside diameter pumped at a given flow rate (barrels per minute) is seen in Equation 4.18.36:

$$V_{CT} = \frac{17.157 \times Q}{d_c^2} \quad (4.18.36)$$

where

d_c = Internal diameter of coiled tube, inches
 Q = Pump rate of fluid, barrels per minute

The calculation for Fluid Flow Velocity (V_{Ann}) in feet per second through the CT OD x Conduit Annulus pumped at a given flow rate (barrels per minute) is seen in Equation 4.18.37:

$$V_{Ann} = \frac{17.157 \times Q}{\text{Conduit } d_b^2 - D_C^2} \quad (4.18.37)$$

where

d_b = Internal diameter of conduit borehole, inches
 D_C = Outside diameter of coiled tube, inches
 Q = Pump rate of fluid, barrels per minute

The calculation for displacement time (minutes) for pumped fluids within the coiled tubing ID at a given flow velocity is seen in Equation 4.18.38:

$$\text{Time} = \frac{0.01667 \times \text{CT Length}}{V_{CT}} \quad (4.18.38)$$

where

CT Length = Segment length of constant wall thickness tube, feet

V_{CT} = Pumped fluid velocity, feet per second

The calculation for displacement time (minutes) for pumped fluids within the CT OD x Conduit ID at a given flow velocity is seen in Equation 4.18.39:

$$\text{Time} = \frac{0.01667 \times \text{CT Length}}{V_{Ann}} \quad (4.18.39)$$

where

CT Length = Segment length of constant conduit ID, feet

V_{Ann} = Pumped fluid velocity, feet per second

4.18.2.11.3 Coiled Tubing Well Control

The “average” hydrostatic pressure (P_{hyd}) in units of psig at a particular depth for a homogenous density fluid can be calculated as seen in Equation 4.18.40:

$$\text{“Average” } P_{hyd} = 0.052 \times \gamma_f \times H_{hyd} \quad (4.18.40)$$

where

γ_f = Specific weight of homogenous fluid within vertical conduit, ppg

H_{hyd} = Vertical column height of homogenous fluid, feet

The equation commonly used to calculate fluid density (in ppg) needed to balance the specified pressure with a true vertical fluid column height (H_{hyd}) is seen in Equation 4.18.41:

$$\rho_f = \frac{P}{0.052 H_{hyd}} \quad (4.18.41)$$

where

- γ_f = Specific weight of homogenous fluid within vertical conduit, ppg
- H_{hyd} = Vertical column height of homogenous fluid, feet

To determine Injectivity Rate (Q_{INJ}) in barrels per minute, the modified Darcy steady-state radial flow equation can be used to predict the volume loss of a clear, penetrating fluid to the formation for a given pressure differential at the completion interval, assuming that the data for required reservoir parameters, as well as the properties for the pumped fluid at reservoir conditions, is available.

$$Q_{INJ} = \frac{4.917 \times 10^{-6} K h (P_{wf} - P_e)}{\mu \beta \left[\ln \left(\frac{r_e}{r_w} \right) + S \right]} \quad (4.18.42)$$

where

- K = Formation permeability to a specific fluid, millidarcy
- h = Height of formation, feet
- P_{wf} = Bottomhole pressure at completion well face, psig
- P_e = Reservoir Pressure at boundary of drainage radius, psig
- μ = Dynamic fluid viscosity, centiPoise
- β = Formation volume factor, reservoir barrels/surface barrels
- r_e = Radius of reservoir drainage, feet
- r_w = Radius of wellbore, inches
- S = Completion skin factor, dimensionless

4.18.2.11.4 Coiled Tubing Accumulator Sizing Calculations

Once the volume needed to actuate the multi-ram coiled tubing well control stack through the API RP 16ST close-open-close sequence (V_{COC}) has been determined, the minimum required accumulator bank volume (V_{acc}) may be calculated using Equation 4.18.43 [3]:

$$V_{acc} = \frac{V_{COC}}{\frac{P_p}{T_{@P} Z_{@P}} \left(\frac{T_{@p+200} Z_{@p+200}}{P_{p+200}} - \frac{T_{@max} Z_{@max}}{P_{max}} \right)} \quad (4.18.43)$$

where

- V_{acc} = Minimum required accumulator volume (gallons)
- V_{COC} = Close-open-close volume for multi-ram stack (gallons)
- P_p = Nitrogen precharge pressure (psia)

- $T_{@P}$ = Nitrogen precharge temperature (°R)
- $Z_{@P}$ = Nitrogen precharge compressibility factor
- P_{p+200} = Nitrogen precharge pressure + 200 psi (psia)
- $T_{@p+200}$ = Nitrogen temperature at precharge + 200 psi (°R)
- $Z_{@p+200}$ = Nitrogen compressibility factor at precharge + 200 psi
- P_{max} = Maximum stabilized accumulator pressure (psia)
- $T_{@max}$ = Nitrogen temperature at P_{max} (°R)
- $Z_{@max}$ = Nitrogen compressibility factor at P_{max}

The Critical Pressure (P_{crit}) to shear coiled tubing at a given maximum anticipated surface pressure is calculated as seen in Equation 4.18.44 where the closing ratio for the shear rams or shear-blind rams and the hydraulic pressure needed to shear the tubing segment at atmospheric pressure ($P_{shear@0psig}$) is known.

$$P_{crit} = P_{shear@0psig} + (P_{MASP}/Closing\ Ratio) \quad (4.18.44)$$

where

- P_{MASP} = Maximum anticipated surface pressure, psig
- Closing Ratio = Ratio of piston area to ram rod area, dimensionless

The Critical Pressure (P_{crit}) to secure coiled tubing at a given maximum anticipated surface pressure is calculated as seen in Equation 4.18.45 where the closing ratio for the sliprams or pipe-slip rams and the hydraulic pressure needed to secure the tubing segment at atmospheric pressure ($P_{slip@0psig}$) is known.

$$P_{crit} = P_{slip@0psig} + (P_{MASP}/Closing\ Ratio) \quad (4.18.45)$$

where

- P_{MASP} = Maximum anticipated surface pressure, psig
- ClosingRatio = Ratio of piston area to ram rod area, dimensionless

4.19 CORROSION IN DRILLING AND WELL COMPLETIONS

Section reviewed by John Farraro

Corrosion is a naturally occurring phenomenon where materials interact with the environment resulting in chemical change. This chemical change is a degradation in structure with a few exceptions such as batteries. When this corrosion reaction with metal continues unabated, the final condition is the complete conversion of the metal into metal salts.

With the exception of noble metal such as gold and silver, metals do not normally exist in their free form in nature. The metals are tied up with other elements to form oxides, chlorides, sulfides etc. This can be explained thermodynamically since the metals are moving towards a lower energy state. When we refine metals from ores, we move the metal to a higher energy state; therefore, we must add energy (typically in the form of heat or electricity). When our refined metals react with the environment to form metal salts or compounds, thereby moving to a lower energy state, this is the process of corrosion. This chapter includes a primer into the science of corrosion with a discussion of thermodynamics and electrochemistry.

Though the subject of corrosion is important to all facets of our society, the subject here is the corrosion problems encountered in drilling and well completions. The solutions to these corrosion problems have created a knowledge base from which we can draw on to avoid the many potential pitfalls in drilling and well completion operations.

A wide variety of engineered tools and structures are used in the oil and gas industry. Drilling tools include drill pipe, tool joints, blowout preventers (BOPs), drilling jars, drill collars, stabilizers, and milling/rock bits and cutters. Well completion tools and products include casing, cementing tools, and liner hangers. Each of these tools has different engineering requirements that equates to different metals and conditions. These metals and their condition exhibit varying susceptibilities to the various potential corrosion reactions prevalent in the oilfield drilling and completion environments.

In addition to exposure to atmospheric, coastal marine, and sea environments, the oil and gas industry encounters additional corrosive constituents in oil and gas drilling and production. In the course of drilling and completing wells, we introduce acids and other corrosive agents that further complicate the application of common engineering materials.

This chapter is structured to provide an introduction to the science of corrosion with an expansion of the subject into the specifics that are applicable to drilling and well completion environments. The common techniques to mitigate the effects of corrosion in these oilfield applications are presented.

4.19.1 Corrosion Science

4.19.1.1 Corrosion Terms

To provide a basis for a discussion of corrosion science, a list of definitions of the various terms used in this chapter is provided herein. The sources for these terms are (1) NACE MR0175 [1] or, when the term is not listed in this standard, (2) the ASM Corrosion Volume of ASM's Metals Handbook [2].

Acid

A chemical substance that yields hydrogen ions (H^+) when dissolved in water.

Activation

The changing of a passive surface of a metal to a chemically active state.

Active Potential

The potential of a corroding material.

Alkaline

(1) Having properties of an alkali. (2) Having a pH greater than 7.

Anion

A negatively charged ion that migrates through the electrolyte toward the anode under the influence of a potential gradient.

Anode

The electrode of an electrolytic cell at which oxidation occurs. Electrons flow away from the anode in the external circuit. It is usually at the electrode that corrosion occurs and metal ions enter solution.

Anodic Reaction

Electrode reaction equivalent to a transfer of positive charge from the electronic to the ionic conductor. An anodic reaction is an oxidation process. A common example in corrosion is $Me \rightarrow Me^{n+} + n e^-$.

Austenite

The face-centered crystalline phase of iron base alloys.

Base

A chemical substance that yields hydroxyl ions (OH^-) when dissolved in water.

Carbon Steel

An alloy of carbon and iron containing up to 2% carbon and up to 1.65% manganese and residual quantities of other

elements, except those intentionally added in specific quantities for deoxidation (usually silicon and/or aluminum). Carbon steels used in the petroleum industry usually contain less than 0.8% carbon.

Cathode

The electrode of an electrolyte cell at which reduction is the principal reaction. Electrons flow toward the cathode in the external circuit. Typical cathodic processes are cations taking up electrons and being discharged, oxygen being reduced, and the reduction of an element or group of elements from a higher to a lower valence state.

Cathodic Reaction

Electrode reaction equivalent to transfer of negative charge from the electronic to the ionic conductor. A cathodic reaction is a reduction process. A common example in corrosion is: $\text{Ox} + ne^- \rightarrow \text{Red}$.

Cation

A positively charged ion that migrates through the electrolyte toward the cathode under the influence of a potential gradient.

Chloride Stress Corrosion Cracking

Failure by cracking under the combined action of tensile stress and corrosion in the presence of chlorides and water.

Corrosion Potential (E_{corr})

The potential of a corroding surface in an electrolyte, relative to reference electrode. Also called the rest potential, open-circuit potential, or freely corroding potential.

Current Density

The current flowing to or from a unit area of an electrode surface.

Electrochemical Cell

An electrochemical system consisting of an anode and a cathode in metallic contact and immersed in an electrolyte. The anode and cathode may be different metals or dissimilar areas on the same metal surface.

Electrode Potential

The potential of an electrode in an electrolyte as measured against a reference electrode. The electrode does not include any resistance losses in potential in either the solution or the external circuit. It represents the reversible work to move a unit charge from the electrode surface through the solution to the reference electrode.

Faraday's Law

(1) The amount of any substance dissolved or deposited in electrolysis is proportional to the total electric charge passed. (2) The amounts of different substances dissolved or deposited by the passage of the same electric charge are proportional to their equivalent weights.

Galvanic Corrosion

Accelerated corrosion of a metal because of an electrical contact with a more noble metal or nonmetallic conductor in a corrosive electrolyte.

Galvanic Couple

A pair of dissimilar conductors, commonly metals, in electrical contact.

Gibbs Free Energy

The thermodynamic function $\Delta G = \Delta H - T\Delta S$, where H is enthalpy, T is absolute temperature, and S is entropy. Also called free energy, free enthalpy, or Gibbs function.

Ion

An atom, or group of atoms, that has gained or lost one or more outer electrons and thus carries an electric charge. Positive ions, or cations, are deficient in outer electrons. Negative ions, or anions, have an excess of outer electrons.

Low Alloy Steel

Steel with a total alloying element content of less than about 5%, but more than specified for carbon steel.

Partial Pressure

Ideally, in a mixture of gases, each component exerts the pressure it would exert if present alone at the same temperature in the total volume occupied by the mixture. The partial pressure of each component is equal to the total pressure multiplied by its mole fraction in the mixture. For an ideal gas, the mole fraction is equal to the volume fraction of the component.

Passivation

(1) A reduction of the anodic reaction of an electrode involved in corrosion. (2) The process in metal corrosion by which metals become passive. (3) The changing of a chemically active surface of a metal to a much less reactive state.

pH

The negative logarithm of the hydrogen-ion activity.

Polarization

(1) A reduction of the anodic reaction rate of an electrode involved in corrosion. (2) The process in metal corrosion

by which metals become passive. (3) The changing of a chemically active surface of a metal to a much less reactive state.

Pressure-Containing Parts

Those parts whose failure to function as intended would result in a release of retained fluid to the atmosphere. Examples are valve bodies, bonnets, and stems.

Residual Stress

Stress present in a component free of external forces or thermal gradients.

Stainless Steel

Steel containing 10.5% or more chromium. Other elements may be added to secure special properties.

Standard Cubic Foot of Gas

The quantity of a gas occupying one cubic foot at a pressure of one atmosphere or 0.10133 Mpa abs (14.696 psi) and a temperature of 15°C (59°F).

Stress Corrosion Cracking (SCC)

Cracking of metal produced by the combined action of corrosion and tensile stress (residual or applied).

Sulfide Stress Cracking (SSC)

Brittle failure by cracking under the combined action of tensile stress and corrosion in the presence of water and H₂S.

Tubular Component

A cylindrical component (pipe) having a longitudinal hole that is used in drilling/production operations for conveying fluids.

4.19.1.2 Thermodynamics of Corrosion

The phenomena of corrosion can be explained by thermodynamics. An initial assessment of corrosion potential typically includes an examination of the relevant thermodynamics. The following questions can be answered by thermodynamics: Why does corrosion occur? How can we determine whether corrosion is possible? Can we quantify the likelihood and obtain an estimate of the kinetics of the reaction (or corrosion rate)?

In thermodynamics, the energies associated with formation or dissolution of a chemical compound or metal can be found in an expression of this energy known as Gibbs free energy. Gibbs free energy is the combination of enthalpy (H) and entropy (S) and is expressed as follows:

$$\Delta G = \Delta H - T\Delta S$$

The 'T' in the equation is the absolute temperature. The general rule for a reaction to occur without the addition of energy is that:

$$\Delta G < 0$$

A good discussion of thermodynamics as it is related with predicting the chemical reactions associated with corrosion reaction can be found in the ASM Metals Handbook volume on corrosion [1] or Gelling's text [3].

4.19.1.3 Electrochemistry of Corrosion

Another way to express and quantify this energy and predict corrosion tendencies is in electrochemical terms. In aqueous (water) or other polar solvents that permit the flow of electrons (conductive), a current will flow during a chemical reaction such as corrosion. During a corrosion process/chemical reaction, two or more reactions take place concurrently with the resultant current flow from a higher potential to a lower potential (or higher energy state to a lower energy state). These reactions are either anodic or cathodic. Anodic reactions are those where electrons are discharged and these electrons are used in the cathodic reaction. This is shown schematically in Figure 4.19.1.

Using electrochemistry, we can obtain predictions of equilibrium data for electrochemical reactions. When reactions are steady state (at equilibrium), it has been shown that we can relate Gibbs Free Energy to an equilibrium constant as shown in the following equation [1].

$$\Delta G^0 = -RT \ln K_{eq}$$

where ΔG^0 is Gibbs free energy at equilibrium
R is the gas constant
T is the absolute temperature
 K_{eq} is the equilibrium constant

The potential that occurs under steady state (equilibrium) conditions is related to Gibbs free energy in the following manner [4].

$$\Delta G^0 = -nFE^0$$

where n is the number of electrons transferred in the reaction
F is the Faraday constant (charge of 1 mole of electrons)
 E^0 is the equilibrium cell potential

The standard electrode potentials discussed above are for standard concentrations (1.000 M) and, in a real application environment, the concentrations will vary from the standard concentration. The same equation (Nernst equation) listed below permits calculation of electrode potentials at nonstandard concentrations or electrode potentials of chemical reactions when reactants or products vary from the

FIGURE 4.19.1 Electrochemical corrosion of metals.

standard concentrations. Similarly, non-equilibrium conditions are related as follows:

$$\Delta G = -nFE$$

where n is the number of electrons transferred in the reaction
 F is the Faraday constant (charge of 1 mole of electrons)
 E is the cell potential

Combining these equations and solving for the equilibrium constant permits the direct relationship with potential:

$$\ln K_{eq} = -nFE^0/RT$$

This equation permits prediction of equilibrium data for electrochemical reactions.

Corrosion is a process of material degradation via a variety of mechanisms. In this discussion of electrochemistry we find direct application to general or weight-loss type corrosion where the mechanism is electrochemical in that the move is towards a lower energy state. To predict whether corrosion is likely to occur, we can combine the individual reactions in the corrosion process. The associated energy with each reaction is combined with all the reactions in the system to yield a total or combined energy. The sign (positive or negative) and the magnitude provide the signpost by which we can predict the likelihood that corrosion will occur.

Taking the corrosion of iron in water as an example, the anodic and cathodic reactions are expressed as follows:

Anodic : $Fe \rightleftharpoons Fe^{+2} + 2e^-$ This is the oxidation reaction.
 Cathodic : $2H^+ + 2e^- \rightleftharpoons H^2$ This is the reduction reaction.

Using standard electrode potentials, [3], the following illustrates the reaction of iron in water:

In the previous example, the reaction of iron in oxygen free water results in a combined energy (electrode potential) of -0.44 V . This indicates that iron will corrode because the number is negative and relatively large. In another example, we can similarly look at copper in an oxygen free water environment.

This example illustrates the reason why copper is often found free as a metal in nature; the positive number indicates that the reaction will not occur naturally. These examples are in an oxygen free environment, looking at the copper reaction above and introducing oxygen results in the following:

In an oxygen containing water environment, copper does corrode naturally. From these examples, we know that knowledge of the chemical reaction and the electrode potential yields the probability of a reaction occurring. Table 4.19.1 contains many of these standard electrode potentials [5].

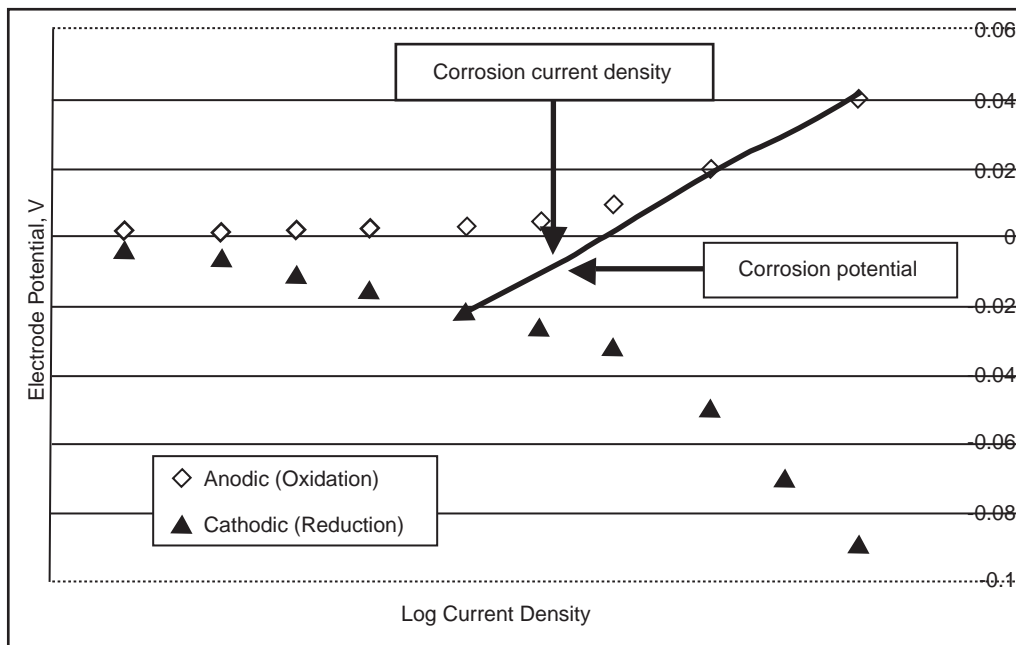

FIGURE 4.19.2 Schematic polarization curves.

Corrosion rates can be determined experimentally in two ways, first by determining weight loss over a known period of time under specific conditions and second by electrochemical methods. The advantage of the weight loss technique is that the corrosion rate is an average rate over time, the disadvantage is that the effect of natural perturbations to the system are unknown. The advantage of the electrochemical method is that the rate determined is almost instantaneous and the changes in the rate can be measured over time [6].

Fundamentally, Tafel [7] found that the current (I) was equivalent to the rate of a single electrode reaction by the following equation:

$$E = a + b (\log I)$$

where E = potential (volts) measured with respect to a reference electrode

a and b = constants

I = current density of the reaction

The ‘b’ constant in the equation is known as the Tafel slope. Both anodic and cathodic processes will exhibit a characteristic Tafel constant or slope, often designated b_a and b_c where the ‘a’ and ‘c’ subscripts designate anodic and cathodic. To determine the Tafel constants and the corroding (open circuit or unperturbed) current and potential, polarization experiments may be conducted.

As shown earlier, where a natural corrosion process will exhibit at least one anodic and one cathodic electrochemical process, the natural system can be perturbed or polarized

in either the anodic or cathodic directions and the effect measured. An example of the resultant relationships from anodic and cathodic polarizations is shown in Figure 4.19.2.

The value of the voltage at the intersection of these Tafel slopes is known as the corrosion potential. The value of the current density at the intersection of these Tafel slopes is known as the corrosion current. From Figure 4.19.2, we can experimentally measure the corrosion potential and the corrosion current density.

The corrosion current density is related to the instantaneous corrosion rate through variations of Faraday’s Law, one form of which is presented below [6].

$$\text{Corrosion rate (mils per year)} = (129 IM)/(z \rho)$$

where I = corrosion current in ma/cm^2

M = average gram atomic weight

z = number of electrons transferred

ρ = density

In general, corrosion studies, the values obtained from electrochemical measurements can be measured against weight-loss measurements under the same environmental conditions. When a sample of known surface area, density and weight is corroded over a known period of time, the weight loss can be converted into a corrosion rate. One such equation is listed below [8,9].

$$\text{Corrosion rate in mpy (mils per year)} = (534 W)/(DAT)$$

where W = weight loss in mg

D = density of metal corroded in g/cm^3

A = area of metal exposed to corrosive environment in square inches
 T = exposure time in hours

4.19.1.4 Passivity

In this discussion of corrosion science and electrochemistry, it is necessary to explore the related subject of passivity to explain why materials do not corrode or stop corroding under particular environmental conditions. The preceding electrochemical discussion needs to be carried further to understand this behavior of metals.

The part missing so far in our discussion is the subject of the characteristics of the products of the chemical reactions or corrosion. There are two interrelated attributes that need to be considered that permit a greater understanding of why metals corrode and do not corrode: (1) the solubility of the reaction products and (2) the stability of the reaction products.

If, for example, a metal under specific conditions corrodes and produces a stable corrosion product that is insoluble in the environment, then the corrosion product could form a protective film or layer on the metal surface preventing further corrosion by becoming a barrier between the environment and the metal surface. This means that under certain conditions, a normally active metal such as iron, can become inert or perform like a noble metal.

Generally, as the oxidizing power or electrode potential increases, the corrosion rate increases. This relationship is presented in Figure 4.19.3.

This corrosion prediction as illustrated above may not accurately describe the corrosion rates because of the corrosion product solubility and stability. The reality of the corrosion prediction may instead include a potential region that is called passive and reflects the inactive or passive nature of the metal surface. This is demonstrated in Figure 4.19.4.

FIGURE 4.19.3 Corrosion rate of a metal as a function of solution oxidizing power (electrode potential) [10].

Note that the x axis is the corrosion rate and these rates can be determined experimentally or via electrochemical techniques. In electrochemical experiments, the x axis would be experimentally measured as current density as described earlier. The passive region in Figure 4.19.4 is where the corrosion rate decreases as the oxidizing power increases as measured by potential (voltage).

The subject of passivation is not completely understood but there are two commonly accepted theories, *oxide film theory* and the *adsorption theory of passivity*. The oxide film theory relates the passivity to the presence of surface films (primarily oxides) that are diffusion barrier films preventing contact of the metal surface with the environment. The adsorption theory relates the passivity to adsorbed gas that causes the barrier preventing diffusion of the metal ions into the surrounding environment.

One useful tool that assists in defining regions of relative passivity are potential-pH diagrams. These are often

FIGURE 4.19.4 Corrosion characteristics of an active passive metal as a function of solution oxidizing power (electrode potential) [10].

FIGURE 4.19.5 Potential – pH diagram for iron.

commonly referred to as Pourbaix diagrams named after the discoverer of the relationship, Marcel Pourbaix, in 1945 [3]. An example of this type of diagram for iron is presented in Figure 4.19.5.

These diagrams are used to predict whether reactions will occur naturally, the composition of the corrosion products and where these reactions occur and do not occur. We can use the regions where structure-damaging reactions do not occur to prevent corrosion attack; this is accomplished by modifying the pH of the environment or by impressing a potential (cathodic protection).

There have been diagrams produced that describe the corrosion behavior without the fields surface film compositions listed [11]. The general corrosion behavior defined as regions of immunity, passivity and corrosion can be overlaid onto the Potential-pH diagram. Looking at the regions represented in Figure 4.19.5, we obtain a diagram such as that presented in Figure 4.19.6.

From the example in Figures 4.19.5 and 4.19.6, we can readily see the conditions that result in corrosion and those that do not. There is good agreement between the composition of the surface films and the corrosion behavior.

4.19.2 Forms of Corrosion Attack

The degradation of materials may occur from a number of forms of corrosion. The many forms that are encountered

in the oil and gas industry are discussed herein. The forms of attack can be categorized broadly into either a corrosion phenomena, a cracking phenomena or a form of attack that is a combination of a corrosion mechanism and another type or form of metal degradation. Corrosion phenomena include general and localized forms of corrosion. Cracking phenomena is a combination of stress and a corrosion reaction of a susceptible material that results in corrosion cracking. Material degradation may also be caused by the combination of a corrosion mechanism and another type or form of material damage such as a fatigue or wear. The combination of these forms of degradation may often be more than additive which indicates that the material damage may be more severe than predicated by only considering one mechanism at a time. These forms of corrosion attack are discussed here.

4.19.2.1 General Corrosion

One of the most common and simplest type of corrosion is general or uniform corrosion. If a material surface degrades in a uniform manner via a chemical reaction without the addition of a non-corrosion mechanism such as wear, then this is general corrosion. This general corrosion is easy to predict using the electrochemical techniques previously discussed and can be easily determined experimentally.

The general corrosion rate as defined by weight loss can be calculated by equations such as the one listed below [8,9].

FIGURE 4.19.6 Immunity, passivity and corrosion regions overlaid onto potential – pH diagram.

Corrosion Rate in mpy (mils per year) = $534W/DAT$

where W = weight loss in mg

D = density of metal corroded in g/cm^3

A = area of metal exposed to corrosive environment in square inches

T = exposure time in hours

The most common environmental factors that effect general corrosion are (1) acidity of environment, (2) oxygen and (3) temperature. The temperature is known to have a strong effect on corrosion rates as can be predicted by Faraday's law. The reaction rate with temperature relationship is predicted by the Arrhenius relationship where the corro-

sion rate approximately doubles every $10^\circ C$. This doubling (exponential relationship) of the corrosion rate is explained by the Arrhenius Equation [3]. This equation is presented below where k is the reaction rate and T is temperature.

$$k = k^0 e^{(nF/RT)}$$

The relationship between corrosion rate and temperature is illustrated in Figure 4.19.7.

The examples in Figure 4.19.7 are typical for 304 type austenitic stainless steel in sulfuric acid (Rate A) and nitric acid (Rate B). The difference between curves A and B in Figure 4.19.7 was explained by Fontana [12] as being caused by the metal being in the passive state being close

FIGURE 4.19.7 Effect of rate on corrosion rate [12].

FIGURE 4.19.8 Prediction of corrosion limit or life based on idealized corrosion rates.

to the transpassive region (see Figure 4.19.3) in nitric acid. As the temperature rises, the oxidizing power increases until the stainless becomes transpassive and, once transpassive, the corrosion rate increases exponentially.

The Arrhenius relationship is the basis for predictive corrosion rate tests. An example would be weight loss corrosion measurements conducted at lower temperatures being used to predict corrosion rates at higher temperatures. The converse is also true, the life of a structure as predicted by metal loss can be predicted at lower temperature by conducting accelerated corrosion experiments at higher temperatures. This permits the measuring of corrosion rates over days and weeks to predict product or structure life in years. An example of such an experiment to yield predictive corrosion rates is presented in Figure 4.19.8.

Using Figure 4.19.8 as the model, it is possible to have physical measurements of corrosion rates (and, therefore, predicted corrosion loss over a period of time) at high temperatures. For example, the estimated useful life due to general corrosion could be measured to be 120 days, 60 days and 30 days respectively at 70°C, 80°C, and 90°C. The resultant relationship could be used to predict an approximate useful life of 2000 days at 30°C without waiting for 2000 days (almost 5½ years) for test results.

Acidity has a tremendous effect on corrosion in materials. This effect is illustrated below in Figure 4.19.9 for mild steel at two temperatures.

The last factor considered here that is noted for its effect on general corrosion is oxygen, where even minute quantities can have devastating effect on material structures.

FIGURE 4.19.9 Effect of pH on corrosion of mild steel [13].

An example of the effect of oxygen is presented in Figure 4.19.10.

Oxygen plays a pivotal role in many forms of corrosion including general corrosion. The primary effect is that a new cathodic reaction is introduced: the oxygen reduction reaction:

4.19.2.2 Pitting Corrosion

There are several forms of localized corrosion; the first type considered here is pitting corrosion. Pitting is one type of corrosion that is normally manifested in materials that are passive in a particular environment and are, therefore, considered to be corrosion resistant. Pitting corrosion is a type of localized corrosion that is one of the first that is considered since it limits the applications of many corrosion resistant alloys and is the cause of many product failures. General corrosion, as was previously discussed, is readily understood and predicted. Conversely, pitting corrosion can

occur when not expected and can exhibit relatively unpredictable propagation rates.

Pitting corrosion occurs in two stages, pit initiation and pit growth. There have been numerous studies on pitting corrosion [15–17]. The initiation stage has been reported by Gellings [3] to usually be on the order of several months.

Corrosion pits vary in size, depth and frequency. The shape (size and depth) of pits have been quantified by measurements of the ratio of the depth to the width. A pitting factor is sometimes defined as the ratio of the deepest pit depth to the average pit depth [9], this is presented in the next equation.

$$\text{Pitting factor} = P/d$$

where P = deepest metal penetration
d = average metal penetration

A pitting factor of 1 would indicate general corrosion where the larger the pitting factor the more severe the pitting corrosion. The application of this pitting factor is demonstrated in Figure 4.19.11.

FIGURE 4.19.10 Effect of oxygen content on the corrosion rate of steel [14].

FIGURE 4.19.11 Sketch of deepest pit with relation to average metal penetration and the pitting factor [9].

The insidious problem with pits is that the pit surface could be covered with corrosion products or be as small as a pinhole but with great depth. These features, when pitting occurs in this manner, renders the pitting attack extremely difficult to detect.

From the environmental details, it has been noted that chloride ions and oxidizing agents such as Cu^{+2} and Fe^{+3} salts frequently are associated with pitting. It is also known that hydroxides, chromates and silicates often inhibit the formation of pitting [3].

The material composition and processing history also influence the occurrence and severity of pitting. We know, for example, that austenitic stainless steels are generally known to be susceptible to pitting corrosion. We also know that inhomogeneities such as secondary phases, inclusions, banding, segregation etc., can be the driving factor in pitting initiation. Table 4.19.2 summarizes geometric and material attributes that can lead to localized corrosion.

There have been several relationships developed that relate the composition of iron based corrosion resistant alloys to the relative pitting resistance in the presence of dissolved chlorides and oxygen (salt solutions such as salt water). The PREN relationship that exists in the ISO Standard 15156 [19] is presented below:

$$\text{PREN} = W_{\text{Cr}} + 3.3(W_{\text{Mo}} + 0.5W_{\text{w}}) + 16W_{\text{N}}$$

where W_{Cr} is the chromium content (% of total composition)

W_{Mo} is the molybdenum content (% of total composition)

W_{W} is the tungsten content (% of total composition)

W_{N} is the nitrogen content (% of total composition)

These percentages are based on the mass fraction of chromium in the alloy expressed as a percentage of the total composition. An example of a PREN calculation for a duplex stainless steel such as UNS S399377 with 24.8% nitrogen would yield the following result:

$$\text{PREN} = 24.8 + 3.3 \times (2.5 + 0.5 \times 1.1) + 16 \times 0.28$$

$$\text{PREN} = 24.8 + 10.1 + 4.5 = 39.4$$

This 39.4 value of the PREN can be used to match up with design criteria or compare with other alloys to rank relative pitting resistance. A note of caution for the PREN relationship presented here is that the relationship was developed for stainless steels and the relationship may not be a good predictor of relative ranking when the alloys being compared includes other types of alloys such as nickel base alloys.

TABLE 4.19.2 Geometric Factors and Heterogeneities in Relation to Localized Attack [18]

System	Metal Area which is Predominantly Anodic*
<i>Metal</i> Dissimilar metals in contact.	Metal which is more reactive in a given solution (i.e., metal which has a greater tendency to ionize).
Crevices, deposits on metal surface or any geometrical configuration which result in differences in the concentration of oxygen or other cathodic depolarizers (e.g., Cu^{2+}).	Metal in contact with the lower concentration—this follows from considerations of an equivalent reversible cell, although the situation is more complex in practice.
Differences in metallurgical structure	Grain boundaries, more reactive phases (solid solutions, intermetallic compounds, etc.).
Differences in metallurgical condition due to thermal or mechanical treatment.	Cold worked areas anodic to annealed areas, metal subjected to external stress anodic to unstressed metal.
Discontinuities in conducting oxide film or scale or discontinuities in applied metallic or non-metallic coatings.	Exposed substrate (provide that this is more electrochemically active than the coating).
<i>Environment</i>	Metal in contact with lower concentration.
Differences in aeration or concentration of cathodic depolarizers.	
Differences in velocity.	Metal in contact with solution of higher velocity.
Differences in pH or salt concentration.	Metal in contact with the solution of lower pH or higher salt concentration.

*The table gives a general indication of the area which is likely to be anodic. There are many exceptions, e.g., grain boundaries can be cathodic, the area of metal in contact with a higher salt concentration will be cathodic if the oxygen concentration is higher, etc.

From the above relationship, the higher the PREN number, the higher the resistance to pitting corrosion. Also, we can see the beneficial effect of elements such as chromium, molybdenum, tungsten and nitrogen on pitting corrosion resistance.

To mitigate the effects of pitting corrosion, we can select alloys that exhibit a higher PREN number. Other ways to prevent or minimize pitting attack include modifying the environment (e.g., lowering the pH), increasing the flow velocity (preventing stagnant conditions) and lowering the temperature.

For most metals there is a critical temperature below which pitting does not occur. This temperature is dependent on the material composition and the specific environment. For stainless steels, the critical pitting temperature is related to the PREN number as expressed earlier.

4.19.2.3 Ringworm Corrosion

A type of corrosion that is found in oil and gas production environments that is a form of localized corrosion is ringworm corrosion. This corrosion is related to pitting corrosion and galvanic corrosion. There are localized pits or corrosion attack that occurs circumferentially near the upset of a tubular section such as drill pipe. An example of this type of corrosion is presented in Figure 4.19.12.

Many tubular products such as drill pipe with upset end regions (hot forged) have a region adjacent to the upset that, if not re-heat treated, leaves it in a metallurgical condition

FIGURE 4.19.12 “Ringworm” corrosion—at the inside of the tubing where grain structure near edge of upset portion makes metal susceptible to rapid corrosion [13].

that differs greatly from the remainder of the drill pipe structure. This localized condition is more anodic and more susceptible to corrosion attack.

The susceptible metallurgical condition results from the thermal gradients of these hot-forming operations. This condition occurs in a narrow band that corrodes preferentially.

4.19.2.4 Crevice Corrosion

Crevice corrosion is a form of localized corrosion attack where the corrosion takes place between adjoining surfaces such as made-up threaded and flanged connections, beneath metal banding and thread protectors, and even beneath scale and corrosion deposits. This type of localized corrosion occurs very similarly to pitting corrosion except that the geometric effects of the crevice influence the initiation and propagation of the attack.

Crevice corrosion is differentiated from pitting corrosion in that the initiation phase is different [20]. Localized variations in the environment cause potential differences and result in local breakdown of passive films and accelerated corrosion. Crevice corrosion has been related to differences in oxygen content commonly known as differential aeration by Gelling [3] and Trethewey and Chamberlain [20]. Oxygen is consumed within the crevice during even low levels of corrosion and the oxygen becomes depleted because the crevice geometry prevents bulk fluid transfer into the crevice (this is a stagnant condition).

In itself, the depleted oxygen does not cause corrosion. Inside the crevice, when even low levels of corrosion occur, there is a corresponding increase in dissolved metal ions and chloride ions (in chloride containing environments). These local changes in the environment result in a decrease in the pH locally thus increasing the aggressiveness of the environment with respect of corrosion. These local changes in the environment cause increased corrosion rates and, since the oxygen is depleted, the damaged surface oxide films providing corrosion protection do not reform or are very sluggish to form. This further accelerates the localized corrosion.

Two examples of crevice type corrosion beneath surface scale and in a crevice are presented in Figures 4.19.13 and 4.19.14, respectively.

In Figure 4.19.13, there is a crevice and differential aeration cell between the iron rust and the iron basemetal.

Crevice corrosion can be avoided or minimized primarily by changing the geometry (first choice) or by selecting a material that is more resistant to corrosion in the intended environment. The material factors that increase a metal’s resistance to pitting corrosion are essentially identical to those factors that increase resistance to crevice corrosion. This means that the equations defined in the discussion on pitting corrosion also apply to crevice corrosion.

FIGURE 4.19.13 Differential aeration cell formed by rust on iron [21].

FIGURE 4.19.14 Crevice corrosion [9].

The temperature factor in pitting corrosion also has a corollary in crevice corrosion. An increase in temperature results in an increased probability of the occurrence of crevice corrosion. There is also a temperature below which the likelihood of crevice corrosion is very low.

The above discussion infers that the risk of crevice corrosion can be minimized through materials selection for the intended environment. The following, list, adopted from Fontana [12] describes methods and procedures related to design that are used to prevent or minimize crevice corrosion:

1. Use welded butt joints instead of riveted or bolted joints in new equipment. Sound welds and complete penetration are necessary to avoid introducing an additional crevice source.
2. Close crevices by using continuous welds, caulk, braze, solder or paint.
3. Avoid stagnant areas and design for complete drainage.
4. Remove scale and other deposits. Remove solids to prevent deposit formation, a source of crevices.
5. Remove wet packing materials during long shutdowns.
6. Provide as uniform an environment as possible such as using backfill materials in pipeline trenching.
7. Weld instead rolling in tubes in tube sheets.

4.19.2.5 Galvanic Corrosion

Galvanic corrosion occurs as a result of electrical contact between two dissimilar metals in an electrically conductive environment (electrolyte). This is depicted in the schematic presented in Figure 4.19.15.

In Figure 4.19.15, the active metal (anodic) is being corroded starting at the connection or interface with the more noble (cathodic) metal.

The factors affecting galvanic corrosion are related to material and geometry. To predict galvanic corrosion, these two areas need to be examined.

From a materials consideration, the electrochemical (or galvanic) differences between the material being coupled is the characteristic evaluated with the basic benchmark being the relative position on the galvanic scale. The value of the material in question is dependent on the specific environment; for example, this is illustrated in Figure 4.19.16 for the galvanic series in seawater and Table 4.19.3 for the galvanic series in neutral water and soil.

The galvanic series, as can be seen from Figure 4.19.16 in seawater and Table 4.19.3 in neutral water, varies with the environment. The position of a specific material may exhibit a shift in the relative position with respect to other materials from one environment to another. Generally, the greater the galvanic difference between two adjoining materials, the greater the likelihood that galvanic corrosion will occur.

In geometric effects, the three factors are relative surface areas, distance between the different materials and shape effects. The greater the ratio of cathodic (more noble) to anodic (less noble) surface area, the greater the likelihood that galvanic corrosion will occur. The driving force here is the increasing anodic current density with greater ratios resulting in greater polarization. An anodic surface area that is greater than the cathodic area results in small or no accelerated galvanic effects because of the predominant polarization of the more noble material [11].

The closer two dissimilar materials are, the greater the potential for galvanic effects between them. The most severe anticipated galvanic effects are in the less noble

FIGURE 4.19.15 Galvanic corrosion.

material immediately adjacent to the more noble material, this characteristic is depicted in Figure 4.19.15. Another factor that can further reduce potential galvanic effects as it relates to distance is solution conductivity because the current flow through the electrolyte is the relevant feature and decreasing current flow decreases potential galvanic effects.

The geometry enters into the evaluation of the galvanic effects because current flows through the path of least resistance, this means that the current will not readily flow around corners. This and the previously discussed distance relationships illustrate that galvanic effects are adjacent effects and are essentially line of sight.

4.19.2.6 Erosion Corrosion

Erosion corrosion is the combined effect of corrosion under the influence of mechanical action in the form of fluid flow. Passive metals generally rely on corrosion resistance through protective surface films. When these films are disturbed or removed, the surface is active for at least the time required to form a new surface film; the surface could also remain active with corrosion as a result. The continued action of surface film removal through fluid flow results in attack that appears as grooves or waves that exhibit a directional pattern in accordance with the direction of fluid flow. This is illustrated in Figure 4.19.17.

Because erosion corrosion is strongly influenced by fluid flow characteristics, there are critical velocities that are dependent on specific materials and environments below which erosion corrosion does not occur. Corrosion rates of various metals in flowing seawater at three velocities are presented in Table 4.19.4 to illustrate this phenomenon.

From Table 4.19.4, the effect of flow rate on corrosion rates can be seen. The critical velocity usually occurs at a specific level that is also presented in Figure 4.19.18.

This critical velocity can be estimated by knowing when a specific fluid flow becomes turbulent. The critical velocity can be calculated by the equation presented in API RP 14E [23] which is

$$V_e = \frac{C}{\sqrt{P}}$$

The critical (or erosion) velocity is related in the above equation to a constant divided by the square root of the fluid density. Erosion corrosion has been observed on a variety of equipment in flowing fluids including components of pipe and tube (especially in changes of direction), nozzles, production and drilling chokes, valves, pumps, blowers, propellers, turbine blades, compressors, mud motors, and drilling products such as rock bits.

In addition to limiting the application for a material in an environment (velocity limitation), we can also reduce or avoid erosion corrosion by (1) using materials with better corrosion resistance, (2) designing to avoid flow restrictions or abrupt changes in flow direction, (3) minimize

FIGURE 4.19.17 Schematic of Erosion Corrosion.

TABLE 4.19.4 Erosion Corrosion Rates in Flowing Seawater (after J.R. Davis¹¹)

Material	Typical Corrosion Rates, mg/dm ² /day		
	0.3 m/s (1 ft/s)	1.2 m/s (4 ft/s)	8.2 m/s (27 ft/s)

protrusions into the flow stream that could change flow rates by introducing turbulent flow, (4) change the environment to reduce the corrosivity, (5) add corrosion inhibitors, (6) modify environment by filtering to remove solids, and (7) use corrosion resistant coatings or hardsurfacings.

4.19.2.7 Cavitation

Cavitation is a type of corrosion damage that is caused by the collapse of vapor bubbles in a liquid on or adjacent to a metal surface. When the vapor bubbles burst, there is energy released in the form of a shock wave that can destroy protective corrosion resistant films on metal sur-

faces. A schematic of this type of damage is presented in [Figure 4.19.19](#).

Cavitation has been observed in production and drilling chokes, mud motors and drilling mud pumps. Cavitation damage can be minimized or avoided by designing to reduce hydrodynamic pressure differences, coating metals with rubber or plastic and using more corrosion resistant alloys.

4.19.2.8 Fretting Corrosion

Fretting corrosion occurs in contact areas between two surfaces that are subjected to small magnitudes of relative

FIGURE 4.19.19 Cavitation corrosion [8].

motion in an environment that is corrosive to at least one of the mating surfaces. In a manner very similar to other mechanical interactions with a corrosion mechanism, the surface protective layer is disturbed by the contact causing accelerated localized corrosion. In order for fretting corrosion to occur, the interface must be under stress, relative motion between two surfaces must occur such as in vibrating motion and the stress and vibration must be great enough to deform the surfaces [5]. A schematic of fretting corrosion is presented in Figure 4.19.20.

The mechanism of fretting corrosion involves either the previously noted disruption of the protective surface films or oxidization/corrosion of wear debris. Fretting corrosion may be avoided or reduced by (1) surface coatings, (2) lubrication, (3) increasing surface hardness, (4) using gaskets to absorb vibrational movement, (5) increasing relative motion between surfaces, and (6) decreasing contact stress. These mitigation techniques are the same as those used to reduce the occurrence of adhesive type wear (galling).

4.19.2.9 Corrosion Fatigue

The combination of corrosion and the extended application of cyclical stresses can result in the mechanism known as

corrosion fatigue. In fatigue situations for steels under non-corrosive conditions, we find that there is a stress level at which fatigue does not occur; this is known as the endurance limit. Conversely, for non-ferrous alloys, we find that there is no endurance limit. In situations where there are stress concentrations resulting from sharp radii (notches etc.) or material defects such as existing cracks, we discover that the fatigue life is depressed or decreased under all stress conditions. These relationships are typically illustrated through plots of number of cycles to failure against stress, the stress is usually expressed as the highest tensile stress level in alternating or changing stress levels. An example of a life-stress plot for these fatigue relationships in the absence of a corrosion mechanism is presented in Figure 4.19.21.

In moderate to low strength steels, we typically find that this endurance limit is in the range of $\frac{1}{2}$ of the tensile strength [24]. Fatigue can occur as the result of cyclical tensile stresses (lower and higher tensile stresses) as well as stresses reversals where the stress cycles between a zero or compressive stress state and a tensile stress state.

Corrosion has large effects on fatigue resistance. Corrosion mechanisms affect fatigue by simultaneously providing notches/defects that result in earlier fatigue crack initiation and decreasing resistance to fatigue propagation though the

FIGURE 4.19.20 Schematic of fretting corrosion (horizontal arrows depict relative motion).

FIGURE 4.19.21 Fatigue behavior of ferrous and nonferrous alloys [10].

cyclical formation and break-down of protective surface films during cyclical stress cycles and the harmful effects of absorbed hydrogen. An example of a corrosion related site that provides a notch is a corrosion pit.

The result of increasing environmental severity and the resultant corrosion on fatigue life is presented in Figure 4.19.22.

One important indicator or measure of environmental severity is the pH or acidity of the environment. In

an aerated saltwater environment, increasing acidity or decreasing pH results in concurrent decreases in fatigue life as presented in Figure 4.19.23.

Corrosion fatigue can be minimized or prevented by (1) reducing the stress through design or operation, (2) increasing material tensile strength, (3) selection of a more corrosion resistant alloy, (4) coatings, (5) limiting applications to environments where the potential for corrosion is low, and (6) corrosion inhibition.

FIGURE 4.19.22 Effect of corrosive environment on fatigue life [25].

FIGURE 4.19.23 Effect of pH on corrosion fatigue in aerated saltwater [26].

4.19.2.10 Stress Corrosion Cracking

Stress corrosion cracking occurs when a susceptible material is subjected to an environment that causes stress corrosion cracking and the application of a tensile stress. There are a set or sets of environmental conditions in which most metals can exhibit stress corrosion cracking. Some examples of specific types of metals and the environmental constituents that can lead to stress corrosion cracking are presented in Table 4.19.5.

From the earlier examples, we can note that material strength level, applied stress, acidity, temperature, and specific agent concentration are frequently important or controlling factors in stress corrosion cracking.

Many mechanisms have been proposed to explain the phenomena of stress corrosion cracking. The identification of the mechanism is complicated because there are a variety of processes and conditions that can cause stress corrosion cracking. For example, we know that stress corrosion

TABLE 4.19.5 Metals and Stress Corrosion Cracking (SCC)

Metal	Environment	Factors that increase risk of SCC
Steels	Hydrogen sulfide	Increasing H ₂ S, moderate temperatures, more acidic, higher strength/hardness, higher stress levels
Steels	Carbonates	Higher strength
Steels	Chlorides	Higher strength, higher stress levels, more acidic
Brass	Ammonia	Higher strength, higher stress levels
Martensitic stainless steels	Hydrogen sulfide	Increasing H ₂ S, moderate temperatures, more acidic, higher strength/hardness, higher stress levels
Austenitic and stainless steels	Chlorides	Higher strength, higher chloride, higher stress levels, more acidic, higher temperatures, presence of H ₂ S
Duplex stainless steels	Chlorides	Higher strength, higher chloride, higher stress levels, more acidic, moderate temperatures, presence of H ₂ S
Titanium	Alcohol	Higher stress levels, lower water content

cracking can occur as result of either anodic or or cathodic corrosion reactions; it is also possible to have both anodic and cathodic reactions promoting stress corrosion cracking simultaneously. One or more of the following environmental reactions between the material and the environment has been proposed as an essential step in stress corrosion cracking [27]: adsorption of environmental species, surface reactions, reactions in the metal ahead of the crack tip and surface films. From these essential reactions, the following potential list of rate-determining steps have been proposed [27]:

1. Mass transport along the crack to or away from the crack tip
2. Reactions in the solution near the crack
3. Surface adsorption at or near the crack tip
4. Surface diffusion
5. Surface reactions
6. Absorption into the bulk
7. Bulk diffusion to the plastic zone ahead of the advancing crack
8. Chemical reactions in the bulk
9. The rate of interatomic bond rupture

In addition to a specific alloy type and the strength/hardness level listed as a factor in Table 4.19.5, there are other metallurgical variables that include grain size, thermal processing history, additional solid phases that may be present in the matrix or in the grain boundary,

concentration of impurities, and segregation of alloying constituents including impurities.

Most stress corrosion cracking typically occurs in three stages: Stage 1 — Initiation, Stage 2 — steady-state crack propagation, and stage 3 — rapid crack propagation or final fracture. The stress below which stress corrosion cracking does not occur is known as the threshold stress intensity. These stages in stress corrosion cracking and the threshold stress intensity are presented in Figure 4.19.24.

For each alloy and condition under a specific set of environmental conditions there is a threshold stress intensity below which stress corrosion cracking will not occur. The stress intensity is effected by bulk applied stress, stress concentration factors, and residual stresses. Values of this stress intensity have been reported to be as low as 10% of the yield strength [8].

There are a number of ways to prevent stress corrosion cracking. The following list is presented as examples of mitigation techniques.

1. Change the material to one that is more resistant to SCC under the specific environmental conditions.
2. Avoid the metallurgical characteristics of the chosen material that could lead to SCC. These include avoiding susceptible microstructures and phases and reducing material stress levels.
3. Alter the environment to reduce the potential for SCC. Examples of altering the environment include adjusting

FIGURE 4.19.24 Schematic of the stages of stress corrosion cracking.

the pH, limiting or changing the operating temperature, reduction of the environmental agents that promote SCC and the addition of corrosion inhibitors.

4. Apply anodic or cathodic protection to change the potential out of the critical range where SCC occurs. Caution, for SCC, the application of an anodic potential may accelerate the cracking.
5. Use metallic or nonmetallic coatings as barriers to the corrosive environment or that are resistant to the corrosion/stress corrosion cracking mechanisms.
6. Reduce stresses by reduction of operating stresses, avoiding stress concentrations and introducing beneficial compressive stresses.

4.19.2.11 Hydrogen-Induced Cracking

There are many forms of damage that occur as a result of hydrogen. These are typically categorized by the role of stress in the mechanism. The three types of damage that are observed are (1) hydrogen induced cracking (HIC), (2) stress-oriented hydrogen induced cracking (SOHIC), and (3) sulfide stress cracking (SSC). In HIC, the externally applied stress is low and does not interact with the cracking mechanism. In SOHIC, this is essentially the same as HIC except that the external stress influences the orientation or direction of the crack propagation. In SSC, the stress is an integral component of the cracking mechanism and does not occur without the application of applied stress.

In HIC, failures can occur at applied stress levels that are a fraction of the yield strength. For example, there have been many well-documented [28] failures due to HIC in low strength pipeline steels in gas transmission lines containing H₂S.

Hydrogen is evolved during corrosion reactions and hydrogen sulfide plays a pivotal role in hydrogen-related damage mechanisms. The hydrogen evolved is mono-atomic or nascent hydrogen and its recombination into molecular hydrogen is inhibited or poisoned by the hydrogen sulfide. The result of this inhibited reaction is greater quantities of the mono-atomic hydrogen that readily diffuses into the metal lattice; the size of the mono-atomic hydrogen is minute and moves easily through metal structures. The reactions of hydrogen sulfide and iron are presented below:

The second reaction above is inhibited or poisoned.

There are several theories that explain the various types of hydrogen damage [1]. Although numerous models and theories exist with respect to HIC, the phenomenon of trapping best quantifies the metal susceptibility to hydrogen

damage [29, 30]. A crack occurs when the atomic hydrogen migrates to one of these trap sites and then becomes “trapped.”

We know that inclusions, especially elongated manganese sulfide inclusions, increase susceptibility to HIC damage. The other known major factor is alloy segregation in the form of banding. Banding is particularly a problem in plate and pipe formed from plate products but can be seen in seamless pipe as well.

To avoid HIC, clean steels with uniform microstructures have the best resistance to this form of cracking. There are standard tests that are used to assess a materials susceptibility to HIC, the most widely accepted standard test method is NACE’s TM-0284 [31].

4.19.2.12 Sulfide Stress Corrosion Cracking

Sulfide stress corrosion cracking, also known as sulfide stress cracking (SSC), is a stress corrosion cracking phenomena that occurs in the presence of hydrogen sulfide. Hydrogen sulfide is known to cause or assist in the mechanism of cracking with many alloy types including low carbon steels, low alloy steels, alloy steels, tool steels, martensitic stainless steels, ferritic stainless steels, austenitic stainless steels, duplex stainless steels, nickel-copper alloys, and nickel-base alloys. For many of these materials, there co-exists the potential for chloride stress corrosion cracking. The presence of hydrogen sulfide often increases the severity of the cracking or enlarges the range of environmental conditions where cracking occurs.

There are several competing mechanisms that result in SSC including internal hydrogen stressing, hydrogen embrittlement, stress corrosion cracking and combinations of these mechanisms. These competing mechanisms have complicated the identification of a universally accepted molecular mechanism that explains all of the observed phenomena.

The oil and gas industry has been actively developing reservoirs containing H₂S since the early 1950s [32]. The presence of numerous early failures resulted in large and widespread efforts to understand and mitigate the effects of H₂S on materials. The noteworthy characteristics of these failure were (1) they were brittle failures, (2) they occurred in relatively short periods of time, and (3) they were not expected by virtue of previous experience in environments that contained either no H₂S or very low levels of H₂S. Three examples of the brittle nature of these failures are presented in Figure 4.19.25.

The amount of H₂S that causes SSC is conditional on other environmental variables but the historical limit has been listed in NACE MR0175 as 0.05 psi partial pressure of H₂S [2, 32]. The environmental factors that influence the existence and extent of SSC include the following:

FIGURE 4.19.25 SSC failure, drillpipe (a); tubing failure (b); coupling (c) [14,22].

1. H₂S concentration
2. Acidity (pH)
3. Time
4. Temperature
5. Water content (also gas/oil ratio and solids content)
6. Chloride content
7. Oxygen content
8. Presence of elemental sulfur

The effects of these variables are interrelated and also very much conditional on the specific alloy, its condition and stress state. Though these effects are therefore complicated, we can explore the effects of some of these variables

in specific cases illustrating trends. Looking at the combination of time and H₂S concentration effects with material hardness we discover that increasing H₂S decreases the time to failure. Conversely, short time exposure can be successful at greater concentrations of H₂S. These relationships are presented in [Figure 4.19.26](#).

When examining the combined effects of time and acidity (pH), we discover that the time to failure decreases with decreasing pH in H₂S containing environments. The effect of pH with time is presented in [Figure 4.19.27](#).

Another way to illustrate the effects of pH is to examine the effect of pH on the critical stress (S_c); the critical stress is one measure of resistance to cracking and, the higher the number, the greater the resistance. This is presented in [Figure 4.19.28](#).

The relationship between the cracking potential and the pH and H₂S content have lead to a relationship between these and regions or domains of usage that apply to carbon and low alloy steels. These pH-H₂S domains have appeared in EFC Publication 17 [35] and NACE MR0175/ISO 15156 [2]. A sketch illustrating these domains is presented in [Figure 4.19.29](#).

Domain 0 in [Figure 4.19.29](#) is considered the region where SSC is not a factor in most carbon and low alloy steels. The environmental severity and, therefore, the care and level of material restriction increases with increasing Domain number. Domain 3 is the region of restrictions that match those historically impose by NACE MR0175/ISO 15156.

One of the other major factors that effects materials selection for cracking resistance for both corrosion resistant alloys (CRAs) and carbon and low alloy steels is temperature. For carbon and low alloy steels, it was observed that the incidences of failure seemed to be more prevalent at lower temperatures. An early investigation conducted by Townsend [36] on high-strength wire line steel revealed a maximum susceptibility to cracking near room temperature. The high strength steels are very susceptible to cracking and the tests conducted demonstrated, in relatively short periods of time, the effects of temperature. This relationship between temperature with environmental severity as measure by time to failure is presented in [Figure 4.19.30](#).

From [Figure 4.19.30](#), we can observe that very severe conditions exist for steels in temperatures below about 80 °C (175 °F). We can also see the effects that this relationship has had on material standards for oil country tubular goods (OCTG) for sour service (H₂S-containing environments). For example, NACE MR0175/ISO 15156 [2] permit the use of higher strength materials at high temperatures where the environment is not as severe. [Table 4.19.6](#) lists some of these OCTG grades and the minimum temperature they can be safely used.

This rationale is supported by laboratory data and experience and permits the use of increasingly less resistant

FIGURE 4.19.26 Approximate failure time of carbon steel in 5% NaCl and various parts per million of hydrogen sulfide [33].

FIGURE 4.19.27 Steel fails much less rapidly when pH is above 7 or 8 [33].

materials in less severe environments as defined by increasing temperature.

One other common variable that effects SSC is the type of oilfield environment that is encountered. Generally, corrosion rates increase with the amount of water present or being produced; the amount of water produced is known as the water cut. The base fluid being gas, oil or brine effects the severity of the environment with respect to cracking. Another early investigation [37] revealed that cracking was much more prevalent in a gas environment as opposed to an oil or brine environment. This relationship is presented in Figure 4.19.31 that correlated the percentage of failures with the hydrogen sulfide content in three distinct phases, brine, oil and gas.

There are numerous other factors that effect SSC such as the presence of oxygen and elemental sulfur that increase the severity of the environment. Care must be taken with materials selection when these are encountered.

4.19.2.13 Microbiologically Induced Corrosion (MIC)

Microorganisms are present throughout our environment. These organisms can result in corrosion by producing a deposit on metal surfaces and/or by increasing the acidity/reducing the pH of the environment. This altering of the environment can occur in the bulk or locally.

FIGURE 4.19.28 Effect of pH on H₂S cracking resistance [34].

There are two basic classes of microbes, anaerobic and aerobic microorganisms. Anaerobic microorganisms flourish in the absence of oxygen such as deep sea or downhole environments. Aerobic microorganisms require oxygen to survive and flourish and are found in all surface environments including salt and fresh waters.

One example of an anaerobic microorganism that is troublesome in the oilfield is the genus *Desulfovibrio*. This is a sulfate-reducing bacteria (SRB) and the resultant corrosion mechanism involves naturally occurring sulfates to hydrogen sulfide. The resultant acid from the hydrogen sulfide can cause or accelerate corrosion or cause HIC or SSC as discussed previously. A simplistic chemical mechanism illustrating corrosion attack on steel by SRB is presented in Figure 4.19.32.

There are many iron oxidizing types of bacteria such as *Gallionella* and *Crenothrix* that can accelerate corrosion by releasing carbon dioxide (CO₂) as one of the corrosion products as illustrated by the following equation.

The iron hydroxide (Fe(OH)₃) is not very soluble and will precipitate on the metal surface. These deposits can cause oxygen concentration cells resulting in corrosion beneath the deposits.

In addition to the bacteria examples mentioned previously, there are also molds, yeasts, algae, and protozoa. Molds, yeasts, algae, and protozoa can have a waste product that enhances corrosion or can result in slimes or deposits. Oxygen concentration cells and localized corrosion attack can result beneath these deposits.

There are a number of techniques used to prevent MIC; these involve modifying the environment or coatings. The environment can be adjusted to prevent growth of these microorganisms such as by adjusting pH (Figures 4.19.33 and 4.19.34), removal of nutrients, and the use of biocides. Coatings and films have been successfully used such as paints, platings, and filming inhibitors.

FIGURE 4.19.29 pH versus H₂S domain diagram.

FIGURE 4.19.30 Time to failure versus temperature for high strength steel in H₂S [34].

TABLE 4.19.6 OCTG Grade versus Safe Use Temperature in H₂S Containing Environments

OCTG Grade	Yield Strength Range, MPa (ksi)	Minimum Temperature
L80 type 1	552–655 (80.0–95.0)	No minimum
C90 type 1	621–724 (90.0–105.0)	No minimum
T95 type 1	655–758 (95.0–110.0)	No minimum
C95 type 1	655–758 (95.0–110.0)	65 °C (150 °F)
P110	758–965 (110.0–140.0)	80 °C (175 °F)
Q125 type 1	862–1034 (125.0–150.0)	107 °C (225 °F)

4.19.3 Oilfield Environments

The concentration of acid gases is related to pH and an illustration of the relationship between them is presented in Figure 4.19.34.

Carbon dioxide is usually associated more with direct effects on corrosion. Carbon dioxide in water results in carbonic acid (a weak acid) and a CO₂ partial pressure

of 1 bar (15 psi) lowers the pH of pure water at 60°C (125°F) to 3.8 [39]. The characteristics of CO₂ corrosion are complex because of the semi-protective nature of the corrosion products. This is contrasted with H₂S where the corrosion products are generally more protective in nature. As discussed previously, the composition and stability of the corrosion products are controlled by pH and temperature.

DeWaard and Milliams [40] published early work in 1975 that became the basis for subsequent models relating corrosion rates to a variety of oilfield conditions. An early nomograph is presented in Figure 4.19.35.

Since that early work, much progress has been made refining these relationships taking into account the stability of protective corrosion product films. The corrosion rate of steels in CO₂-containing oilfield environments as a function of partial pressure of CO₂ and temperature is presented in Figure 4.19.36.

Hydrogen sulfide also has a similar effect on the corrosion rate of steels. The effect of H₂S concentration on the corrosion rate of steel is presented in Figure 4.19.37.

The effect of H₂S when combined with CO₂ is complicated by the interaction of the sulfide corrosion products with the carbonate corrosion products. The sulfide corrosion products from the H₂S often increase the stability of the surface film thereby reducing the corrosion rate.

FIGURE 4.19.31 Relationship between percentage failures in steels and H₂S content in brine, oil, and gas phases [37].

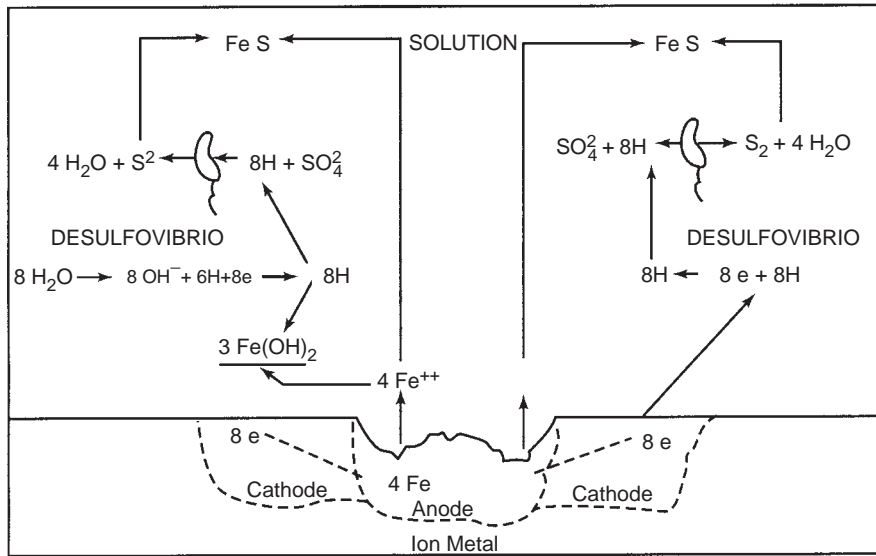

FIGURE 4.19.32 Diagram of polarization of local cathode by a film of hydrogen gas bubbles (cathodic area to right of anode is polarized) [38].

4.19.3.1 Corrosion Effects of Temperature, Flow Rates, and Chlorides

In CO₂ corrosion on steels, the effect of temperature is illustrated in Figure 4.19.36. The relationship shown here is only valid for the specific environment and this relationship is strongly influenced by other environmental constituents that cause/effect corrosion such as hydrogen sulfide, sulfates and chlorides that generally increase corrosion rates and carbonates, bicarbonates and alkalis that generally decrease

corrosion rates. Chlorides effect general corrosion rates by changing the stability of corrosion products and interference with the formation of protective oxides. The effect of sulfates, chlorides and bicarbonates on steel corrosion is demonstrated by the trends presented in Figure 4.19.38.

At high temperatures, chlorides can also destroy the passivity of many corrosion resistant alloys such as the stainless steels resulting in localized corrosion attack and increased general corrosion rates.

FIGURE 4.19.33 Effect of pH on corrosion rate.

FIGURE 4.19.34 Simplified relationship between pH and corrosion rate (steel with CO₂ at 93 °C [200 °F]).

4.19.3.2 Environments Causing Cracking

The oil field has a diverse list of potential environments that can cause cracking as well as corrosion. In production operations, we can have heavy brines, production gases/fluids including H₂S and CO₂, chlorides, organic acids and elemental sulfur. In drilling operations, we can have alkaline (high pH) drilling fluids, brines and the exposure with production fluids. In well stimulation and workover operations, we can have acids (hydrochloric, fluoric and organic) and oxygen. It is this diverse nature that complicates the mitigation of corrosion and environmental cracking.

The risk of environmental cracking is a function of the material and the stresses (service and residual) as well as the severity of the environment. There are a number of oil field environments that can cause cracking in susceptible materials. For example, on one end of the spectrum, we

have ultra high strength steels that, if improperly processed could exhibit environmental cracking in mild salt containing environments. These high strength steels can crack in carbonate containing environments and highly alkaline environments. On the other end of the spectrum, we have hot salty gas-water systems that contain elemental sulfur that can cause cracking in many of the normally crack resistant alloys.

High pH drilling fluids can cause SCC in high strength steels. The factors that increase susceptibility (decreasing life) are increasing temperature, increasing stress level and increasing the alkali concentration (increasing pH). The effect of temperature and alkali concentration (NaOH) on SCC cracking of steels is presented in Figure 4.19.39.

The effects of hydrogen sulfide on sulfide stress corrosion and hydrogen induced cracking we discussed

FIGURE 4.19.35 Calculation of corrosion rate as a function of temperature and CO₂ [40].

FIGURE 4.19.36 Effect of temperature on CO₂ corrosion [41].

previously. We can add to this by adding a discussion on chlorides, elemental sulfur and oxygen.

The chlorides are known to cause stress corrosion cracking in stainless steels at elevated temperatures. The potential

FIGURE 4.19.37 Corrosion rate of mild steel in distilled water containing varying concentrations of hydrogen sulfide [26].

for SCC increases with increasing temperature, stress and chloride content. The potential for SCC can be influenced by the presence of hydrogen sulfide and even small amount of oxygen or elemental sulfur has a dramatic negative effect on susceptibility to SCC.

FIGURE 4.19.38 Influence of sulfate, chloride and bicarbonate on the corrosion of steel [26].

FIGURE 4.19.39 Effect of temperature and concentration on alkali SCC cracking of steel [14].

4.19.3.3 Petroleum Phases (Oil, Gas and Water)

Corrosion occurs as a result of contact with water phases that may contain one or more potential corrodents. The corrosion rates generally increase with increasing water content (also known as water cut). When water is present with a gas phase, the gases dissolve in the water and this acidifies the water. A gas phase that contains a small water fraction could be more corrosive due to its acidified nature.

Other phases, such as brines and oil have varying effects on corrosion. Oil phases typically reduce corrosion rates and

when the oil is present in sufficient enough quantities, the metal surfaces in contact with the petroleum fluid(s) will be wetted with oil. This results in an oil film barrier. The corrosion rates (and cracking tendencies) are dramatically reduced when the contacting phase is oil.

Brines have a mixed corrosion relationship. Generally, by themselves, brines may be very corrosive, and corrosion rates may increase with increasing brines content; this is especially true of some of the heavy acid brines such as zinc bromide. The other effect of brines is the reduction of gas solubility; as the brine's salt content increases, the

solubility of acid gases decreases. The end result is less acid gas present to lower pH and increase corrosion rates. The effect of brines, gas, and oil on the failure rate of steels with increasing H₂S contents was presented previously in Figure 4.19.31.

4.19.3.4 Injected Fluids (Drilling Fluids, Oxygen and Acids)

Drilling fluids are comprised of many potential constituents. The drilling fluid could be water based, oil based or synthetic based. Brines are a form of water-based fluids. The fluids could have the pH adjusted to high levels with the use of alkalis such as sodium and potassium hydroxide. The role of the drilling fluid on corrosion is related to many factors, including the pH, the chloride content, and the oxygen content.

Two of common failure modes in drill strings are fatigue and corrosion fatigue. An example of a corrosion related affect is increasing chloride contents decrease the fatigue life in drilling fluids. Figures 4.19.40, 4.19.41 and 4.19.42 summarizes the corrosion fatigue tests conducted by Azar [42] that related chloride content to fatigue life in different drilling fluids.

The highest corrosion rates are found in corrosive systems in the presence of even minute quantities of oxygen. Oxygen has anodic and cathodic effects in that it acts as a cathodic depolarizer and an anodic polarizer. Oxygen accelerates corrosion due to other corrodents such as CO₂, H₂S, salt solutions, and injected mineral acids.

FIGURE 4.19.40 Chloride fatigue test—dispersed lignosulfonate mud, 9.5 pH [42].

FIGURE 4.19.41 Chloride fatigue test—nondispersed bentonite mud, 8.5 pH [42].

FIGURE 4.19.42 Chloride fatigue test—nondispersed bentonite mud, 9.5 pH [42].

In drilling operations, the fluids used in drilling are exposed to air and this leads to oxygen being dissolved in the drilling fluid. This dissolved oxygen with chlorides increases corrosion as previously presented in Figure 4.19.10 and as presented below in Figure 4.19.43.

FIGURE 4.19.43 Corrosion in sodium chloride solution containing dissolved oxygen [26].

The effect of oxygen was found to be linear with the range and conditions in Figure 4.19.43 but this is not typical. Oxygen also decreases corrosion fatigue life. Corrosion fatigue tests have been conducted by Azar [42] demonstrating the relationship between oxygen content and fatigue life in drilling muds. This data is presented in Figures 4.19.44 and 4.19.45.

An additional problem exists when the injected oxygen containing fluid mixes with production fluids that may contain acid gases. When H₂S is present, the oxygen could reduce the hydrogen sulfide to elemental sulfur with potential drastically increased environment severity. When combined with CO₂ even at low parts per million (ppm) levels, the corrosion rates increase dramatically. An example of the effect of small oxygen contents on the corrosion rate of steel with CO₂ is presented in Figure 4.19.46.

Acids can result in very rapid corrosion rates and they can render normally passive materials active. When passive materials become active, there can be localized as well as general corrosion. One risk in many downhole anaerobic conditions is that the active pits may not re-passivate when the acids are no longer in contact with the metal.

Mineral acids are often injected to stimulate production by cleaning out formations. These acids are typically hydrochloric acid or a mixture of hydrochloric and hydrofluoric acids. These mineral acids are very corrosive at ambient temperatures and the increase in temperature in downhole environments can render the acid attack even more aggressive. The effect of temperature on corrosion

FIGURE 4.19.44 Oxygen fatigue test—lignosulfonate mud, 9.5, pH [42].

rates was previously discussed and the relationship can be seen in Figures 4.19.7 and 4.19.8.

These acids are most often inhibited to prevent corrosion on tubing string but the inhibitor used may not be effective in the specific downhole condition, not protective against

FIGURE 4.19.45 Oxygen fatigue test—nondispersed mud, 8.5 pH [42].

one of the materials of construction used or may cause corrosion by the flow of spend acid where the inhibitor is no longer present or effective.

4.19.4 Drilling and Well Completion Equipment and Materials

In this segment of the oil and gas industry, the following tools are discussed with the typical materials of construction and types of corrosion problems encountered: drill pipe, collars, tool joints, stabilizers, drilling jars, drill bits,

milling tools, mud motors, cementing equipment, casing, tool joints, coiled tubing, blow-out preventers (BOPs), and drilling risers.

4.19.4.1 Drill String Components

The drill string serves the purposes of conducting drilling fluids to the drilling bit, conducting rotational forces to the drill bit, controlling the amount of weight on bit and providing an annulus space between the formation or casing and the drill string to allow for removal of cuttings and drilling fluids. Components that fit into the drill string include drill pipe, drill collars, stabilizers, tool joints, jars, and miscellaneous crossovers and subs. The two basic types of tubulars are the drill pipe itself and drill collars. The drill pipe is composed of the pipe body and either integrally forged (upset) connections or forged and welded-on tool joints.

The typical materials of construction for drill pipe, stabilizers, collars, and tool joints are chromium — molybdenum (Cr-Mo) low alloy steels in the quenched and tempered condition such as specific alloys 4135, 4140, and 4145. There has also been some use of aluminum drill pipe and nonmagnetic collars and subs made from beryllium copper and austenitic type stainless steels.

In drilling environments, the corrosion is typically minimized through the use of pH control, inhibitors and/or the use of natural or synthetic oil based fluids. Corrosion when the controlled drilling environment is functioning as designed is generally not a concern except in some cases of stress corrosion cracking and hydrogen embrittlement in very high strength steels. An exception is aluminum alloy equipment that may experience accelerated general corrosion in high pH environments as well as low pH environments.

FIGURE 4.19.46 Effect of carbon dioxide concentration on corrosion rate [43].

FIGURE 4.19.47 Corrosion—fatigue failure of drillpipe caused by internal pitting [14].

In underbalanced drilling and where drilling fluid control is lost, the drilling equipment may encounter production fluids that may be mixed with lower quantities of drilling fluids. In these cases, accelerated general corrosion rates may be encountered and the risk of environmental cracking increases with increasing concentrations of H_2S and lower pH levels.

As mentioned previously, fatigue and corrosion fatigue are common failure mechanisms in drill string components. When the drilling fluids are not properly controlled, make-up torque not properly applied, when production fluids come in contact with drilling fluids and when operational circumstances concentrate rotating bending stress (such as rotating a connection for an extended period through a severe bend in the drill string, fatigue failures can result. An example of a corrosion fatigue failure in drill pipe is presented in [Figure 4.19.47](#).

4.19.4.2 Motors, Jars and Drilling Bits

Drilling motors, jars and bits are very complicated pieces of hardware that utilize a variety of materials that serve very specialized functions. These components are grouped together because they are used in conjunction with each other and each utilizes specialized materials with unique types of service. The bits and motors exhibit a relatively short finite life.

Drilling motors, specifically downhole mud motors, work by taking the hydraulic action of the drilling fluid and converting it to a rotational force. Instead of rotating an entire drill string, the mud motor will be at the end of a non-rotating work string or coiled tubing and provide the rotational forces necessary to drill the formation.

The materials in the mud motors are composed of hardened steel rotors and stators. The rotors are typically coated with metallic plating and the stators have a mating

(to the rotor) elastomeric member bonded to the ID. There is a non-elastomeric version of the stator/rotor arrangement that utilizes specialized wear components including copper based alloys and cobalt based hardsurfacing alloys.

Jars are composed of high strength materials and their function is to store energy that can be released to create a jar or impact on the bottom hole assembly (BHA) that is usually comprised of the bit, subs and collars. The impact motion of the jar is used to free “stuck” pipe or BHAs. The jars are made from Cr–Mo and Ni–Cr–Mo steels with 4140 and 4340 types being typical. The jars are subjected to fatigue and impact type failures. Corrosion is not an expected failure mode for this product.

Drilling bits may either be the tricone “rotating cone” or the drag “fixed cone” variety. Both types incorporate hard drilling elements that cut into the formation by cutting and fracturing forces aided by hit hydraulics.

The cutting elements of the drilling bits are either the mining grade type of cemented tungsten carbides or natural/synthetic diamonds. The diamonds may be as natural stones or formed into polycrystalline diamond compacts (PDCs). The body of the drag bit may be a matrix head (a high strength braze type material with hard particles embedded in it or a hardened steel head with the cutting elements brazed or press-fit into it. The tricone type of drilling bit is composed of three drilling cones or heads that are attached to three legs or bodies and the assembly is joined together. The steel cones and legs are typically alloyed Ni–Cr–Mo carburizing grades of steel such as 4820 and 9310. The bearings that permit bit rotation under extremely high bearings forces are very highly engineered and utilize such materials as beryllium copper, spinoidal copper alloys, cobalt base wear resistant alloys, hardened tool and stainless steels and cemented tungsten carbides.

Though there are occasionally corrosion failures in these products, the product lives are normally too short to be subjected to the majority of the potential corrosion mechanisms. This is not true if the drilling fluid is not controlled, the action of corrosion in production fluids such as hydrogen sulfide containing gas/water phases can cause cracking in very short periods of time (minutes or hours).

One problem shared by mud motors and drilling bits is the susceptibility to premature failure due to environmental interactions between the mud motor elastomer or tricone bit seal and the drilling fluid. There have been instances of motor and bit failures that have resulted from elastomer property deterioration in drilling fluids.

4.19.4.3 Blow-Out Preventers

Blow-out preventers (BOPs) are used at the surface (or subsea) for pressure control during drilling and work-over operations. Their primary purpose is safety; the key here is to prevent uncontrolled release of production fluids or

“blow-outs.” The two basic types are ram style and annular style BOPs. They are named for the action of the piston activating the BOP. A ram style utilizes opposing rams that are piston activated whereas the annular type utilizes compression that activates on a spherical or annular type sealing element. Pipe ram or variable ram type BOPs are used to isolate the annulus from the atmosphere. Blind ram BOPs or annular type BOPs too are used to shut off open hole pressure. There is also a shear ram BOP that is designed to sever tubing or drill pipe in the advent of pressure coming up through the tubing or drill pipe. Several BOPs are typically mounted together to form a BOP stack as illustrated in Figure 4.19.48.

A diverter is sometimes used in conjunction with a BOP stack to divert the gas from the annulus away from the stack.

BOPs and diverters are made from low alloy steels, the most common are modifications to 8630 and Cr–Mo steels such as $2\frac{1}{4}$ Cr–1Mo. BOPs may be subjected to corrosive production fluids when used for well control. Since the fluids may contain H₂S, the BOPs are built of materials in the conditions that are resistant to SSC. Corrosion problems with BOPs occur in seal areas that could become corroded by contact with aerated seawater and/or production fluids. The other potential is environmental interactions between the drilling fluid and the BOP sealing elements. There are drilling fluids that cause dramatic property changes in

FIGURE 4.19.48 Typical arrangement of a BOP stack.

specific elastomers and care must be taken to ensure that the elastomers and the drilling fluids are compatible.

4.19.4.4 Casing and Hangers

Casing is a pipe that is used in the oil and gas industry to ensure a pressure tight connection from the surface to the reservoir being produced. There are many reasons for using casing including the following listed by Petroleum Extension service [44].

1. Prevent cave-in or wash-out of the hole
2. Prevent contamination of freshwater sands by fluids from lower zones
3. Exclude water from the producing formation
4. Confine production to the wellbore
5. Provide a means of controlling well pressure
6. Permit installation of artificial lift equipment for producing the well
7. Provide a flow path for produced fluids

The casing is divided into several types including conductor pipe, surface casing, intermediate casing, liner string and production casing. These casing types are shown in Figure 4.19.49.

The casing can be made from a variety of materials ranging from low carbon steels to very highly alloyed nickel base alloys. The alloy and grade selection is based on strength requirements and the anticipated type of corrosion service. Liner hangers and casing are generally made from similar materials though the liner hangers are often made of higher strength corrosion resistant alloys.

The corrosion problems that could occur in casing and liner hangers include SSC, SCC, pitting corrosion, crevice corrosion, and general corrosion.

4.19.4.5 Cementing Equipment

Cementing equipment is used to control the location and flow of cement for cementing operations. This equipment includes a float collar, a guide (cementing) shoe and plugs. The purpose is to lock into place the casing and prevent migration of fluids from one position along the casing to another; this prevents communication between the different downhole formations such as those producing water and hydrocarbons. A schematic of some of this equipment is presented in Figure 4.19.50.

The cementing equipment is composed of materials that are relatively easy to mill or remove by subsequent drilling operations. The materials of construction are often aluminum alloys, cast iron, phenolic plastics and composite materials. There are generally no corrosion problems

FIGURE 4.19.49 The various strings of casing used in a well.

with these products in drilling fluids and cement. There can be corrosion problems in production environments or acids.

4.19.4.6 Coiled Tubing

Coiled tubing can serve many functions including milling, drilling, injection, production tubing and intervention/

FIGURE 4.19.50 Cementing equipment.

workover operations. The coiled tubing is continuous length meaning that there are no joints or connections.

The coiled tubing is usually made from HSLA type steels with the most popular type being a weathering type of HSLA steel. The strength level of the coiled tubing ranges from about 400 MPa (60 ksi) to about 750 MPa (110 ksi). The weathering type of steel has small intentional additions of chromium, copper and nickel to improve corrosion resistance.

Other materials have been made and used in coiled tubing including 13% chromium stainless steel, 15% chromium stainless steel and titanium.

The coiled tubing is susceptible to fatigue and corrosion fatigue, pitting corrosion, general corrosion and SSC in the high strength grades of coiled tubing. One of the biggest problems with respect to corrosion and coiled tubing is the pitting corrosion that can occur as a result of acidizing operations.

4.19.4.7 Wireline and Testing Equipment

Wireline is used to convey a large number of different types of tools. Wireline operations are generally quick

and completed in a number of hours. Wireline is typically an alloy steel but can be made from corrosion resistant alloys. The wireline is normally very high strength material and some materials can be susceptible to cracking (SSC and SCC). The factors affecting this susceptibility are time, temperature and the contacting environment. Wireline equipment survives in aggressive environments despite its susceptibility because of the typical short duration of the wireline operations.

4.19.4.8 Marine Risers

Marine risers are subjected to offshore environments that range from surface marine, splash zone, and submerged sea exposure. All of the typical marine forms of corrosion are possible including general corrosion, galvanic corrosion, localized corrosion including pitting and crevice corrosion. The splash zone and near surface regions are of particular importance because of the washing motions and oxygen contents.

The marine risers are typically made from line pipe steels (usually high strength low alloy steels known as HSLA steels) such as X65, X70, and X80 and low alloy steels such as 4130.

Another consideration that affects all oilfield equipment, but should be stressed for drilling equipment, is the storage and care of equipment between uses. Other equipment types that more commonly encounter corrosion problems are generally better suited to withstand coastal or offshore storage than drilling equipment. Drilling equipment that functions well in the intended drilling environments may exhibit severe corrosion during storage periods.

4.19.5 Mitigation Techniques

Mitigation techniques include controlled strength level range steels, coatings, inhibitors, corrosion resistant alloys and surfacings. Some of the common mitigation techniques that are applicable to the corrosion mechanism are discussed in the section where the mechanism is discussed. This section summarizes some of these techniques and relates them to drilling and completion equipment.

The selection of the mitigation technique starts with an assessment of the product or tool material and the intended application environment. This assessment can be turned into design criteria whereby the mitigation techniques can be investigated and selected. This process is illustrated in Figure 4.19.51.

4.19.5.1 Materials Selection

In addition to corrosion resistance, the factors that to be considered in materials selection include strength level, product form, impact toughness, meeting code requirements and cost. It is frequently the case that some of the other

product requirements take precedence over the corrosion resistance. It may also be that permitting corrosion and adding a corrosion allowance to the design is the most cost effective materials design selection.

Some of the specific drilling equipment and the applicable materials are presented in Table 4.19.7.

4.19.5.2 Design

Often the design of the equipment is as important as the material selection in preventing serious corrosion problems. Many types of corrosion such as sulfide stress corrosion (SSC) and stress corrosion cracking (SCC) may be mitigated by reducing the stress level and avoiding stress concentrations. Crevice corrosion may be avoided by preventing tight crevices.

4.19.5.3 Coatings and Surfacing

There are several types of coatings that are used to prevent corrosion in drilling and well completion equipment. These can be broadly classed as metallic coatings, inorganic coatings and organic coatings. With all of these classes, the one feature that has a huge role in the final success rate is the surface preparation. The surface needs to be clean and free of contaminants and exhibit the proper surface profile for the specific coating being applied.

Metallic coatings include (1) hot-dip galvanizing, (2) electroplating of nickel, chromium, copper, tin, and zinc, (3) electroless nickel plating, (4) high velocity (oxy-fuel) spray coatings—also known as HVOF, (5) metallizing (arc

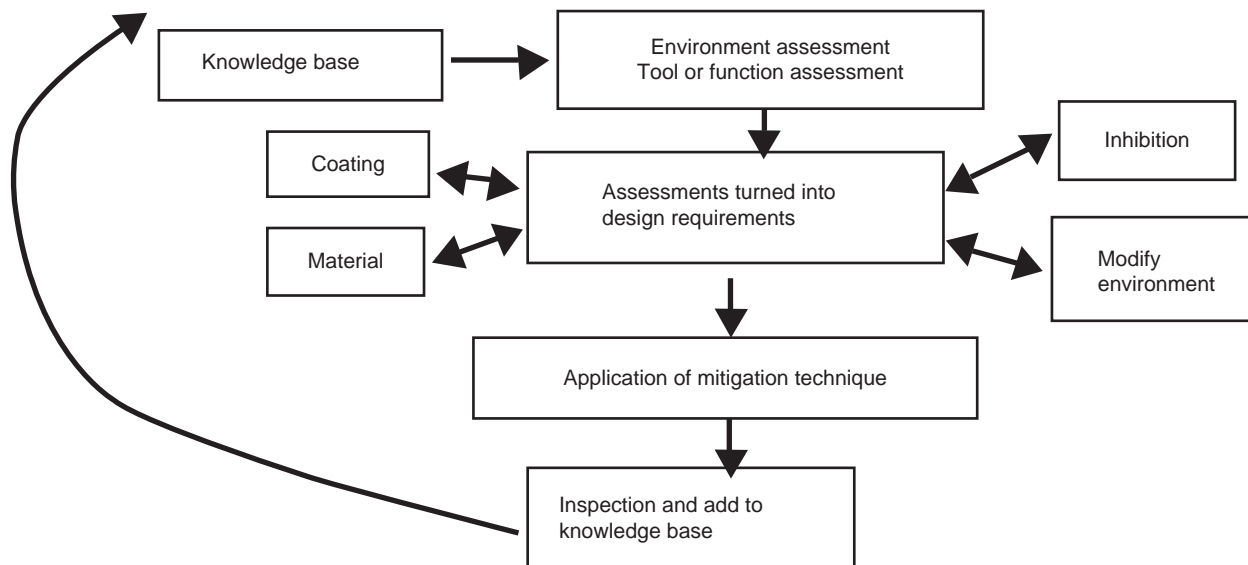

FIGURE 4.19.51 Design scheme for corrosion mitigation.

TABLE 4.19.7 Equipment and Materials Choices

Equipment	Yield Strength, ksi	Material Choices
Drill pipe	75–135 ksi	Cr-Mo steels (4140, 4145)
Tool joints	110 ksi	Cr-Mo steels (4135M)
Collars and Subs	105–120 ksi	Cr-Mo steels, beryllium copper, stainless steel
Jars	110–170 ksi	Ni-Cr-Mo steels (4340, 4330)
Tricone rock bits	110–150 ksi	Ni-Cr-Mo steels (4820, 8620, 9310)
Casing	55–150 ksi	Carbon and low alloys steels, stainless steels
Liner hangers	80–140 ksi	Low alloys steels, stainless steels, nickel base
Blow-out preventers	60–80 ksi	Cr-Mo & Ni-Cr-Mo (8630, 4130)
Cementing equipment	–	Phenolics, aluminum, cast iron
Coiled tubing	70–110 ksi	HSLA steels, stainless steels
Wireline	200 + ksi	Carbon steel (1067), stainless and nickel base
Drilling risers	65 ksi–80 ksi	Carbon, HSLA and low alloy steels

or flame spraying), (6) plasma (PVD) and ion implantation, (7) chemical vapor deposition (CVD) coatings, (8) cladding, and (9) weld overlays. The major use of these metallic coatings is to prevent corrosion on carbon and low alloy steels. There are applications of copper plating and hard surfacing for reasons other than corrosion control.

Inorganic coatings include (1) surface conversions, (2) inorganic zinc silicate, (3) HVOF ceramic coatings, and (4) flame and arc spray ceramic coatings. The common surface conversions are anodizing used on aluminum, phosphating and oxidizing processes used on steels and chromate surface conversions on steel.

Organic coatings include (1) epoxy paints, (2) acrylic paints, (3) polyurethane paints, (4) organic zinc paints, (5) phenolic coatings, (6) epoxy-phenolic coatings, (7) fluorocarbon based coatings, (8) molybdenum disulfide coatings, (9) and silicone paints and coatings. Generally, where the word paint appears in the above list, the coating consists of at least two components, one a carrier and one the paint. In many cases, with two or more part products that are mixed, the paint undergoes a chemical reaction causing or assisting in the curing and/or drying cycles. The coatings listed above that do not list plant generally require a heat curing cycle that sets the coating onto the substrate.

Most of the common paint systems designed for marine and offshore oil and gas drilling and surface well completion equipment will be coated successively with two or more layers of paint to provide the desired corrosion protection. One common three-coat system is described in [Table 4.19.8](#).

TABLE 4.19.8 Typical Three Coat Marine Paint

Coating Layer	Thickness	Coating Type	Purpose
(1) Prime	0.08 mm	Inorganic zinc	Corrosion protection — galvanic
(2) Intermediate	0.15 mm	Epoxy	Corrosion protection — barrier
(3) Finish	0.10 mm	Polyurethane	Appearance, UV protection — barrier

4.19.5.4 Environmental Control

Controlling or altering the factors that effect corrosion can reduce or eliminate corrosion. In drilling fluids, we can monitor the composition of the fluid and make adjustments to avoid too much abrasive sand and adjust the pH to the range where we can avoid corrosion and environmental cracking problems.

We know that corrosion rates generally increase with temperature and the temperature of drilling fluids can be controlled through the use of cooling towers. We also know that injected air (and oxygen) greatly affects the corrosion rates and reduces the life due to corrosion fatigue. The oxygen effects on fatigue life were demonstrated in Figures 4.19.44 and 4.19.45. There could also be entrained acid gases that contaminate the drilling fluid decreasing the pH; a degasser unit can remove these entrained gases.

In Figures 4.19.40, 4.19.41, and 4.19.42, the effects of chlorides on drill string corrosion fatigue were presented. The chloride content can be minimized through freshwater dilution.

The H₂S in the environment can be scavenged through the use of zinc and iron based compounds. There are two types of zinc based scavengers, the slightly water soluble inorganic compounds such as carbonates and the organic zinc-chelate type that is highly water soluble. The zinc carbonate combines with hydrogen sulfide in the following manner:

The zinc sulfide is insoluble and precipitates out of the environment. This type of scavenger works at neutral to basic pH values. These scavengers work well in drilling fluids. The organic zinc-chelates are more expensive but work over a wider pH range including the acidic levels and are typically used in brine type drilling fluids.

The iron-based scavenger used is magnetite. This a very effective H₂S scavenger that works best in acidic conditions; the scavenging rate is slow at high pH levels. The magnetic reacts with H₂S in the following manner:

Oil based drilling fluids are highly effective in controlling corrosion but their use is restricted by costs and environmental considerations. The oil-based fluids work because the fluids are non-conductive and do not support the flow of electrons necessary for corrosion reactions (there is no electrolyte).

4.19.5.5 Inhibition

An inhibitor is a substance that slows or stops a chemical reaction. When an inhibitor is present in sufficient enough quantity to slow a corrosion reaction, the corrosion is prevented. The basic mechanisms by which inhibitors function are as follows [45]:

1. They absorb onto the corroding material as a thin film.
2. They induce formation of a thick corrosion product, which forms a passive layer.
3. They change the characteristics of the environment either by producing protective particulates or by removing or inactivating an aggressive constituent in the environments.

As a type of material, the inhibitor may be an organic or an inorganic compound. Inorganic inhibitors include chromates (CrO₄⁻²), silicates (SiO₃⁻²) and phosphates (PO₄⁻²). The three basic types of inorganic inhibitors are anodic passivating inhibitors, cathodic inhibitors and cathodic precipitators. There are also mixed inhibitors that suppress both anodic and cathodic reactions.

Anodic inhibitors suppress or prevent anodic reactions by assisting the natural passivation of metal surfaces or by forming films/deposits that isolate the metal from the environment. These anodic inhibitors are sometimes categorized by being either highly oxidizing or by being much less oxidizing. Examples of the highly oxidizing anions include chromates, nitrites and nitrates. Sodium nitrite and sodium chromate are two of the most effective; their effect on the reduction-oxidation (redox) potentials are presented below [46]:

The low oxidizing anodic inhibitors include phosphates, molybdates, and tungstates. The low oxidizing anions require an external source of oxygen for passivation. These low oxidizing anions are sometimes referred to as dangerous inhibitors because they can actually cause pitting when present in low concentrations. Anodic inhibitors are also considered dangerous because cathodic reactions may not be inhibited on unprotected areas [46].

The cathodic inhibitors suppress the cathodic chemical reaction and these are further subgrouped by the way in which the cathodic reaction is affected. The three basic types are cathodic poisons, cathodic precipitators

FIGURE 4.19.52 A semipolar molecule [47].

and oxygen scavengers. Of these, oxygen scavengers are the type that are used in drilling and well completion operations.

The oxygen scavenger works by combining with free oxygen, this inhibitor type prevents cathodic depolarization. One common effective oxygen scavenger is sodium sulfite and the reaction to scavenge oxygen is as follows:

The organic type of inhibitors affect the entire surface of the metal by forming films on the surface. The organic inhibitors are semi-polar in that the make-up of the inhibitor includes a polar (conductive) and a non-polar (non-conductive) component. The semi-polar nature renders one end of the molecule hydrophobic (water repelling) and the other hydrophilic (water loving). This semi-polar molecule is illustrated in Figure 4.19.52.

These semi-polar molecules bond or attach to the metal surface on the polar (conductive) end of the chemical compound. A thin film only a few molecules thick is adsorbed according to the ionic charge of the inhibitor molecule and the charge of the metal surface. These organic inhibitors can preferentially attach to either the cathode or the anode of the system; these inhibitors are termed cationic inhibitors (positively charged) and anionic inhibitors (negatively charged). Amines are examples of organic cationic inhibitors and sulfonates are examples of organic anionic inhibitors. The bonding of these inhibitors is illustrated in Figure 4.19.53.

One advantage of the organic inhibitors is that they are typically self-healing when the inhibitor is present in sufficient concentration; if the film is damaged or removed through flowing conditions, the film reforms. The factors that effect how well the inhibitor works includes:

1. Molecule size
2. Bond strength to the metal surface
3. Type and number of bonding atoms
4. Filming characteristics

The value of the corrosion inhibitor is related to how much the corrosion rate is lowered by use of the inhibitor. This can be calculated by the use of the following formula:

$$E = 100(R_0 - R_i)/R_0$$

where E = inhibitor efficiency
 R_0 = rate of corrosion without inhibitor
 R_i = rate of corrosion with inhibitor

These inhibitors are used and applied in a number of ways. First, an inhibitor can be used directly on the metal requiring protection such as drill pipe. This is typically sprayed onto the metal surface. Second, the inhibitor can be added to the environment such as additions made to drilling fluids.

When the inhibitor is added to the environment, it is either added continuously or by batch. When added continuously, a small quantity is added to maintain a minimum concentration in the environment. When added by batch, a much larger concentration is added at intervals that are determined through monitoring.

When inhibition is selected as the means by which corrosion is prevented, the environment should be monitored to ensure a minimum effectiveness of the inhibitor. This is true regardless of the addition method, continuous or batch.

4.19.6 Corrosion Monitoring and Equipment Inspection

One way to combat corrosion is to maintain an effective corrosion-monitoring program to supplement good preventative measures. It is also very important to keep complete records of monitoring programs, control programs and failures that occur.

An effective corrosion control program should be able to detect evidence of corrosion and identify the causes. Therefore, continuous monitoring is essential during drilling operations because the nature of drilling fluid corrosivity changes as the hole is drilled and different formations are penetrated. Several techniques of monitoring corrosion should be used simultaneously whenever possible, and records need to be kept.

4.19.6.1 Linear Polarization Instruments

Linear polarization instruments provide an instantaneous corrosion-rate data, by utilizing polarization phenomena. These instruments are commercially available as two-electrode and three electrode types (Figure 4.19.54). The instruments are portable, with probes that can be utilized at several locations in the drilling fluid circulatory

FIGURE 4.19.53 Schematic of film-forming inhibitor [48].

systems. The technique involves monitoring electrical potential of one of the electrodes with respect to one of the other electrodes as a small electrical current is applied. The amount of applied current necessary to change potential (no more than 10 to 20 mV) is proportional to corrosion intensity. The electronic meter converts the amount of current to read out a number that represents the corrosion rate in mpy. Before recording the data, sufficient time should be allowed for the electrodes to reach equilibrium with the environment. The corrosion-rate reading obtained by these instruments is due to corrosion of the probe element at that instant [22].

The limitation of these instruments is that they only indicate overall corrosion rates. Their sensitivity is affected by deposition of corrosion products, mineral scales or accumulation of hydrocarbons. Corrosivity of a system can be measured only if the continuous component of the system is an electrolyte. These devices may not adequately predict localized corrosion.

4.19.6.2 Galvanic Probe

The galvanic probe continuously monitors the corrosion characteristics of the drilling fluid. The probe (Figure 4.19.55) consists of two dissimilar metal electrodes, usually brass and steel. The electrodes are mounted on, but insulated from a threaded high-pressure plug. These electrodes are connected to each other through a DC ammeter capable of detecting microamperes when the probes are immersed in an electrolyte. Enough time is allowed for the electrodes to reach equilibrium and read the current flow through the external loop. The corrosion process occurring on the electrodes generates the current measured [22].

The amount of current flow is a measure of its corrosiveness. The probe generally registers low-current flow (0–10 mA) in slightly corrosive environments. However, high-current flows (40–100 mA) have been recorded in severely corrosive environments. The current intensity generally depends on oxygen concentration of the system, since oxygen depolarizes the brass cathode, thereby continuing

FIGURE 4.19.54 Linear polarization instrument probes.

FIGURE 4.19.55 Typical galvanic probe.

the corrosion process of the cell. Among various locations of a surface circulatory system, the instrument can be installed downstream of a deaerator and in the standpipe.

If the instrument indicates current surge in an air-free system, it generally implies hydrogen sulfide contamination, but the galvanic probe is usually best suited to detect corrosion influenced by oxygen contamination. Other limitations of this instrument are the same as those of linear polarization instruments discussed earlier.

4.19.6.3 Hydrogen Probe

The hydrogen probe (Figure 4.19.56) basically consists of a hollow, thin-walled, steel tube that is sealed on one end and the other end is equipped with a pressure gage. Once mounted in the system, the probe body corrodes. Some of the nascent hydrogen generated by the corrosion process in the presence of hydrogen sulfide diffuses through the tube wall. Once inside the valid space in the tube, the hydrogen atoms combine to form molecular hydrogen gas. As these hydrogen gas molecules are too large to diffuse back through the tube wall, the pressure in the tube rises. The pressure rise in the tube is a function of the amount of hydrogen generated by the corrosion process.

One problem with hydrogen probes do not perform well in aerated fluids [47].

4.19.6.4 Corrosion Coupons

The most direct method of evaluating the corrosivity of an environment is the use of corrosion coupons. In drilling operations, a drill string corrosion coupon is a ring coupon machined from a section of tubing and sized to fit into the relief groove in the tool joint box.

To employ effective control measures, it is very important to determine the type of corrosion attack. Spot analysis

of the corrosion film and careful visual examination of the coupon surface can help in determining the type and severity of corrosion attack. Generalized corrosion is represented by continuous attack over the entire surface, but no pitting. The pitting type of corrosion is represented by a high concentration of pits on the coupon surface. This type of corrosion attack is the most serious attack resulting from drilling fluids, as discussed earlier.

Weighing the coupon before and after exposure, and evaluating the change in weight permits a determination of the severity of general corrosion attack. Before installation the coupon must be clean (i.e., free of any corrosion, grease marks, drops of perspiration, etc.) and weighed. After exposure to the system for a known period of time, the coupon is retrieved, visually examined, then cleaned and reweighed within one tenth of a milligram. The difference between the initial and final weights is attributed to corrosion and converted to a corrosion rate knowing the surface area of the corrosion coupon exposed to the environment.

There are several factors such as handling, surface preparation and cleaning, etc., which can affect the results of the tests. The results obtained from this test assume uniform corrosion. Therefore, for proper analysis it becomes very important to include a complete description of the exposed coupons. One of the most important factors is visual inspection of the coupon, describing the form of attack and identifying the corrosion by-product.

In assessing drill string corrosion, there are limitations in using corrosion coupons. The coupon experiences the same downhole conditions as the drill string does and represents the corrosive effects of the downhole environment. However, the coupon is only exposed to the one side (inside) of the drill string and is not subject to the same stresses. Stresses can and do influence corrosion rates and corrosion on the outside of the drill string may not be adequately assessed. The results obtained are only for a certain depth of

FIGURE 4.19.56 Hydrogen probe.

exposure, while the corrosion may vary appreciably up and down the hole. Finally, the results are not available until the tool containing the coupon is pulled out of the hole.

4.19.7 Recommended Practices

Equipment failure due to corrosion is one problem that inevitably rears its ugly head during drilling operations. Corrosion control is an essential factor in any engineering design and must be considered as early as the initial phase of the operation. An effective and most cost-efficient corrosion control program is imperative for a successful drilling operation. Some recommended practices are as follows [2, 14, 19, 22, 49, 50].

4.19.7.1 Drilling Operations

1. Use quenched and tempered drill pipe that meets the API requirements for drill pipe.
2. Avoid the use of shrink-type tool joints on drill pipes and drill collars (connectors, in this case). Flash-welded or friction welded tool joints for drill pipes and integral drill-collar joints should be used.
3. Utilize proper make-up torque on tool joints.
4. Use internally, plastic-coated drillpipe at all times. The coating must be holiday-free to be effective.
5. Consider the use of heavy-wall (thick wall) drillpipe in severely corrosive conditions. Heavy walls reduce stress levels and extend the service life of drill pipe.
6. Materials used for tool joints are generally modified 4135 steel. They are heat treated by quenching and tempering at temperatures equal to or above 1150°F to hardness of Rc 30 to Rc 37 and yield strength ranging from 120,000 psi to 135,000 psi.
7. Most drill collars are also made with materials similar to those used for tool joints. Where possible, use heavy walls are used to reduce stress levels.
8. limit exposure time of the drillstem to the corrosive environment during drillstem tests. A maximum of one hour is recommended.
9. Sustained exposure of drill pipe to operating temperatures above 300°F (149°C) must be limited to a maximum of 10 hr.
10. Run enough drill collars to keep all drill pipe in tension in order to reduce wear and stress on tool joints.
11. Use controlled drilling fluids at all times and minimize contamination by potential corrodents.
12. Use oxygen and hydrogen sulfide scavengers when appropriate to reduce corrosion rates.

4.19.7.2 Transportation

1. Drillpipes and drill collars should be tied down with suitable chains at the bolsters when being transported.
2. Load with all couplings on the same end of the truck.
3. Use thread protectors on tool joints when moving or racking pipes.
4. Avoid chafing a tool-joint shoulders on adjacent joints.
5. Keep load binding chains tight at all times.
6. Avoid damaging coatings as well as the pipe itself.

4.19.7.3 Handling

1. Before unloading, make sure that the thread protectors are tightly in place.
2. Avoid rough handling that can damage the pipe in any way.
3. The pipe must not be dropped at any time.
4. Unload one joint at a time.
5. When rolling down skids, roll pipe parallel to the stack. Do not let the pipe gather any momentum and strike the ends. This can damage threads even when the protectors are in place.
6. Avoid creating knicks or notches on the drillpipe.

4.19.7.4 Chemical Additives

1. When high temperatures above 300°F are expected, do not use sulfur-containing compounds as drilling fluid additives.
2. Use only chemical additives that are compatible with drilling fluids in circulatory systems.
3. Avoid using copper-based compounds such as copper carbonate. Copper can “plate out” on steel and set up galvanic corrosion cells, resulting in accelerated corrosion of the steel.
4. Maintain the pH level of the drilling fluid around 9.5 to reduce corrosion. However, when aluminum drill pipes are in use, the pH must be maintained between 9.5 and 7.
5. Minimize salt contents.
6. Caustics should be dissolved in water before being added. The mixture should be mixed well with mud guns in the pit prior to pumping into the hole.

4.20 ENVIRONMENTAL CONSIDERATIONS FOR DRILLING OPERATIONS

Section reviewed by Catherine Rivera Lyons

4.20.1 Introduction

Non-technical risk (NTR) elements are just as important to understand and manage appropriately as the technical aspects of a drilling operation. NTRs include the environmental, health and safety, and social or stakeholder components that may impact a project and need to be understood early and at the onset of exploration and development. In some companies, NTRs are referred to within the organization as one or more of the following nomenclature: environmental and regulatory; socioeconomic; and sustainability. In addition, some companies may have standards or elements within their management system or internal requirements that prescribe a process to identify and manage NTRs. It should be understood that NTRs are important aspects that will need to be managed across the life cycle of the project (exploration, development, production, operation, and asset retirement). Figure 4.20.1 depicts and lists a subset of the NTR or “sustainability” risks and activities that should be evaluated and conducted, as appropriate, within each phase of a project life cycle regardless of facility type.

Although NTRs may be identified at a particular point in a project, they will also need to be evaluated periodically or at specific stage gates to understand any changes to requirements, regulations, or internal standards that may trigger additional controls to manage risks and maintain regulatory compliance. Engineers are responsible for understanding applicable NTRs and incorporating those elements in applicable aspects of the design: including, but not limited to, site selection, layout, operations, controls, etc. to manage NTRs. If the engineer is not familiar with NTR aspects, internal company advisors or external consultants should be engaged to support in the identification and management of NTRs. Delays in both schedule and budget may occur if the NTRs are not understood and managed concurrently with the technical components of the project. In addition, technical design of the facility and operation may need to be altered or operational flexibility may be limited, as regulatory or permit requirements—or stakeholder demands—do not align with the design. Historically, these considerations were performed post-design completion or several months prior to operation. However, due to delays and budget exceedances that have occurred to manage NTR conflicts that were identified at the late stages of a project, NTRs should be identified at the initial or Stage 1 project planning and site selection activities. Figure 4.20.2 depicts the causes of delay for the 53% of oil and gas projects over the period between 2008 and 2012. Delays due to NTRs aspects were

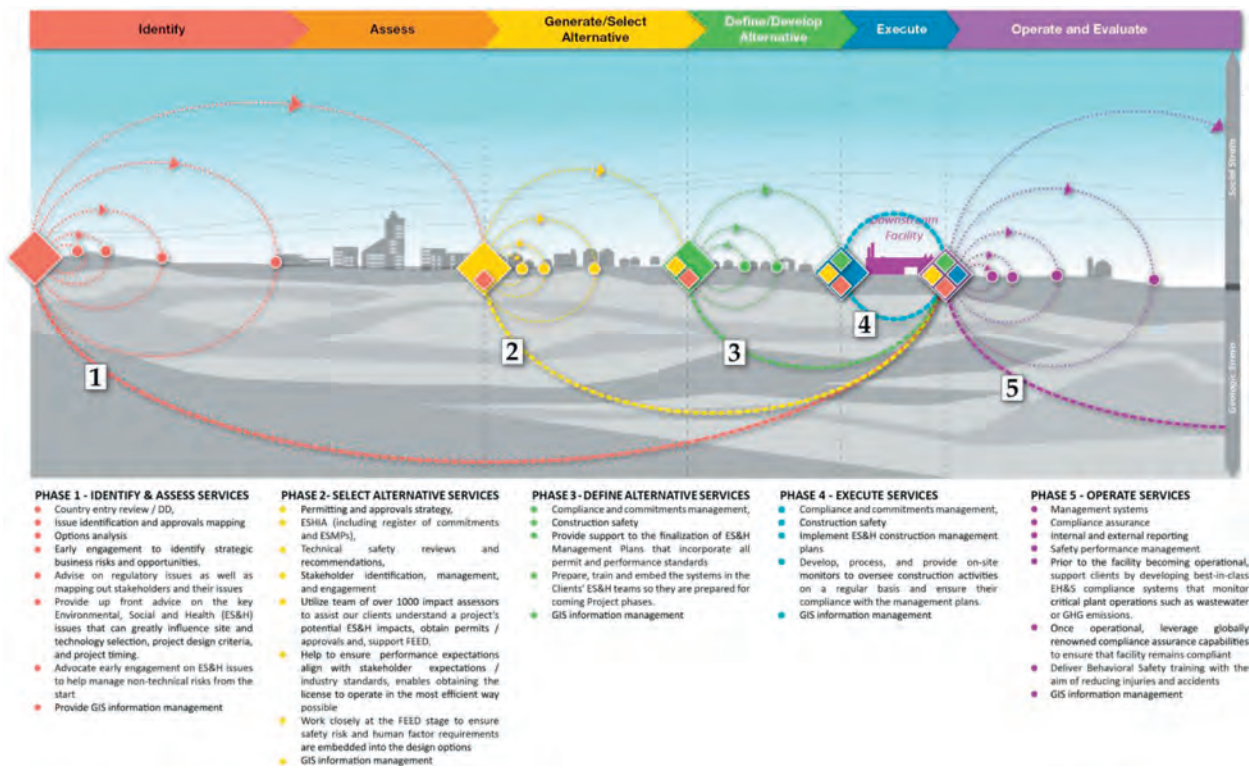

FIGURE 4.20.1 Non-technical risk management across project life-cycle (ERM, 2015) [1].

FIGURE 4.20.2 Causes for oil and gas project delays (ERM, 2014) [2].

the majority (53%) of reasons the project did not start on schedule as planned.

This section will not describe all NTR aspects that need to be considered, but will focus on select environmental considerations for awareness and further evaluation of how it may be applicable within a project. To identify and understand all potential NTR aspects, a critical issues analysis should be performed and a regulatory compliance plan documented for each project to understand the NTR applicable aspects to manage and control. This document should be retained within the project plans and the critical issues should be incorporated into the risk management plans and project scheduling, so as to manage appropriately and reduce the potential for delays and budget over-runs.

4.20.2 Regulations

Most developed countries have identified government bodies to regulate oil and gas development and operations. These agencies have developed regulations applicable for oil and gas operators and operations, including specifying requirements; such as, well registrations, permits, and operational controls to support environmental protection. Some countries, like the United States of America, have additional regulations for each state and, at times, county or city (e.g., local). These additional and sometimes more stringent requirements supersede the national or federal agency regulations. However, in some parts of the world and in many developing countries, environmental agencies and associated regulations either do not exist or are not specific

(e.g., no specific controls or permits required but a general statement to “protect the environment”). Therefore, it is the engineer’s responsibility to understand applicable regulations and associated requirements for all phases of the oil and gas project to support appropriate planning, permitting, and design (e.g., controls) to maintain compliance with all applicable regulations throughout the project life cycle. Not only will the appropriate controls protect the environment and reduce impact to adjacent landowners and workers health and safety, but it will also protect the company’s reputation and reduce the potential for the operator or engineer to receive regulatory fines or imprisonment for non-compliance.

Identifying and understanding potential applicable regulations that may impact everything from site selection to operational controls should be performed as part of the critical issues analysis and documented in a regulatory compliance plan for the project. Key environmental regulations will include multi-media aspects, such as: water resources, storm water management, wastewater discharge, air emissions, waste storage and management, spill prevention and management, chemical handling and disposal, leak prevention requirements (e.g., liners), and remediation. Understanding and incorporating regulatory requirements early in the design and planning stages will reduce delays and support effective, yet flexible operations that meet regulatory requirements and protect the environment and stakeholders. Section 6.9 provides more detail regarding regulatory agencies and associated requirements for drilling and oil and gas operations considerations re: oil pollution prevention, waste management, spill prevention, remediation, and produced water management.

4.20.3 Site Selection

When planning a drilling operation, site selection must take into account the critical issues that have been identified. A location should be selected based on the geographic proximity to sensitive receptors, such that it will reduce potential NTRs throughout all phases of the project while supporting operational flexibility. For example, although the access to the site and the ultimate location must be able to support the traffic load and site operational equipment, evaluation of the proximity to adjacent or nearby homes, schools, parks, cultural resources, historic buildings, water sources, wetlands, and ecosystems that may be home to endangered, threatened, or sensitive species must be performed and understood to determine if the site may potentially result in a negative impact to these receptors. Or, if there may be sensitive receptors in the near vicinity, additional controls may be needed to reduce or prevent negative impact to these receptors throughout the project life cycle. Although not typically required to be performed in all countries, an environmental social health impact assessment (ESHIA) or a similar evaluation may be warranted and is best practice to identify the controls and activities needed to be incorporated into the design and operational procedures to reduce negative impact to the surrounding environment, workers, and people. Depending on the ownership of the land and mineral rights, plans may be required that also contain this type of information for submittal and approval prior to site mobilization and construction. In addition, it is important to understand baseline conditions and, if needed, develop a stakeholder engagement plan to communicate development details and how potential impacts will be managed.

In the United States, drilling plans are submitted to the Bureau of Land Management (BLM) or state oil and gas commissions in the form of an Application for Permit to Drill (APD), depending on ownership of mineral resources. Other countries have similar requirements. In addition to these agencies, other appropriate surface management agencies may have to be considered, including the BLM, National Park Service, Tribal Authorities, State Environmental Program, and County Environmental Program (see Chapter 6, Table 6.9.1 for a partial listing of federal and state agencies).

In the permitting process, it is important to have the entire operation planned. It is a necessary component of most APDs. In a federal APD, the 13-point surface use plan must address the following items before approval:

1. Location of site and existing roads
2. Planned access roads
3. Location of existing wells
4. Location of existing or proposed production facilities
5. Location and type of water supply
6. Source of construction materials
7. Methods of handling waste disposal

8. Ancillary facilities
9. Well site layout
10. Plans for restoration of the surface
11. Surface ownership
12. Information such as proximity to water, inhabited dwellings, and archeological, historic or cultural sites
13. Certification of liability

Details of the actual drilling program are not considered in detailed in an APD except for the casing and cementing program and how they are designed to protect any underground sources of drinking water (USDW). The bulk of the APD permit is designed to address the impact on surface resources and the mitigating procedures the operator plans to take to lessen these impacts [1].

4.20.4 Site Construction

4.20.4.1 Access and Pad

The road to the wellpad should be constructed to prevent erosion and be of dimensions suitable for traffic. A 16-ft top-running width with a 35-ft bottom width has been shown to sustain typical oil field traffic. The road should be crowned to facilitate drainage, and culverts should be placed at intersections of major runoff (Figure 4.20.3). Before the pad and access is surveyed for final layout, preliminary routes should be evaluated and site visit performed. Trained personnel should note any significant attributes of the area such as archeological evidence, plants, and animals. Because of this survey, the most favorable access route is designated weighing and primarily linked to

- Drilling fluid program
- Periodic operations
- Completions
- Proximity to sensitive receptors

The rig selection will dictate the basic layout of the pad. Based on the necessary area needed to support its functions, ancillary equipment may be added in space-conservative measures. In addition to the placement of various stationary rig site components, other operations such as logging, trucking, and subsequent completion operations must be provided for. The most environmentally sensitive design will impact the least amount of area and will therefore be the most economic. Potential pad sites and access routes should be laid out on a topographic map or geographic information system. At this time, construction costs can be estimated and compared. The cost of the well/pad should include the cost of reclamation such as any remediation, recontouring, and reseeding of native plants. In the event of a producing well, only that area needed to support the production operations is left in place. The reserve pit and all outlying areas are reclaimed.

FIGURE 4.20.3 Oilfield access road dimensions (typical).

4.20.4.2 Rig Considerations

A rig layout diagram provided from the contractor gives the dimensions necessary for planning the drill site. Figure 4.20.4 depicts a layout for a 10,000-ft mobile drilling rig. The main components to the rig are the drive-in unit, substructure, mud pits, pumps, light plant, catwalk, pipe racks, and fuel supply. This type of rig, with a telescoping derrick, may be laid on less than 0.37 acre. The outstanding area is taken by the positioning of the deadmen. The deadmen to which the guy wires are connected are specified by safety considerations for each rig model. A standard drilling rig with a 10,000-ft capacity will have a longer laydown side, as it is measured from the well center. During rig up, the derrick is assembled on the ground and then lifted onto the A legs. The laydown side of the site must allow for this operation. As depicted in Figure 4.20.5, the standard rig exceeds the overall aerial dimensions of the mobile rig at 0.41 acre with the laydown dimension of 130 ft, compared with 90 ft for the telescoping mast unit. A standard drilling rig with a 20,000-ft capacity may run a laydown of 185 ft, with all other dimensions proportionally increased.

With the basic rig layout defined, the ancillary equipment may be determined and laid out adjacent to the

structures in place. Access usually is determined where casing, mud, and other equipment may be delivered without disturbance of the infrastructure. When a crane (or forklift) is used, this may mean a simple loop from the rear to the laydown on the working side of the location. A loop is the optimum arrangement whereby multiple truck interference may be avoided. In the event a crane is not available, extra space is needed to accommodate the activity of gin trucks positioning materials. Figure 4.20.6 provides an overall location plan view.

4.20.4.3 Drilling Fluid Considerations

The drilling fluid program defines to some extent a major portion of the pad, including the reserve pit, blow pit, and equipment space. The program may include a closed system or a conventional one. The fluids can be oil-based mud, air, foam, water, or other media. Although the basic rig layout considers most mud drilling activities, it does not figure in mud storage, additional water storage, or air drilling systems. The overall layout may even be reduced in some cases. A closed mud system or air drilling eliminates the requirement for a large reserve pit.

FIGURE 4.20.4 Basic mobile 10,000-ft drilling rig layout.

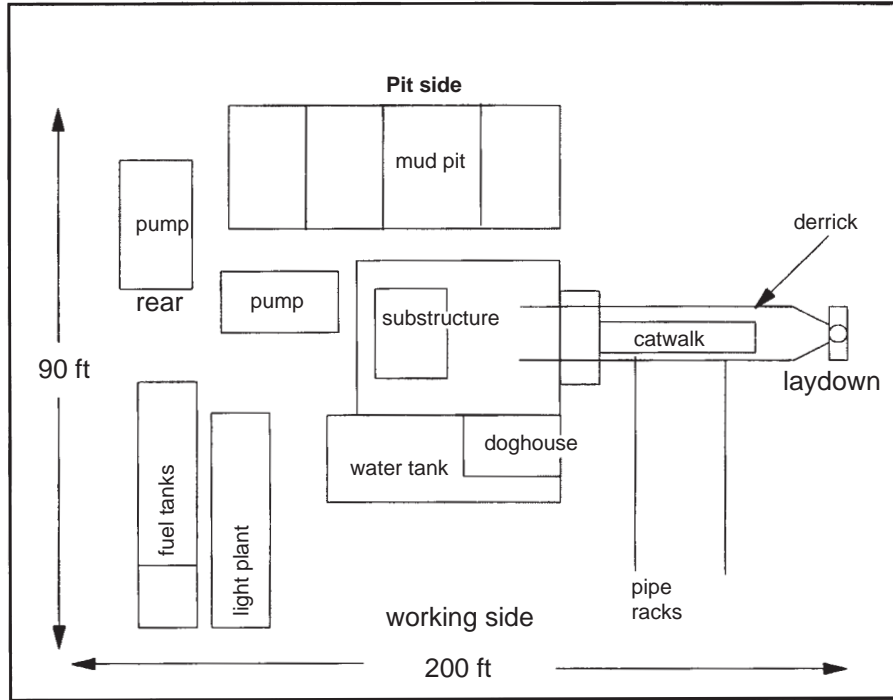

FIGURE 4.20.5 Basic layout for drilling rig with standard derrick.

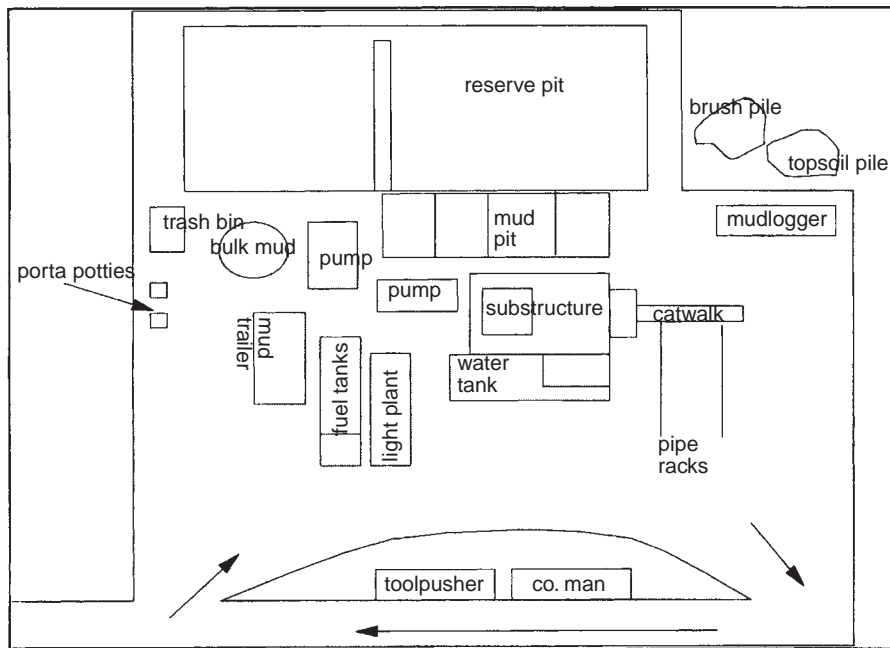

FIGURE 4.20.6 Overall location plan.

Air Drilling

In the event of air drilling, the blooie line will exit from under the substructure and away from the rig. Depending on the nature of the pay zone, the blooie line will extend different lengths from the rig. For example, a well producing

20 MMCFD in addition to the injection of 2,000 cfm air will require an extension of at least 150 ft because of heat and dust accumulation. The blow pit with berm will often extend another 40 ft beyond that to include both the blow pit and berm. The blow pit is then connected to the reserve

pit. This allows the transfer of any injected or produced fluid to a storage area away from the blow pit. The blow pit and the berm should be designed with considerable contingency and include an appropriate liner, as required by regulations to reduce infiltration. During operations, the well may be producing oil or natural gas, or both. In the case of oil, the well will have to be mudded up after the well is under control. In the process of getting the well under control, the oil may be sprayed a great distance if the blow pit and berm are not properly constructed. If natural gas is encountered, drilling is usually advanced with a flare in place. The pit and the perm must then be able to protect the surrounding area from fire and to sustain the impact from a steady bombardment of drilling particles. A distance of 30 ft should be allowed from the end of the blooie line to the edge of the berm, with only 5 ft of depth needed at the pit sloping toward the reserve pit built to maintain a flowing velocity of 2 fps. The berm itself should be 20 ft high and composed primarily of 12-ft or larger-diameter stones on the face and backed with a soil having poor permeability (Figure 4.20.7). A lip should overhang from the top of the berm whereby the ejected materials are diverted back to the pit. The air compressors and boosters are typically located at the rear of the location, with the air piped from that point to the standpipe to alleviate additional piping. Figure 4.20.8 shows an air-drilling layout. Notice that the location may be compacted somewhat because of the reduced reserve pit.

Mud Drilling

The conventional drill site includes mud pits, mud cleaning equipment, water storage, mud storage, pumps, and mixing facilities. Often, the reserve pit associated with the conventional mud system is as large as the leveled location. A large reserve pit allows for contingency, but it also increases cost of reclamation and construction. Generally, a 3-ft freeboard is maintained for safety, and it may be relied on for contingency. A good field estimate for a reserve pit size needed for a conventional operation is

$$V_t = 2(V_s + V_i + V_p) + 281D_d + 16.84MV + 3WL \quad (4.20.1)$$

$$WL = \frac{V_r}{H} \quad (4.20.2)$$

where

V_t = volume of reserve pit in ft^3

V_s = volume of surface hole (ft^3)

V_i = volume of intermediate hole (ft^3)

V_p = volume of production hole (ft^3)

D_d = forecasted drilling time in days

MV = mud pit volume in bbl

L = pit length: 0.5–0.75 ft of location in ft

W = pit width: 0.25–0.5 ft of pit in ft

H = pit depth ≤ 10 ft

Equation 4.20.1 assumes that for each operation, a volume of cuttings is put into the reserve pit plus a mud volume equivalent to the circulation system. The additional volumes are attributed to mud dilution and maintenance. An additional contingency is added through 3 ft of freeboard. The reserve pit should be located in an area where capacity may be increased in an emergency or additional fluid trucked away.

Closed Mud System

The closed mud system is the modern solution to an environmentally sensitive drilling operation. The circulation system on the rig is fully self-supporting, requiring only the discharge of drill cuttings. On a simple system, this may only necessitate the addition of a mud cleaner or centrifuge to the drilling rig's conventional mud system. A bid package to the drilling contractor may stipulate a closed system and the requirements, thereby letting the burden of design fall to the contractor, although the liability still rests on the operator. With a closed system, the additional area is sometimes needed within the basic layout for mud cleaning

FIGURE 4.20.7 Side view of blow pit.

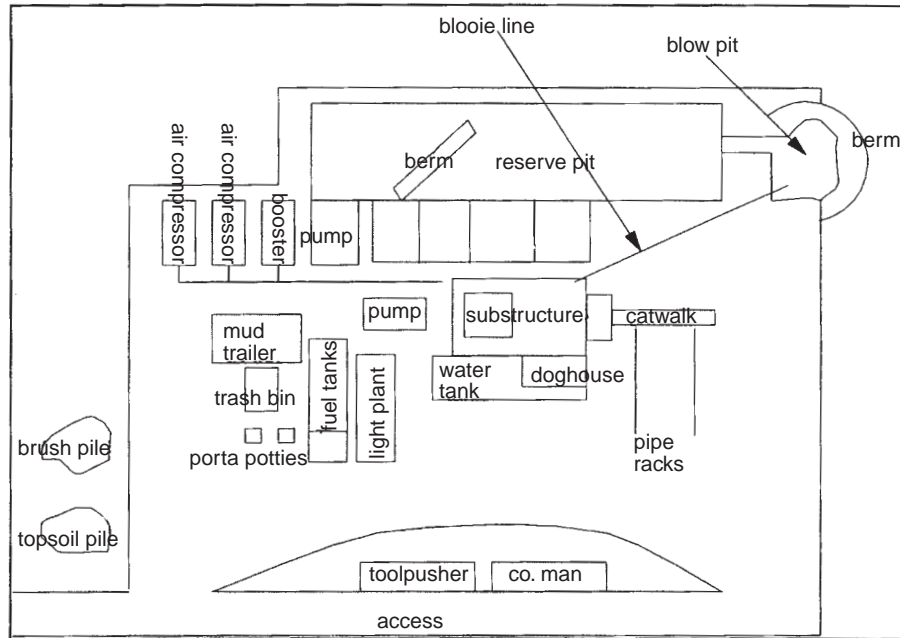

FIGURE 4.20.8 Air drilling pad.

equipment and mud storage. A trench located at the pit side of the mud pits may be allowed then for cutting disposal. In the event of oil-based mud, the cuttings may be collected in a sloped container, where residual fluid is allowed to drain from the cuttings before disposal.

4.20.4.4 Periodic Operations

Periodic operations include cementing, running casing, and logging. Room must be allocated for the storage of casing. Running 10,000 ft of range 3, 5½ in. casing requires a 40 × 115 ft area. The casing may be stacked, although never in excess of three layers and preferably only two layers. Cementing operations may include placement of bulk tanks in addition to pump trucks and bulk trailers. These are usually located near the water source and rig floor. Laying down drill pipe and logging both necessitate approximately 30 ft of space in front of the catwalk.

4.20.4.5 Completions

If a well proves productive, the ensuing completion operation may require an area in excess of the drilling area. This may mean allocation for frac tank placement, blenders, pump trucks, bulk trucks, and nitrogen trucks. In today's economic climate, the operator should weigh the probability of success, Bayes theorem (Equation 4.20.3), with the cost of constructing and reclaiming an additional area needed for stimulation (Equation 4.20.4). Plans such as these should be considered and proposed in the APD.

The operator may then construct the additional space without a permitting delay.

$$P_s = PR(E/R)$$

$$= \frac{PR(E)PR(R/E)}{PR(E)PR(R/E) + PR(\text{not } E)PR(R/\text{not } E)} \quad (4.20.3)$$

$$P_s C_b \leq C_a \quad (4.20.4)$$

where

P_s = probability of success

$PR(E/R)$ = probability of event E given information R

C_b = construction cost of additional space before drilling in \$

C_a = construction cost of additional space after drilling in \$

4.20.4.6 Pad Construction

Once access and size of the pad have been determined, the areas may be physically flagged to further reduce the amount of dirt moved. Important features of the area should be noted at this time, including

- Depth of water table
- Natural drainage patterns
- Vegetation types and abundance
- Surface water
- Proximate structures

These features should be quantified, as well as testing for contamination in soil and water, to develop baseline and reduce unnecessary litigation over previous pollution.

In construction of the pad, brush and trees are pushed to one area. Topsoil is then removed from the site and stockpiled for respreading during subsequent seeding operations. The leveled pad is slightly crowned using additional material with a lower permeability factor, if native soils are not sufficient, to reduce vertical infiltration of spills. The pad is sloped to move fluids collected on the pad to the perimeter, where drainage ditches divert this fluid to the reserve pit. In the event a subsurface pit is not possible, the drainage will run into a small sump. This sump is used as a holding tank for pumping of collected fluids to an elevated reserve pit.

When possible, the reserve pit is placed on the low side of the location to reduce dirt removal. In this event, the pit wall should be keyed into the earth and the summation of forces and moments on the retaining wall calculated to prevent failure. Pits most often fail because of leaking liners undercutting the retaining wall and sliding out. A minimum horizontal-to-vertical slope of 2 is recommended for earthen dams [6]. The pit bottom should be soft filled to prevent liner tears. Other key factors of the location provide for the drainage of all precipitation away from the location. This prevents the operator from unduly managing it as a waste product. Any water landing on the location must be diverted to the reserve pit.

Material management at the site can include a system whereby wastes are diverted to separate holding facilities according to the hazard imposed by the waste. Separate pits are created to hold rig washing and precipitation wastes, solid wastes, and drilling fluids [5]. The waste is then reused, disposed on site, or hauled away for offsite treatment. The system reduces contamination of less hazardous materials with more hazardous materials, thereby reducing disposal costs.

4.20.5 Operations

4.20.5.1 Drilling

A blowout primarily consisting of oil presents the greatest environmental hazard while drilling. During normal drilling situations, downhole drilling fluids are usually the greatest potential threat to the environment. In the case of oil-based mud, the cuttings also present a problem though absorption of the diesel base. These cuttings are presently landfarmed, landspread, reinjected, or thermally treated to drive off the hydrocarbons.

Most wells encounter shales when drilling. The oil-based muds are quite effective in reducing the swelling tendencies of the shale in addition to presenting less intrusive invasion characteristics to the reservoir. The oil-based

muds may be sold back to the distributor, where they are recycled. An alternative to oil-based muds may be found in using a synthetic-based material [6]. Saline mud is also used to reduce the shale's swelling characteristics. Chlorides may be found to be within toxic levels in the drilling fluid, making its use less desirable. Because the swelling of the clay is attributed to the cation exchange capacity (CEC), the chloride levels may be reduced by replacement with another anion. Calculation of the shale's CEC estimates the amount of cations that can be added to the drilling mud to effectively reduce swelling tendencies. Generally, a multivalent cation is more effective in reducing hydration of the clay. An equilibrium equation is used to define the CEC of a shale (Equation 4.20.5). Figure 4.20.9 shows the CEC relationships among several multivalent cations and sodium in attapulgite clay [7].

While drilling, the drilled cutting's CEC is usually tested with methylene blue (Equation 4.20.6). Table 4.20.1 shows CEC of several clays encountered in drilling situations [8]. In reducing the amount of any one type cation or anion present in the drilling mud, the environmental risks

FIGURE 4.20.9 Selectivity number K_k vs. exchangeable ion composition on an attapulgite clay.

TABLE 4.20.1 Cation Exchange Capacity of Materials Encountered in Drilling

Material	mEq/100 g – Moisture Free
Wyoming bentonite	75
Soft shale	45
Kaolinite	10
Drilled cuttings	8

are reduced. A mixed salt solution containing several salt combinations, each of which is below the toxic limits, may produce the desired effects. Thus,

$$K_k = \frac{(\text{NaX})^c(\text{M})}{(\text{MX})(\text{Na})^c} \quad (4.20.5)$$

where

NaX = sodium on the shale in mEq
 M = multivalent cation in mEq
 c = charge of multivalent cation

$$\text{MBC} = \frac{\text{MB}}{M_{\text{shale}}} = \text{CEC}_{\text{shale}} \quad (4.20.6)$$

where

MBC = methylene blue capacity in mEq/100 g
 MB = methylene blue capacity in mEq
 M_{shale} = weight of shale in 100 g

There are a variety of toxic chemicals used in the drilling fluid makeup. Chromates and asbestos were once commonly used but are now off the market. A mud inventory should be kept for all drilling additives. Included in the inventory is the Material Safety Data Sheet (MSDS) that describes each material's pertinent characteristics. The chemicals found on the MSDS should be compared with the priority pollutants, and any material should be eliminated if a match is found. The chemicals should also be checked on arrival for breakage and returned to the vendor if defective packaging is found. All mud additives should be housed in a dry area and properly card for to prevent waste. Chemicals should always be mixed in packaged proportions. Wasted chemicals, ejected to the reserve pit by untrained personnel, can present future liabilities to the operator, who is responsible for them from cradle to grave.

4.20.5.2 Rig Practice

All drilling fluids should be contained in the mud pits for reserve pit. The cellar should have a conduit linking it to the reserve pit such that accumulation of mud from connections does not spread over the location. In the case of toxic mud, a bell should be located beneath the rotary table to direct such fluids back into the drilling nipple or into the mud pit in the case of a rotating head. The use of a mud bucket is also recommended in situations where the pipe cannot be shaken dry.

Many operators are now requiring that absorbent or catch pans be placed beneath the drilling rig. Oil and grease leaks or spills are common to the drilling rig operation. Even if the drilling rig is new, leaks and spills are inevitable. Fuel and oil racks should be provide a spill-resistant pour device for direct placement of the lubricant or fuel into equipment. Oil changed on location must be caught in

barrels and recycled by the contractor. Pipe dope should be environmentally sound and not a metal type. Thread cleaning on casing is now frequently done with machines that catch the solvent for reuse on subsequent operations.

Drilling contractors should be advised about the requirements and standards outlined in the environmental and/or waste management plan prior to mobilization. Contractors know that the standard practices of throwing dope buckets, and everything else into the reserve pit is no longer acceptable. However, each contractor may operate under different standards or practices, and it is the operators responsibility to confirm the drilling contractors are disposing of waste properly.

4.20.5.3 Completions

Inherent to the completion operations are the stimulation fluids used to carry sand or otherwise enhance producing qualities of the well. These stimulations fluids may or may not be toxic in nature. The stimulation fluid, although sometimes batch mixed at the service company's facility, may also be mixed on location. The latter system is preferable unless the service company is willing to let form the operator any liability common to the fluid in case of excess.

Many frac jobs are mini-fraced before the actual operation and the design criteria established before the actual frac job is accomplished. The method helps prevent the screening out of the well beforehand. The screened-out well causes potential problems not only in productivity but also in waste management. The unused mixed chemicals, such as KCl makeup water in frac tanks leftover due to the screenout, must be properly disposed. An alternative to this is the mixing of chemicals on the fly instead of preblending and stocking in frac tanks. Some chemicals, such as KCl in water, must be mixed well in advance on location to attain heightened concentrations. In theses in instances, a properly designed frac job, based on the mini-frac, will allow for some certainty in getting the designed job away. Frac flow back may be introduced to the reserve pit after separation from any hydrocarbons. Current frac fluids are composed of primarily of natural organics such as guar gum, but they may contain other components that may be harmful to the environment. Containment of flowback in a lined reserve pit before disposal is a prudent practice.

Acid jobs may also be designed according to prior investigation, although most service companies accept unused acid back into their facilities. Spent acid flowback may be introduced to the lined reserve pit with little consequence. Often, the residual contains salts such as CaCl_2 preciously introduced to the pit. Live acid is occasionally flowed back to surface. This acid may be flowed to the lined pit, given acceptance of the liner material for low pH. The buffer capacity of most drilling fluids is significant, and it is able to assimilate the excess hydrogen ions introduced

to the system. The buffer capacity of the fluid may be calculated from Equations 4.20.7 and 4.20.8 [9]. From a water analysis, pH and alkalinity are determined, and the remaining parameters may then be calculated.

$$\beta = \frac{dC}{dpH} \tag{4.20.7}$$

$$\beta = 2.3 \left[\frac{\alpha_1 ([ALK] - [OH^-] + [H^+]) \left([H^+] + \frac{K'_1 K'_2}{[H^+]} + 4K'_2 \right)}{K' \left(1 + \frac{2K'_2}{[H^+]} \right) + [H^+] + [OH^-]} \right] \tag{4.20.8}$$

$$[ALK] = [HCO_3^-] + 2[CO_3^{2-}] + [OH^-] - [H^+] \tag{4.20.9}$$

$$[Ct] = [H_2CO_3^*] + [HCO_3^-] + 2[CO_3^{2-}] \tag{4.20.10}$$

$$K'_1 = \frac{\gamma [HCO_3^-] (H^+)}{[H_2CO_3^*]} \tag{4.20.11}$$

$$K'_2 = \frac{\gamma^4 [HCO_3^{2-}] (H^+)}{\gamma [HCO_3^*]} \tag{4.20.12}$$

$$\alpha_1 = \frac{1}{1 + \frac{K'_2}{(H^*)} + \frac{(H^+)}{K'_1}} \tag{4.20.13}$$

$$\text{Log } \gamma = -AZ^2 \left[\frac{[\sqrt{I}]}{[1 + \sqrt{I}]} \right] \tag{4.20.14}$$

where

β = buffer capacity, (equivalents/unit pH change)

C = equivalents of buffer available = assumed equal to [ALK]

[ALK] = equivalents of alkalinity

K = equilibrium coefficients

γ = the monovalent activity coefficient

I = the ionic strength

Z = the charge of the species of interest

A = $1.82 \times 106(DT)^{-1.5}$

D = the dielectric constant for water, 78.3 at 25°C

T = °K

() = activity of the ion

[] = concentration of the ion

The buffer capacity of the pit fluid is equal to the change in alkalinity of the system per unit change of pH. Figure 4.20.10 shows the buffer intensity (capacity) of a 0.1M carbonate pit fluid [10]. Calculating the initial buffer capacity of the pit fluid allows for prediction of the pH change on introduction of live acid and any addition of buffer, such as sodium bicarbonate, required to neutralize the excess hydrogen ions.

Care should be taken in every stimulation circumstance to allow fluids to drain to the reserve pit. In the completion operation, it is exceedingly difficult to accomplish this because of traffic, and the service company should therefore provide leak-free hoses, lines, and connections. On completion of the job, the hoses should be drained to a common area for holding subsequent to introduction to the reserve pit. Every precaution should be taken to prevent accumulation of fluids on the pad proper, thereby posing a potential risk to groundwater and runoff of location.

As with the drilling operation, the equipment on location providing the completion service may leak oil. The use of absorbents and catch pans is advised.

FIGURE 4.20.10 Nonideal buffer characteristics of a 0.10 M carbonate reserve pit fluid.

In the case of produced liquid hydrocarbons and other chemicals spilled during operations, subsequent remediation may be necessary. This section (see also Chapter 6, Environmental Considerations) details some remediation techniques currently employed.

4.20.5.4 Reclamation of the Drill Site

In the event of a dry hole, the reserve pit water usage should be maximized to prepare the mud spacers between plugs. Water in excess of this may be pumped into the hole, including solids. All USDWs must be protected in this event. Once the hole has been properly plugged and the drilling rig removed, the mousehole and rathole should be backed filled immediately to preclude any accidents. Trash is removed from the location and adjacent area and is hauled to permit facilities.

4.20.5.5 Reserve Pit Closure

The reserve pit commonly holds all fluids introduced to the wellbore during drilling and completion operations. This includes the drilling and completion fluids in the event the well is stimulated for production and those cuttings produced during the drilling operation. The reserve pit, on completion of the initial rig site activities, must be reclaimed. On removal of the drilling rig, the reserve pit is fenced to prevent wildlife and livestock from watering. The fence is removed on initiation of reclamation.

The fluids from the reserve pit may be hauled away from location for disposal, reclaimed in situ, or pumped into the wellbore given a dry hole. The operator of the well site is responsible for the transportation offsite of the drilling fluids. The fluids may be considered hazardous in nature due to the toxic characteristics of most drilling and completion fluids.

4.20.5.6 Evaporation

Evaporation of the water held in the pit is often the first step in the reserve pit remediation because of economic considerations about trucking and disposal. The evaporation may be mechanically driven or take place naturally. Natural evaporation is very effective in semi-arid regions. The Meyer equation (Equation 4.20.15), as derived from Dalton's law, may be used to estimate the local natural evaporation [6].

$$E = C(e_w - e_a)\psi \quad (4.20.15)$$

$$\Psi = 1 + 0.1w \quad (4.20.16)$$

where

E = evaporation rate (in 30 days)

C = empirical coefficient equal to 15 for small shallow pools and 11 for large deep reservoirs

e_w = saturation vapor pressure corresponding to the monthly mean temperature of air for small bodies and monthly mean temperature of water for reservoirs (in.Hg)

e_a = actual vapor pressure corresponding to the monthly mean temperature of air and relative humidity 30 ft above the body of water (in.Hg)

Ψ = wind factor

w = monthly mean wind velocity measured at 30 ft above body of water (miles/hr)

Some mechanically driven systems include heated vessels or spraying of the water to enhance the natural evaporation rate. In heating, the energy needed to evaporate the water is equal to that needed to bring the water to the temperature of vaporization plus the energy required for the evaporation, where for constant volume this is

$$\Delta E = C_p dT + \Delta H_{vap} \quad (4.20.17)$$

The heat capacity of ΔH_{vap} of pure water at 14.7 pisa are commonly taken as 1 btu/lbm (°F) and 970 btu/lbm [10]. Ionic content in the pit fluid raises the energy necessary to evaporate the fluid. Figure 4.20.11 shows this relationship for brine water containing primarily NaCl [8].

In field evaporative units using natural gas as the fuel source, the primary driving force is the heat supplied to the water. The theoretical evaporation rate for these units may be expressed as

$$\frac{H_c Q_g}{\Delta E \rho_w} = Q_{evap} \quad (4.20.18)$$

where

H_c = natural gas heating value (btu/mcf)

Q_c = natural gas flow rate to burner (mcfpd)

ρ_w = density of water (ppg)

Q_{evap} = evaporation rate (gpd)

Mechanical efficiency may range from 25% to 75% of the theoretical evaporation rate. Efficiencies may be raised with the application of multi-effect or vapor compression evaporators. The more complicated the systems can seldom be warranted due to the short service offered.

Spray systems rely on forming minuscule droplets of water and allowing the vaporization thereof while in suspension over the reserve pit. Allowance for wind carriage of the droplets beyond the pit must be made to prevent salting damage to the surrounding area. The shear force extended

FIGURE 4.20.11 Maximum limit of evaporation as defined by TDS (NaCl).

on each droplet in combination with the relative humidity provides the driving force for the operation. Neglecting the shear component, driving force is actual and saturation vapor pressure differential. A derivation of Fick’s law may be used to express the molar flux of water in air.

$$N_a = \frac{DA}{1000RT} \frac{dV_p}{dx} \quad (4.20.19)$$

where

- N_a = moles of water diffused to the air (mol/sec)
- D = diffusivity of water in air (0.256 cm²/sec at 25°C, 1 atm)
- A = the area perpendicular to the flux (cm²)
- V_p = vapor pressure of water in air (atm)
- R = gas law constant (0.0821 atm L/mol °K)
- X = the thickness of the film where dV_p exists (cm)

Inspection of Equation 4.20.19 shows that increasing the area of the active water surface will allow for greater evaporation rates. In the case of the spray systems,

$$N_a = 0.01256 \frac{nD}{RT} \frac{dV_p}{dx} \quad (4.20.20)$$

Because of the differences in determining x , the thickness of the film between the two vapor pressures, an overall transfer coefficient is introduced. Based on the two-film theory, the overall transfer coefficient is used. In the case of water evaporation, the gas film is the controlling mechanism and the resulting equation is

$$N_a = \frac{K_{ga}}{RT} (V_{Psat} - V_{Pact}) \quad (4.20.21)$$

where K_{ga} = the overall mass transfer coefficient (t⁻¹)

Service companies offering evaporation services can supply the operator with values of K_{ga} maybe used comparatively between all systems for economic analysis.

Using the Meyer equation (Equation 4.20), the evaporative rate from a 5000 ft² pit is estimated. The average temperature in an area in the winter is 40°F, and the corresponding saturated vapor pressure is 0.26 in.Hg, with the actual average vapor pressure residing at 0.19 in.Hg. Wind velocity reaches a peak at 40 mph with a time weighted mean velocity of 5 mph, such that the evaporation rate may be estimated as

$$E = 15(0.26 - 0.19)(1 + 0.1(5)) = 1.58 \text{ in./mo or } 111 \text{ bbl/mo (0.00083 mol sec}^{-1}\text{)}$$

Given this evaporation rate, the overall mass transfer coefficient may then be calculated from Equation 4.20.21:

$$K_{ga} = \frac{N_a RT}{(V_{Psat} - V_{Pact})} = 7.94 \text{ sec}^{-1}$$

4.20.5.7 Fixation of Reserve Pit Water and Solids

Another method of reclaiming the reserve pit involves combining water-absorbing materials to the water and mud. Usually, the pit contents are pumped through tanks where sorbent is combined with the pit fluid and solids. The mixture is dried and subsequently buried. Care must be taken with this method such that any harmful containment is immobilized to prevent contamination to the surroundings. Studies have shown that for muds, once most of the water has been evaporated or pulled from the pit, the remainder may be solidified to comply with existing regulations. This may be done with cement, fly ash, pozzalin, or any number

of absorbents. Polymers have been developed to handle high pH, salt, and oil contents, for which the previous mixtures fell short. The mixture is then allowed to dry and the bulk mass is then buried. This method requires the forethought on pit construction whereby complete mixing of the slurry is accomplished. If primarily bentonite and water are used, evidence has shown minor or no migration from the pit [11].

$$W = \sum M_{at...n} R_{wi...n} \quad (4.20.22)$$

where

W = water available in pit (bbls)

M_r = mass of absorbent (lbm)

R_w = water required by absorbent (bbl/lbm)

However, even though materials such as bentonite can absorb tremendous amounts of water, they may not solidify to an extent that the pit may be reclaimed. In moist instances, a dozer must be able to walk out to the center of the pit under a load of pushed dirt. In the event the pit materials are wet, the dozer may become mired and unable to complete the work. It is often better to pick a sorbent that will harden sufficiently for this purpose.

4.20.5.8 Final Closure

On elimination of the fluids, the liner to the pit is folded over the residual solids in a way to prevent fluid migration. The liner is then buried in place. The operator may choose to remove the liner contents completely to reduce the potential for future contamination. In the case of a producing well, the location is reclaimed up to the deadmen. The adjacent areas are contoured to provide drainage away from the production facilities. In the case of a dry hole, the entire location is reclaimed to the initial condition. All of the reclaimed areas should be ripped to enhance soil conductivity. The topsoil is then spread over the reclaimed area, followed by seeding. Local seed mixtures are broadcast to quicken reintroduction of native plants.

4.21 OFFSHORE DRILLING OPERATIONS

Section reviewed by Dana Witt

One of the more remarkable technological accomplishments of the modern era is the ability of mankind to explore for and produce commercial quantities of oil and natural gas in what are often remote and hostile offshore environments. While offshore petroleum operations have existed for more than half a century, major advances in seismic, drilling and production technology have recently pushed the frontiers to ever deeper waters. What a few years ago was considered deep water—about 650 feet—is no longer regarded as extraordinary, and the very definition of deep water has expanded to 3,000 feet and beyond. In the wake of these innovations, offshore provinces have grown to account for about 25% to 30% of all U.S. production and about 30% of estimated undiscovered reserves.

The basic principles of drilling that rule onshore operations also hold true in offshore environments. However, a fundamental difference offshore is that a stable, self-contained platform must be provided for drilling and support equipment. Communication with a well through possibly thousands of feet of water calls for mechanical as well as procedural differences, primarily in well control and platform positioning. Onshore technology can be applied to offshore operations in many instances when using bottom supported rigs, but the widespread use of floating vessels has necessitated the development of new technology tailored to the floating offshore environment.

Beyond that, well planning, logistics and execution take on added responsibility when carried out in a distant, often harsh marine environment hundreds of miles from sight of the nearest landmass [1-8].

4.21.1 Drilling Vessels

Drilling vessels, called Mobile Offshore Drilling Units (MODU's), are the predominant offshore drilling and exploration rigs and are of two types – either bottom supported or floating-type vessels. Water depth is generally the governing factor as to which type of vessel is employed [9].

Bottom supported vessels include jackup rigs, submersibles and drilling barges. A jackup rig (Figure 4.21.1) is used for drilling in water depths up to about 400 ft. Jackup rigs are usually towed to their location, where the support legs are jacked-down through the water until they are embedded in the sea floor. The drilling package on a jackup can be raised or lowered on the legs of the vessel to allow for use in various water depths and sea floor soil conditions. These rigs can also be used alongside production platforms for developmental drilling. Jackup rigs thus provide a mobile, bottom supported drilling vessel suitable for use in relatively shallow water.

Drilling barges, commonly employed in inland waters and marshes, can be used where water depths do not exceed about 20 ft. These self-contained vessels provide the least expensive drilling option, but have limited applicability because of water depth and environmental limitations.

Submersible rigs likewise are used strictly in shallow water—in depths of 80 ft or less. They have two hulls—the upper containing crew quarters and the drilling rig and the lower filled with air, making the vessel buoyant. Submersibles are towed to their location, where the air in the bottom hull is displaced with sea water for weight and the rig is lowered to the sea floor.

Drillships and semisubmersible rigs are the two dominant types of floating drilling vessels – and can operate in shallow, deep and ultra-deep water.

A drillship (Figure 4.21.2) is a large ocean-going vessel that features a drilling package and large derrick positioned in the middle of its main deck, with a hole or “moonpool” extending down through the hull – through which the drill string is extended through the water and seabed to the target location. Some drillships are designed to work in waters more than 10,000 ft deep. They are kept on location by complex mooring and/or dynamic positioning systems. Dynamic positioning systems utilize electrically driven propellers, or thrusters, on the underside of the ship's hull, capable of moving the vessel in any direction. They are controlled by the ship's computer system, which uses satellite positioning technology, along with ship-board sensors and seafloor beacons located on the seafloor or drilling template located on the sea floor to ensure that the ship remains directly above the drill site.

Semisubmersible rigs (Figure 4.21.3)—the most common type of floating drilling vessel—can be used in water up to 10,000 ft deep, and provide a drilling platform generally more stable than does a drillship. Since a major portion of the vessel is submerged, wave effects can be minimized. Mooring systems of semisubmersibles utilize dynamic positioning and/or huge anchors weighing upwards of 15 tons. Ballast can be preferentially shifted within the vessel to provide stability during rough weather.

When choosing an offshore drillsite, the primary considerations are the likelihood of hydrocarbon-laden formations, water depth, the location of shipping lanes, foundation

FIGURE 4.21.1 Jackup drilling rig.

FIGURE 4.21.2 Drillship.

FIGURE 4.21.3 Semisubmersible drilling rig.

stability (for bottom supported vessels), and the possible presence of shallow gas. Seismic surveys and core analysis generally provide suitable information on foundation stability, and seismic studies can indicate the presence of potentially dangerous shallow gas deposits.

4.21.1.1 Marine Riser Systems

The most striking difference between onshore and offshore drilling occurs when the wellhead is located at the sea floor. This configuration makes communication with the well more complex. A marine riser provides communication and circulation capability between the surface and the sea floor, and is used at some point during all offshore drilling. The riser consists of large diameter ($13^{5/8}$ to $21^{3/4}$) steel

pipe joints of 45- to 90-foot lengths, equipped with quick connect couplings, integral choke, kill, and riser boost lines. The bottom of the riser is connected to the BOP stack, which is connected to the wellhead located at the seafloor. A diverter system is usually attached at the surface [8,9].

Vertical vessel motion is accommodated by adding a telescoping (slip) joint at the surface. This joint will usually allow up to 50 ft (double amplitude) of vertical vessel motion. Lateral motion is compensated for by the use of ball/flex joint connections at the sea floor and surface.

The riser can be quickly detached from the wellhead or blowout preventer stack to facilitate vessel movement during adverse weather conditions. Figure 4.21.4 shows in more detail a typical riser system that would be used while drilling the intermediate hole from a floating vessel.

A marine riser must be held in tension to prevent the riser from buckling and failing under its own weight. This can be accomplished by mechanical tensioning devices (Figures 4.21.5, 4.21.6) and by adding buoyant material to the riser pipe at increasing water depths. Many operators drill the conductor hole (approximately, 1,000 ft) without using a riser. When drilling with a floating vessel, the shallow portion of the surface hole is considered expendable, and can easily be abandoned in case of shallow gas flow, deviation difficulties, or other shallow-hole problems. Drilling is accomplished by circulating returns to the sea floor. Once the conductor hole is drilled, casing is run, and a subsea wellhead installed, then the marine riser can be attached and used to drill the remainder of the well.

4.21.1.2 Casing Programs

Casing programs offshore typically consist of 30-in. structural, 20-in. conductor, $13^{3/8}$ -in. surface, and $9^{5/8}$ -in. intermediate casing strings. Because seawater is in perfect communication with the sediments, pore pressure is increased by increasing water depth, and the margin between fracture pressure and pore pressure is lessened.

In deepwater, the narrowing of the pore pressure to fracture gradient window drives the need to run and set a greater number of large diameter casing strings, especially in the shallower hole sections. It is common for a deepwater well to have between five and eight strings of casing. Typical deepwater Gulf of Mexico casing programs are: $36'' \times 20'' \times 16'' \times 13^{5/8}'' \times 11^{7/8}'' \times 9^{7/8}'' \times 7^{3/4}''$ or $36'' \times 28'' \times 22'' \times 18'' \times 16'' \times 13^{5/8}'' \times 11^{7/8}'' \times 9^{7/8}'' \times 7^{3/4}''$. The large number of casing strings, and especially the small annular clearances this dictates, cause additional drilling and cementing problems. Also, abnormal pore pressure is found in many offshore geological environments, requiring fairly stringent casing designs. Several intermediate casing strings or liners are often required to reach the target depth. Most operators prefer to set 7-in.

FIGURE 4.21.4 Marine riser for floating system.

FIGURE 4.21.5 Buoyant riser tensioning device.

FIGURE 4.21.6 Mechanical riser tensioning device.

production casing to facilitate larger production tubing and quicker payout [9, 10].

4.21.1.3 Well Control

Offshore, well control equipment and associated operations present some differences from that seen and used onshore. In some instances, onshore equipment can be employed, but the offshore environment generally dictates a modification of equipment and procedures. There are several different well control equipment configurations used offshore depending on the type of drilling unit employed and the stage of the drilling operation, and each configuration requires the use of specific well control procedures that should be followed. A well may be controlled with a surface blowout preventer stack; a subsea blowout preventer stack, riser and diverter system; a riser and diverter system with no blowout preventer; or a diverter only [10, 11].

4.21.1.4 Surface Blowout Preventer Stacks

When a development platform has been set, or a bottom supported drilling rig is used, wells can be drilled with a “land-type” well design. Conductor casing is set from above sea level, through the water, to as much as 1,500 feet subsea. The conductor provides a conduit for mud returns, and allows blowout preventers to be located at the surface, increasing system flexibility and easing maintenance requirements. This BOP equipment layout is essentially identical to that used onshore, as are the well control procedures employed [10, 11].

4.21.1.5 Subsea Blowout Preventer Stacks

During floating drilling operations, the potential exists for the drilling rig to lose station keeping capability and drift off from over the subsea wellhead. Because of this, the blowout preventers are located on top of the wellhead on the sea

floor, allowing the well to be shut in and controlled at the sea floor, independent of drilling rig location. The detachable marine drilling riser allows mud returns between the wellbore and the rig. This action removes the drilling vessel from the responsibility of maintaining surface position at

all times. Figure 4.21.7 shows a typical subsurface blowout preventer stack. Note the presence of choke and kill lines extending from the surface to the stack. These lines allow fluids to flow out of the well or be pumped into the well, bypassing the marine riser [9–11].

FIGURE 4.21.7 Subsea blowout preventer stack.

4.21.1.6 Well Control Procedures

There are several mechanical differences between onshore and offshore equipment that lead to procedural differences in well control. When a well is shut in by a subsea blowout preventer, fluids must be circulated down the drillstring, up the casing annulus, and up the choke or kill line to the surface. The marine riser/drillstring annulus is thus bypassed. Choke line friction pressure should be considered when planning and executing the well kill operation. Neglecting choke line friction pressure may result in excessive back pressure being placed on the well bore. The choke line friction pressure can be determined by circulating the well through the choke and kill lines, respectively, at the pump rate selected for the well kill operation and measuring the resulting friction pressure. Choke line friction can be reduced by using larger I.D. choke and kill lines, circulating at slower pump rates, or by circulating the well through both the choke and kill lines. [9–11].

When the well is circulated through the choke line, a rapid loss in hydrostatic pressure is encountered when the kick fluid begins to enter the choke line. Hydrostatic pressure is lost because low-density gas is displacing the drilling mud from the small volume of choke line. Small kick volumes can result in long columns of gas in the choke line. Surface choke response must be rapid enough to prevent a loss of bottom hole pressure, otherwise new kick fluid may enter the wellbore due to the reduction in bottom hole pressure. Also, when kill fluid enters the choke line and begins to displace the kick fluid, hydrostatic pressure will increase rapidly, thus increasing bottomhole pressure. Slow response by the choke operator can fracture the formation. A choke operator is faced with a demanding job when pumping out a kick through a subsurface blowout preventer.

4.21.1.7 Diverter Systems

Shallow gas hazards are a common potential danger offshore. Quite often, these hazards can be spotted in seismic analysis, and a surface location chosen to avoid the hazard. However, there is always a risk of encountering a shallow gas flow with insufficient casing in the well to allow a shut-in. In this instance a diverter system is used as a safety device. In many cases the diverter system simply provides enough time to evacuate the rig [9–11].

Figure 4.21.8 shows a typical diverter system setup. The components of the system are the annular-type preventer, vent lines, the control system, and the conductor or structural casing. The major operational consideration when using a diverter system is to make certain that the valves on the vent lines are fully open before the annular-type

preventers are closed. When a shallow gas flow is encountered while drilling the conductor or surface hole, shutting in the well may cause a subsurface blowout that is likely to broach to the surface. This cannot be tolerated when drilling from a bottom-supported vessel. Larger diameter vent lines free from turns or bends lower the backpressure placed on the well by the diverter system, therefore reducing the risk of a subsurface blowout. The lack of bends in the lines greatly reduces the erosion potential of the surface lines due to the well flow. Sufficient conductor casing depth is also very important in preventing a subsurface blowout.

The BSEE requires a minimum 10-inch-diameter diverter vent lines, but many operators are now using as large as 16-inch-diameter vent lines.

While a bottom-supported vessel must divert when shallow gas is encountered, a floating vessel has the additional option of simply abandoning the well. This option has led to the use of riserless systems when drilling the surface hole. However, a dynamic kill provides the only means of controlling the well. A dynamic kill makes use of annular circulating friction as well as a heavier mud to hold backpressure on the formation. If very short wellbores are involved, the dynamic kill rates are usually too large to be practical.

4.21.2 Deepwater Well Planning Considerations

As the offshore industry moves into ever-deeper water to globally explore for and produce oil and natural gas in commercial quantities, particular and complex challenges arise in terms of health, safety and environmental considerations—which are always of the highest priority—as well as well planning and logistics.

Deepwater drilling is one of the greatest drilling challenges in existence today. Failures in the design of the structural casing string and wellhead have proven to be very expensive. A conservative design approach, incorporating stringent safety, environmental and regulatory requirements compliance factors and considering the risks and uncertainties of “worst-case” design assumptions is followed when planning these wells.

Deepwater well planning requires special attention be given to such considerations as reduced annular clearances, higher equivalent circulating densities (ECD's), increased cementing difficulty, well angle, hydrate formation, ocean currents, deepwater hydrostatic pressures and stresses, casing design, drilling fluids, flow control, kick prevention, detection and response, well testing and intervention operations.

FIGURE 4.21.8 Diverter system.

The narrowing of the pore pressure/frac gradient window requires more casing strings to reach the well objectives. The small annular clearances resulting from the need to set a large number of casing strings are particularly problematic, affecting all facets of the well drilling operation. For example, tight annular clearances restrict the flow of the drilling mud in the casing and wellbore annuli, resulting in high annular circulating pressures. This raises the equivalent circulating density (ECD) of the drilling mud to the point where wellbore “breathing” (ballooning) and lost circulation often may occur. The problem is even more severe when performing casing cementing operations, where the high ECD’s may result in lost circulation, making it very difficult to achieve a good primary cement job. Well control becomes more difficult because the elevated ECD’s increase the probability that shoe fracture pressure will be exceeded while killing the well.

Managed Pressure Drilling (MPD) techniques have been developed, in part, to help alleviate the effects of tight annular clearances in deepwater. MPD allows manipulation of wellbore pressures to more closely mimic the natural pressure gradient. While all MPD variations can be beneficial in managing wellbore annular pressure profiles, the dual gradient drilling (DGD) MPD variant provides the greatest flexibility in manipulating the annular pressure profile. DGD can effect the greatest reduction in annular friction pressure, even to the point of being able to replicate the effect of the seawater column hydrostatic in the well’s natural state. One immediate benefit is the restoration of “riser margin”, where the weight of the drilling fluid in the wellbore below the mudline can be of a density sufficient to maintain control of the well, using mud weight alone, should the riser become disconnected from the wellhead. Changes in wellbore pressures become easier to

detect. Another potential benefit resulting from the ability to manipulate wellbore pressures is to eliminate the need for many of the shallow casing strings currently required to successfully drill the well. A reduction in the number of shallow casing strings means that fewer casings will be required to reach total depth (TD). Annular clearances become larger, and ECD's are reduced. The ECD reduction will mean fewer instances of lost circulation and better cement jobs. In many instances it is possible to reach TD with a larger hole size, enhancing completion options. MPD technology is continuing to mature and it will be interesting to see what the future holds.

Reservoir Engineering

Reservoir engineering covers a broad range of subjects including the occurrence of fluids in a gas or oil-bearing reservoir, movement of those or injected fluids, and evaluation of the factors governing the recovery of oil or gas. The objectives of a reservoir engineer are to maximize producing rates and to ultimately recover oil and gas from reservoirs in the most economical manner possible.

This chapter presents the basic fundamentals useful to practical petroleum engineers. Topics are introduced at a level that can be understood by engineers and geologists who are not expert in this field. Various correlations are provided where useful. Newer techniques for improving recovery are discussed.

The advent of programmable calculators and personal computers has dramatically changed the approach of solving problems used by reservoir engineers. Many repetitious and tedious calculations can be performed more consistently and quickly than was possible in the past. The use of charts and graphs is being replaced by mathematical expressions of the data that can be handled with portable calculators or personal computers. Programs relating to many aspects of petroleum engineering are now available. In this chapter, many of the charts and graphs that have been historically used are presented for completeness and for illustrative purposes. In addition, separate sections will be devoted to the use of equations in some of the more common programs suitable for programmable calculators and personal computers.

5.1 BASIC PRINCIPLES, DEFINITIONS, AND DATA

Section reviewed by Heru Danardatu

5.1.1 Reservoir Fluids

5.1.1.1 Oil and gas

Reservoir oil may be saturated with gas, the degree of saturation being a function, among others, of reservoir pressure and temperature. If the reservoir oil has dissolved

in it all the gas it is capable of holding under given conditions, it is referred to as saturated oil. The excess gas is then present in the form of a free gas cap. If there is less gas present in the reservoir than the amount that may be dissolved in oil under conditions of reservoir pressure and temperature, the oil is then termed undersaturated. The pressure at which the gas begins to come out of solution is called the saturation pressure or the bubble-point pressure. In the case of saturated oil, the saturation pressure equals the reservoir pressure and the gas begins coming out of solution as soon as the reservoir pressure begins to decrease. In the case of undersaturated oil, the gas does not start coming out of solution until the reservoir pressure drops to the level of saturation pressure.

Apart from its function as one of the propulsive forces, causing the flow of oil through the reservoir, the dissolved gas has other important effects on recovery of oil. As the gas comes out of solution the viscosity of oil increases and its gravity decreases. This makes more difficult the flow of oil through the reservoir toward the wellbore. Thus the need is quite apparent for production practices tending to conserve the reservoir pressure and retard the evolution of the dissolved gas. [Figure 5.1.1](#) shows the effect of the dissolved gas on viscosity and gravity of a typical crude oil.

The dissolved gas also has an important effect on the volume of the produced oil. As the gas comes out of solution the oil shrinks so that the liquid oil at surface conditions will occupy less volume than the gas-saturated oil occupied in the reservoir. The number of barrels of reservoir oil at reservoir pressure and temperature which will yield one barrel of stock tank oil at 60°F and atmospheric pressure is referred to as the formation volume factor or reservoir volume factor. Formation volume factors are described in a subsequent section. The solution gas–oil ratio is the number of standard cubic feet of gas per barrel of stock tank oil.

Physical properties of reservoir fluids are determined in the laboratory, either from bottomhole samples or from recombined surface separator samples. Frequently, however, this information is not available. In such cases, charts such as those developed by M.B. Standing and

FIGURE 5.1.1 Change in viscosity and gravity of crude oil due to dissolved gas.

reproduced as Figures 5.1.2, 5.1.3, 5.1.4, and 5.1.5 have been used to determine the data needed [1, 2]. The correlations on which the charts are based present bubble-point pressures, formation volume factors of bubble-point liquids, formation volume factors of gas plus liquid phases, and density of a bubble-point liquid as empirical functions of gas-oil ratio, gas gravity, oil gravity, pressure, and temperature. More recent correlations will be presented subsequently.

Most estimates of PVT properties were obtained by using charts and graphs of empirically derived data. With

the development of programmable calculators, graphical data are being replaced by mathematical expressions suitable for computer use. In a later section, the use of such programs for estimating PVT properties will be presented. In the initial sections, the presentation of graphical data will be instructive to gaining a better understanding of the effect of certain variables.

5.1.1.2 Water

Regardless of whether a reservoir yields pipeline oil, water in the form commonly referred to as interstitial or connate is present in the reservoir in pores small enough to hold it by capillary forces.

The theory that this water was not displaced by the migration of oil into a water-bearing horizon is generally accepted as explanation of its presence.

The amount of the interstitial water is usually inversely proportional to the permeability of the reservoir. The interstitial water content of oil-producing reservoirs often ranges from 10% to 40% of saturation.

Consideration of interstitial water content is of particular importance in reservoir studies, in estimates of crude oil reserves and in interpretation of electrical logs.

5.1.1.3 Fluid Viscosities

5.1.1.3.1 Gas Viscosity

Viscosities of natural gases are affected by pressure, temperature, and composition. The viscosity of a specific natural gas can be measured in the laboratory, but common practice is to use available empirical data such as those shown in Figures 5.1.6 and 5.1.7. Additional data are given in the Handbook of Natural Gas Engineering [3]. Contrary to the

EXAMPLE

REQUIRED:

Bubble point pressure at 200°F of a liquid having a gas-oil ratio of 350 CFB, a gas gravity of 0.75, and a tank oil gravity of 30° API.

PROCEDURE:

Starting at the left side of the chart, proceed horizontally along line 350 CFB line to a gas gravity of 0.75. From this point drop vertically to the 30° API line. Proceed horizontally from the tank oil gravity scale to the 200°F line. The required pressure is found to be 1930 PSIA.

FIGURE 5.1.2 Bubble point pressure graph [1, 2].

EXAMPLE

REQUIRED:

Formation volume at 200° F of a bubble point liquid having a gas-oil ratio of 350 CFB, a gas gravity of 0.75, and a tank oil gravity of 30° API.

PROCEDURE:

Starting at the left side of the chart, proceed horizontally along the 350 CFB line to a gas gravity of 0.75. From this point drop vertically to the 30° API line. Proceed horizontally from the tank oil gravity scale to the 200° F line. The required formation volume is found to be 1.22 barrel per barrel of tank oil.

FIGURE 5.1.3 Formation volume of bubble point liquids [1,2].

EXAMPLE

REQUIRED:

Formation volume of the gas plus liquid phases of a 1500 CFB mixture, gas gravity = 0.80, tank oil gravity = 40° API, at 200° F and 1000 PSIA.

PROCEDURE:

Starting at the left side of the chart proceed horizontally along the 1500 CFB line to the 0.80 gas gravity line. From this point drop vertically to the 40° API line. Proceed horizontally to 200° F and from that point drop to line 1000 PSIA pressure line. The required formation volume is found to be 5.0 barrels per barrel of tank oil.

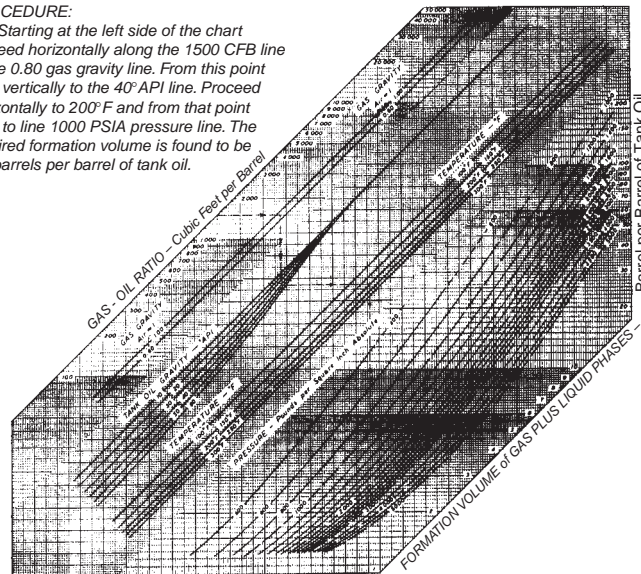

FIGURE 5.1.4 Formation volume of gas with liquid phases [1,2].

EXAMPLE

REQUIRED:

Density at 200° F at a bubble point liquid having a gas-oil ratio at 350 CFB, a gas gravity of 0.75 on a tank oil gravity of 30° API.

PROCEDURE:

From Chart 3 determine formation volume of 1.22 barrels per barrel of tank oil. Starting a left side of chart proceed horizontally along the 350 CFB line to a gas gravity of 0.75. From this point drop vertically to the 30° API line. Proceed horizontally from the tank oil gravity scale to the formation volume of 1.22. The required density is found to be 47.5 pounds per cubic foot.

FIGURE 5.1.5 Density and specific gravity of mixtures [1,2].

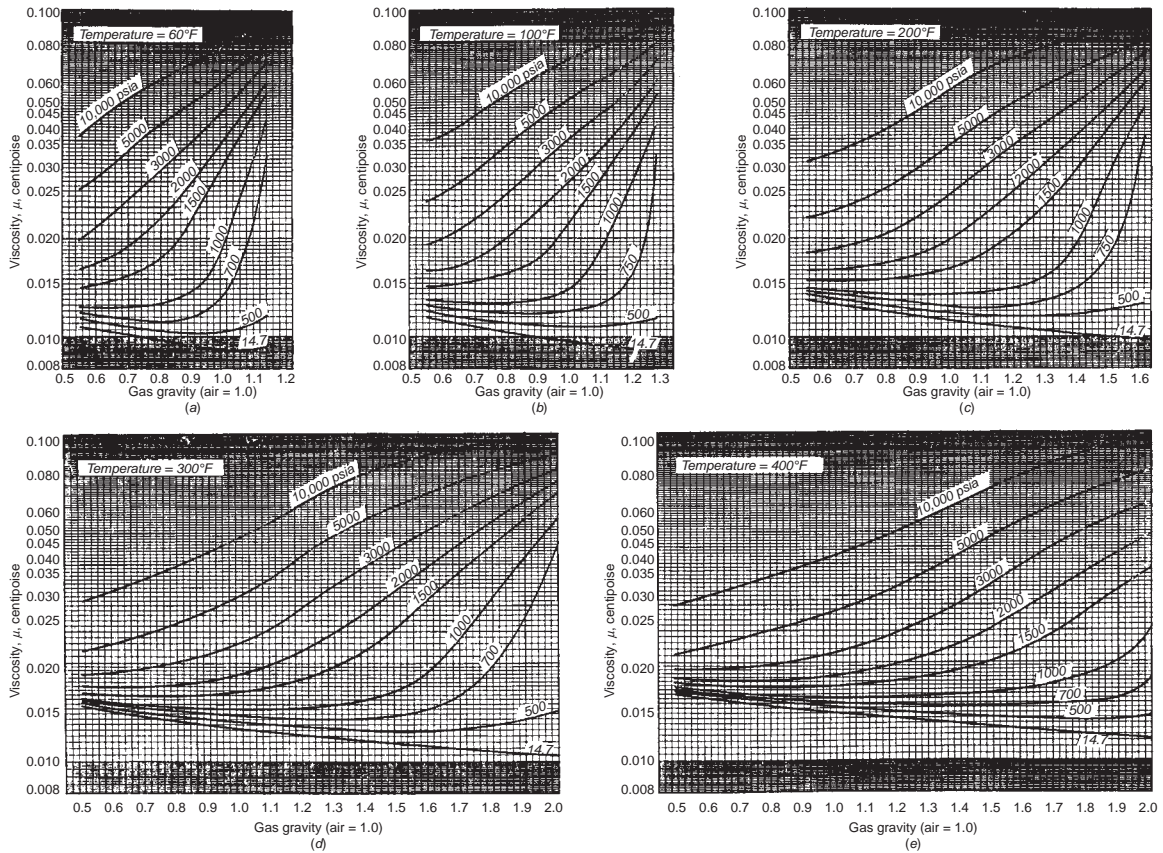

FIGURE 5.1.6 Gas viscosity versus gravity at different temperatures [3].

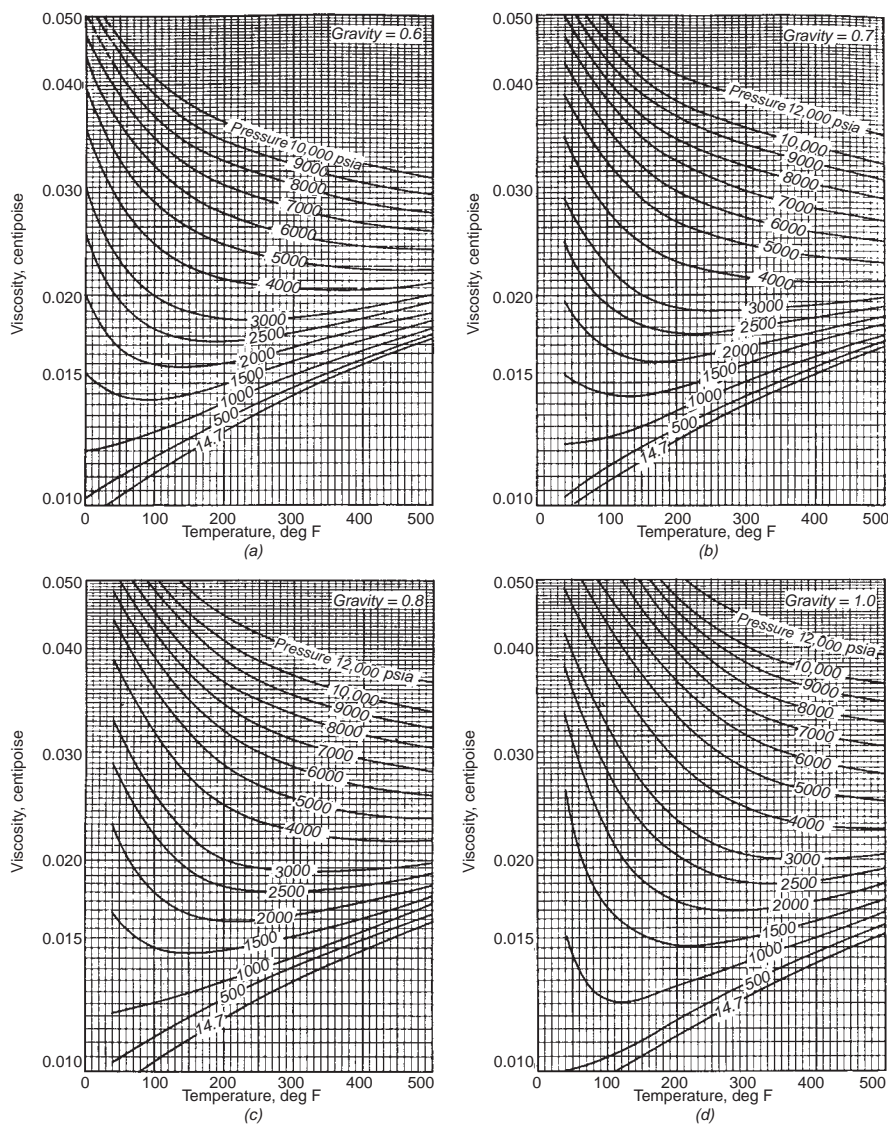

FIGURE 5.1.7 Gas viscosity versus temperature at different gravities [3].

case for liquids, the viscosity of a gas at low pressures increases as the temperature is raised. At high pressures, gas viscosity decreases as the temperature is raised. At intermediate pressure, gas viscosity may decrease as temperature is raised and then increase with further increase in temperature.

5.1.1.3.2 Oil Viscosity

The viscosity of crude oil is affected by pressure, temperature, and most importantly, by the amount of gas in solution. Figure 5.1.8 shows the effect of pressure on viscosities of several crude oils at their respective reservoir temperatures [4]. Below the bubble-point, viscosity decreases with increasing pressure because of the thinning effect of gas going into solution. Above the bubble-point, viscosity increases with increasing pressure because of compression of the liquid. If a crude oil is undersaturated at the original

reservoir pressure, viscosity will decrease slightly as the reservoir pressure decreases. A minimum viscosity will occur at the saturation pressure. At pressures below the bubble-point, evolution of gas from solution will increase the density and viscosity of the crude oil as the reservoir pressure is decreased further.

Viscosities of hydrocarbon liquids decrease with increasing temperature as indicated in Figure 5.1.9 for gas-free reservoir crudes [5]. In cases where only the API gravity of the stock tank oil and reservoir temperature are known, Figure 5.1.9 can be used to estimate dead oil viscosity at atmospheric pressure. However, a more accurate answer can be obtained easily in the laboratory by simply measuring viscosity of the dead oil with a viscometer at reservoir temperature.

FIGURE 5.1.8 Effect of pressure on crude oil viscosities [4].

FIGURE 5.1.9 Crude oil viscosity as a function of API gravity [5].

With the dead oil viscosity at atmospheric pressure and reservoir temperature (either measured or obtained from Figure 5.1.9), the effect of solution gas can be estimated with the aid of Figure 5.1.10 [6]. The gas-free viscosity and solution gas-oil ratio are entered to obtain viscosity of the gas-saturated crude at the bubble-point pressure.

FIGURE 5.1.10 Viscosities of gas-saturated crude oils at reservoir temperature and bubble-point pressure [6].

This figure accounts for the decrease in viscosity caused by gas going into solution as pressure is increased from atmospheric to the saturation pressure.

If the pressure is above the bubble-point pressure, crude oil viscosity in the reservoir can be estimated with Figure 5.1.11 [5]. This figure shows the increase in liquid viscosity due to compression of the liquid at pressures higher than the saturation pressure. Viscosity of the crude can be estimated from the viscosity at the bubble-point pressure, and the difference between reservoir pressure and bubble-point pressure.

Recent correlations [7] were presented in equation form for the estimation of both dead oil and saturated oil viscosities. These correlations, which are presented in the section on programs for hand-held calculations, neglect the dependence of oil viscosity on composition of the crude. If compositional data are available, other correlations [8–10] for oil viscosity can be used.

5.1.1.3.3 Water Viscosity

In 1952, the National Bureau of Standards conducted tests [11] which determined that the absolute viscosity of pure water was 1.0019cp as compared with the value of 1.005cp that had been accepted for many years. Effective July 1, 1952, the value of 1.002cp for the absolute viscosity of water was recommended as the basis for the calibration of viscometers and standard oil samples. Any literature values based on the old standard are in slight error. Water viscosity decreases as temperature is increased as shown in Table 5.1.1.

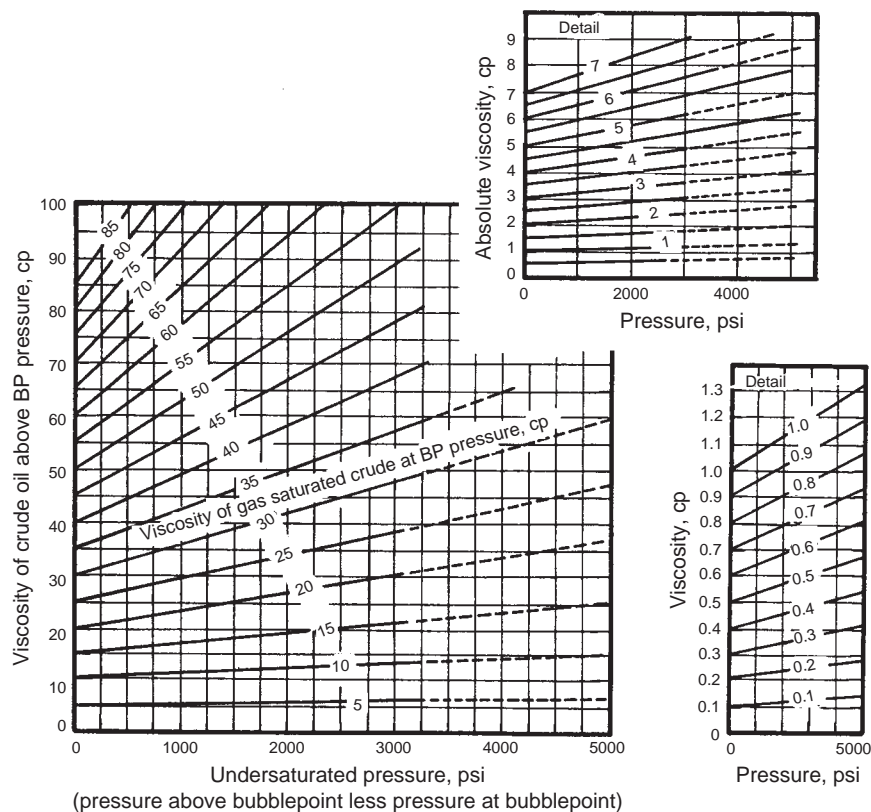

FIGURE 5.1.11 Increase in oil viscosity with pressure above bubble-point pressure [5].

TABLE 5.1.1 Viscosity of Pure Water at Various Temperatures

T, °C	T, °F	Viscosity (cp)
0	32	1.787
10	50	1.307

90	194	0.3147
100	212	0.2818

From Reference 12.

Although the predominate effect on water viscosity is temperature, viscosity of water normally increases as salinity increases. Potassium chloride is an exception to this generality. Since most oilfield waters have a high sodium chloride content, the effect of this salt on viscosity of water is given in Table 5.1.2.

For temperatures of interest in oil reservoirs (> 60°F), the viscosity of water increases with pressure but the effect is slight. Dissolved gas at reservoir conditions should reduce the viscosity of brines; however, the lack of data and the slight solubility of gas in water suggest that this effect is usually ignored. Figure 5.1.12 is the most widely cited data for the effect of sodium chloride and reservoir temperature on water viscosity [13].

5.1.1.4 Formation Volume Factors

These factors are used for converting the volume of fluids at the prevailing reservoir conditions of temperature and pressure to standard surface conditions of 14.7 psia and 60°F.

5.1.1.4.1 Gas Formation Volume Factor

The behavior of gas can be predicted from:

$$pV = znRT \quad (5.1.1)$$

where p = absolute pressure
 V = volume of gas
 T = absolute temperature
 n = number of moles of gas
 R = gas constant
 z = factor to correct for nonideal gas behavior

For conventional field units, p is in psia, V is in ft^3 , T is in $^{\circ}\text{R}$ ($^{\circ}\text{F} + 460$), z is dimensionless, n is in lb moles, and R is $10.73 \text{ psia ft}^3/\text{lb mole } ^{\circ}\text{R}$ [14]. The gas formation volume factor, B_g , is the volume of gas in the reservoir occupied by a standard ft^3 of gas at the surface:

$$B_g = \frac{V \text{ ft}^3}{5.615 \text{ ft}^3/\text{bbl}} = \frac{znR(T_R + 460)}{5.615} \quad (5.1.2)$$

where T_R is the reservoir temperature in $^{\circ}\text{F}$.

Since one lb mole is equivalent to 379 ft^3 at 60°F and 14.7 psia [15]:

$$B_g = \frac{\frac{1}{379} \times 10.73}{5.615} \frac{zT_R}{p} = 0.00504 \frac{zT_R}{p} \quad (5.1.3)$$

In this expression, B_g will be in reservoir barrels per standard ft^3 (RB/scf).

Gas formation volume factor can also be expressed in units of reservoir barrels per stock tank barrel or ft^3 of gas at reservoir conditions per ft^3 of gas at standard conditions:

$$B_g = 0.02827(460 + T_R) \frac{z}{p} \quad (5.1.4)$$

Because the gas formation volume factor can be expressed in so many different units (including the reciprocal of B_g), caution should be exercised when B_g is used. In much of the recent petroleum literature, notably SPE, B_g is expressed in RB/scf. If units of ft^3/scf are given, B_g can be divided by 5.615 or multiplied by 0.1781 to get RB/scf.

Gas formation volume factors can be estimated by determining the gas deviation factor or compressibility factor, z , at reservoir pressure, p , and temperature T_R from the correlations of Standing and Katz [16] (Figure 5.1.13). To obtain the z factor, reduced pressure, p_r , and reduced temperature, T_r , are calculated:

$$p_r = \frac{p}{p_c} \quad (5.1.5)$$

where p_c is the critical pressure and k

$$T_r = \frac{T}{T_c} \quad (5.1.6)$$

where T_c is the critical temperature. The critical pressure and temperature represent conditions above which the liquid and vapor phase are indistinguishable.

Compressibility factor and gas formation volume factor can be more conveniently estimated by the use of programs available for hand-held calculators. These programs will be subsequently discussed.

5.1.1.4.2 Oil Formation Volume Factor

The volume of hydrocarbon liquids produced and measured at surface conditions will be less than the volume at reservoir conditions. The primary cause is the evolution of gas from the liquids as pressure is decreased from the reservoir to the surface. When there is a substantial amount of dissolved gas, a large decrease in liquid volume occurs. Other factors that influence the volume of liquids include changes in temperature (a decrease in temperature will cause the liquid to shrink) and pressure (a decrease in pressure will cause some liquids to expand). All of these factors are included in the oil formation volume factor, B_o , which is the volume of oil in reservoir barrels, at the prevailing reservoir conditions of pressure and temperature, occupied by a stock tank barrel of oil at standard conditions. The withdrawal of reservoir fluids can be related to surface production volumes by obtaining laboratory PVT data with reservoir fluids. Such data include B_g (the gas formation volume factor), B_o (the oil formation volume factor), and R_s (the solution gas-oil ratio which is the volume of gas in standard ft^3 that will dissolve in one stock tank barrel of oil at reservoir conditions).

The formation volume factor is used to express the changes in liquid volume accompanied by changes in pressure. Changes in formation volume factor with pressure for an undersaturated crude are displayed in Figure 5.1.14

FIGURE 5.1.12 Water viscosities for various salinities and temperatures [13].

[17]. As the initial reservoir pressure decreases, the all-liquid system expands and the formation volume factor increases until the bubble-point pressure is reached. As pressure decreases below the bubblepoint, gas comes out of solutions, the volume of oil is reduced, and B_o decreases. For a saturated crude, the trend would be similar to that observed to the left of bubble-point pressure in Figure 5.1.14.

When two phases exist, the total formation volume factor or 2-phase formation volume factor is [17]:

$$B_t = B_o + B_g(R_{si} - R_s) \quad (5.1.7)$$

which includes the liquid volume, B_o , plus the gas volume times the difference in initial solution gas-oil ratio, R_{si} , and the solution gas-oil ratio at the specific pressure, R_s . At pressures above the bubblepoint, R_{si} equals R_s , and the single-phase and 2-phase formation volume factors are identical. At pressures below the bubblepoint, the 2-phase factor increases as pressure is decreased because of the

gas coming out of solution and the expansion of the gas evolved.

For a system above the bubblepoint pressure, B_o is lower than the formation volume factor at saturation pressure because of contraction of the oil at higher pressure. The customary procedure is to adjust the oil formation volume factor at bubble-point pressure and reservoir temperature by a factor that accounts for the isothermal coefficient of compressibility such as [18]:

$$B_o = B_{ob} \exp[-c_o(p - p_b)] \quad (5.1.8)$$

where B_{ob} is the oil formation volume factor at bubblepoint conditions, p_b is the bubble-point pressure in psi, and c_o is oil compressibility in psi^{-1} .

The basic PVT properties (B_o , R_s , and B_g) of crude oil are determined in the laboratory with a high-pressure PVT cell. When the pressure of a sample of crude oil is reduced, the quantity of gas evolved depends on the conditions of liberation. In the flash liberation process, the gas evolved during any pressure reduction remains in contact with the

FIGURE 5.1.13 Compressibility factors [16].

oil. In the differential liberation process, the gas evolved during any pressure reduction is continuously removed from contact with the oil. As a result, the flash liberation is a constant-composition, variable-volume process and the differential liberation is a variable-composition, constant-volume process. For heavy crudes (low volatility, low API gravity oils) with dissolved gases consisting primarily of methane and ethane, both liberation processes yield similar

FIGURE 5.1.15 Comparison of measured and calculated composite oil volume [19].

quantities and compositions of evolved gas as well as similar resulting oil volumes. However, for lighter, highly volatile crude oils containing a relatively high proportion of intermediate hydrocarbons (such as propane, butane, and pentane), the method of gas liberation can have an effect on the PVT properties that are obtained. An example of differences in formation volumes with flash and differential liberation processes can be seen in Figure 5.1.15 [19]. Actual reservoir conditions may be somewhere between these extremes because the mobility of the liberated gas is greater than the oil, the gas is produced at a higher rate, and the oil in the reservoir is in contact with all of the initial solution gas for only a brief period [20]. Since volatile

FIGURE 5.1.14 Formation volume factor of the Big Sandy Field reservoir oil, by flash liberation at reservoir temperature of 160°F [17].

oil situations are uncommon [20], many engineers feel the differential liberation process typifies most reservoir conditions [19]. For reservoir fluids at the bubblepoint when a well is put on production, the gas evolved from the oil as the pressure declines does not flow to the well until the critical gas saturation is exceeded. Since the greatest pressure drop occurs near the wellbore, the critical gas saturation occurs first near the well, especially if the pressure drop is large. In general, differential liberation data are applicable if the reservoir pressure falls considerably below the bubble-point pressure and the critical gas saturation is exceeded in the majority of the drainage area, as indicated by producing gas-oil ratios considerably in excess of the initial solution gas-oil ratio [17]. Flash liberation data may be applicable to reservoirs where there is only a moderate pressure decline below the bubblepoint, as indicated by producing gas-oil ratios not much higher than the initial solution gas-oil ratio, since the liberated gas stays in the reservoir in contact with the remaining oil [17].

Several correlations are available for estimating formation volume factors. Single-phase formation volume factors can be estimated from solution gas, gravity of solution gas, API gravity of the stock tank oil, and reservoir temperature by using the correlations of Standing [1, 2]. Figure 5.1.3 provides Standing's empirical correlation of bubble-point oil formation volume factor as a function of the variables mentioned. Total formation volume factors of both solution gas and gas-condensate systems can be obtained from Standing's correlations given in Figure 5.1.4.

Empirical equations have been developed [21] from Standing's graphical data. These equations provide the oil formation volume factor and the solution gas-oil ratio as functions of reservoir pressure [21]:

$$B_o = a p^{1.17} + b \quad (5.1.9)$$

where a is a constant that depends on temperature, oil API gravity and gas gravity and b is a constant that depends on temperature. Values of both constants are given in Table 5.1.3, other values can be interpolated.

Solution gas-oil ratio can be estimated from:

$$R_s = y p^{1.17} \quad (5.1.10)$$

where y is a constant that depends on temperature, gas gravity, and oil gravity. Values of y are provided in Table 5.1.4.

Additional correlations suitable for use with programmable calculators are discussed in a later section of this chapter.

5.1.1.4.3 Water Formation Volume Factor

The factors discussed that affected B_o also affect the water formation volume factor, B_w . However, gas is only slightly soluble in water so evolution of gas from water has a negligible effect on B_w . Expansion and contraction of water

due to reduction of pressure and temperature are slight and offsetting. Hence, B_w is seldom greater than 1.06 [18] and is usually near unity (see Table 5.1.5).

Several correlations for B_w are available, including the effect of gas saturation in pure water and the effect of salinity [23], and the effect of natural gas on B_w as a function of pressure and temperature [24]. However, since B_w is not greatly affected by these variables, only a simplified correction is presented [18]:

$$B_w = (1 + \Delta V_{wp})(1 + \Delta V_{wT}) \quad (5.1.11)$$

where ΔV_{wp} and ΔV_{wT} are the volume changes caused by reduction in pressure and temperature, respectively. Values of these corrections are given in Figures 5.1.16 and 5.1.17.

5.1.1.5 Fluid Compressibilities

5.1.1.5.1 Gas Compressibility

The compressibility of a gas, which is the coefficient of expansion at constant temperature, should not be confused with the compressibility factor, z , which refers to the deviation from ideal gas behavior. From the basic gas equation (see Equation 5.1.2), Muskat [25] provided an expression for the coefficient of isothermal compressibility:

$$c_g = \frac{1}{p} - \frac{1}{z} \frac{dz}{dp} \quad (5.1.12)$$

For perfect gases ($z = 1$ and $dz/dp = 0$), c_g is inversely proportional to pressure. For example, an ideal gas at 1,000 psia has a compressibility of $1/1,000$ or $1,000 \times 10^{-6} \text{ psi}^{-1}$. However, natural hydrocarbon gases are not ideal gases and the compressibility factor, z , is a function of pressure as seen in Figure 5.1.18 [17]. At low pressures, z decreases as pressure increases and dz/dp is negative; thus, c_g is higher than that of an ideal gas. At high pressures, dz/dp is positive since z increases, and c_g is less than that of a perfect gas.

Compared to other fluids or to reservoir rock, the compressibility of natural gas is large; c_g ranges from about $1,000 \times 10^{-6} \text{ psi}^{-1}$ at 1,000 psi to about $100 \times 10^{-6} \text{ psi}^{-1}$ at 5,000 psi [27]. Compressibility of natural gases can be obtained from laboratory PVT data or estimated from the correlations given by Trube [27] (see Figures 5.1.19a and 5.1.19b). Trube defined the pseudo-reduced compressibility of a gas, c_{pr} , as a function of pseudo-reduced temperature and pressure, T_{pr} and p_{pr} , respectively [27]:

$$c_g = \frac{1}{p_{pc}} \left[\frac{1}{p_{pr}} - \frac{1}{z} \left(\frac{dz}{dp_{pr}} \right) T_{pr} \right] \quad (5.1.13)$$

where p_{pc} is the pseudo-critical pressure (reduced and critical pressures have been defined earlier). Gas compressibility is computed for the pseudo-reduced compressibility from the appropriate figure:

$$c_g = \frac{c_{pr}}{P_{pr}} \quad (5.1.14)$$

Pseudo-critical pressures and temperatures can be calculated from the mole fraction of each component present in hydrocarbon gas mixture or estimated from Figure 5.1.20 [3].

5.1.1.5.2 Oil Compressibility

The compressibility of oil, c_o , can be obtained in the laboratory from PVT data. In the absence of laboratory data, Trube's correlation [28] for compressibility of an undersaturated oil in Figure 5.1.21 can be used in a similar fashion as previously discussed for c_g . Pseudo-critical temperature and pressure can be estimated from Figure 5.1.22 or 5.1.23. With the pseudo-reduced compressibility from Figure 5.1.21, oil compressibility can be estimated:

$$c_o = \frac{c_{pr}}{P_{pc}} \quad (5.1.15)$$

For conditions below the bubblepoint, dissolved gas must be taken into account. In the absence of laboratory data, the changes in R_s and B_o with changes in pressure can be approximated from Figures 5.1.24 and 5.1.25, which were developed by Ramey [26] from Standing's [1] data:

$$\left(\frac{\partial B_o}{\partial p}\right)_T = \left(\frac{\partial R_s}{\partial p}\right)_T \left(\frac{\partial B_o}{\partial R_s}\right)_T \quad (5.1.16)$$

B_o can be estimated from Figure 5.1.3, and gravities of both oil and gas must be known. Oil compressibility is often on the order of 10×10^{-6} psi⁻¹.

There are several types of petroleum-engineering software equipped with the so-called "PVT data" generator code. Engineers only need fill in the known fluid properties or pressure-temperature data. By choosing the suitable correlation, the software will provide all pertinent PVT data.

5.1.1.5.3 Water Compressibility

Although the best approach is to obtain water compressibilities from laboratory PVT tests, this is seldom done and

^aFrom Reference 22.

the use of correlations [22] such as are given in Figures 5.1.26 and 5.1.27 is often required. The compressibility of nongas-saturated water ranges from $2 \times 10^{-6} \text{ psi}^{-1}$ to $4 \times 10^{-6} \text{ psi}^{-1}$ and a value of $3 \times 10^{-6} \text{ psi}^{-1}$ is frequently used [13]. The compressibility of water with dissolved gas ranges from $15 \times 10^{-6} \text{ psi}^{-1}$ at 1,000 psi to $5 \times 10^{-6} \text{ psi}^{-1}$ at 5,000 psi [26].

5.1.1.6 Estimation of Fluid Properties with Programmable Calculators and Personal Computers

With the recent widespread use of hand-held programmable calculators and desk-top personal computers, engineers are no longer faced with estimating fluid properties from charts and graphs. Much of the data in the literature have been transmitted to empirical equations suitable for use with programmable calculators or personal computers. In some cases, improved empirical data have been presented. This section provides a number of the expressions available for computer use and also provides references for recent books devoted to programs for hand-held calculators. References to some of the software available for personal computers will be given.

Data from Figure 5.1.12 have been used to develop a correlation for water viscosity that can be used on programmable calculators [29]:

$$\mu_w = \left(A + \frac{B}{T} \right) f_{pt} \quad (5.1.17)$$

FIGURE 5.1.16 Change in water volume due to pressure reduction [18].

FIGURE 5.1.17 Change in water volume due to temperature reduction [18].

FIGURE 5.1.18 Gas compressibility from the gas deviation factor versus pressure [17].

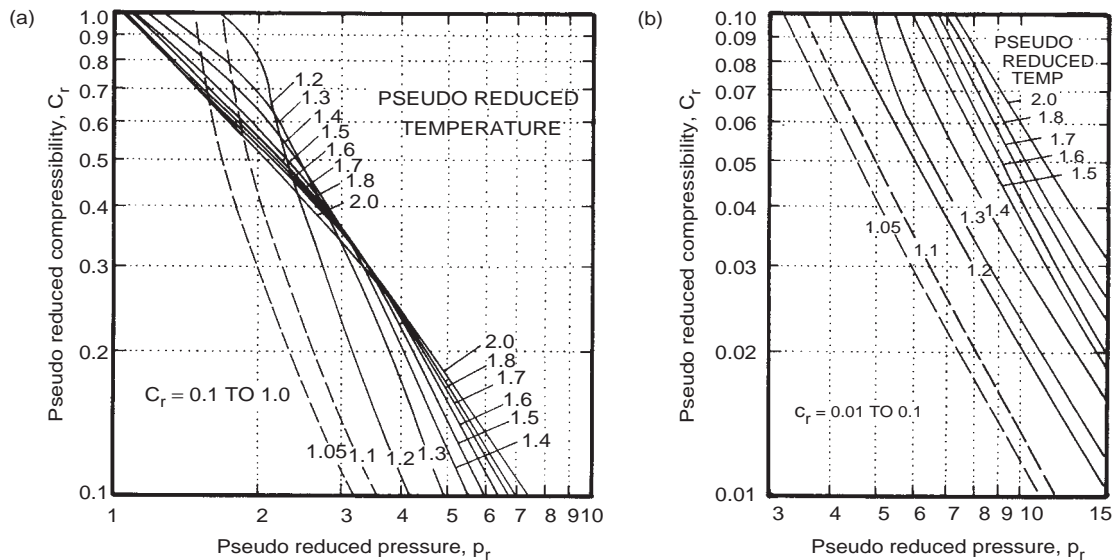

FIGURE 5.1.19 (a and b) Variation of reduced compressibility with reduced pressures for various fixed values of reduced temperature [27].

where $A = -0.04518 + 0.009313 (\% \text{NaCl}) - 0.000393 (\% \text{NaCl})^2$
 $B = 70.634 + 0.09576 (\% \text{NaCl})^2$
 $T = \text{temperature, } ^\circ\text{F}$
 $f_{pt} = 1 + [3.5 E - 12 p^2 (T - 40)]$

The correlation should only be used as an estimate and applies for pressures less than 10,000 psi, salinity less than 26% NaCl, and in a temperature range of 60° to 400°F.

In 1977, Standing's classic work [2] was reprinted [30] by the Society of Petroleum Engineers and an appendix

FIGURE 5.1.20 Pseudo-critical properties of natural gases [3].

FIGURE 5.1.21 Variation of pseudo-reduced compressibility with pseudo-reduced pressures for various fixed values of pseudo-reduced temperature [28].

FIGURE 5.1.22 Approximate variation of pseudo-critical pressure and pseudo-critical temperature with specific gravity of liquid corrected to 60°F [28].

FIGURE 5.1.23 Variation of pseudo-critical temperature with specific gravity and bubble point of liquid corrected to 60°F [28].

FIGURE 5.1.24 Change of gas solubility in oil with pressure vs. gas in solution [26].

was added by Standing that provides equations for several of the charts in the original work. Most of the equations were developed by simple curve fitting procedures. Some equations were based on computer solutions by other individuals; details of this will not be presented here and the reader is referred to Appendix 2 of Reference 30. Gas viscosity can be estimated from the correlations of Carr, Kobayashi, and Burrows [31] (the basis of Figures 5.1.6 and 5.1.7); first the atmospheric value of gas gravity at reservoir temperature, estimated from gravity and nonhydrocarbon content:

FIGURE 5.1.25 Change of oil formation volume factor with gas in solution vs. oil formation volume factor [26].

$$\mu_1 = (\mu_1 \text{ uncorrected}) + (N_2 \text{ correction}) + (CO_2 \text{ correction}) + (H_2S \text{ correction}) \quad (5.1.18)$$

where

$$(\mu_1 \text{ uncorrected}) = [1.709(10^{-5}) - 2.062(10^{-6})\gamma_g] \times T + 8.188(10^{-3}) - 6.15(10^{-3}) \log \gamma_g$$

$$(N_2 \text{ correction}) = y_{N_2}[8.48(10^{-3}) \log \gamma_g + 9.59(10^{-3})]$$

$$(CO_2 \text{ correction}) = y_{CO_2}[9.08(10^{-3}) \log \gamma_g + 6.24(10^{-3})]$$

$$(H_2S \text{ correction}) = y_{H_2S}[8.49(10^{-3}) \log \gamma_g + 3.73(10^{-3})]$$

is adjusted to reservoir conditions by a factor based on reduced temperature and pressure:

$$\ln \left[\left(\frac{\mu_g}{\mu_i} \right) (T_{pr}) \right] = a_0 + a_1 p_{pr} + a_2 p_{pr}^2 + a_3 p_{pr}^3 + T_{pr}(a_4 + a_5 p_{pr} + a_6 p_{pr}^2 + a_7 p_{pr}^3) + T_{pr}^2(a_8 + a_9 p_{pr} + a_{10} p_{pr}^2 + a_{11} p_{pr}^3) + T_{pr}^3(a_{12} + a_{13} p_{pr} + a_{14} p_{pr}^2 + a_{15} p_{pr}^3) \quad (5.1.19)$$

where

$$\begin{aligned} a_0 &= -2.46211820E-00 & a_8 &= -7.93385684E-01 \\ a_1 &= 2.97054714E-00 & a_9 &= 1.39643306E-00 \\ a_2 &= -2.86264054E-01 & a_{10} &= -1.49144925E-01 \\ a_3 &= 8.05420522E-03 & a_{11} &= 4.41015512E-03 \\ a_4 &= 2.80860949E-00 & a_{12} &= 8.39387178E-02 \end{aligned}$$

FIGURE 5.1.26 Effect of dissolved gas on the compressibility of water [22].

$$a_5 = -3.498\ 033\ 05E - 00 \quad a_{13} = -1.864\ 088\ 48E - 01$$

$$a_6 = 3.603\ 703\ 20E - 01 \quad a_{14} = 2.033\ 678\ 81E - 02$$

$$a_7 = -1.044\ 324\ 13E - 02 \quad a_{15} = -6.095\ 792\ 63E - 04$$

(= 0.00 060 957 9263)

A reasonable fit to Beal's correlation (Figure 8 of Reference 5) of gas-free or dead oil viscosity (which is not very precise) is given by Standing:

$$\mu_{oD} = \left[0.32 + \frac{1.8(10^7)}{^\circ\text{API}^{4.53}} \right] \left(\frac{360}{T + 200} \right)^a \quad (5.1.20)$$

where $a = \text{antilog} \left(0.43 + \frac{8.33}{^\circ\text{API}} \right)$

The dead oil viscosity can then be adjusted for dissolved gas with the correlation by Chew and Connally [6] (Figure 5.1.10) for saturated oil:

$$\mu_{ob} = A(\mu_{oD})^b \quad (5.1.21)$$

where A and b are functions of solution gas-oil ratio.

Fit of A and b values given in Table 3 of Reference 6 are

$$A = \text{antilog} \{ R_s [2.2(10^{-7})R_s - 7.4(10^{-4})] \}$$

$$b = \frac{0.68}{10^{8.62(10^{-5})R_s}} + \frac{0.25}{10^{1.1(10^{-3})R_s}} + \frac{0.062}{10^{3.74(10^{-3})R_s}}$$

The equation for compressibility factors of natural gases (Figure 5.1.13) is:

$$Z = A + (1 - A)/e^B + C p_{pr}^D \quad (5.1.22)$$

where

$$A = 1.39(T_{pr} - 0.92)^{0.5} - 0.36T_{pr} - 0.101$$

FIGURE 5.1.27 Solubility of natural gas in water [22].

$$B = (0.62 - 0.23T_{pr})p_{pr} + \left[\frac{0.066}{(T_{pr} - 0.86)} - 0.037 \right] p_{pr}^2 + \frac{0.32}{10^9(T_{pr} - 1)} p_{pr}^6$$

$$C = (0.132 - 0.32 \log T_{pr})$$

$$D = \text{antilog} (0.3106 - 0.49T_{pr} + 0.1824T_{pr}^2)$$

T_{pr} is the dimensionless pseudo-reduced temperature, and p_{pr} is the dimensionless pseudo-reduced pressure. The relationship between formation volume factor of bubble-point liquids and gas-oil ratio, dissolved gas gravity, API oil gravity, and temperature (Figure 5.1.3) is [30]:

$$B_{ob} = 0.9759 + 12(10^{-5})(CN)_{B_{ob}1.2} \quad (5.1.23)$$

where

$$(CN)_{B_{ob}} = R_s \left(\frac{\gamma_g}{\gamma_o} \right)^{0.5} + 1.25 T$$

where

$(CN)_{B_{ob}}$ = bubble-point formation volume factor

correlating number

R_s = solution gas-oil ratio in ft^3/bbl

γ_g = gas gravity (air = 1)

γ_o = oil specific gravity (water = 1)

T = temperature in $^\circ\text{F}$

The correlation of bubble-point pressure with dissolved gas-oil ratio, dissolved gas gravity, API oil gravity, and temperature (Figure 5.1.2) is [30]:

$$P_b = 18.2[(CN)_{pb} - 1.4] \quad (5.1.24)$$

where

$$(CN)_{pb} = \left(\frac{R_s}{\gamma_g} \right)^{0.83} [10^{(0.00091T - 0.125^\circ\text{API})}]$$

where $(CN)_{pb}$ is the bubble-point pressure correlating number and the other terms have been previously defined.

Standing also presents equation for; density correction for compressibility of liquids; density correction for thermal expansion of liquids; apparent liquid densities of natural gases; effect of condensate volume on the ratio of surface gas gravity to well fluid gravity; pseudo-critical constants of gases and condensate fluids; pseudo-liquid density of systems containing methane and ethane; and pseudo-critical temperatures and pressures for heptane and heavier.

Beggs and Robinson [7] collected PVT data and presented a better estimate of the dead oil viscosity as a function of temperature and oil specific gravity:

$$\mu_{OD} = 10^X - 1 \quad (5.1.25)$$

where μ_{OD} = viscosity in cp of the gas-free oil at temperature, T , and $X = yT^{-1.163}$, $y = 10^Z$, and $Z = 3.0324 - 0.02023 \gamma_o$, with T in $^\circ\text{F}$ and the oil gravity γ in $^\circ\text{API}$. An expression was also given for the saturated oil viscosity, μ , or live oil below the bubblepoint which results from a linear relationship between $\log \mu_{OD}$ and $\log \mu$ for a given value of dissolved gas, R_s :

$$\mu = A \mu_{OD}^B \quad (5.1.26)$$

where $A = 10.715 (R_s + 100)^{-0.515}$

$$B = 5.44(R_s + 150)^{-0.338}$$

R_s = scf/STB

In the first book specifically for hand-held calculators, Hollo and Fifadara [32] presented programs for estimating gas deviation factor (based on data of Standing and Katz):

$$Z = 1 + (A_1 + A_2/T_R + A_3/T_R^3)\rho R + (A_4 + A_5/T_R)\rho R^2 + A_6\rho R^2/T_R^3 \quad (5.1.27)$$

where $\rho R = 0.27 P_R/ZT_R$ $T_R = T/T_C$ $P_R = P/P_C$

$A_1 = 0.31506$ $A_2 = -1.0467$ $A_3 = -0.5783$

$A_4 = 0.5353$ $A_5 = -0.6123$ $A_6 = 0.6815$

A program was also presented to calculate the single-phase formation volume factor using the correlation developed by Standing:

$$B_o = 0.972 + \frac{1.47}{10^4} \left[(R_s) \left(\frac{\gamma_g}{\gamma_o} \right)^{0.5} + 1.25 T \right]^{1.75} \quad (5.1.28)$$

where γ_g = solution gas specific gravity
 γ_o = stock tank oil specific gravity
 (141.5/131.5 + °API)
 T = temperature, °F
 R_s = solution gas-oil ratio, scf/STB
 B_o = single-phase formation volume factor, RB/STB
 °API = stock tank oil gravity, °API

In 1980 Vazquez and Beggs [33] published improved empirical correlations for some of the commonly required crude oil PVT properties. Their study utilized a much larger database than was used in previous work so the results are applicable to a wider range of oil properties. The empirical correlations, presented as a function of gas specific gravity, oil API gravity, reservoir temperature, and pressure, are particularly convenient to use with hand-held calculators. Gas gravity was found to be a strong correlating parameter. Since gas gravity depends on gas-oil separation conditions, Vazquez and Beggs chose 100 psig as a reference pressure, which resulted in a minimum oil shrinkage for the separator tests available. Thus, gas gravity must first be corrected to the value that would result from separation at 100 psig:

$$\gamma_{gs} = \gamma_{gp} [1 + 5.912 \times 10^{-5} (\gamma_o)(T) \log(p/114.7)] \quad (5.1.29)$$

where γ_{gs} = gas gravity (air = 1) that would result from separator conditions of 100 psig

γ_{gp} = gas gravity obtained at separator conditions of p and T

p = actual separator pressure, psia

T = actual separator temperature, °F

γ_o = oil gravity, °API

For both dissolved gas and oil formation volume factor, improved correlations were obtained when the measured data were divided into two groups, with the division made at an oil gravity of 30°API. The expression for dissolved gas was presented:

$$R_s = C_1 \gamma_{gs} p^{C_2} \exp\{C_3 [\gamma_o / (T + 460)]\} \quad (5.1.30)$$

Values for the coefficients are as follows.

Coefficient	$\gamma_o \leq 30$	$\gamma_o > 30$
C_1	0.0362	0.0178
C_2	1.0937	1.1870
C_3	25.7240	23.9310

For saturated oils (reservoir pressure less than bubble-point), oil formation volume factor was expressed as:

$$B_o = 1 + C_1 R_s + C_2 (T - 60)(\gamma_o / \gamma_{gs}) + C_3 R_s (T - 60)(\gamma_o / \gamma_{gs}) \quad (5.1.31)$$

The values for the coefficients depend on oil gravity and are given by the following:

Coefficient	$\gamma_o \leq 30$	$\gamma_o > 30$
C_1	4.677×10^{-4}	4.670×10^{-4}
C_2	1.751×10^{-5}	1.100×10^{-5}
C_3	-1.811×10^{-8}	1.337×10^{-9}

Since the oil formation volume of an undersaturated crude depends on the isothermal compressibility of the liquid, the oil formation volume as pressure is increased above bubble-point pressure was calculated from:

$$B_o = B_{ob} \exp[c_o(p - p_b)] \quad (5.1.32)$$

The correlation for compressibility of oil was given as:

$$c_o = (a_1 + a_2 R_s + a_3 T + a_4 \gamma_{gs} + a_5 \gamma_o) / a_6 p \quad (5.1.33)$$

where $a_1 = -1,433.0$

$$a_2 = 5.0$$

$$a_3 = 17.2$$

$$a_4 = -1,180.0$$

$$a_5 = 12.61$$

$$a_6 = 105$$

Vazquez and Beggs also presented an equation for viscosity of undersaturated crude oils that used the correlations of Beggs and Robinson:

$$\mu_o = \mu_{ob}(p/p_b)^m \quad (5.1.34)$$

where $m = C_1 p^{C_2} \exp(C_3 + C_4 p)$

$$C_1 = 2.6$$

$$C_2 = 1.187$$

$$C_3 = -11.513$$

$$C_4 = -8.98 \times 10^{-5}$$

The improved correlations of Vazquez and Beggs were incorporated by Meehan in the development of programs for hand-held calculators. These programs were presented in a series of articles in the *Oil and Gas Journal* [34,35]. Reference 34 contains the programs for calculating gas gravity, dissolved gas-oil ratio, oil formation volume factor, and oil compressibility. Reference 35 contains the program for calculating oil viscosity.

See References 36–40 for a list of books devoted to the use of programs for handheld calculators and personal computers.

5.1.2 Properties of Fluid-Containing Rocks

5.1.2.1 Porosity

The porosity, ϕ , is equal to the void volume of the rock divided by the bulk volume and is expressed as a percent or fraction of the total bulk volume of the rock. Oil-bearing sandstones have porosities which often range from 15% to 30%. Porosities of limestones and dolomites are usually lower.

Differentiation must be made between absolute and effective porosity. Absolute porosity is defined as the ratio of the total pore volume of the rock to the total bulk volume of the rock whereas effective porosity is defined as

the ratio of the interconnected pore volume of the rock to the total bulk volume of the rock.

Factors affecting porosity are compactness, character and amount of cementation, shape and arrangement of grains, and uniformity of grain size or distribution.

In problems involving porosity calculations it is convenient to remember that a porosity of one percent is equivalent to the presence of 77.6 barrels of pore space in a total volume of one acre-foot of sand.

5.1.2.2 Pore Volume

The pore volume of a reservoir is the volume of the void space, that is, the porosity fraction times the bulk volume. In conventional units, the pore volume, V_p , in reservoir barrels is:

$$V_p = 7758 V_b \phi = 7,758 A h \phi \quad (5.1.35)$$

where V_b is the bulk volume in ac-ft. A is the area in ft^2 , h is the reservoir thickness in ft. and ϕ is the porosity expressed as a fraction.

5.1.2.3 Permeability

The permeability of a rock is a measure of the ease with which fluids flow through the rock. It is denoted by the symbol k and commonly expressed in units of darcies. Typical sandstones in the United States have permeabilities ranging from 0.001 to a darcy or more, and for convenience the practical unit of permeability is the millidarcy which equals 0.001 darcy. Some other useful conversion factors are given in Table 5.1.6.

5.1.2.4 Absolute Permeability

If a porous system is completely saturated with a single fluid, the permeability is a rock property and not a property of the flowing fluid (with the exception of gases at low pressure). This permeability at 100% saturation of a single fluid is termed the absolute permeability.

5.1.2.5 Darcy Equation

The Darcy equation relates the apparent velocity, v , of a homogeneous fluid in a porous medium to the fluid viscosity, μ , and the pressure gradient, $\Delta p/L$:

$$v = -\frac{k\Delta p}{\mu L} \quad (5.1.36)$$

This equation states that the fluid velocity is proportional to the pressure gradient and inversely proportional to

TABLE 5.1.6 Permeability Conversion Factors

$$\begin{aligned}
 1 \text{ darcy} &= 1,000 \text{ millidarcies; } 1 \text{ millidarcy} \\
 &= 0.001 \text{ darcy} \\
 &= 0.9869233 \mu\text{m}^2 (1 \text{ md} \cong 10^{-3} \mu\text{m}^2) \\
 k &= \frac{q\mu}{(A)(\Delta p/L)} \\

 \end{aligned}$$

From Reference 19.

fluid viscosity. The negative sign indicates that pressure decreases in the L direction when the flow is taken to be positive. The flow rate, q, is understood to be positive during production and negative during injection. As shown in Table 5.1.6, the Darcy equation can be written as:

$$k = \frac{q\mu L}{A\Delta p} \quad (5.1.37)$$

5.1.2.5.1 Linear Flow

In the Darcy equation for linear displacement:

$$q = \frac{kA(\Delta p)}{\mu L} \quad (5.1.38)$$

where q = fluid flow rate, cm³/sec
 A = cross-sectional area of rock perpendicular to flow, cm²
 p = pressure difference (in atm) across the distance L parallel to flow direction, cm
 μ = viscosity of fluid, cp

A rock has permeability of one darcy if it permits the flow of one cc per second of a one-phase fluid having viscosity of one centipoise under the pressure gradient of one atmosphere per gradient of one atmosphere per centimeter. For liquid flow in a linear porous system, the flow rate q in barrels per day is [20]:

$$q = \frac{1.127 kA(p_e - p_w)}{\mu L} \quad (5.1.39)$$

where k is in darcies, A is in ft², μ is in cp, L is in ft, and pressures are in psia. For laminar gas flow in a linear system [20]:

$$q = \frac{0.112 kA(p_e^2 - p_w^2)}{\mu z TL} \quad (5.1.40)$$

where q is in Mscf/D, T is in °R (°F + 460), z is the dimensionless compressibility factor, and the other terms are in units consistent with Equation 5.1.39.

5.1.2.5.2 Radial Flow

Production from or injection into a reservoir can be viewed as flow for a cylindrical region around the wellbore. For the steady-state radial flow of an incompressible fluid [19]:

$$q = \frac{2\pi kh(p_e - p_w)}{\mu \ln(r_e/r_w)} \quad (5.1.41)$$

where q = volume rate of flow, cc/sec

k = permeability, darcies

h = thickness, cm

μ = viscosity, cp

p_e = pressure at external boundary, atm

p_w = pressure at internal boundary, atm

r_e = radius to external boundary, cm

r_w = radius to internal boundary, cm

ln = natural logarithm, base e

For the flow rate, q, in the barrels per day of a liquid [19]:

$$q = \frac{7.08 kh(p_e - p_w)}{\mu \ln(r_e/r_w)} \quad (5.1.42)$$

where k is in darcies, h is in ft., pressures are in psia, μ is in cp, and the radii are in consistent units, usually feet. For the laminar flow of a gas in Mscf/D [20]:

$$q = \frac{0.703 kh(p_e^2 - p_w^2)}{\mu z T \ln(r_e/r_w)} \quad (5.1.43)$$

where T is in °R, z is the dimensionless compressibility factor, and the other terms are as defined in Equation 5.1.42.

5.1.2.6 Capacity

Flow capacity is the product of permeability and reservoir thickness expressed in md ft. Since the rate of flow is proportional to capacity, a 10-ft thick formation with a permeability of 100 md should have the same production as a 100-ft thick formation of 10 md, if all other conditions are equivalent.

5.1.2.7 Transmissibility

Transmissibility is flow capacity divided by viscosity or kh/μ with units of md ft/cp. An increase in either reservoir permeability or thickness or a decrease in fluid viscosity will improve transmissibility of the fluid in the porous system.

5.1.2.8 Resistivity and Electrical Conductivity

Electrical conductivity, the electrical analog of permeability, is the ability of a material to conduct an electrical current. With the exception of certain clay minerals, reservoir rocks are nonconductors of electricity. Crude oil and gas are also nonconductors. Water is a conductor if dissolved salts are present so the conduction of an electric current in reservoir rocks is due to the movement of dissolved ions in the brine that occupies the pore space. Conductivity varies directly with the ion concentration of the brine. Thus, the electrical properties of a reservoir rock depend on the fluids occupying the pores and the geometry of the pores.

Resistivity, which is the reciprocal of conductivity, defines the ability of a material to conduct electric current:

$$R = \frac{rA}{L} \quad (5.1.44)$$

where R is the resistivity in ohm-meters, r is the resistance in ohms, A is the cross-sectional area in m^2 , and L is the length of the conductor in meters. As seen in [Figure 5.1.28](#), resistivity of water varies inversely with salinity and temperature [41].

During flow through a porous medium, the tortuous flow paths cause the flowing fluid to travel an effective length, L_e , that is longer than the measured length, L . Some authors have defined this tortuosity, τ , as (L_e/L) while $(L_e/L)^2$ has been used by others.

5.1.2.9 Formation Resistivity Factor

The formation resistivity factor, F_R , is the ratio of the resistivity of a porous medium that is completely saturated with an ionic brine solution divided by the resistivity of the brine:

$$F_R = \frac{R_o}{R_w} \quad (5.1.45)$$

where R_o is the resistivity (ability to impede the flow electric current) of a brine-saturated rock sample in ohm-m,

R_w is the resistivity of the saturating brine in ohm-m, and F_R is dimensionless. The formation resistivity factor, which is always greater than one, is a function of the porosity of the rock (amount of brine), pore structure, and pore size distribution. Other variables that affect formation factor include composition of the rock and confining pressure (overburden).

Archie [42] proposed an empirical formula that indicated a power-law dependence of F_R on porosity:

$$F_R = \phi^{-m} \quad (5.1.46)$$

where ϕ is porosity and m is a constant (commonly called the cementation factor) related to the pore geometry. The constant, m , was the slope obtained from a plot of F_R vs. porosity on log-log paper. For consolidated, shale-free sandstones, the value of m ranged from 1.8 to 2. For clean, unconsolidated sands, m was found to be 1.3, and Archie speculated that m might vary from 1.3 to 2 for loosely or partly consolidated sands. [Equations 5.1.45](#) and [5.1.46](#) were also combined by Archie to give:

$$R_o = R_w \phi^{-m} \quad (5.1.47)$$

so that a reasonable estimate of F_R or R_o can be made if the slope, m , is obtained.

Several other correlations [43–55], mostly empirical, between formation factor and porosity have been reported in the literature and these are summarized in [Table 5.1.7](#).

From an analysis of about 30 sandstone cores from a number of different reservoirs throughout the United States, Winsauer et al. [45] presented what is now known as the Humble relation:

$$F_R = 0.62\phi^{-2.15} \quad (5.1.48)$$

Wyllie and Gregory [46], citing their results and the results of Winsauer et al. [45], proposed that the data for consolidated porous media could be best described empirically by:

$$F_R = a\phi^{-m} \quad (5.1.49)$$

Results of a logging study in the Brown Dolomite formation, in which the resistivity of the mud filtrate was the same as the connate water, were used by Owen [48] to establish a relationship between the true formation factor and porosity. Shown in [Figure 5.1.29](#) are the relationships obtained with the equations of Archie, Winsauer, et al., and Tixier.

Hill and Milburn [49] provided data from 450 core samples taken from six different sandstone formations and four different limestone reservoirs. The sandstone formations were described as ranging from clean to very shaly. The formation factor was determined at a water resistivity of 0.01 ohm-m since, at that value, the apparent formation

FIGURE 5.1.28 Resistivity of saline solutions [41].

factor approached the true formation factor when the rock contained low-resistivity water. From their data, the following equation was provided:

$$F_R = 1.4\phi^{-1.78} \quad (5.1.50)$$

An expression was also provided for the case in which the constant, a, in Equation 5.1.49 is taken as unity:

$$F_R = \phi^{-1.93} \quad (5.1.51)$$

Using 981 core samples (793 sandstone and 188 carbonate), Carothers [52] established a relationship for sands:

$$F_R = 1.45\phi^{-1.54} \quad (5.1.52)$$

and for limestones:

$$F_R = 0.85\phi^{-2.14} \quad (5.1.53)$$

TABLE 5.1.7 Correlations of Formation Resistivity Factor and Porosity

Source	Relation	Notes
Archie [42]	$F_R = \phi^{-m}$	For consolidated sands, $m = 1.8$ to 2.5 . For unconsolidated sands, $m = 1.3$
Wyllie and Rose [43]	$F_R = \frac{\tau^{1/2}}{\phi}$	Tortuosity $\tau = L_e/L$
Tixier [44]	$F_R = \frac{1}{\phi^2}$	For limestone
Winsauer et al. [45]	$F_R = \frac{\tau^2}{\phi}$	Theory
	$F_R = \frac{\tau^{1.67}}{\phi}$ $F_R = 0.62 \phi^{-2.15}$	Experimental (transport time of flowing ions) Sandstones containing varying amounts of clay
Wyllie/Gregory [46]	$F_R = a\phi^{-m}$	General form of Archie relation
Cornell and Katz [47]	$F_R = \frac{L_e^2}{\phi L}$	F_R directly proportional to length and inversely proportional to area
Owen [48]	$F_R = 0.68 \phi^{-2.23}$	Logs in dolomite, mud filtrate same resistivity as connate water
Hill and Milburn [49]	$F_R = 1.4\phi^{-1.78}$ $F_R = \phi^{-1.93}$	Results of 450 sandstone and limestone cores with R_w of 0.01 ohm-m When $a = 1$
Wyllie/Gardner [50]	$F_R = \frac{1}{\phi^2}$	Model of capillary bundle, for conducting wetting phase
Sweeney/Jennings [51]	$F_R = \phi^{-m}$ $m = 1.57$ $m = 1.92$ $m = 2.01$	25 various carbonates Water-wet Intermediate wettability Oil-wet
Carothers [52]	$F_R = 1.45 \phi^{-1.54}$ $F_R = 0.85 \phi^{-2.14}$	Sandstones Limestones
Porter/Carothers [53]	$F_R = 2.45 \phi^{-1.08}$ $F_R = 1.97 \phi^{-1.29}$	From California logs From Gulf Coast logs. All sandstones, $S_w = 100\%$
Timur [54]	$F_R = 1.13 \phi^{-1.73}$	Analysis of over 1,800 sandstone samples
Perez-Rosales [55]	$F_R = 1 + G(\phi^{-m} - 1)$ $F_R = 1 + 1.03(\phi^{-1.73} - 1)$	General theoretical relation Theoretical relation for sandstones

As shown in Figure 5.1.30, a relationship was suggested for calcareous sands:

$$F_R = 1.45\phi^{-1.33} \quad (5.1.54)$$

and for shaly sands:

$$F_R = 1.65\phi^{-1.33} \quad (5.1.55)$$

Using these data, the nomograph in Figure 5.1.31 was constructed to solve the modified Archie expression (Equation 5.1.49) when it is desired to vary both constants.

Using 1,575 formation factors from California Pliocene well logs, Porter and Carothers [53] presented an in-situ relation:

FIGURE 5.1.29 Formation factor vs. porosity from logs of Brown Dolomite formation [48].

$$F_R = 2.45\phi^{-1.08} \quad (5.1.56)$$

and a similar relation for 720 formation factors from Texas-Louisiana Gulf Coast logs:

$$F_R = 1.97\phi^{-1.29} \quad (5.1.57)$$

This investigation used well log data from sandstone formations known to have water saturations of 100%.

These samples included 569 core plugs (from Alaska, California, Louisiana, Colorado, Trinidad, Australia, and the Middle East) plus 28 samples from Winsauer et al. [45], 362 samples from Hill and Milburn [49], 788 from Carothers [52], and 85 samples from other sources [54].

In a recent paper [55], Perez-Rosales presented the following theoretical expression:

$$F_R = 1 + G(\phi^{-m} - 1) \quad (5.1.58)$$

and a generalized equation for sandstones:

$$F_R = 1 + 1.03(\phi^{-1.73} - 1) \quad (5.1.59)$$

Perez-Rosales notes that the previous expressions are fundamentally incorrect since they do not satisfy the requirement that $F_R = 1$ when $\phi = 1$. A graphical comparison of expressions, provided by Perez-Rosales, is shown in Figure 5.1.32 for Equations 5.1.48, 5.1.58, and 5.1.59. In porosity ranges of practical interest, the three expressions yield similar results.

From an analysis of over 1,800 sandstone samples, Timur et al. [54] presented the following expression:

$$F_R = 1.13\phi^{-1.73} \quad (5.1.60)$$

Coates and Dumanoir [56] listed values for the cementation exponent of the Archie equation for 36 different formations in the United States. These data are presented in the following section under "Resistivity Ratio."

In the absence of laboratory data, different opinions have existed regarding the appropriate empirical relationship. Some authors [57] felt that the Archie equation (Equation 5.1.46) with $m=2$ or the Humble equation (Equation 5.1.48) yields results satisfactory for most engineering purposes, but Equation 5.1.50 may be more valid (these authors point out that the relationship used should be based on independent observations of interest). Another opinion was that, while the Humble relation is satisfactory for sucrosic rocks and the Archie equation with $m = 2$ is acceptable for chalky rocks, in the case of compact or oolitic rocks the cementation exponent in the Archie equation may vary from 2.2 to 2.5 [58]. Based on the more recent work of Timur et al. [54], it appears that Equation 5.1.59 may be more appropriate as a general expression for sandstones, if individual formation factor-porosity relationships are not available for specific cases.

Water in clay materials or ions in clay materials or shale act as a conductor of electrical current and are referred to as conductive solids. Results in Figure 5.1.33 show that clays contribute to rock conductivity if low-conductivity, fresh, or brackish water is present [59, 60]. The effect of clay on formation resistivity depends on the type, amount, and distribution of clay in the reservoir, as well as the water salinity. Values of m in Equation 5.1.49 for several clays are given in Table 5.1.8 [61].

Other variables that affect resistivity of natural reservoir rocks include overburden pressure and temperature during measurement. The value of the cementation exponent, m , is normally higher at overburden conditions [62], especially if porosity is low or with rocks that are not well-cemented. Thus, F_R increases with increasing pressure. Although the effect of temperature depends on clay content of the sample, F_R tends to increase with increasing temperature, but the effect is not as great as pressure [63, 64]. At a fixed pressure, F_R may go through a minimum and then increase as temperature is increased; the combined increase of both temperature and pressure will cause an increase in F_R [64].

FIGURE 5.1.30 Formation factor vs. porosity for clean sands, shaly sands, and calcareous sands [52].

Factors that affect the exponent, m , and the coefficient, a , in the modified Archie expression (Equation 5.1.49) are summarized in Tables 5.1.9 and 5.1.10, respectively [65].

To summarize the general relationship between formation resistivity factor and porosity (see Equation 5.1.49), the normal range for the geometric term, a , is 0.6 to 1.4, and the range for the cementation exponent, m , is 1.7 to 2.5 for most consolidated reservoir rocks [62]. Since the exact values depend on pore geometry and composition of the rock, formation factors should be determined with samples of the reservoir rock of interest, under the reservoir conditions of temperature and overburden pressure.

Based on core analyses of 793 sandstone and 188 carbonate samples, Carothers [52] observed different

permeabilities and formation factors for samples from the same core even though porosity was identical. Furthermore, permeability generally decreased as formation factor increased. For permeabilities above 10 md, there appeared to be a relation between formation factor, permeability, and lithology. For sandstones, the general relationship was:

$$k = \frac{7 \times 10^8}{F_R^{4.5}} \quad (5.1.61)$$

and the relation for carbonates was:

$$k = \frac{4 \times 10^8}{F_R^{3.65}} \quad (5.1.62)$$

FIGURE 5.1.31 Nomograph for solving $F_R = a/\phi^m$ [52].

Carothers stated that more data are needed to confirm these observations. Any such relation should be used with caution.

5.1.2.10 Rock Compressibility

The isothermal rock compressibility is defined as the change in volume of the pore volume with respect to a change in pore pressure:

$$c_f = \frac{1}{V_p} \left(\frac{\partial V_p}{\partial p} \right)_T \tag{5.1.63}$$

where c_f is the formation (rock) compressibility with common units of psi^{-1} , V_p is pore volume, p is pressure in psi, and the subscript T denotes that the partial derivative is taken at constant temperature. The effective rock compressibility is considered a positive quantity that is additive to fluid compressibility; therefore, pore volume decreases as fluid pressure decreases [26,66]. Since overburden pressure

FIGURE 5.1.32 Graphical comparison of relationship between formation resistivity factor and porosity [55].

of a reservoir is essentially constant, the differential pressure between the overburden pressure and the pore pressure will increase as the reservoir is depleted. Thus, porosity will decrease slightly, on the order of only one-half percent for a 1,000 psi change in internal fluid pressure [17]. For different reservoirs, porosities tend to decrease as overburden pressure (or depth) increases. Therefore, porosity under reservoir conditions may differ from values determined in the laboratory [67]. For sandstones with 15% to 30% porosity, reservoir porosity was found to be about 1% lower under reservoir conditions; for low porosity limestones, the difference was about 10% [68].

One of the commonly cited correlations between rock compressibility and porosity was developed by Hall [69] (Figure 5.1.34) for several sandstone and limestone reservoirs. All measurements were conducted with an external pressure of 3,000 psi and internal pressures from 0 to 1,500 psi. Fatt [67] found no correlation between compressibility and porosity, although the porosity range studied (10% to 15%) was very narrow. Van der Knapp [68], citing his measurements and those of Carpenter and Spencer [70], observed a general trend of increasing pore volume

compressibility with decreasing porosity. For a particular limestone reservoir, Van der Knapp [68] found that pore compressibility and porosity were related by a simple empirical formula. However, in a more extensive study, Newman [71] suggests that any correlation between pore volume compressibility and porosity does not apply to a wide range of reservoir rocks. As shown in Figure 5.1.35a, Newman's study in limestones showed poor agreement with the correlations of Hall and Van der Knapp. Figures 5.1.35b to 5.1.35d show a comparison of Newman's data with Hall's correlation for consolidated sandstones, friable sandstones, and unconsolidated sandstones. While the general trend of Newman's data on consolidated sandstones (Figure 5.1.35b) is in the same direction as Hall's correlation, the agreement is again poor. Figure 5.1.35c shows no correlation for Newman's friable sandstones and Figure 5.1.35d for unconsolidated sandstones shows an opposite trend from the correlation presented by Hall. From Newman's data, ranges of compressibilities for various types of reservoir rocks are given in Table 5.1.11. Clearly, formation compressibility should be measured with samples from the reservoir of interest.

5.1.3 Properties of Rocks Containing Multiple Fluids

5.1.3.1 Total Reservoir Compressibility

The total compressibility of oil- or gas-bearing reservoirs represents the combined compressibilities of oil, gas, water, and reservoir rock in terms of volumetric weighting of the phase saturations:

$$c_t = c_o S_o + c_w S_w + c_g S_g + c_f \quad (5.1.64)$$

where c_t is the total system isothermal compressibility in vol/vol/psi, c_o , c_w , c_g , and c_f are the compressibilities in psi^{-1} of oil, water, gas, and rock (pore volume), respectively, S is fluid saturation, and the subscripts, o , w , and g refer to oil, water, and gas, respectively.

Based on the treatment by Martin [72], Ramey [26] has expressed volumes in terms of formation volume factors with consideration for gas solubility effects:

$$\begin{aligned} c_t = S_o & \left[\frac{B_g}{B_o} \left(\frac{\partial R_s}{\partial p} \right) - \frac{1}{B_o} \left(\frac{\partial B_o}{\partial p} \right) \right] \\ & + S_w \left[\frac{B_g}{B_w} \left(\frac{\partial R_{sw}}{\partial p} \right) - \frac{1}{B_w} \left(\frac{\partial B_w}{\partial p} \right) \right] \\ & + S_g \left[-\frac{1}{B_g} \left(\frac{\partial B_g}{\partial p} \right) \right] + c_f \end{aligned} \quad (5.1.65)$$

where p is pressure in psi, R_s is the solubility of gas in oil in scf/STB oil, R_{sw} is the solubility of gas in water in scf/STB water, and B_g , B_o , and B_w are the formation volume factors of gas, oil, and water, respectively.

FIGURE 5.1.33 Effect of clays on formation resistivity factor [59,60].

4. The occurrence of an open fracture.

From Reference 65.

Fluid and rock compressibilities have been discussed in prior sections of this chapter. Table 5.1.12 provides a summary of these data.

The rock compressibilities in Table 5.1.12 represent a majority of the consolidated sandstone and limestone data from Newman [71] that have porosities in the range of 10% to 30%. Oil compressibility increases as a function of increasing API gravity, quantity of solution gas, or temperature [17]. As pointed out by Ramey [26], when the

magnitude of water compressibility is important, the effect of solution gas in the water will be more important. Clearly, the magnitude of gas compressibility will dominate the total system compressibility if gas saturations are high.

In many gas reservoirs, only the gas terms in Equation 5.1.64 may be significant so that the total system compressibility becomes [26]:

TABLE 5.1.10 Factors that Influence the a Coefficient in Equation 5.1.49

1. Surface conductance and ionic mobility occurring in water films adsorbed to solid surfaces.
 - a. The cation exchange capacity of particular solid materials.
 - b. The quantity of water adsorbed to clay[-4pt] particles in the rock framework or within the interstices
2. Salinity of formation water.
3. Wettability relations between particular solid surfaces and hydrocarbons, as they influence cation exchange.
4. The presence and distribution of electrically conductive solid minerals.

From Reference 65.

$$c_t = c_g S_g \quad (5.1.66)$$

In certain cases of high pressure and high water saturation, rock and water compressibility may be significant so that Equation 5.1.65 must be used [26].

In oil reservoirs, gas saturations may be low and, even though gas compressibility is much larger than the other compressibilities, each term in Equation 5.1.64 or 5.1.65 should normally be considered [26]. In some cases, not all of the compressibility terms will be important. For example,

if reservoir pressure is above the saturation pressure, the gas saturation will be zero [20]. However, if the gas saturation exceeds 2% or 3%, the gas compressibility term dominates the total system compressibility and the other terms become insignificant [20].

5.1.3.2 Resistivity Index

Since crude oil and natural gas are nonconductors of electricity, their presence in reservoir rock increases resistivity. The resistivity index or ratio, I , is commonly used to characterize reservoir rocks that are partially saturated with water and also contain oil or gas, or both:

$$I = \frac{R_t}{R_o} \quad (5.1.67)$$

where R_t is the resistivity of the rock at some condition of partial water saturation, S_w , and R_o is the resistivity of the rock when completely saturated with water or brine.

Citing the work of Martin et al. [74], Jakosky and Hopper [75], Wyckoff and Botset [76], and Leverett [77], in which the variation in resistivity with water saturation was studied, Archie [42] plotted the resistivity ratio versus S_w on log-log paper (Figure 5.1.36). For water saturations down to about 0.15 or 0.20, the following approximate equation appeared to hold, regardless of whether oil or gas was the nonconducting fluid:

FIGURE 5.1.34 Effective rock compressibility vs. porosity [69].

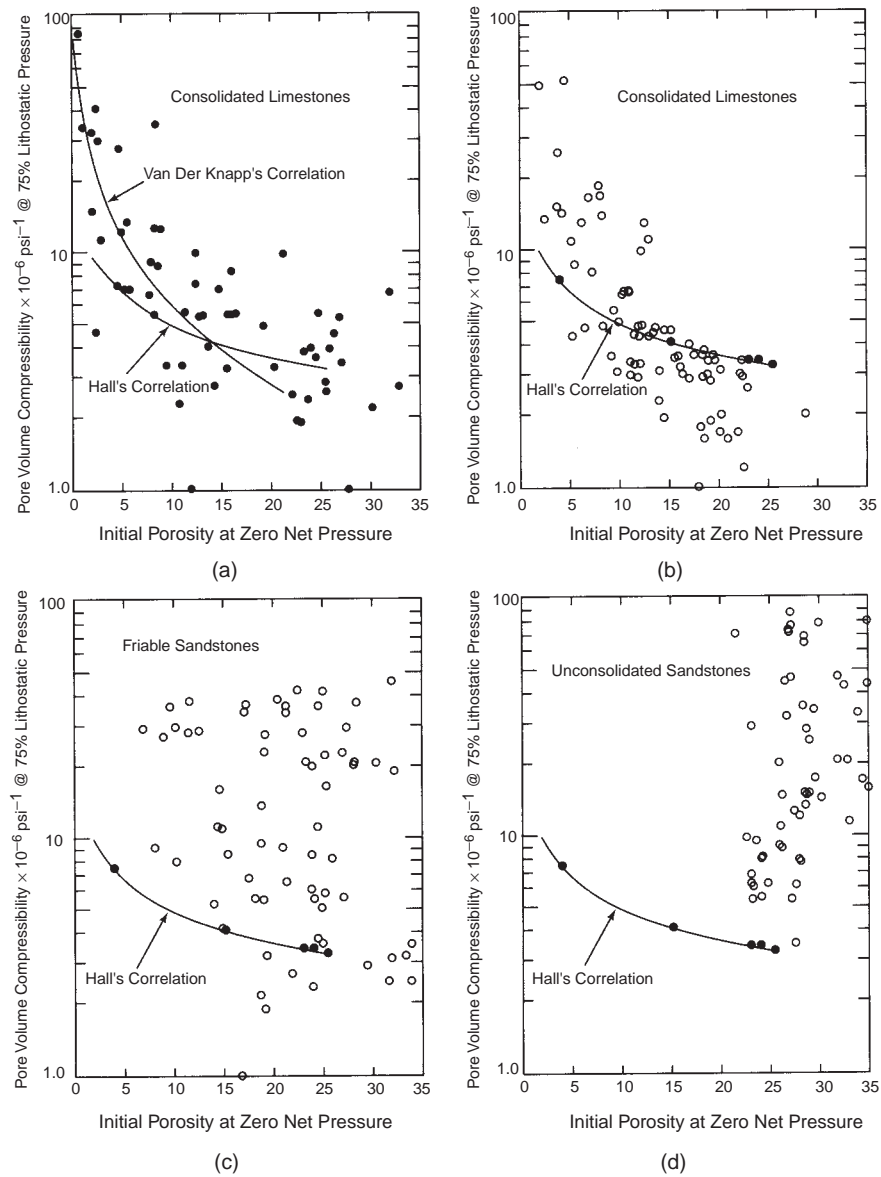

FIGURE 5.1.35 Pore-volume compressibility at 75% lithostatic pressure vs. sample porosity [71].

Formation	Pore volume compressibility', psi ⁻¹
Consolidated sandstones	1.5 × 10 ⁻⁶ to 20 × 10 ⁻⁶
Consolidated limestones	2.0 × 10 ⁻⁶ to 35 × 10 ⁻⁶
Friable sandstones	2.5 × 10 ⁻⁶ to 45 × 10 ⁻⁶
Unconsolidated sandstones	5.5 × 10 ⁻⁶ to 85 × 10 ⁻⁶

From Reference 71.

$$S_w = \left(\frac{R_o}{R_t} \right)^{1/n} \tag{5.1.68}$$

where n has been commonly referred to as the saturation exponent. For clean sands and for consolidated sandstones, the value of n was close to 2.0, so the approximate relation was given by Archie as:

$$S_w = \left(\frac{R_o}{R_t} \right)^{1/2} \tag{5.1.69}$$

By substituting the equation for R_o (refer to Equation 5.1.47), Archie presented the relationship between water

FIGURE 5.1.36 Variation of resistivity index with water saturation [42].

TABLE 5.1.12 Summary of Compressibility Values

	Compressibility, psi^{-1}	
	Range	Typical value
Consolidated rock*	2×10^{-6} to 7×10^{-6}	3×10^{-6}
Oil [17,73]	5×10^{-6} to 100×10^{-6}	10×10^{-6}
Water (gas-free) [26]	2×10^{-6} to 4×10^{-6}	3×10^{-6}
	Compressibility, psi^{-1}	
	At 1,000 psi	At 5,000 psi
Gas [26]	$1,000 \times 10^{-6}$	100×10^{-6}
Water (with dissolved gas) [26]	15×10^{-6}	5×10^{-6}

*See Figure 5.1.35 (for most of samples having porosities of $20 \pm 10\%$ in Figures 5.1.35a and 5.1.35b).

saturation, formation resistivity factor, brine resistivity, and the resistivity of the rock at the given S_w :

$$S_w = \left(\frac{F_R R_w}{R_t} \right)^{1/2} \quad (5.1.70)$$

The more general form of Equation 5.1.70, commonly used, is:

$$S_w = \left(\frac{F_R R_w}{R_t} \right)^{1/n} = \left(\frac{R_w \phi^{-m}}{R_t} \right)^{1/n} \quad (5.1.71)$$

An even more general form recognizes that the constant, a , in Equation 5.1.49 is not necessarily unity:

$$S_w = \left(\frac{a R_w}{\phi^m R_t} \right)^{1/n} \quad (5.1.72)$$

The foregoing equations are close approximations in clean formations having a regular distribution of porosity. The accuracy of the equations will not be as good in formations with vugs or fractures.

As shown in Figure 5.1.37, Patnode and Wyllie [59] found that the presence of clays affected the relationship between water saturation and resistivity index. As the water saturation is reduced toward zero, the resistivity approaches that of the clays rather than approaching infinity as with clean sands. Relationships between resistivities and fluid content in the presence of conductive solids have been presented in the literature [78,79].

Early investigations, using data from the Woodbine sand of east Texas, suggested that the saturation exponent, n , may range from 2.3 to 2.7 [80, 81]. Wyllie and Spangler [82] presented data (Figure 5.1.38) for several natural and synthetic porous media that showed a variation of the saturation exponent from 1.4 to 2.5. Other investigators found that the distribution of fluids within the core sample, at the same water saturation, could affect the resistivity index for both sandstones [83] and for limestones [84]. The exponent, n , was also found to vary depending upon the manner in which the conducting wetting phase saturation was varied [82, 85].

FIGURE 5.1.37 Effect of conductive solids on the relationship between resistivity index and water saturation [59].

FIGURE 5.1.38 Relationship between resistivity index and water saturation for several media [82].

Data [56] from a number of different reservoirs for the values of m , the cementation or shape factor, and n , the saturation exponent, in Equation 5.1.71 are presented in Table 5.1.13.

Based on these data and other reasoning, Coats and Dumanoir [56] have proposed that the two exponents, m and n , can be assumed to be equal for water-wet, consolidated reservoirs. Ransome [65] has proposed that the saturation exponent may be a special case of the porosity exponent, and the two exponents may bear certain similarities but not necessarily the same value.

As pointed out by Dorfman [86], data in Table 5.1.13 strongly suggest that assuming a saturation exponent of 2 can result in serious errors in the estimation of water saturation. In low-porosity formations, such as the Cotton Valley sandstone, the saturation was found to vary greatly from the value of 2 [87]. If n is always assumed to be 2, Dorfman contends that many hydrocarbon zones will be overlooked and many water-producing zones could be tested. As related by Hilchie [88], most of the values for the saturation exponent have been obtained at atmospheric conditions and there is the need to obtain laboratory measurements under simulated reservoir pressure and temperature. At atmospheric pressure, the percentage of smaller pores is larger than at reservoir pressure [64], which results in the wrong saturation exponent and a higher value of water saturation [88].

5.1.3.3 Surface and Interfacial Tensions

The term *interface* indicates a boundary or dividing line between two immiscible phases. Types of interfaces include: liquid-gas, liquid-liquid, liquid-solid, solid-gas, and solid-solid. For fluids, molecular interactions at the interface result in a measurable tension which, if constant, is equal to the surface free energy required to form a unit area of interface. For the case of a liquid which is in contact with air or the vapor of that liquid, the force per unit length required to create a unit surface area is usually referred to as the surface tension. Interfacial tension is used to describe this quantity for two liquids or for a liquid and a solid. Interfacial tension between two immiscible liquids is normally less than the surface tension of the liquid with the higher tension, and often is intermediate between the individual surface tensions of the two liquids of interest. Common units of surface or interfacial tension are dynes per centimeter (or the identical ergs/cm^2) with metric units in the equivalent milli-Newton per meter (mN/m).

The surface tension of pure water ranges from 72.5 dynes/cm at 70°F to 60.1 dynes/cm at 200°F in an almost linear fashion with a gradient of 0.095 dynes/cm/°F [25]. Salts in oilfield brines tend to increase surface tension, but surface active agents that may dissolve into the water from

the oil can lower surface tension. At standard conditions, surface tensions of brines range from 59 to 76 dynes/cm [25]. As shown in Figure 5.1.39, dissolved natural gas reduces surface tension of water as a function of saturation pressure [89].

At a given temperature, surface tension of hydrocarbons in equilibrium with the atmosphere or their own vapor increases with increasing molecular weight (Figure 5.1.40) [90]. For a given hydrocarbon, surface tension decreases with increasing temperature. At 70°F, surface tensions of crude oils often range from 24 to 38 dyne/cm [25].

The presence of dissolved gases greatly reduces surface tension of crude oil as shown in Figure 5.1.41 [91]. Dissolved natural gas reduces surface tension of crude oil more than previously noted for water, but the amount and nature of gas determines the magnitude of the reduction. The direct effect of a temperature increase on reduction of surface tension more than counterbalances the decreased gas solubility at elevated temperatures. Thus, surface tension at reservoir temperature and pressure may be lower than indicated by Figure 5.1.41 [25].

Under reservoir conditions, the interfacial interaction between gas and oil involves the surface tension of the oil in equilibrium with the gas. Similarly, the interaction between oil and water determines the interfacial tension between the crude and brine. Listed in Table 5.1.14 are the surface and interfacial tensions for fluids from several Texas fields [92].

The effect of temperature on interfacial tensions for some oil-water systems is shown in Figure 5.1.42 [92]; the reduction in interfacial tension with increasing temperature is usually somewhat more pronounced than is observed for surface tension. Although no quantitative relation is observed, the general trend suggests lower interfacial tensions for the higher API gravity crudes. However, in studies with a crude oil containing large amounts of resins and asphaltenes, different effects of temperature on interfacial tension were observed when measurements made at aerobic conditions were compared to anaerobic tests [93]. Interfacial tension between the crude and reservoir brine showed a decrease with an increase in temperature under aerobic conditions, whereas at anaerobic conditions, interfacial tension increased with increasing temperatures. This difference in behavior was attributed to oxidation of the stock tank oil in the aerobic tests. At conditions of reservoir temperature and pressure, interfacial tension of the live reservoir oil was higher than the stock tank oil. The study concluded that live reservoir crude should be used in measurements of interfacial properties and that if stock tank oil is used, at least the temperature should correspond to reservoir conditions.

Figure 5.1.43 shows the effect of dissolved gas and pressure on the interfacial tension of three oil-water systems [89]. For each system, interfacial tension increases as the

amount of dissolved gas increases, but drops slightly as pressure is increased above the bubblepoint.

Surface and interfacial tensions are important in governing the flow of fluids in the small capillaries present in oil-bearing reservoirs. The capillary forces in oil or gas reservoirs are the result of the combined effect of surface and interfacial tensions, pore size distribution, pore shape, and the wetting properties of the hydrocarbon/rock system.

5.1.3.4 Wettability and Contact Angle

The contact angle (θ_c), existing between two fluids in contact with a solid and measured through the more dense phase, is a measure of the relative wetting or spreading by a fluid on a solid. A contact angle of zero indicates complete wetting by the more dense phase, an angle of 180° indicates complete wetting of the less dense phase, and an angle of 90° means that neither fluid preferentially wets the solid.

FIGURE 5.1.41 Surface tension of several crude oils [91].

From a combination of Dupre’s equation for wetting tension and Young’s equation [94], the adhesion tension (τ_A) can be given as [19,95,97]:

$$\tau_A = \sigma_{os} - \sigma_{ws} = \sigma_{wo} \cos \theta_{wo} \tag{5.1.73}$$

where σ_{os} is the interfacial tension between the solid and the less dense fluid phase, σ_{ws} is the interfacial tension between the solid and the more dense phase, and σ_{wo} is the interfacial tension between the fluids of interest. With gas-oil systems, oil is the more dense phase and is always the wetting phase [96]. With oil-water systems water is almost always the more dense phase, but either can be the wetting phase. For oil and water, a positive adhesion tension ($\theta_c > 90^\circ$) indicates a preferentially water-wet surface, whereas a negative adhesion tension ($\theta_c < 90^\circ$) indicates a preferentially oil-wet surface. For a contact angle of 90° , an adhesion tension of zero indicates that neither fluid preferentially wets the

solid. Examples of various contact angles are depicted in Figure 5.1.44 [96].

The importance of wettability on crude oil recovery has been recognized for many years. This subject is discussed in a subsequent section of this chapter. Although Nutting [98] observed that some producing formations were oil-wet, many early workers considered most oil reservoirs to be water-wet (e.g., References 23, 99, and 100; discussion and comments in Reference 96). From a thermodynamic standpoint, it was felt that pure, clean silica must be wetted by water in preference to any hydrocarbon. In one study [101], no crude oils were tested that had a greater adhesion than pure water. Other results [102] tended to support this contention: capillary pressure tests suggested that all cores tested were water-wet with contact angles ranging from 31° to 80°. However, there are two reasons why these results were obtained [103]: (1) the cores were extracted with chloroform prior to the tests which could have affected the natural wettability, and (2) only receding (decrease in wetting phase saturation) contact angles were measured during the capillary pressure tests. As with cap-

FIGURE 5.1.42 Influence of temperature on interfacial tensions for crude oil/water systems [92].

FIGURE 5.1.43 Effect of dissolved gas and pressure on interfacial tension between crude oil water [89].

illary pressures, there is a hysteresis in the receding and advancing (increase in wetting phase saturation) contact angles; receding angles are smaller than advancing angles [97]. Bartell and coworkers [95–97] were among some of the first investigators to measure contact angles with crude oil systems that suggested the possibility that oil reservoirs may not be water-wet. Furthermore, they concluded that spontaneous displacement of oil by water should occur only when both advancing and receding angles are less than 90°, and no spontaneous imbibition should occur if the two angles are on opposite sides of 90° [97].

A common technique for measuring advancing contact angles using polished mineral crystals is described in the literature [104]. For many crude oil systems, a considerable

amount of time may be required before an equilibrium contact angle on a pure mineral is obtained. As shown in Figure 5.1.45 [104], some systems that initially appear to be preferentially water-wet become more oil-wet. Small amounts of polar compounds in some crude oils can adsorb on the rock surfaces and change wettability from preferentially water-wet to more oil-wet [96]. A detailed study on how crude oil components affect rock wettability has been made by Denekas et al. [105]. Imbibition tests have been described to examine wettability of reservoir cores [106, 107]. A preferred technique of inferring reservoir wetting from core samples is the Amott method [108] which involves spontaneous imbibition and forced displacement tests; ratios of spontaneous displacement volumes to total displacement volumes are used as an index of wettability. Based on the correlation suggested by Gatenby and Marsden [109], Donaldson et al. [110–112] developed a quantitative indication of wettability, called the U.S. Bureau of Mines (USBM) test, by measuring the areas under capillary pressure curves. The USBM method has the advantage of working well in the intermediate wettability region. A multitude of techniques for the qualitative indication of wettability that have been proposed will not be described but have been discussed in the literature [133].

In a fairly extensive examination of 55 different reservoirs, Treiber, Archer, and Owens [114] arbitrarily assigned water-wet conditions for contact angles of 0° to 75° and oil-wet conditions for contact angles of 105° to 180° with contact angles of 75° to 105° representing an intermediate (referred to as neutral by others) wettability. With these designations, 27% of the samples were water-wet, 66% were oil-wet, and the remaining 7% were of intermediate

* Based on contact angle/wettability relation suggested by Treiber, Archer, and Owens [114].

** Based on contact angle/wettability relation suggested by Morrow [115].

wettability. Subsequently, Morrow [115] has defined an intermediate wettability when neither fluid spontaneously imbibe in a “squatters’ rights” situation. Morrow found that for contact angles less than 62° , the wetting phase would spontaneously imbibe, and for contact angles above 133° , the nonwetting phase would spontaneously imbibe; therefore, the intermediate wettability condition would be

operative for contact angles from 62° to 133° . Using Morrow’s guidelines, the data of Treiber, Archer, and Owens indicate that 47% of the samples were of intermediate wettability, 27% were oil-wet, and 26% were water-wet. The distribution in wettability according to lithology is given in Table 5.1.15. In either case, it is apparent that a majority of the samples were not water-wet.

Using 161 core samples representing various carbonate reservoirs, Chilingar and Yen [116] found that 8% were water-wet ($\theta_c > 80^\circ$), 12% were intermediate ($\theta_c = 80^\circ - 100^\circ$), 65% were oil-wet ($\theta_c = 100^\circ - 160^\circ$), and 15% were strongly oil-wet ($\theta_c = 160^\circ - 180^\circ$). The arbitrary definitions of wettability differ from Trieber et al. [114] and Morrow [115], but the distributions appear to be similar to the carbonate data in Table 5.1.15.

In the previous discussion, it was implied that pore surfaces within a reservoir rock are uniformly wetted. The concept whereby a portion of the reservoir surfaces are preferentially oil-wet while other portions are preferentially water-wet was termed fractional wettability by Brown and Fatt [117] and Fatt and Klikoff [118]. Fractional wetting was believed to be a result of the varying amount of adsorption of crude oil components on the different minerals present in a reservoir. Other evidence [119, 120] supported the existence of a heterogeneous wetting (also called spotted or Dalmation wettability in the literature). Salathiel [121] introduced the concept of a mixed-wettability condition, a special case of fractional wetting, in which the fine pores and grain contacts are preferentially water-wet and the large pore surfaces are strongly oil-wet. Salathiel concluded that the oil-wet paths can be continuous to provide a means for oil to flow even at very low oil saturations; these results were offered to explain the very good oil recovery noted in some field projects. Morrow, Lim, and Ward [122] introduced the concept of a speckled wettability in which a rationale is presented whereby oil tends to be trapped in pore throats rather than pore bodies. Speckled wettability mimics behavior of strongly water-wet conditions observed during waterflooding: water breakthrough is abrupt, relative permeability to water at residual oil saturation is low, water

is imbibed spontaneously, and oil is not imbibed spontaneously.

When cores are obtained for laboratory tests where wettability is important, precautions must be taken to ensure the wetting preference of the formation is not altered during coring. Mud additives, such as dispersants, weighting agents, lost circulation materials, thinners or colloids, that possess surface-active properties may drastically change core wettability. Surface active agents should be avoided so that the core samples have the same wettability as the reservoir rock. Listed in Table 5.1.16 are the effects of various mud additives on wettability of water-wet and oil-wet cores [107].

In the case of water-wet sandstone or limestone cores, rock-salt, bentonite, carboxymethylcellulose (CMC), and barite had no effect on wettability. However, oil-wet sandstone cores were reversed to a water-wet condition when exposed to CMC, bentonite, or lime solutions. Additional tests with bentonite solutions indicated that wettability of oil-wet cores is not reversed if the solution pH is lowered to a neutral or slightly acidic value. These results suggest that from a wettability standpoint, the best coring fluid is water (preferably formation brine); if bentonite is used, mud pH should be neutral or slightly acidic. If appreciable hydrogen sulfide is suspected in the interval being cored, it may be undesirable to lower pH. In fact, a very alkaline mud (pH 10–12) may be used to keep the sulfide in the ionized state for safety and corrosion considerations. Subsequent work [123] suggests the preferred system to obtain fresh cores is a natural water-base mud with no additives, or a bland mud consisting of bentonite, salt, and CMC. However, recent results [124] conclude that bland muds may not, in fact, be bland. While none of the bland additives altered

TABLE 5.1.16 Effect of Water-Base Mud Additives on the Wettability of Cores

Wettability of Test Cores after Exposure to Filtrate

wettability of water-wet rock samples, all of the components with the exception of bentonite made oil-wet samples significantly less oil-wet. The bland additives that were tested included bentonite, pregelatinized starch, dextrid (an organic polymer), drispac (a polyanionic cellulose polymer), hydroxyethylcellulose, xanthan gum polysaccharide, and CMC. All of the drilling mud components considered to be bland decreased the amount of oil imbibed into a core and increased the amount of water imbibed.

Preventing wettability changes in core material, after it has been recovered at the surface, is equally important so that subsequent laboratory measurements are representative of reservoir conditions. Changes in wettability of core material that occur during handling or storage are usually caused by oxidation of the crude oil, evaporation of volatile components, or decreases in temperature or pressure which cause the deposition of polar compounds, asphaltenes, or heavy hydrocarbon compounds [107, 125]. Because of the complexity of the mechanisms involved, the magnitude and direction of changes in wetting conditions, when reservoir cores are preserved, are not fully understood. Weathering of water-wet cores has been reported to frequently cause the grain surfaces to become oil-wet [107]. In other experiments [126] oil-wet cores changed to water-wet upon contact with air. Therefore it is necessary to preserve core samples at the well-site to ensure that wettability is not altered by contamination, oxidation, or evaporation. Two methods of preserving conventional cores, immediately after they have been removed from the core barrel, will prevent changes in wettability for several months [107]. One method consists of immersing the core in deoxygenated formation brine or suitable synthetic brine (i.e., drilling mud filtrate) and keeping the sample in suitable nonmetallic containers that can be sealed to prevent leakage and the entrance of oxygen. In a second method, the cores are wrapped in Saran or polyethylene film and aluminium foil, and then coated with wax or strippable plastic. Cores obtained by either of these methods are referred to as preserved, native-state, or fresh cores, and are preferred for many laboratory tests.

For certain laboratory tests, it may be possible to clean reservoir cores with solvents and resaturate with reservoir fluids to restore the original wetting conditions. Details of preparing such restored-state or extracted cores are discussed subsequently in the section "Coring and Core Analysis." The concept of the method is to clean the core thoroughly until it is water-wet, saturate with reservoir brine, flush with crude oil, and age for over 1,000 hours at reservoir temperature.

Regardless of the method of core handling employed, the rock samples used in the laboratory should have a surface state as close as possible to that present in the reservoir. If preserved cores are used, it is essential they be stored under air-free conditions because exposure to air

for as little as 6–8 hours can cause water evaporation and other changes in core properties. If extracted cores are used, drying of the cores can be very critical when hydratable minerals, capable of breaking down at low temperatures are present. Contamination from core holders that contain certain types of rubber sleeves can be prevented by using an inner liner of tubular polyethylene film. Because of the instability of many oilfield waters, it is usually desirable to prepare synthetic brines to prevent core plugging caused by deposition of insolubles.

When possible, tests should be made under reservoir conditions of temperature and pressure using live reservoir oil. This is an improvement over room condition techniques where tests are made at atmospheric conditions with refined laboratory oils. Use of the live crude exposes the rock to compounds present in the oil that might influence wettability, and establishes an environment as close as possible to reservoir conditions. Cores evaluated at atmospheric conditions may be more oil-wet than similar tests at reservoir conditions because of the decreased solubility of wettability-altering compounds at lower temperatures and pressures [107, 123]. In a recent contact angle study [93] with calcium carbonate crystals and a crude oil containing 27.3% resins and 2.2% asphaltenes, a complete reversal from a predominantly oil-wet system at lower temperatures to a predominantly water-wet system at higher temperatures was found. While pressure alone had little effect on the wettability of the system, the study speculated that the addition of gas-in-solution with increasing pressure should favor a more water-wet situation than would be indicated from laboratory tests at atmospheric conditions. Even when all precautions have been taken, there is no absolute assurance that reservoir wettability has been duplicated.

5.1.3.5 Capillary Pressure

Curvature at an interface between wetting and nonwetting phases causes a pressure difference that is called capillary pressure. This pressure can be viewed as a force per unit area that results from the interaction of surface forces and the geometry of the system.

Based on early work in the nineteenth century of Laplace, Young, and Plateau (e.g., Reference 94), a general expression for capillary pressure, P_c , as a function of interfacial tension, σ , and curvature of the interface is [19]:

$$P_c = \sigma \left(\frac{1}{r_1} + \frac{1}{r_2} \right) \quad (5.1.74)$$

where r_1 and r_2 are the principal radii of curvature at the interface. These radii are not usually measured, and a mean radius of curvature is given by the capillary pressure and interfacial tension.

TABLE 5.1.17 Empirical Relative Permeability Equations

From Reference 20.		

For a cylindrical vertical capillary, such as a small tube, the capillary pressure for a spherical interface is [19]:

$$P_c = \frac{2\sigma \cos \theta_c}{r} = gh(\rho_1 - \rho_2) \quad (5.1.75)$$

where r is the radius of the tube, θ_1 is the contact angle measured through the more dense phase that exists between the fluid and the wall of the tube, g is the gravitational constant, ρ is density, h is column height, and the subscripts refer to the fluids of interest. For a fluid that wets the wall of a capillary tube, the attraction between the fluid and the wall causes the fluid to rise in the tube. The extent of rise in the capillary is proportional to the interfacial tension between the fluids and the cosine of the contact angle and is inversely proportional to the tube radius.

An analogous situation can occur during two-phase flow in a porous medium. For example if capillary forces dominate in a water-wet rock, the existing pressure differential causes flow of the wetting fluid to occur through the smaller capillaries. However, if viscous forces dominate, flow will occur through the larger capillaries (from Pouisselle's law, as a function of the 4th power of the radius).

Figure 5.1.46 depicts a typical capillary pressure curve for a core sample in which water is the wetting phase.

Variation of capillary pressure is plotted as a function of water saturation. Initially, the core is saturated with the wetting phase (water). The nonwetting phase, oil in this case, is used to displace the water. As shown in the figure, a threshold pressure must be overcome before any oil enters the core. The initial (or primary) drainage curve represents the displacement of the wetting phase from 100% saturation to a condition where further increase in capillary pressure causes little or no change in water saturation. This condition is commonly termed the irreducible saturation, S_{iw} . The imbibition curve reflects the displacement of the nonwetting phase (oil) from the irreducible water saturation to the residual oil saturation. Secondary drainage is the displacement of the wetting phase from the residual oil saturation to the irreducible water saturation. A hysteresis is always noted between the drainage and imbibition curves. Curves can be obtained within the hysteresis loop by reversing the direction of pressure change at some intermediate point along either the imbibition or secondary drainage curve. The nonuniform cross-section of the pores is the basic cause of the hysteresis in capillary pressure observed in porous media. Therefore, capillary pressure depends on pore geometry, interfacial tension between the fluids, wettability of the system (which will be discussed later in this chapter), and the saturation history in the medium.

FIGURE 5.1.46 Example capillary pressure curves

Leverett [100] introduced a reduced capillary pressure function (subsequently termed the Leverett J function by Rose and Bruce [127]) that was suggested for correlating capillary pressure data:

$$J(S_w) = \frac{P_c}{\sigma \cos \theta_c} \left(\frac{k}{\phi} \right)^{1/2} \quad (5.1.76)$$

where $J(S_w)$ = the correlating group consisting of the

terms of Equation 5.1.75

k = the permeability

ϕ = porosity of the sample

The J function was originally proposed as means of converting all capillary pressure data for clean sand to a universal curve. A series of capillary pressure curves are shown as a function of permeability in Figure 5.1.47 [20]. An example of the J function curve generated from these data is shown in Figure 5.1.48 [20]. While the J function sometimes correlates capillary pressure data from a specific lithology within the same formation, significant variations can be noted for different formations.

Common laboratory methods of measuring capillary pressure include [19]: mercury injection, porous diaphragm or plate (restored state), centrifuge method, and steady-state flow in a dynamic method. While the restored state test is generally considered the most accurate, mercury injection is routinely used. However, it is necessary to correct the mercury injection data for wetting conditions before comparison to results from the restored state test.

FIGURE 5.1.47 Capillary pressures of different permeability core samples [20].

A very valuable use of capillary pressure data is to indicate pore size distribution. Since the interfacial tension and contact angle remain constant during a test such as already described, pore sizes can be obtained from capillary pressures. For rocks with more uniform pore sizes, capillary pressure curves will be close to horizontal. The slope of the

FIGURE 5.1.48 J function plot for data in Figure 5.1.47 [20].

capillary pressure curve will generally increase with broader pore-size distribution.

If laboratory capillary pressure data are corrected to reservoir conditions, the results can be used for determining fluid saturations. Figure 5.1.49 shows a close agreement in water saturations obtained from capillary pressure and electric logs [48].

Capillary pressure data are helpful in providing a qualitative assessment of the transition zones in the reservoir. A transition zone is defined as the vertical thickness where saturation changes from 100% water to irreducible water for water-oil contact, or from 100% liquid to an irreducible water saturation for gas-oil contact.

5.1.3.6 Effective Permeability

In the previous section, "Absolute Permeability," it was stated that permeability at 100% saturation of a fluid (other than gases at low pressure) is a characteristic of the rock and not a function of the flowing fluid. Of course, this implies that there is no interaction between the fluid and the rock (such as interaction between water and mobile or swelling clays). When permeabilities to gases are measured, corrections must be made for gas slippage which occurs when the capillary openings approach the mean free path of the gas. Klinkenberg [128] observed that gas permeability depends on the gas composition and is approximately a linear function of the reciprocal mean

FIGURE 5.1.49 Comparison of water saturations from capillary pressure and electric logs [48].

pressure. Figure 5.1.50 shows the variation in permeability as a function of mean pressure for hydrogen, nitrogen, and carbon dioxide. Klinkenberg found that by extrapolating all data to infinite mean pressure, the points converged at an equivalent liquid permeability (k_l), which was the same as the permeability of the porous medium to a nonreactive single-phase liquid. From plots of this type, Klinkenberg showed that the equivalent liquid permeability could be obtained from the slope of the data, m , the measured gas permeability, k_g , at a mean flowing pressure \bar{p} , at which k_g was observed:

$$k_l = \frac{k_g}{1 + (b/\bar{p})} = k_g - \frac{m}{\bar{p}} \quad (5.1.77)$$

where b is a constant for a given gas in a given medium and is equal to m divided by k_l . The amount of correction, known as the Klinkenberg effect, varies with permeability and is more significant in low permeability formations.

In recent studies [129, 130] with very low permeability sandstones, liquid permeabilities were found to be less than

FIGURE 5.1.50 Gas slippage in core [128].

gas permeabilities at infinite mean pressure, which is in contrast with the prior results of Klinkenberg. Furthermore, it has been shown [130] that liquid permeabilities decreased with increasing polarity of the liquid. For gas flow or brine flow in low-permeability sandstones, permeabilities were independent of temperature at all levels of confining pressure [130]. The data [130] showed that for a given permeability core sample at a given confining pressure, the Klinkenberg slip factors and slopes of the Klinkenberg plots were proportional to the product of viscosity and the square root of absolute temperature.

As shown in Figure 5.1.51 permeability of reservoir rocks can decrease when subjected to overburden pressure [131]. When cores are retrieved from a reservoir, the confining forces are removed and the rock can expand in all directions which can increase the dimensions of the available flow paths. In reservoirs where this is significant, it is imperative that permeability measured in the laboratory be conducted at the confining pressure that represents the overburden pressure of the formation tested.

As a general trend, air permeability decreases with increasing connate water saturation. Relationships between air permeability and connate water saturation in Figure 5.1.52 show a linear decrease in the logarithm of permeability as a function of water saturation that depends on the individual field [132].

The fluid system of an oil reservoir consists usually of gas, oil, and water. In the case of such a heterogeneous system, flow of the different phases is a function of fluid saturation in the reservoir by the different phases. The lower the saturation of a certain liquid, as compared to

FIGURE 5.1.51 Air permeability at different overburden pressures [131].

other liquids, the lower the permeability to that liquid. This type of permeability is termed effective permeability and is defined as permeability of the rock to one liquid under conditions of saturation when more than one liquid is present. Typical permeability-saturation relations for oil and gas and for oil and water are shown in Figure 5.1.53.

From the practical point of view, permeability may be considered as a measure of productivity of the producing horizon. Knowledge of permeability is useful in a number of reservoir problems. The concept of effective permeability is of particular importance since it emphasizes a need for pro-

FIGURE 5.1.52 Relationship between air permeability and connate water saturation [132].

FIGURE 5.1.53 Effective permeabilities.

duction practices, which tend to maintain good permeability of the reservoir to oil.

Thus, the absolute permeability is the permeability measured when the medium is completely saturated with a single fluid. Effective permeability is the permeability to a particular fluid when another fluid is also present in the medium. For example, if both oil and water are flowing,

the effective permeability to oil is k_o and that to water is k_w . The sum of the effective permeabilities is always less than the absolute permeability [17]. As noted in the previous section, permeability is commonly expressed in millidarcies (md).

5.1.3.7 Relative Permeability

If the effective permeabilities are divided by a base permeability (i.e., the absolute permeability), the dimensionless ratio is referred to as the relative permeability, namely k_{rg} for gas, k_{ro} for oil, and k_{rw} for water:

$$k_{rg} = \frac{k_g}{k}; \quad k_{ro} = \frac{k_o}{k}; \quad k_{rw} = \frac{k_w}{k} \quad (5.1.78)$$

where k_g , k_o , and k_w are the effective permeabilities to gas, oil, and water, respectively, and k is some base permeability that represents the absolute permeability. For gas-oil two-phase relative permeabilities, the base permeability is often the equivalent liquid permeability. For oil-water two-phase relative permeabilities, three different base permeabilities are often used [133]:

1. The permeability to air with only air present.
2. The permeability to water at 100% S_w .
3. The permeability to oil at irreducible water saturation.

Wyckoff and Botset [76] are generally credited with performing the first gas and liquid relative permeabilities which were conducted in unconsolidated sandpicks in 1936. In these early experiments, a relationship was observed between the liquid saturation of a sand and the permeability to a liquid or gas phase [76, 134]. At about the same time, Hassler, Rice, and Leeman [135] measured relative air permeabilities in oil-saturated cores. In 1940, relative permeability measurements were extended to consolidated cores by Botset [136]. Since then, a number of dynamic (fluid displacement or fluid drive) methods [83, 137–143] and static (or stationary-phase) methods [144–150] have been proposed to determine relative permeabilities in core samples. In the latter methods, only the nonwetting phase is allowed to flow by the use of a very low pressure drop across the core; hence, this method is applicable only to the relative permeability of the nonwetting phase. The dynamic methods include: (1) steady-state methods in which fluids are flowed simultaneously through a core sample at a fixed gas-oil or water-oil ratio until equilibrium pressure gradients and saturations are achieved, and (2) unsteady-state methods in which an oil-saturated core is flooded with either gas or water at a fixed pressure drop or flow rate so that the average fluid saturation changes result in a saturation gradient. The most popular steady-state procedure is the Penn State method [83], but the most common dynamic test is the unsteady-state method because of the reduced

FIGURE 5.1.54 Example of water-oil relative permeability data.

time requirement. The various methods have been evaluated [139, 151] and generally provide similar results.

Based on the initial work of Leverett [100] and Buckley and Leverett [152], Welge [153] was the first to show how to calculate relative permeability ratios in the absence of gravity effects. Subsequently, Johnson, Bossler, and Naumann [154] showed that each of the relative permeabilities could be calculated even when gravity is not neglected. Other calculations of relative permeabilities have been proposed by Higgins [155], Guerrero and Stewart [156, 157], and a graphical technique has been presented by Jones and Rozelle [158].

An example of water-oil relative permeability plot vs. water saturation is given in Figure 5.1.54. Several features will be described that pertain to generating relative permeability curves from cores in the laboratory. If a clean, dry core is completely saturated with water, the permeability at 100% S_w should be similar to the equivalent liquid permeability obtained from gas flow measurements at 100% S_g . Exceptions to this generality include some low-permeability systems and other cores that contain clays or minerals that interact with the water used. If a clean core is used, it will probably be strongly water-wet when saturated with brine. As crude oil is injected into the core, the relative permeability to water decreases during the drainage cycle (decreases in wetting phase) while the relative permeability to oil increases. Some water that resides in the nooks and

crannies of the pore space cannot be displaced by the oil, regardless of the throughput volume. This water saturation, which does not contribute significantly to occupying the flow paths, is called the irreducible water saturation, S_{iw} . With the core at S_{iw} , there is 100% relative permeability to oil (only oil is flowing) and no permeability to water. At this point, the core can be closed in for about 1,000 hours to allow sufficient time for wettability changes to occur. Then the core is flooded with water in an unsteady-state test, or fixed ratios of water and oil are injected in the steady-state test. If water continues to be the wetting phase, the relative permeability to water (which will be only a function of saturation) will be the same during the drainage and imbibition cycles. (The importance of wettability on relative permeabilities will be discussed in the next section of this chapter.) As the water is injected into the oil-flooded core, k_{rw} increases while k_{ro} decreases. Not all of the oil can be displaced from the core, regardless of the water throughput (at modest flow rates or pressure drops), and this is referred to as the waterflood residual oil saturation, S_{or} .

Similar observations apply to gas-oil relative permeability data as displayed in Figure 5.1.55. Typically, the gas-oil relative permeabilities are plotted against the total liquid saturation, which includes not only the oil but also any connate water that may be present. In the presence of gas, the oil (even if connate water is present) will be the wetting phase in preference to gas. As a result, the k_{ro} curve from

FIGURE 5.1.55 Gas-oil relative permeability data [20].

FIGURE 5.1.56 Comparison of oil recovery for oil-wet and water-wet cores [133].

gas-oil flow tests resembles the drainage k_{rw} curve from oil-water flow tests. As seen in [Figure 5.1.56](#), the irreducible gas saturation (also called the equilibrium or critical gas saturation) is usually very small. When gas saturation is less than the critical value, gas is not mobile but does impede oil flow and reduces k_{ro} .

Three-phase relative permeabilities pertaining to simultaneous flow of gas, oil, and water have been provided in the literature [19, 50]. Since the occurrence of such three-phase flow in a reservoir is limited [20], relative permeabilities for these conditions will not be discussed in this chapter, and the reader is referred to other sources [19, 20, 60, 137, 140, 159, 160].

Based on the work of Corey [150] and Wyllie [23, 50], empirical equations have been summarized by Slider [20] to estimate relative permeabilities. These equations permit the estimation of k_{ro} from measurements of k_{rg} . Other empirical equations for estimating two-phase relative permeabilities in consolidated rocks are available in the literature [161].

Early work in unconsolidated sands showed that fluid viscosity or the range of permeability had negligible effects on the relationship between relative permeability and fluid saturation [76, 100]. Geffen et al. [141] confirmed that relative permeabilities in cores are not affected by fluid properties provided wettability is not altered. However, others [162, 163] have found that viscosity ratio influences relative permeability data when the displacing fluid is non-wetting. For constant wettability conditions, the higher the viscosity of one of the liquids, the lower is the relative permeability of the other liquid [163].

Geffen et al. [141] did cite a number of factors, in addition to fluid saturations, that affect relative permeability results. Because of capillary hysteresis, saturation history was important in that fluid distribution in the pores was altered. Flow rates during laboratory tests need to be sufficiently high to overcome capillary end effects (retention of the wetting phase at the outlet end of the core) [141]. According to Wyllie [23], relative permeability varies because of varying geometry of the fluid phases present, which is controlled by effective pore size distribution, method of obtaining the saturation (saturation history); heterogeneity of the core sample, and wettability of the rock-fluid system.

Controversy continues to exist regarding the effect of temperature on relative permeabilities (for example see the discussion and prior citations in References 164 and 165). Miller and Ramey [164] observed no change in relative permeability with temperatures for clean systems, and speculated that for reservoir fluid/rock systems, effects such as clay interactions or pore structure would need to be considered. Honarpour et al. [165] summarized the effects of temperature on two-phase relative permeabilities as measured by various researchers. In field situations, the

larger overburden pressure associated with greater depths may be more important in affecting relative permeabilities than the associated temperature increases. As with many other tests, relative permeability measurements should be conducted at reservoir conditions of overburden pressure and temperature with crude oil and brine representative of the formation under study.

5.1.3.8 Effect of Wettability on Fluid-Rock Properties

5.1.3.8.1 Oil Recovery and Fluid Saturations

Since a reservoir rock is usually composed of different minerals with many shapes and sizes, the influence of wettability in such systems is difficult to assess fully. Oil recovery at water breakthrough in water-wet cores is much higher than in oil-wet cores [106, 110, 166–169], although the ultimate recovery after extensive flooding by water may be similar, as shown in [Figure 5.1.56](#). These authors have shown that oil recovery, as a function of water injected, is higher from water-wet cores than from oil-wet cores at economical water-oil ratios. In 1928, Uren and Fahmy [170] observed better recovery of oil from unconsolidated sands that had an intermediate wettability, and several investigators have suggested better oil recovery from cores of intermediate or mixed wettability [106, 108, 121, 123, 171]. More recent evidence by Morrow [172] and Melrose and Brandner [173] suggests that mobilization of trapped oil is more difficult in the intermediate wettability region, but the prevention of oil entrapment should be easier for advancing contact angles slightly less than 90° .

With water-wet cores in laboratory waterfloods, the oil production at water breakthrough ceases abruptly and water production increases sharply. With systems that are not water-wet, water breakthrough may occur earlier, but small fractions of oil are produced for long periods of time at high water cuts. In strongly water-wet systems, the residual oil that is permanently trapped by water resides in the larger pores, whereas in oil-wet systems trapping occurs in the smaller capillary spaces [106, 133].

5.1.3.8.2 Relative Permeability Characteristics

For a system having a strong wetting preference for either oil or water, relative permeability of the wetting phase is a function of fluid saturation only [76, 137, 160]. Details of the effect of wettability on relative permeabilities have been discussed by several authors [113, 133, 174, 175]. In a detailed study using fired Torpedo (outcrop sandstone) cores, Owens and Archer [174] changed wettability by adding surface active agents to either the oil or water. Firing of the cores stabilized any clay minerals present and provided more constant internal conditions. Both gas-oil and water-oil relative permeabilities were obtained. Some of the water-oil relative permeability data, all started at the same water saturation and obtained with the Penn

FIGURE 5.1.57 Effect of wettability on water-oil relative permeabilities [174].

State steady-state method, are reproduced in Figure 5.1.57. As the contact angle was increased to create more oil-wet conditions the effective permeability to oil decreased. Because of the differences in flow paths for the different wettability conditions, oil-wet systems had lower k_{ro} and higher k_{rw} when compared to water-wet conditions at the same water saturation. As the level of oil-wetting increased, k_{ro} at any saturation decreased whereas k_{rw} increased.

Craig [133] has presented typical relative permeability curves, such as given in Figure 5.1.58, to point out differences in strongly water-wet and strongly oil-wet conditions. Craig suggests that several rules of thumb can help in distinguishing wetting preferences; typical characteristics of water-oil relative permeability curves are given in Table 5.1.18 [133]. Additionally, the strongly oil-wet relative permeability curves tend to have more curvature. Craig suggests the generality that relative permeability curves of intermediate wettability systems will have some of the characteristics of both water-wet and oil-wet conditions. However, as mentioned earlier in the section “Wettability and Contact Angle,” a speckled wettability form of intermediate

wetting mimics the relative permeability characteristics of strongly water-wet conditions [122].

5.1.3.8.3 Capillary Pressure Curves

By convention, oil-water capillary pressure, P_c , is defined as the pressure in the oil phase, p_o , minus the pressure in the water phase, p_w :

$$P_c = p_o - p_w \quad (5.1.79)$$

Depending on wettability and history of displacement, capillary pressure can be positive or negative. Figure 5.1.59 presents the effect of wettability on capillary pressure as related by Killins, Nielsen, and Calhoun [176]. Drainage and imbibition curves can have similarities, but the capillary pressure values are positive for strongly water-wet and negative for strongly oil-wet conditions. In the intermediate wettability case shown in Figure 5.1.59, the small posi-

FIGURE 5.1.59 Effect of wettability on capillary pressure [176].

tive value of threshold pressure during the drainage cycle suggests the sample was moderately water-wet [133]. After the drainage cycle, the sample spontaneously imbibed water until the capillary pressure was zero at a water saturation of 55%. Then, as water pressure was applied, the maximum water saturation of about 88% was achieved. As discussed previously, capillary pressure curves can be used as a criterion of wettability.

5.1.3.8.4 Resistivity Factors and Saturation Exponents

As shown previously in Table 5.1.7, Sweeney and Jennings [51] found that the formation resistivity factor changed when wettability was altered. However, the naphthenic acid they used to alter wettability may have also reduced porosity which could account for the increase in the saturation exponent in Equation 5.1.46. Other investigators [177, 178] have found no significant effect of wettability on formation factors. Because of the scarcity of data and the difficulty of altering wettability without affecting other properties, the effect of wettability on formation resistivity remains unclear.

As related by Mungan and Moore [178], three assumptions are made in the Archie saturation expression (Equation 5.1.68): all of the brine contributes to electrical flow: the saturation exponent, n , is constant for a given porous media; and only one resistivity is measured for a given saturation. Since the saturation exponent depends on the distribution of the conducting phase, which is dependent on wettability, the foregoing assumptions are valid only for strongly water-wet conditions. When wettability is altered, the differences in fluid distribution cause variations in the cross-sectional areas of conductive paths and in the tortuous path lengths. These variations affect resistivity, which results in different resistivity-saturation relationships such as were presented for carbonate cores by Sweeney and Jennings [51] in Figure 5.1.60. The saturation exponent, which is the slope of the lines, was about 1.6 for water-wet cores, about 1.9 for neutral-wet cores, and about 8 for oil-wet cores [51]. Similar data in sandstone cores were provided by Rust [177]; saturation exponents were about 1.7 and 13.5 for water-wet and oil-wet conditions respectively. These differences in oil-wet rocks most likely occur because of

FIGURE 5.1.60 Resistivity-saturation relationships for different wettability carbonate cores [51].

the isolation of trapped brine in dendritic fingers or dead-end pores which do not contribute to electrical conductivity.

Table 5.1.19, presenting data given by Mungan and Moore [178], shows that the effect of wettability on sat-

FIGURE 5.1.61 Influence of wettability on saturation exponent [179].

uration exponent becomes more important at low brine saturations. Morgan and Pirson [179] conducted tests on fractionally wetted bead packs in which portions of the beads were water-wet and portions were treated so that they were mildly oil-wet. From their data, plotted in Figure 5.1.61, the saturation exponent increased as the extent of oil-wetting increased.

The foregoing data suggest that unless the reservoir is known to be water-wet, the saturation exponent should be measured with native-state (preferably) or restored cores. If the reservoir is oil-wet and clean cores are used that may be water-wet, the saturation exponents that are obtained can lead to an underestimate of connate water saturation in the formation tested.

5.2 FORMATION EVALUATION

Section reviewed by Heru Danardatu

Formation evaluation, as applied to petroleum reservoirs, consists of the quantitative and qualitative interpretation of formation cores, geophysical well logs, mud logs, flow tests, pressure tests, and samples of reservoir fluids. The goal of the interpretation is to provide information concerning reservoir lithology, fluid content, storage capacity, and producibility of oil or gas reservoirs. The final analysis includes an economic evaluation of whether to complete an oil or gas well and, once completed, an ongoing analysis of how to produce the well most effectively. These interpretations and analyses are affected by geological complexity of the reservoir, rock quality, reservoir heterogeneity, and, from a logistical standpoint, the areal extent and location of the project of interest. In the early stages of development, the purpose of formation evaluation is to define reservoir thickness and areal extent, reservoir quality, reservoir fluid properties, and ranges of rock properties. The key rock properties are porosity, permeability, oil, gas, and water saturations. Because of space limitations and the importance of these properties, methods of measuring porosity, permeability, and fluid saturations will be emphasized.

5.2.1 Coring and Core Analysis

Routine or conventional core analyses refer to common procedures that provide information on porosity, permeability, resident fluids, lithology, and texture of petroleum reservoirs. [Table 5.2.1](#) lists the types of analyses that are obtained and how the results of each analysis are used. Specialized core analyses, such as are listed in [Table 5.2.2](#), are done less

often, but are important for specific applications. Routine core analyses can be performed on whole cores or on small plugs that are cut from a larger core. With the exception of petrographic analyses (thin sections, x-ray; scanning electron microscopy, etc.), special core analyses are normally done with core plugs. After a well is drilled and logs are available to identify zones of interest, very small portions of the reservoir can be obtained with percussion sidewall or sidewall drilled cores. Sidewall cores are less expensive and are valuable for petrographic analyses, but are generally not suitable for special core analyses.

The subject of coring and core analysis was summarized in a series of articles [2–10]. An overview article [11] described how core analyses can aid reservoir description. A handbook [12] is available that describes procedures and tools for conventional coring as well as methods for routine core analysis. Procedures for routine core analysis and methods of preserving cores have been recommended by the American Petroleum Institute [13]. Some of the information available in these sources will be highlighted.

5.2.1.1 Coring

Well coring refers to the process of obtaining representative samples of the productive formation in order to conduct a variety of laboratory testing. Various techniques are used to obtain core samples: conventional diamond-bit coring, rubbersleeve coring, pressure coring, sidewall coring, and recovery of cuttings generated from the drilling operation. Conventional coring is normally done in competent formations to obtain full-diameter cores. Rubber sleeve-coring improves core recovery in softer formations. Pressure coring, although relatively expensive, is used to obtain cores that have not lost any fluids during lifting of the core to the surface.

A common problem with all of these techniques is to decide when to core. In many instances, cores from the interval of interest are not obtained because of abrupt stratigraphic changes. A second problem is that, typically, nonproductive intervals of the desired strata are obtained. These intervals did not initially contain a significant amount of hydrocarbon.

5.2.1.2 Core Preservation

The importance of not altering wettability with drilling mud filtrate has been discussed in this chapter in the section entitled "Wettability and Contact Angle." Preventing wettability changes in core material, after it has been recovered at the surface, can be equally important so that subsequent laboratory measurements are representative of formation conditions.

Cores obtained with drilling muds that minimize wettability alteration, and that are protected at the well-site to prevent evaporation or oxidation, are called preserved cores.

TABLE 5.2.1 Routine Core Analysis Tests

Type of analysis	Use of results
Porosity	A factor in volume and storage determinations.
Permeability—horizontal and vertical	Defines flow capacity, crossflow, gas and water coning and relative profile capacity of different zones, pay and nonpay zones.
Saturations	Defines presence of hydrocarbons, probable fluid recovery by test, type of recovery, fluid contacts, completion interval.
Lithology	Rock type, fractures, vugs, laminations, shale content used in log interpretation, recovery forecasts, capacity estimates.
Core-gamma ray log	Relates core and log depth.
Grain density	Used in log interpretation and lithology.
<i>From Reference 1.</i>	

They are also referred to as fresh cores or native-state cores. Cores that are cleaned with solvents and resaturated with reservoir fluids are called restored-state cores or extracted cores. The restoring process is often performed on nonpreserved or weathered cores, but the same technique could apply to cores that had been preserved.

Two methods of preserving conventional cores, immediately after they have been removed from the core barrel, will prevent changes in wettability for several months. One method consists of immersing the core in deoxygenated formation brine or suitable synthetic brine (i.e., drilling mud filtrate) and keeping the samples in suitable containers that can be sealed to prevent leakage and the entrance of oxygen. In the second method, the cores are wrapped in Saran or polyethylene film and aluminum foil and then coated with wax or strippable plastic. The second method is preferred for cores that will be used for laboratory determination of residual oil content, but the first method may be preferred for laboratory displacement tests. Plastic bags are often recommended for short-term (2–4 days) storage of core samples. However, this method will not ensure unaltered rock wettability. Air-tight metal cans are not recommended because of the possibility of rust formation and potential leakage.

Cores taken with a pressure core barrel are often frozen at the well-site for transportation to the laboratory. (Cores are left in the inner core barrel.) Normally, the inner barrel containing the cores is cut into lengths convenient for transport. Because of the complexity of the operation, the pressure core barrel is not used as extensively as the conventional core barrel. An alternate procedure involves bleeding off the pressure in the core and core barrel while the produced liquids are collected and measured. Analysis of the depressured core is done by conventional techniques. Fluids collected from the barrel during depressuring are proportionately added to the volumes of liquid determined

from core analysis. In this manner a reconstructed reservoir core saturation is provided.

5.2.1.3 Core Preparation

Depending on the type of core testing to be done, core samples may be tested as received in the laboratory or they may be cleaned to remove resident fluids prior to analysis. Details for cutting, cleaning, and preparing core plugs can be found in API RP-40: Recommended Practice for Core-Analysis Procedure [13], available from API Production Department, 211 North Ervay, Suite 1700, Dallas, TX 75201.

5.2.1.4 Core Analysis

Conventional core analysis procedures are described in detail in API RP-40 and elsewhere [12]. A good discussion on core analysis procedures is in the textbook written by Amyx, Bass, and Whiting [5.1.19].

5.2.1.4.1 Porosity

A number of methods [13] are suitable for measuring porosity of core samples. In almost all the methods, the sample is cleaned by solvent extraction and dried to remove liquid. Porosity can be determined by saturating the dry core with brine and measuring the weight increase after saturation. Another common method includes compressing a known volume of gas (usually helium) at a known pressure into a core that was originally at atmospheric pressure. Several other techniques have been used; one of the more common methods is the mercury porosimeter in which pressure on the core plug is reduced and the volume of the expanded air or gas is measured accurately. A summation of fluids technique, which measures and sums the oil, gas and water volumes in a freshly recovered reservoir core sample, is often used for plugs or sidewall samples of non-vuggy consolidated rocks that contain minimum amounts of clay [9].

TABLE 5.2.2 Special Core Analysis Tests

Type of test	Use of results
Capillary pressure	Defines irreducible fluid content, contacts.
Rock compressibility	Volume change caused by pressure change.
Permeability and porosity vs. pressure	Corrects to reservoir conditions.
Petrographic studies	
mineral	Used in log interpretation.
diagenesis	Origin of oil and source bed studies.
clay identification	Origin of oil and log analysis.
sieve analysis	Selection of screens, sand grain size.
Wettability	Used in capillary pressure interpretation and recovery analysis-relative permeability.
Electrical	
formation factor	Used in log interpretation.
resistivity index	
Acoustic velocity	Log and seismic interpretation.
Visual inspection	Rock description and geological study.
Thin sections, slabs	
Air, water, and other liquid permeability	Evaluates completion, workover, fracture and injection fluids; often combined with flood-pot test.
Flood-pot test and waterflood evaluation	Results in values for irreducible saturations, values for final recovery with special recovery fluids such as surfactants, water, and polymers.
Relative permeability	Relative permeability is used to obtain values for effective permeability to each fluid when two or more fluids flow simultaneously; relative permeability enables the calculation of recovery versus saturation and time while values from flood-pot test give only end-point results.
gas-oil	
gas-water	
water-oil	
oil-special fluids	
thermal	

From Reference 1.

Equations commonly used for calculation of porosity by gas expansion or compression include:

$$\phi = \left(\frac{V_p}{V_b} \right) 100 \quad (5.2.1)$$

$$\phi = \left(\frac{V_b - V_{gr}}{V_b} \right) 100 \quad (5.2.2)$$

where ϕ = porosity expressed as a percent

V_p = pore volume

V_b = bulk volume

V_{gr} = grain volume

All volumes should be in consistent units, commonly cm^3 . If pore volume is measured directly in cores that contain vugs (such as some carbonates), Equation 5.2.1 may give erroneously high porosity because the bulk volume may be erroneously low [9]. If bulk volume of vuggy cores is determined by submerging the core in mercury or water, Equation 5.2.2 may yield erroneously low porosity [9]. Thus valid porosity values can only be obtained if bulk volume and grain volume measurements are accurate.

5.2.1.4.2 Permeability

The permeability of core plugs is determined by flowing a fluid (air gas, or water) through a core sample of known dimensions. If the absolute permeability is to be determined, the core plug is cleaned so that permeability is measured at 100% of the saturating fluid. Methods of measuring permeability of core plugs are described in API RP-27: Recommended Practice for Determining permeability of Porous Media [14]. Equation 5.1.36 can be used to calculate permeability of core plugs.

5.2.1.4.3 Fluid Saturations

Coring procedures usually alter the fluid content of the reservoir rock during the coring process. Drilling fluid is jetted against the formation rock ahead of the coring bit and the core surface as it enters the core barrel; as a result of this flushing action by the drilling mud filtrate, most free gas and a portion of the liquid are displaced from the core. When water base drilling fluid is used, the mud filtrate may displace oil until a condition of residual oil saturation is obtained. Also, this flushing action may result in the fluid content of the core being predominately that of the drilling fluid. When oil base drilling fluid is used, the core sample that is obtained may be driven to an irreducible water saturation.

5.2.1.4.4 Factors Affecting Oil Displaced During Coring

During the coring operation, it is important to avoid extreme flushing conditions that could cause mobilization of residual oil [15]. Some of the variables that control the amount of oil flushed from a core by mud filtrate are: borehole-to-formation differential pressure (overbalance), coring penetration rate, core diameter, type of drill bit, drilling mud composition (including particle size distribution), depth of invasion of mud particles into the core, rate of filtrate production (both spurt loss and total fluid loss), interfacial tension of mud filtrate, permeability of the formation (both horizontal and vertical), and nature of the reservoir (uniformity, texture, etc.). In one type of system investigated in the laboratory [16], the amount of oil stripped from cores varied directly with the overbalance pressure, filtration production rate, core diameter and core permeability; it varied inversely with penetration rate. In that system, the overbalance pressure exerted more influence than the other factors. When

large pressure gradients exist near the core bit, unintentional displacement of residual oil may occur in coring operations. In this region close to the bit, high velocities caused by this high pressure may mobilize some of the residual oil. Drilling mud composition can affect subsequent laboratory oil displacement tests in core samples by: changing wettability of the reservoir rock, altering interfacial tension of the mud filtrate, being penetrated by mud particles into the zone of interest, and yielding undesirable fluid loss properties. Since fluids with lower interfacial tension contribute to additional oil recovery, whenever possible, the use of mud additives that lower interfacial tension should be avoided. Greater amounts of residual oil are displaced from cores as the filtrate production rate is increased. High API filter loss or smaller core diameters will generally lead to larger amounts of flushing, but a key factor in the amount of mobilized residual oil is the spurt loss (the rapid loss to the formation that occurs before an effective filter cake is formed). As stated previously, uniformity of the formation being cored will influence the amount of oil that will be displaced. Identical drilling conditions may yield varying results with changes in lithology or texture of the reservoir. In particular, drastic differences may be observed in reservoirs that contain both sandstone and carbonate oil-bearing strata.

5.2.1.4.5 Factors Affecting Oil Saturation Changes During Recovery of Cores

Surface oil saturations should be adjusted to compensate for shrinkage and bleedings [123]. Shrinkage is the term applied to the oil volume decrease caused by a temperature change or by a drop in pressure which causes dissolved gases to escape from solution. Shrinkage of reservoir fluids is measured in the laboratory by differentially liberating the samples at reservoir temperature. The formation volume factors are used to adjust surface oil volume back to reservoir temperature and pressure. Gases coming out of solution can cause some oil to flow out of the core even though it may have been flushed to residual oil by mud filtrate. Bleeding is the term applied to this decrease in oil saturation as the core is brought to the surface. Calculations have been proposed [123] to account for shrinkage and bleeding (see the discussion in this chapter entitled "Estimation of Waterflood Residual Oil Saturation").

5.2.1.4.6 Measurement of Fluid Saturations

There are two primary methods of determining fluid content of cores; these methods are discussed in API RP-40: Recommended Practice for Core-Analysis Procedure [13]. In the retort or vacuum distillation method, a fluid content still is used to heat and vaporize the liquids under controlled conditions of temperature and pressure. Prior to testing, the

gas space in the core is displaced with water. The fluids produced from the still are condensed and measured, and the fluid saturations are calculated. Normally the percent oil and water are subtracted from 100% to obtain the gas saturation; however, considerable error may be inherent in this assumption. The second common method is the distillation-extraction method in which water in the core is distilled, condensed, and accumulated in a calibrated receiving tube. Oil in the core is removed by solvent extraction and the oil saturation is calculated from the weight loss data and the water content data.

Conventional core samples have oil content determined by atmospheric distillation. The oil distilled from a sample is collected in a calibrated receiving tube where the volume is measured. Temperatures up to 1,200°F (about 650°C) are used to distill the oil from the sample which causes some coking and cracking of the oil and the loss of a small portion of the oil. An empirically derived correction is applied to the observed volume to compensate for the loss. Calibration tests are made on each type of oil.

Whole core samples have oil content determined by vacuum distillation. This technique is used to remove oil from the sample without destroying the minerals of the sample. A maximum temperature of 450°F is used. The oil distilled from the sample is collected in a calibrated receiving tube which is immersed in a cold bath of alcohol and dry ice at about -75°C . This prevents the oil from being drawn into the vacuum system. As in the atmospheric distillation method, corrections must be applied to the measured volumes.

The oil content (V_o) divided by the pore volume (V_p) yields the oil saturation (S_o) of a sample in percent of pore space:

$$S_o = \left(\frac{V_o}{V_p} \right) 100 \quad (5.2.3)$$

Two sources of error are inherent in the retort method. At the high temperatures employed, water of crystallization within the rock is driven off which causes the water saturation to appear to be higher than the actual value. Another error results from the cracking of the oil and subsequent deposition of coke within the pore structure. Thus, a calibration curve should be prepared on various gravity crudes to compensate for the oil lost from the cracking and coking. Both of the above errors will result in a measured oil saturation that is lower than the actual saturation in the rock. Another possible source of error is the liberation of carbon dioxide from carbonate material in the core at elevated temperatures; this would cause a weight loss that can be interpreted as a change in saturation. The solvent extraction method has the disadvantage in that it is an indirect method since only the water removed from the core is measured. However the extraction method has the advantage that the

TABLE 5.2.3 Densities of Common Minerals in Reservoir Rocks

Material	Matrix density* (gm/cm ³)
Sand (consolidated)	2.65
Sand (unconsolidated)	2.65
Limestone	2.71
Dolomite	2.8–2.9
Shale	1.8–2.7
Gypsum	2.32
Anhydrite	2.9–3.0
Halite	2.16

From Reference 5.1.41.

**These figures are averages and may vary from area to area, depending on types and abundance of secondary minerals.*

core is usually not damaged and can be used for subsequent tests.

5.2.1.4.7 Grain Density and Core Description

Grain density and lithologic descriptions are often provided in data for routine core analysis. Grain density depends on the lithology and composition of the reservoir of interest. Densities of some common minerals found in reservoir rocks are listed in [Table 5.2.3](#) [5.1.41].

5.2.1.4.8 Results of Core Analyses from Various Reservoirs

Typical core analyses [5.1.23] of different formations from various states and regions of the U.S. are listed in [Table 5.2.4a](#) to [5.2.4i](#). In addition to ranges in permeability, porosity, oil saturation, connate water saturation, the depth and thickness of the productive intervals are given.

5.2.1.4.9 Special Core Analysis Tests

Special core analysis testing is done when specifically required. Visual inspection and some petrographic studies are frequently done. For sandstones and conglomerates, particle size is often obtained by disaggregating and sieving reservoir rock material. Fractions of the various sizes of grains are determined and described according to the nomenclature in [Table 5.2.5](#). Larger grain size is associated with higher permeability, and very small grain sizes include silt and clay fractions that are associated with lower permeabilities.

5.2.2 Drill Stem Tests

A drill stem test (DST) is some form of temporary completion of a well that is designed to determine the productivity and fluid properties prior to completion of the well.

Although a DST can be performed in uncased hole (open hole) or in cased hole (perforation tests), the open hole test is more common. The tool assembly which consists of a packer, a test valve, and an equalizing valve, is lowered on the drill pipe to a position opposite the formation to be tested. The packer expands against the hole to segregate the mud-filled annular section from the interval of interest, and the test valve allows formation fluids to enter the drill pipe during the test. The equalizing valve allows pressure equalization after the test so the packer can be retrieved. Details of the DST and DST assemblies are described elsewhere [13,19,66] and will only be summarized here. By closing the test valve, a build up in pressure is obtained; by opening the test valve, a decline in pressure is obtained. (Pressure buildup and falloff analyses are discussed subsequently in this section of the chapter.) During the DST, both pressures and flow rates are measured as a function of time.

Interpretation of DST results is often regarded as an art rather than a science. Certainly, a DST can provide a valuable indication of commercial productivity from a well, provided engineering judgment and experience are properly utilized. Interpretations of various pressure charts are shown in [Figure 5.2.1](#) [13, 17] and [5.2.2](#) [1]; details of interpreting DST data are described in the literature [18,66].

5.2.3 Logging

5.2.3.1 Introduction

This section deals with the part of formation evaluation known as well logging. Well logs are a record versus depth of some physical parameter of the formation. Parameters such as electrical resistance, naturally occurring radioactivity, or hydrogen content may be measured so that important producing characteristics such as porosity, water saturation, pay thickness, and lithology may be determined. Logging instruments (called *sondes*) are lowered down the borehole on armored electrical cable (called a *wireline*). Readings are taken while the tool is being raised up the hole. The information is transmitted uphole via the cable where it is processed by an on-board computer and recorded on magnetic tape and photographic film. In older logging units, downhole signals are processed by analog circuits before being recorded.

Well logging can be divided into two areas: open hole and cased hole. Open hole logging is done after drilling, before casing is set. The purpose of open hole logging is to evaluate all strata penetrated for the presence of oil and gas. Open hole logs give more reliable information on producing characteristics than cased hole logs. Cased hole logs provide information about cement job quality, casing corrosion, fluid flow characteristics, and reservoir performance. In areas where the geologic and producing characteristics of a reservoir are well known, as in development wells, cased hole logs are used for correlation. In recent years, many new open- and cased-hole logs and services have become available, including fluid samplers, sidewall cores,

fracture height log, and seismic services. These products, in
(text continued on page 85).

^aGeneral geologic sections taken at different points in Oklahoma-Kansas areas indicate some variations in the properties and an appreciable variations in the occurrence and relative depths of many of the more important oil- and/or gas-producing zones, formations, geologic groups, and their members. The general identification of core samples from these producing intervals reflect local conditions or activities significantly. In the development of the average data values, an attempt has been made to combine data originally reported for locally named zones into more generally recognized formations or geologic groups. In some instances (i.e., Deese, Cherokee) data are reported for a major geologic group as well as for some of its individual members. The values designated by the major group name represent areas where the general characteristics permit identification as to the geologic group but not as to group members. In other areas the group members or zones are readily identifiable. The combinations of data and the use of local rather than regional geologic names in some instances are explained in the footnotes.

^bT Represents transition zone or production of both water and either gas or oil.

^cIncludes data reported as Dornick Hills and Dutcher.

^dIncludes Bromide First and Second as reported on McClain Country area.

^eData reported locally as Bromide Third, Bromide Upper third, and Bromide Lower have been considered as part of the Tulip Creek.

^fIncludes data reported as Cleveland Sand, Cleveland, Lower, and Cleveland Upper.

^gIncludes the numerous zones (Deese First, Second, Third, Fourth, Fifth, Zone A, Zone B, Zone C, and Zone D) reported locally for the Anadarko, Ardmore, and Marietta Basin areas. In northwest Oklahoma, these different zones are normally referred to as Cherokee. In other areas the zones are frequently identifiable and properties are reported as for Redfork, Bartlesville, etc.

conjunction with new computer processing techniques, provide the engineer and geologist with an enormous amount of data for any well.

5.2.3.2 Parameters that Can Be Calculated or Estimated from Logs

5.2.3.2.1 Porosity

Porosity is defined as the ratio of volume of pores to the total volume of the rock. It occurs as primary (depositional) or secondary (diagenetic or solution) porosity. Primary and secondary porosity can be read directly from neutron, density, and sonic logs. These tools do not measure pore volume directly, rather they measure physical parameters of the formation and relate them to porosity mathematically or empirically. Since the sonic tool only

records primary (or matrix) porosity, it can be combined with total porosity tools, such as density or a combined neutron and density, to determine secondary porosity:

$$\phi_{\text{secondary}} = \phi_{\text{total}} - \phi_{\text{sonic}} \quad (5.2.4)$$

where $\phi_{\text{secondary}}$ = porosity due to vugs and fractures

ϕ_{total} = total porosity as determined from cores, density log, neutron-density crossplot, or local knowledge

ϕ_{sonic} = porosity determined from sonic log.

The combinable magnetic resonance (CMR) tool capable of measuring porosity independent of lithology and measuring movable or bound fluid, which can be used to measure effective porosity in the rock.

5.2.3.2.2 Water Saturation

Connate water saturation (S_w) and flushed zone water saturation (S_{xo}) can be calculated from information supplied by well logs.

Connate water saturation is the fraction of pore volume in an undisturbed formation filled with connate water.

$$S_w = \frac{\text{volume of water}}{\text{volume of pores}} \quad (5.2.5)$$

Flushed zone saturation (S_{xo}) is the fraction of the pore volume filled with flushing agent (normally drilling fluid).

$$S_{xo} = \frac{\text{volume of flushing agent}}{\text{volume of pores}} \quad (5.2.6)$$

Prior to penetration by a drill bit, only two fluids are assumed to be present in the formation—water and hydrocarbons. Therefore, all pore space that is not occupied by water is occupied by hydrocarbons. With this assumption hydrocarbon saturation can be calculated:

$$S_h = 1 - S_w \quad (5.2.7)$$

where S_h = hydrocarbon saturation.

5.2.3.2.3 Pay Thickness

The thickness of a hydrocarbon-bearing formation (h_{pay}) is easily determined from well logs once ϕ and S_w cutoffs are established. The S_w cutoff is the maximum value for S_w for a given rock type. The ϕ cutoff is the minimum value for ϕ below which hydrocarbons cannot be produced. For example:

Depth	ϕ	S_w	Comment
3,668–3,670	1%	53%	ϕ too low
3,666–3,668	2%	50%	ϕ too low
3,664–3,666	6%	38%	possible hydrocarbons
3,662–3,664	6%	36%	possible hydrocarbons
3,660–3,662	8%	31%	possible hydrocarbons
3,658–3,660	7%	74%	too wet
3,656–3,658	8%	100%	too wet

In this case, the water saturation cutoff is a maximum of 60% and the porosity cutoff is a minimum of 3%, so this well will have 6 feet of pay ($h_{\text{pay}} = 6$ ft). Other factors that may reduce h_{pay} include shaliness, shale streaks, low permeability, and low reservoir pressure. Porosity and water saturation cutoffs are usually established for specific regions or reservoirs based on detailed production and geologic information.

5.2.3.2.4 Lithology

It is often necessary to know the rock type in order to properly design downhole assemblies, casing programs, and

completion techniques. Data from well logs can provide the geologist or engineer with an estimate of the lithologic makeup of any formation. The accuracy of this estimate is a function of the complexity of the formation (mineralogic makeup and fluid types) and the kinds of tools used to investigate the rocks. More tools are needed to accurately determine compositions of complex formations. Simple lithologies (three or less minerals, or gas) can be determined with combined neutron, density, and sonic logs. This technique will be discussed later. More complex lithologies can be determined with the aid of special logging tools and computers.

Since well logs infer lithology from physical and chemical parameters, certain rocks will look the same on logs though they differ in their geologic classification. Sandstone, quartz, and chert are all SiO_2 and appear the same on porosity logs. The same is true of limestone and chalk. Dolomite, anhydrite, and salt have very distinct characteristics and are easily distinguished from other rock types. Shales are composed of clay minerals. The type and amount of different clay minerals, which vary widely between shales, can affect their bulk properties.

5.2.3.2.5 Permeability

Permeability is one of the essential properties used in evaluation of a potentially producing formation. Unfortunately there are no logging devices that read permeability. This is because permeability is a dynamic property. Most logging tools spend only a few seconds in front of any one point of a formation, therefore it is impossible to measure any time-dependent parameter. There are methods to estimate permeability from well logs, but they are based on general assumptions. From a practical standpoint, log parameters only provide an “order of magnitude” approximation. Several methods of inferring permeability with well logs are discussed where applicable in each section.

Two relationships between porosity and irreducible water saturation (S_{wi}) are used to estimate permeability:

1. The Timur relationship [19] (Figure 5.2.3) for granular rocks (sandstones and oolitic limestones), which generally gives a more conservative estimate of permeability.
2. The Wyllie and Rose relationship [43] modified by Schlumberger [20] (Figure 5.2.4), which generally gives a higher estimate of permeability.

To enter these charts, porosity and irreducible water saturation (S_{wi}) must be known. Porosity can be obtained from cores or any porosity device (sonic, neutron, or density). Irreducible water saturation must be found from capillary pressure curves or it can be estimated. The permeabilities from these charts should be considered “order of magnitude” estimates.

5.2.3.3 Influences on Logs

The purpose of well logging is to determine what fluids are in the formation and in what quantity. Unfortunately the

Figure 5.2.2

Figure 5.2.2, Cont'd.

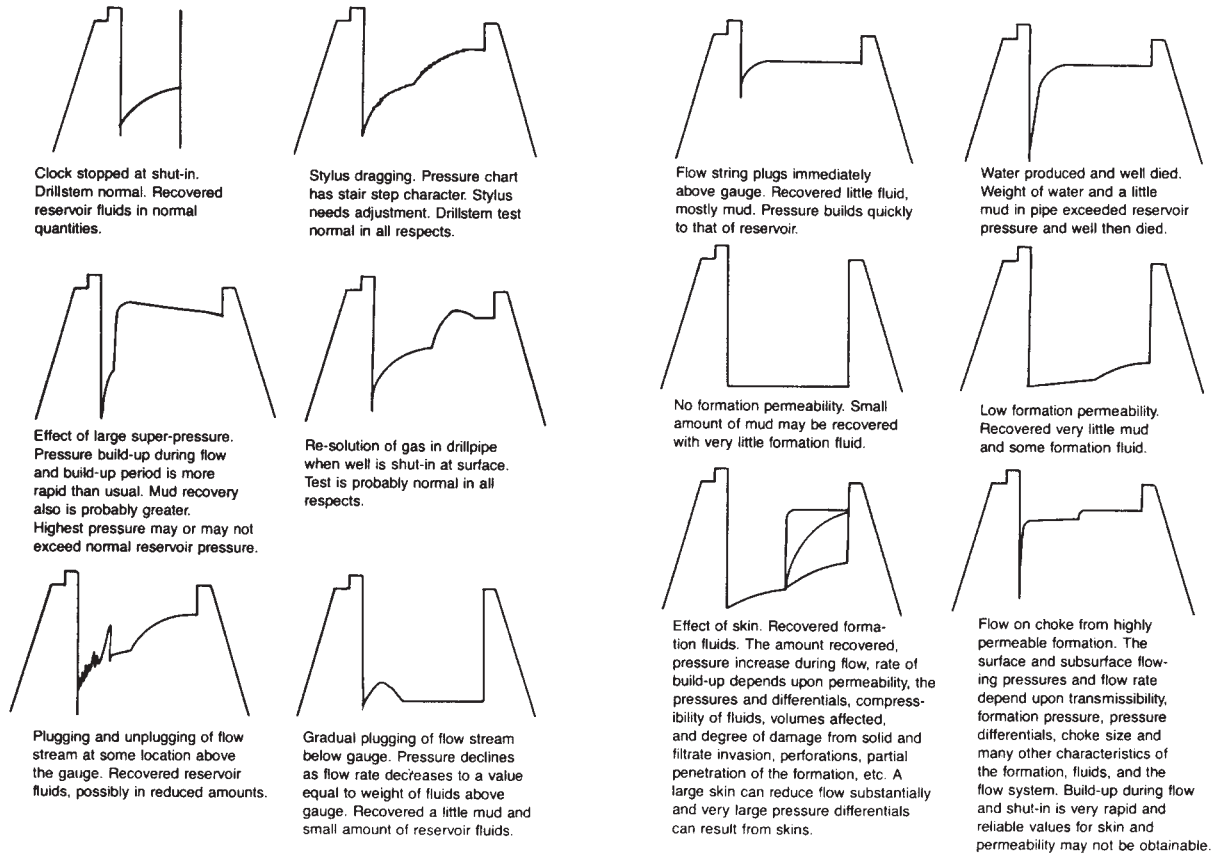

Figure 5.2.2, Cont'd.

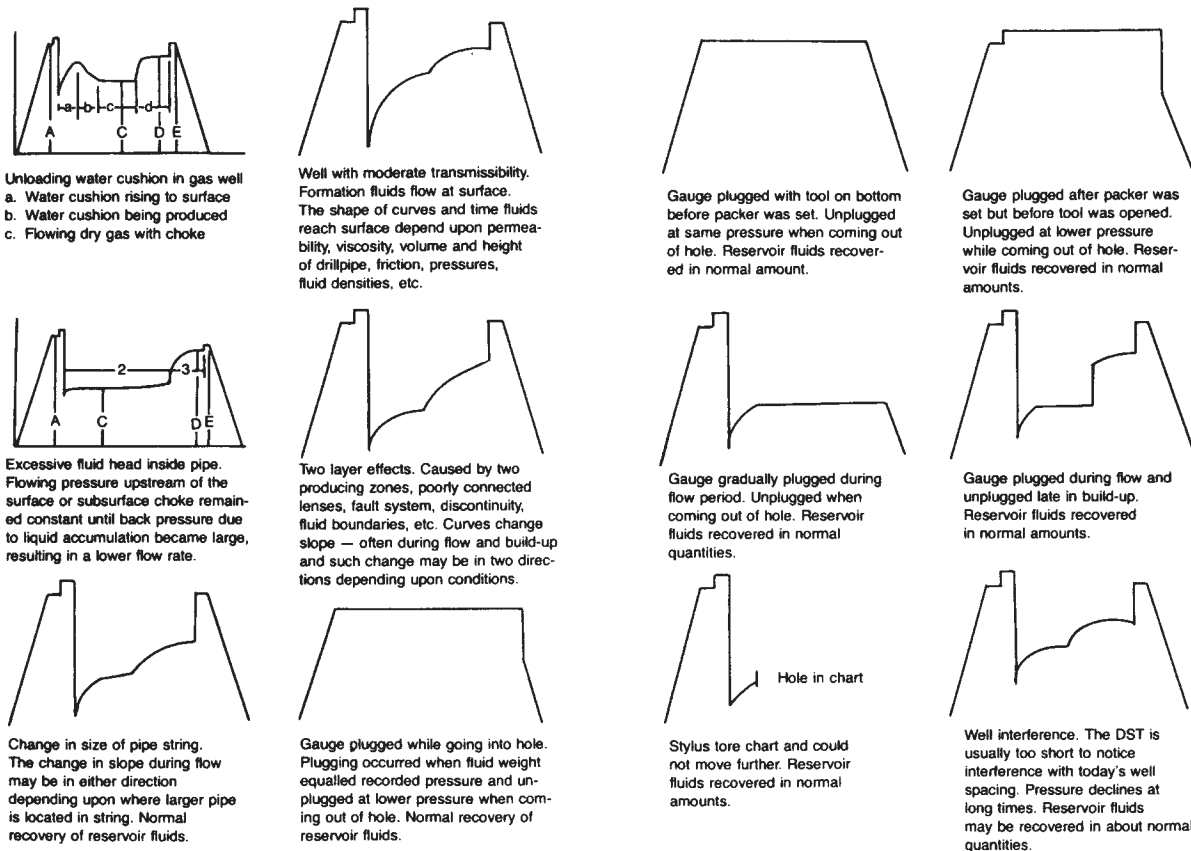

Figure 5.2.2, Cont'd.

Figure 5.2.2, Cont'd.

FIGURE 5.2.3 Timur chart for estimating permeability [19].

FIGURE 5.2.4 Schlumberger chart (after Wyllie and Rose) for estimating permeability [20].

drilling process alters the fluid saturations by flushing the pores near the borehole and filling them with the fluid fraction of the drilling mud (mud filtrate). To correct for these influences, the invasion profile must be identified. Figure 5.2.5, an idealized cross-sectional view of the borehole and formations, shows an invasion profile and the appropriate symbols for each part of that profile [20].

5.2.3.3.1 Mud Relationships

Since the borehole is filled with mud and the adjacent portion of the formation is invaded with mud filtrate, mud properties must be accurately known so they can be taken into account. Mud has a minor influence on most porosity tools; however, it can have a large effect on the resistivity tools. In general:

$$R_{mc} > R_m > R_{mf}$$

This is because the mudcake is mostly clay particles and has very little water associated with it. The clay particles in the mudcake tend to align themselves parallel to the borehole wall, developing a high horizontal resistivity R_h

(Figure 5.2.6). Since the mud filtrate is composed only of fluid and has no solids, it will have a lower resistivity. If the resistivity of the mud (R_m) is known, R_{mc} and R_{mf} can be estimated with the following equations:

$$R_{mf} = K_m(R_m)^{1.07} \tag{5.2.8}$$

$$R_{mc} = 0.69(R_{mf}) \left(\frac{R_m}{R_{mf}} \right)^{2.65} \tag{5.2.9}$$

where $K_m =$

0.847	for 10 lb/gal
0.708	11 lb/gal
0.584	12 lb/gal
0.488	13 lb/gal
0.412	14 lb/gal
0.380	16 lb/gal
0.350	18 lb/gal

These relationships work well for most muds (except lignosulfonate) with resistivities between $0.1 \Omega\text{-m}$ and $10 \Omega\text{-m}$.

FIGURE 5.2.5 Diagram of the borehole environment showing the various zones and their parameters [20].

FIGURE 5.2.6 Resistivity components on mud cake that develop opposite a permeable formation.

Another approximation that works well for salt muds is:

$$R_{mf} = 0.75R_m \quad (5.2.10)$$

$$R_{mf} = 1.5 R_m \quad (5.2.11)$$

Fluid resistivity at any formation depth can be found using the Arps Equation if the resistivity at any temperature and formation temperature are known [20]:

$$R_2 = R_1 \frac{T_1 + 6.77}{T_2 + 6.77} \quad (5.2.13)$$

where R_2 = fluid resistivity at formation temperature, Ω -m

R_1 = fluid resistivity at some temperature, Ω -m

T_2 = formation temperature, $^{\circ}\text{F}$

T_1 = temperature R_1 was measured at, $^{\circ}\text{F}$

A monograph that solves this equation graphically is presented in Figure 5.2.8 [20].

5.2.3.3.2 Temperature Relationships

Mud resistivity is a function of temperature and ion concentration. Since temperature increases with depth due to geothermal gradient, the mud resistivity is lower at the bottom of the hole than at the surface (pits). The temperature of a formation can be found with an equation suggested by Hilchie [21]:

$$T_f = (T_{TD} - T_s) \frac{D_f}{D_{TD}} + T_s \quad (5.2.12)$$

where T_f = formation temperature ($^{\circ}\text{F}$)

T_{TD} = temperature at total depth (BHT) ($^{\circ}\text{F}$)

T_s = average surface temperature ($^{\circ}\text{F}$)

D_f = formation depth (ft)

D_{TD} = total depth (ft)

Average surface temperatures in various oilfield areas are:

Alberta	40 $^{\circ}\text{F}$
California	65 $^{\circ}\text{F}$
Colorado-Northern New Mexico	55 $^{\circ}\text{F}$
Gulf Coast	80 $^{\circ}\text{F}$
Oklahoma	65 $^{\circ}\text{F}$
Permian Basin	65 $^{\circ}\text{F}$
Wyoming	45 $^{\circ}\text{F}$

Figure 5.2.7 solves this equation graphically [20].

5.2.3.4 Openhole Logs and Interpretation

5.2.3.4.1 SP (Spontaneous Potential)

The SP log has 4 basic uses: (1) recognition of permeable zones, (2) correlation of beds, (3) determination of R_w , and (4) qualitative indication of shaliness. The SP can only be used in fresh mud and is run with several resistivity tools. The curve is presented in Track 1 and is scaled in millivolts (mV).

The SP log is a record of the naturally occurring electrical currents created in the borehole. These currents or circuits usually occur at bed boundaries and are created by the interaction between fresh drilling mud and salty formation water. The curve represents the potential difference between a stationary electrode on the surface (ground) and a moving electrode in the borehole.

5.2.3.4.2 Theory

The total potential (E_t) can be separated into two components: the electrochemical (E_c) and the electrokinetic (E_k). The electrokinetic component is generally very small

EXAMPLE: Bottom hole temperature, BHT, is 200°F at 11,000 ft (Point A).
 Temperature at 8,000 ft is 167°F (Point B).

FIGURE 5.2.7 Chart for estimating formation temperature [20].

and is often ignored. It is created when an electrolyte (mud filtrate) flows through a nonmetallic permeable material. The magnitude of E_k is a function of the pressure drop across the material and the resistivity of the electrolyte. The electrokinetic (or streaming) potential is most significant in low pressure (depleted) formations, overbalanced mud conditions and opposite low permeability formations. See Doll's classic paper [201] for more detailed information.

The electrochemical component (E_c) is the sum of the liquid-junction potential (E_{lj}) and the membrane potential (E_m). The liquid junction potential occurs at the interface between fresh mud filtrate and salty formation water. This interface is usually a few inches to a few feet away from the borehole. Only two ions are assumed to be in solution in the mud and formation water: Na^+ and Cl^- . Chloride ions are concentrated in the formation water, and being more mobile than Na^+ ions, move toward lower concentrations in the

borehole (Figure 5.2.9). This creates a net negative charge near the borehole and a current flows toward the undisturbed formation. The liquid-junction potential accounts for about 20% of the electrochemical component.

The membrane (E_m) potential is created at the bed boundary between a permeable bed (sand) and an impermeable bed (shale). The shale acts as an ion-selective membrane, allowing only the smaller Na^+ ion to move through the clay crystal structure from the salty formation water toward the fresh drilling fluid in the bore. This creates a net positive charge along the shale. It also creates a large concentration of negative charges associated with the Cl^- ion in the permeable bed. This phenomena is also shown in Figure 5.2.9. The membrane potential accounts for about 80% of the electrochemical potential. The total effect of these two potentials is a net negative charge within the permeable zone when the connate water is saltier than the mud filtrate.

FIGURE 5.2.8 Chart for determining salinity, solution resistivity and for converting resistivity to formation temperature [20].

5.2.3.4.3 Interpretation

The total electrochemical component of the total potential is what the SP records. It can be calculated with the following equation:

$$E_c = -K \log \frac{a_w}{a_{mf}} \quad (5.2.14)$$

where $-K = -(0.133 T + 61)$ (T in $^{\circ}\text{F}$)

a_w = chemical activity of formation water

a_{mf} = chemical activity of drilling mud filtrate

Since the chemical activity of a solution cannot be used, it must be converted to its equivalent electrical resistivity. Chemical activity of a fluid is approximately equal to the inverse of its equivalent electrical resistivity. Conversion to equivalent resistivities makes the equation:

$$E_c = -K \log \frac{R_{mf eq}}{R_{weq}} \quad (5.2.15)$$

Since E_c is equal to the maximum SP deflection recorded on a log (SSP), Equation 5.2.15 can be rewritten to read:

$$\text{SSP} = -K \log \frac{R_{mf eq}}{R_{weq}} \quad (5.2.16)$$

where SSP is the static (or maximum) spontaneous potential recorded opposite a permeable formation. Since the purpose of an SP log is to find R_{weq} and then R_w , if we know SSP we can solve Equation 5.2.16 for R_{weq} :

$$R_{weq} = \frac{R_{mf eq}}{10^{(-\text{SSP}/-K)}} \quad (5.2.17)$$

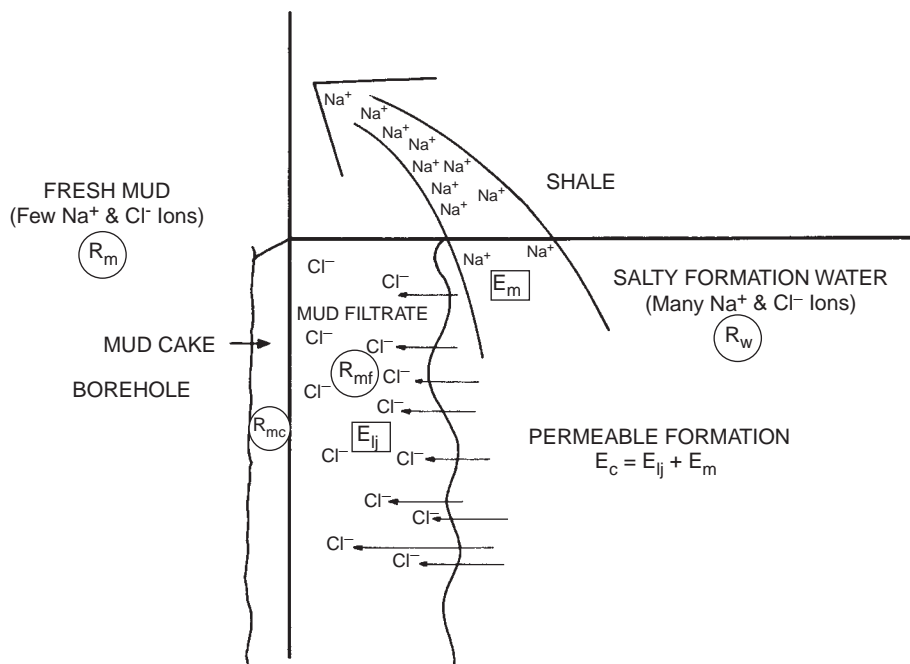

FIGURE 5.2.9 Ionic movement that contributes to the development of an SP curve.

Once R_{weq} is known, it is converted to R_w using the chart shown in Figure 5.2.10 [20]. SSP can come directly from the log if the bed is thick and the SP curve reaches a constant value and develops a “flat top.” If the curve is pointed or rounded, it must be corrected for bed thickness.

The shape and amplitude of the SP are affected by:

1. Thickness and resistivity of the permeable bed (R_t).
2. Diameter of invasion and resistivity of flushed zone (R_{xo}).
3. Resistivity of the adjacent shales (R_s).
4. Resistivity of the mud (R_m).
5. Borehole diameter (d_h).

All of these must be accounted for when examining the SP, and any necessary corrections should be made. To find the magnitude of the SP, take the maximum deflection from the average shale value (shale baseline) to the most negative value. (Figure 5.2.11 shows a curve that needs correction and one that does not.) Bed thickness corrections can be made from Figure 5.2.12 and should *always* increase the magnitude of the SP.

Another use for the SP log is finding permeable zones. Any negative deflection of the curve indicates a potentially permeable zone. The magnitude of the deflection has no relation to the amount of permeability (in millidarcies); it merely indicates that the rock has ionic permeability. No quantitative information on this parameter can be derived from the SP. Figure 5.2.13 shows an example of permeable and impermeable zones on an SP log.

Interpretation of an SP log follows a few basic rules:

1. If the SP curve is concave to the shale line, the formation is permeable.
2. If the SP curve is convex to the shale line, the formation is impermeable.
3. Constant slope means high resistivity—usually impermeable.
4. High resistivity formations cause the bed boundaries to become rounded.
5. A thin permeable bed does not reach maximum deflection.
6. A thin shale streak does not reach the shale baseline.
7. Bed boundaries are picked at the inflection points in clean sands. Bed boundaries should be confirmed with some other log such as the gamma ray.

5.2.3.4.4 Resistivity Tools

The purpose of resistivity tools is to determine the electrical resistance of the formation (rock and fluid). Since most formation waters contain dissolved salts, they generally have low resistivities. Hydrocarbons do not conduct electricity, therefore rocks that contain oil and/or gas show high resistivity. This is the way hydrocarbon-bearing zones are differentiated from water zones.

Resistivity tools are divided into three types based on the way measurements are made: (1) non-focused (normal) tools, (2) induction tools, and (3) focused resistivity tools. Microresistivity tools will be treated under a separate heading.

Resistivity tools are further divided by depth of investigation. Tools may read the flushed zone (R_{xo}), the transition

FIGURE 5.2.10 Chart for converting R_{mf} to R_{mfeg} and R_{weq} to R_w for SP- R_w calculations [20].

zone between the flushed and uninvaded zones (R_i), or the uninvaded zone (R_t). For purposes of this discussion, all tool names are for Schlumberger equipment. Comparable tools offered by other logging companies are summarized in Table 5.2.6.

5.2.3.4.5 Theory Nonfocused (Normal Tools)

The first tools to be used were nonfocused tools [58]. The electrode arrangement is as shown in Figure 5.2.14a [58]. As shown earlier, resistivity, R , is found using Ohm's Law ($r = V/I$):

$$R = \frac{rA}{L} \quad (5.1.44)$$

where V = voltage read from meter

I = current read from meter

A = surface area, m^2

L = length, m

R = resistivity, ohm-m

r = resistance, ohms

The tools work well in low-resistivity formations with thick beds and in slightly conductive muds.

5.2.3.4.6 Inductions Tools

Since a slightly conductive mud is necessary for the normal tools, they cannot be used in very fresh muds or in oil-base muds. The induction tool overcomes these problems by inducing a current into the formation instead of passing it through the mud-filled borehole. Figure 5.2.14b shows a simplified two-coil induction tool [58]. High-frequency alternating current is sent into the transmitter coil. The alternating magnetic field that is created induces secondary in circular paths called ground loops. These currents in turn create a magnetic field which induces currents in the receiver coil. The signal received is proportional to the formation conductivity. Conductivity readings are then converted to resistivity. Additional coils are used to focus the tool so that conductive beds as thin as four feet can be detected. Inductions tools work well in oil-base, foam, air, gas, and fresh mud. The induction tool is unreliable above $500 \Omega\text{-m}$ and useless above $1,000 \Omega\text{-m}$ or in salt muds. Readings are only considered reasonable below $100 \Omega\text{-m}$ and are accurate between 1 and $20 \Omega\text{-m}$ when mud is very fresh.

FIGURE 5.2.11 Example of an SP curve that requires correction and one that does not.

5.2.3.4.7 Phasor Induction Tools

Since the early 1960's, induction logging tools have become the principal logging device for fresh, slightly conductive to non-conductive (oil-base) muds. However, these devices are significantly affected by environmental (bore-hole size and mud composition) and geological (bed thickness and invasion) conditions. Also, high formation resistivities (> 50 to 100 Ω-m) dramatically increase the difference between apparent R_t and true R_t [58A, 199]. In 1986, Schlumberger introduced a new induction log to offset these problems [58A]. This device is known by the trade name Phasor Induction SFL and uses a standard dual induction tool array. The difference between the conventional and phasor devices is in signal processing made possible by miniaturization of computer components. Induction tools all produce two

signals: the inphase (R-signal) induction measurement and the quadrature (X-signal) induction signal. The R-signal is what is presented on standard dual induction-SFL log presentations. The R-signal and X-signal measurements are combined during advanced processing in the logging tool itself to produce a log with real time corrections for environmental and geological conditions. Apparent R_t is nearly equal to true R_t in most situations. Vertical resolution of this device is about the same as conventional induction tools (about 6 feet), but enhanced and very enhanced resolution phasor tools are available that have vertical resolutions down to 2 feet [58A]. The primary advantages of this tool include much better R_t readings in high resistivity formations (i.e. > 100 Ω-m) and more accurate readings in salty muds than previously possible.

FIGURE 5.2.12 SP bed thickness correction chart for the SP [21,22].

5.2.3.4.8 Focused Resistivity Tools (Laterologs)

The Laterologs are the primary salt-mud resistivity tools. Salt mud presents a problem in that the path of least resistance is within the borehole. Therefore the current must be forced into the formation which has higher resistance. To do this, secondary electrodes (A_1 , and A_2) are placed above and below the measuring current-emitting electrode (A_0). These secondary electrodes emit “focusing” or “guard” currents with the same polarity as the measuring currents. Small monitoring electrodes (M_1 , M_2 , M'_1 and M'_2) adjust the focusing currents so that they are at the same potential as A_1 and A_2 . A sheet of current measuring one to two feet thick is then forced into the formation from A_0 . The potential is then measured between M_2 and M_1 and a surface ground. Since I_0 is a constant, any variation in M_1 and M_2 current is proportional to formation resistivity. Figure 5.2.14c shows the electrode arrangement [58].

5.2.3.4.9 Corrections

As previously mentioned, resistivity tools are affected by the borehole, bed thickness, and invaded (flushed) zone. If bed thickness and mud resistivity are known, these effects can be accounted for. Major service companies (Schlumberger, Atlas Wireline, Welex Halliburton) provide correction charts for their tools. Several charts for Schlumberger tools are included in this chapter (Figures 5.2.15 to 5.2.21) [20] and can be used with logs from other service companies. Complete chart books are available from most wireline service companies. Current chart books should be used and can be obtained by calling the appropriate service company or by asking the logging engineer. Correction and interpretation charts for order tools (normals and laterals) are no longer published by service companies, but can be found in a text by Hilchie [23] and in a recent publication [203]. All log readings should be corrected with these charts to obtain accurate R_t and R_{xo} readings.

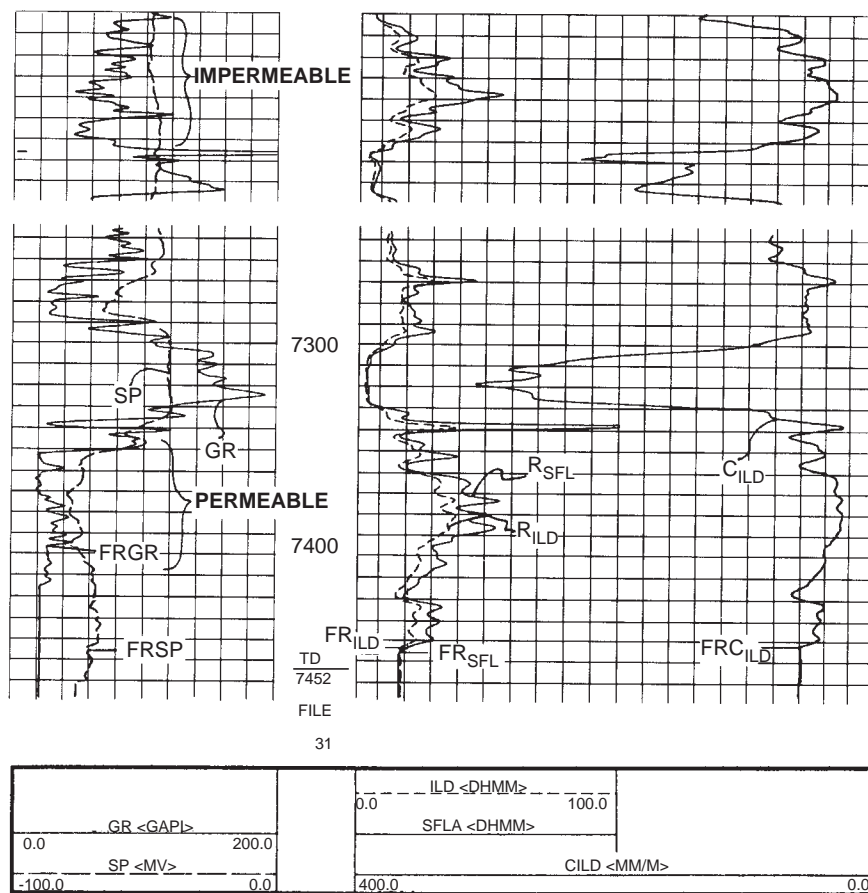

FIGURE 5.2.13 Examples of an SP log through an impermeable and a permeable zone.

The dual induction logs should be corrected for borehole, bed thickness, and invasion effects if three curves are present. The induction-SFL, induction-LL-8, and induction-electric log combinations require an R_{x0} curve to make corrections. If no R_{x0} device is presented, the deep induction curve is assumed to read true R_t . The specific charts included in this text are Figure 5.2.15 for induction log borehole corrections, Figures 5.2.16 and 5.2.17 for induction log bed-thickness corrections, and Figure 5.2.18a to 5.2.18c for invasion corrections (check log to see if an SFL or a LL-8 log was used with the induction curves and select the appropriate Tornado chart). Phasor induction logs only require invasion correction. This is accomplished with the appropriate Tornado Charts (Figures 5.2.18d to 5.2.18k) [20]. An invasion correction Tornado Chart for phasor induction tools with other frequencies are also available [58a].

The dual laterolog- R_{x0} combination should be corrected for borehole effects; bed thickness corrections are not normally made. Figure 5.2.19a is used to make the borehole corrections of the deep and shallow laterologs, respectively

[20]. Figure 5.2.20 is used to correct the micro-SFL logs for mud cake effects [20]. Invasion effects are corrected by using Figure 5.2.21 [20].

5.2.3.4.10 Interpretation

With Equation 5.2.20, water saturation can be found using corrected values of R_t derived from the Tornado charts, R_w can be found from an SP log or chemical analysis, and F_R from a porosity log and Table 5.1.7.

If a porosity log is not available, F_R can be found using Equation 5.1.45. R_o is selected in a water-bearing zone from the deepest reading resistivity curve. Care should be taken to select R_o in a bed that is thick, permeable, and clean (shalefree). The zone should be as close to the zone of interest as possible. R_o can sometimes be selected from below the water/hydrocarbon contact within the zone of interest. Archie's equation (as described earlier) can then be used to calculate water saturation:

$$S_w = \left[\frac{F_R R_w}{R_t} \right]^{1/2} \quad (5.1.70)$$

 $R_{xo}/R_m \approx 20$, DIT-E or Equivalent, Frequency = 20 kHz

FIGURE 5.2.18 e Invasion correction chart for the phasor dual induction-spherically focused log combination for $R_{xo}/R_m = 20$ [20].

This chart uses the raw, unboosted induction signals and the ID-Phasor value to define the invasion profile in a rock drilled with oil-base mud. To use the chart, the ratio of the raw, unboosted medium induction signal (IIM) and the deep Phasor induction (IDP), is entered in abscissa. The ratio of the raw, unboosted deep induction signal (IID) and the deep Phasor induction (IDP) is entered in ordinate. Their intersection defines d_i , R_{XO}/R_t , and R_t .

EXAMPLE: $R_{IDP} = 1.6 \Omega \cdot m$
 $R_{IID} = 2.4 \Omega \cdot m$
 $R_{IIM} = 2.4 \Omega \cdot m$
 Giving, $R_{IID}/R_{IDP} = 2.4/1.6 = 1.5$
 $R_{IIM}/R_{IDP} = 2.4/1.6 = 1.5$
 Therefore, $d_i = 50$ in.
 $R_{XO}/R_t = 15$
 $R_t/R_{IDP} = 0.94$
 $R_t = 0.94 (1.6)$
 $= 1.5 \Omega \cdot m$

FIGURE 5.2.21 Invasion correction chart for the dual laterolog- R_{xo} log combination [20].

If no porosity log or water zone is available, the ratio method can be used to find water saturation. The saturation of the flushed zone (S_{xo}) can be found by:

$$S_{xo} = \left[\frac{FR_{mf}}{R_{xo}} \right]^{1/2} \quad (5.2.19)$$

When Equation 5.1.70 is divided by Equation 5.2.19, the result is a ratio of water saturations:

$$\frac{S_w^2}{S_{xo}^2} = \frac{R_{xo}R_w}{R_tR_{mf}} \quad (5.2.20)$$

Poupon, Loy, and Tixier [204] found that for “average” residual oil saturations:

$$S_{xo} = S_w^{1/5} \quad (5.2.21)$$

Substituting Equation 5.2.21 into Equation 5.2.20 and rearranging terms:

$$S_w = \left[\frac{R_{xo}/R_t}{R_{mf}/R_w} \right]^{5/8} \quad (5.2.22)$$

FIGURE 5.2.22 Chart for determining water saturation by the ratio method [20].

With this equation, water saturation can be found without knowing ϕ . Note, however, that this interpretation method is based on the assumption that $S_{xo} = S_w^{1/5}$. This relation is for “average” granular rocks and may vary considerably in other rock types. Figure 5.2.22 is a chart [20] that solves Equation 5.2.22.

When two or more resistivity logs with different depths of investigation are combined, permeable zones can be identified. In a permeable zone, the area closest to the borehole will be flushed of its original fluids; mud filtrate fills the pores. If the mud filtrate has a different resistivity than the original formation fluids (connate water), the shallowest-reading resistivity tool will have a different value than the deepest-reading tool (Figure 5.2.23). Many times this difference is significant. The separation of the resistivity curves that result is diagnostic of permeable zones.

Care should be taken not to overlook zones in which curves do not separate. Curve separation may not occur if:

1. The mud filtrate and original formation fluids (i.e., connate water and hydrocarbons) have the same resistivity; both shallow and deep tools will read the same value. This is usually not a problem in oil or gas-saturated rocks.
2. Invasion of mud filtrate is very deep, both shallow and deep tools may read invaded-zone resistivity. This occurs when a long period of time elapses between drilling and logging or in a mud system with uncontrolled water loss.

5.2.3.4.11 Microresistivity Tools

Microresistivity tools are used to measure the resistivity of the flushed zone. This measurement is necessary to calculate

FIGURE 5.2.23 Example of resistivity log curve separation as an indication of permeability.

flushed zone saturation and correct deep-reading resistivity tools for invasion. Microresistivity tools are pad devices on hydraulically operated arms. The microlog and proximity log are the two main fresh-mud microresistivity tools, while the micro SFL and microlaterolog are the two main salt-mud microresistivity tools.

Figure 5.2.24 [58,21,26] shows the electrode pads and current paths for the Microlog (5.2.24a), Micro SFL (5.2.24b), and proximity log (5.2.24c), and Microlaterolog. Figure 5.2.24d shows the Micro SFL. sonde.

5.2.3.4.12 Theory

The microlog makes two shallow nonfocused resistivity measurements, each at different depths. The two measurements are presented simultaneously on the log as the micronormal and microinverse curves. Positive separation (micronormal reading higher than the microinverse) indicates permeability. R_{xo} values can be found by using Figure 5.2.25 [20]. To enter Figure 5.2.25, R_{mc} must be corrected to formation temperature, and mudcake thickness (h_{mc}) must be found. To find h_{mc} subtract the caliper reading

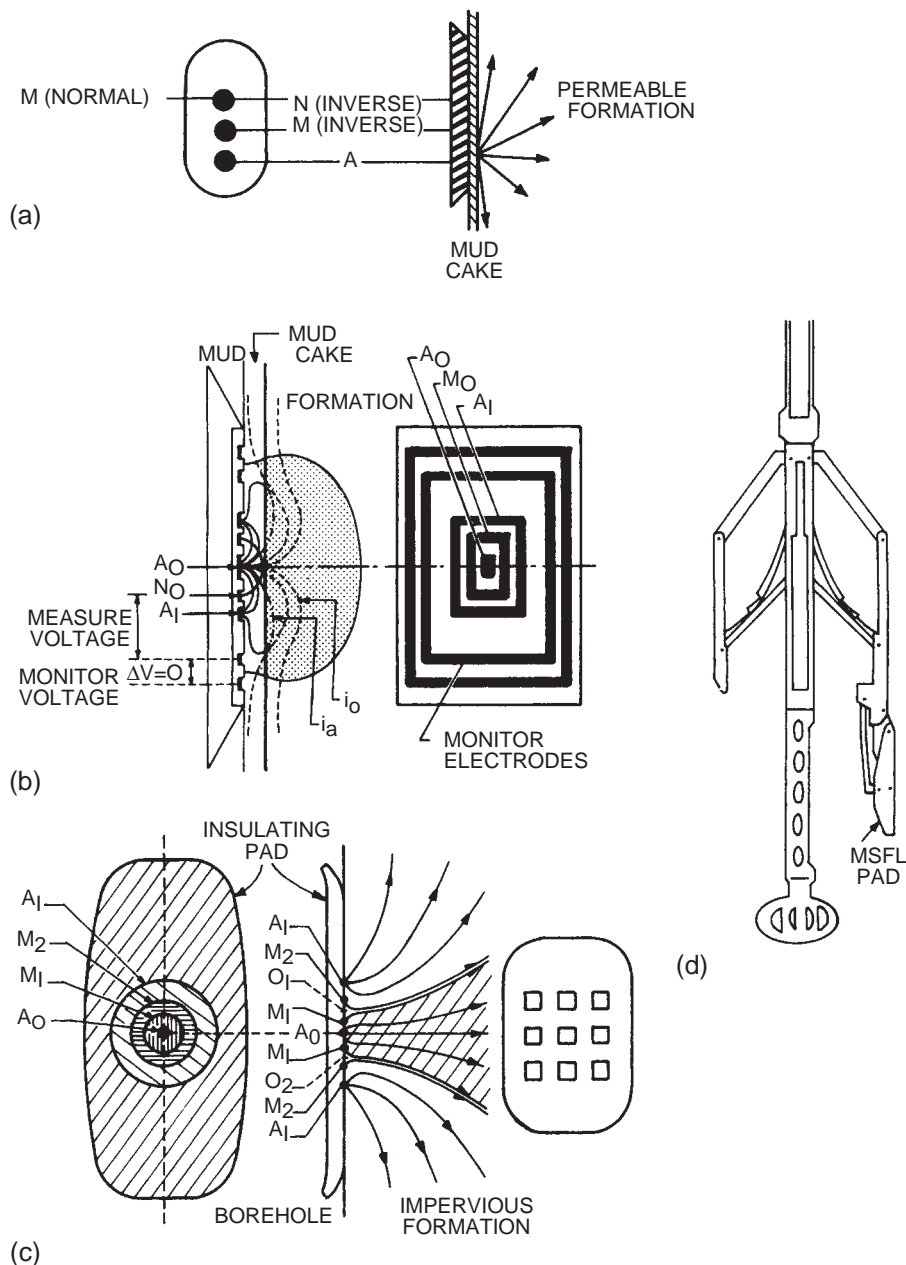

FIGURE 5.2.24 Electrode arrangements for various microresistivity devices: (a) microlog; (b) microspherically focused log; (c) microlaterolog; (d) location of the micro pad on the dual laterolog sonde [21,26,58].

(presented in track 1) from the borehole size and divide by two. In washed out or enlarged boreholes, h_{mc} must be estimated. The microlog gives a reasonable value of R_{xo} when mudcake thickness is known. The main disadvantage of this tool is that it cannot be combined with an R_t device, thus a separate logging run is required. The microlog is primarily a fresh mud device and does not work very well in salt-based muds [206]. Generally the mudcake is not thick enough in salt-based muds to give a positive separation opposite permeable zones. The backup arm on the microlog tool, which provides a caliper reading, is also

equipped with either a proximity log or a Microlaterolog. The proximity log is designed for fresh muds where thick mudcakes develop opposite permeable formations. There is essentially no correction necessary for mudcakes less than $\frac{3}{4}$ in. If invasion is shallow, the R_{xo} measurement may be affected by R_t because the proximity log reads deeper into the formation than the other microresistivity logs. When the microlog is run with a proximity log, it is presented in track 1 with a microcaliper. The proximity log is presented in tracks 2 and 3 on a logarithmic scale (Figure 5.2.26).

FIGURE 5.2.25 Chart for finding R_{xo} from microlog readings [20].

Since its introduction, the microlog (Schlumberger) has become the standard tool for recognizing permeable zones. The theory behind it is similar to using multiple resistivity devices. The tool consists of three electrode buttons on a rubber pad which is pressed against the borehole wall.

In a permeable zone, mud filtrate will enter the formation leaving the clay particles behind on the borehole wall. These clay particles may form a mudcake up to an inch thick. The resistivity of the mudcake is less than the resistivity of the formation saturated with mud filtrate. Two resistivity readings, the microinverse and the micronormal, are taken simultaneously. The microinverse has a depth of investigation of only an inch; therefore, it reads mostly mudcake (if present). The micronormal has a depth of investigation of 3 to 4 in. and is influenced primarily by fluids in the flushed zone. The difference in resistivity shows up on the log as a separation of the curves with the micronormal reading higher than the microinverse. This is referred to as “positive separation.” In impermeable formations, both readings are very high and erratic, and negative separation may occur (micronormal less than microinverse). Shales commonly show negative separation with low resistivities (Figure 5.2.27).

In salt muds, the microlaterolog and micro spherically focused log (MSFL) are used for R_{xo} readings. The microlaterolog is a focused tool with a shallower depth of investigation than the proximity log. For this reason, the microlaterolog is very strongly affected by mudcakes thicker than $\frac{3}{8}$ in. It is presented in tracks 2 and 3 like the proximity log. The MSFL is the most common R_{xo} tool for salt muds. It is a focused resistivity device that can be combined with the dual laterolog, thus providing three simultaneous resistivity readings. Although the depth of investigation is only a few inches, the tool can tolerate reasonably thick mudcakes $\frac{3}{4}$ in. The tool is also available in a slim-hole version. The only disadvantage to this device is that the pad can be easily damaged in rough boreholes.

5.2.3.4.13 Interpretation

The saturation of the flushed zone can be found from Equation 5.2.20. R_{mf} must be at formation temperature. Moveable hydrocarbons can be found by comparing S_{xo} and S_w . If $S_w/S_{xo} < 0.7$ then the hydrocarbons in the formation are moveable (this is also related to fluid permeability).

FIGURE 5.2.26 Example log showing positive separation of the microlog curves opposite a permeable formation at 4,030 to 4,050 feet.

FIGURE 5.2.27 Example of a natural gamma spectroscopy log presentation.

If $S_w/S_{x0} > 0.7$, either there are no hydrocarbons or the hydrocarbons present are not moveable.

5.2.3.4.14 Gamma Ray Logs

The gamma ray log came into commercial use in the late 1940s. It was designed to replace the SP in salt muds and in air-filled holes where the SP does not work. The gamma ray tool measures the amount of naturally occurring radioactivity in the formation. In general, shales tend to have high radioactivity while sandstone, limestone, dolomite, salt, and anhydrite have low radioactivity. There are exceptions, where tools have been designed to separate gamma rays into their respective elemental sources, potassium (K), thorium (Th), and uranium (U).

5.2.3.4.15 Theory

Gamma rays are high-energy electromagnetic waves produced by the decay of radioactive isotopes such as K40, Th, and U. The rays pass from the formation and enter the borehole. A gamma ray detector (either scintillation detector or Geiger-Muller tube) registers incoming gamma rays as an electronic pulse. The pulses are sent to the uphole computer where they are counted and timed. The log, presented in track 1 in Figure 5.2.13, is in API units.

As previously mentioned, there are new gamma ray tools available that determine which elements are responsible for the radioactivity. The incoming gamma rays are separated by energy levels using special energy-sensitive detectors. The data are collected by the computer and analyzed statistically. The log presents total (combined) gamma ray in track 1 and potassium (in %), and uranium and thorium (in ppm) in tracks 2 and 3 (Figure 5.2.27). Combinations of two components are commonly presented in track 1. The depth of investigation of the natural gamma tools is 2–10 in. depending on mud weight, formation density, hole size, and gamma ray energies.

5.2.3.4.16 Interpretation

The interpretation of a total gamma ray curve is based on the assumption that shales have abundant potassium-40 in their composition. The open lattice structure and weak bonds in clays encourage incorporation of impurities. The most common of those impurities are heavy elements such as uranium and thorium. Thus, shales typically have high radioactivity. Sandstones (quartzose), carbonates and evaporites have strong bonds and generally do not allow impurities. Limestones undergo rearrangement of crystal structure and addition of magnesium to become dolomites. Impurities like uranium (which is very soluble) may enter the crystal lattice during recrystallization. Feldspathic sandstones contain an abundance of potassium-40 and therefore show higher radioactivity than quartzose sandstone. Some evaporite minerals (Such as KCl) contain high amounts of

potassium-40 and may appear as shales on the log. Serra et al. [28] provide an excellent discussion of interpretation of the natural or spectral gamma-ray tool.

5.2.3.4.17 Sonic (Acoustic) Log

The sonic (acoustic or velocity) total measures the time it takes for a compressional wave to travel through one vertical foot of formation. It can be used to determine porosity (if the lithology is known) and to determine seismic velocities for geophysical surveys when combined with a density log. The sonic log also has numerous cased hole applications.

5.2.3.4.18 Theory

A 20 kHz sound wave is produced by the tool and travels through the mud into the formation. The wave travels vertically through the formation. The first arrival of the compressional wave is picked up by a receiver about one foot away from the transmitter. The wave continues through the formation and is picked up by the far receiver (normally 2-ft below the near receiver). The time difference between the near and far receivers is used to determine formation travel time (Δt). Fractures, vugs, unconsolidated formations, gas-cut mud, lost circulation materials, and rough boreholes can cause sharp increases in Δt , called cycle skips.

5.2.3.4.19 Interpretation

Table 5.2.7 shows the velocity and travel time for several commonly encountered oilfield materials. The t_{ma} value in the fourth column is at 0% porosity. Porosity increases travel time. Wyllie and coworkers [208] developed an equation that relates since travel time to porosity:

$$\phi = \frac{\Delta t_{log} - \Delta t_{ma}}{\Delta t_f - \Delta t_{ma}} \quad (5.2.23)$$

where $\Delta t_{log} = \Delta t$ value read from log, μ sec/ft

Δt_{ma} = matrix velocity at 0% porosity, μ sec/ft

$\Delta t_f = 189$ – 190 μ sec/ft (or by experiment)

The Wyllie equation works well in consolidated formations with regular intergranular porosity ranging from 5%–20% [209]. If the sand is not consolidated or compacted, the travel time will be too long, and a compaction correction factor (C_p) must be introduced [208]. The reciprocal of C_p is multiplied by the porosity from the Wyllie equation:

$$\phi = \left(\frac{\Delta t_{log} - \Delta t_{ma}}{t_f - t_{ma}} \right) \left(\frac{1}{C_p} \right) \quad (5.2.24)$$

The compaction correction factor (C_p) can be found by dividing the sonic porosity by the true (known) porosity. It can also be found by dividing the travel time in an adjacent shale by 100:

TABLE 5.2.7 Matrix Travel Times

Material	Velocity range ft/sec	Δt range μ sec/ft	Δt commonly used μ sec/ft	Δt at 10% porosity μ sec/ft
Sandstone	18,000–19,500	51.0–55.5	55.0 or 51.0	69.0 or 65.0
Limestone	21,000–23,000	43.5–47.6	47.5	61.8
Dolomite	23,000–24,000	41.0–43.5	43.5	58.0
Salt	15,000	66.7	66.7	—
Anhydrite	20,000	50.0	50.0	—
Shale	7,000–17,000	58.0–142	—	—
Water	5,300	176–200	189	—
Steel casing	17,500	57.0	57.0	—

From References 21 and 36.

$$C_p = \frac{\Delta t_{\text{shale}}}{100} C \quad (5.2.25)$$

where C is a correction factor, usually 1.0 [200]. In uncom-
pared sands, porosities may be too high even after correction
if the pores are filled with oil or gas. Hilchie [200] suggests
that if pores are oil-filled, multiply the corrected porosity by
0.9; if gas-filled, use 0.7 to find corrected porosity.

Raymer, Hunt, and Gardner [210] presented an
improved travel-time to porosity transform that has been
adopted by some logging companies. It is based on field
observations of porosity versus travel time:

$$\Delta t_{\text{log}} = (1 - \phi)^2 \Delta t_{\text{ma}} + \phi \Delta t_f \quad (5.2.26)$$

This relationship is valid up to 37% porosity.

The heavy set of lines in Figure 5.2.28 [20] was derived
using the Raymer et al. [210] transform, and the lighter set
represents the Wyllie relationship.

The sonic porosity derived from the Wyllie equation
(Equation 5.2.23) does not include secondary porosity (vugs
and fractures), so it must be cautiously applied in carbonate
rocks.

5.2.3.4.20 Density Log

The formation density tool measures the bulk electron
density of the formation and relates it to porosity. It is a
pad device with a caliper arm. The tool is usually run in
combination with a neutron log, but it can be run alone.

5.2.3.4.21 Theory

The density tool emits medium energy gamma rays from a
radioactive chemical source (usually Cs-137). The gamma
ray penetrate the formation and collide with electron clouds
in the minerals in the rock. With each collision the gamma
ray loses some energy until it reaches a lower energy state.
This phenomenon is called “Compton scattering.” Some

gamma rays are absorbed, and a high-energy electron is
emitted from the atom. This phenomenon is called the
“photoelectric absorption” effect, and is a function of the
average atomic weight of each element. Both the Compton-
scattered gamma ray and the photo-electrically produced
electron return to the borehole where they are detected by
scintillation tubes on the density tool. The main result is
that a porous formation will have many returning gamma
rays while a nonporous formation will have few returning
gamma rays. Each tool has two detectors; one is near
the source (short-spacing detector) and another is 1–1.5 ft
(35–40 cm) away from the near detector (long-spacing
detector).

The long-spacing detector provides the basic value of
bulk electron density. The short-spacing detector is used to
make a mudcake correction. This correction, made automati-
cally by computer by most service companies, is based on
the “spine and ribs” plot (Figure 5.2.29) [5]. The “spine”
is the heavy, nearly vertical line from 1.9 to 2.9 g/cc. The
ribs are the lighter curved lines trending left to right. The
experimental data for constructing the “ribs” are shown in
the corners of the plot. Long-spacing count-rates are on the
abscissa and short-spacing count-rates are on the ordinate
axis. The computer receives data from the sonde and plots
it on the chart. If the point falls off the “spine,” it is brought
back along one of the ribs. Bringing the point back along
the “rib” will change the intersection point on the “spine.”
The correction that is produced is called $\Delta\rho$ and may be
either positive or negative depending on the mud properties.
Negative $\Delta\rho$ values occur in heavy (barite or iron), weighted
muds. Positive values occur in light muds and when the
density pad is not flush against the borehole wall as occurs
in rough or “rugose” boreholes. The $\Delta\rho$ curve is useful for
evaluating the quality of the ρ_b reading. Excursions from 0
that are more than ± 0.20 gm/cc on the $\Delta\rho$ curve indicate a
poor quality reading.

FIGURE 5.2.28 Chart for evaluating porosity with a sonic log [20].

5.2.3.4.22 Interpretation

An equation similar to the Wyllie equation is used to calculate porosity values from bulk density.

$$\phi = \frac{\rho_{ma} - \rho_b}{\rho_{ma} - \rho_f} \quad (5.2.27)$$

where ρ_{ma} = bulk density of matrix at 0% porosity, g/cc
 ρ_b = bulk density from log, g/cc
 ρ_f = bulk density of fluid, g/cc

Table 5.2.8 lists commonly used values for ρ_{ma} and ρ_f , and, along with Figure 5.2.30 shows how ρ_f changes with temperature and pressure [58]. As with the sonic tool, an incorrect choice of matrix composition may give negative porosity values.

If a zone is hydrocarbon saturated but not invaded by mud filtrates, the low density of the hydrocarbons will increase the porosity reading to a value that is too high. In this case, Hilchie [21] suggests using the following equation:

$$\phi = \frac{0.9 \left(\frac{R_w}{R_t} \right)^{1/2} (\rho_w - \rho_h) + \rho_{ma} - \rho_b}{\rho_{ma} - \rho_h} \quad (5.2.28)$$

where ρ_w = density of formation water, g/cc (estimated from Figure 5.2.30) [58]

ρ_h = density of hydrocarbons, g/cc (from Figure 5.2.31) [199]

5.2.3.4.23 Neutron Log

Neutron tools measure the amount of hydrogen in the formation and relate it to porosity. High hydrogen content indicates water (H_2O) or liquid hydrocarbons (C_xH_z) in the pore space. Except for shale, sedimentary rocks do not contain hydrogen in their compositions.

5.2.3.4.24 Theory

Neutrons are electrically neutral particles with mass approximately equal to that of a hydrogen atom. High-energy neutrons are emitted from a chemical source (usually AmBe or PuBe). The neutrons collide with nuclei of the formation minerals in elastic-type collisions. Neutrons will

FIGURE 5.2.29 Spine and ribs plot used to correct bulk density readings for mudcake effects [58].

lose the most energy when they hit something with equal mass, such as a hydrogen atom. A few microseconds after being released, the neutrons have lost significant energy and enter the thermal state. When in the thermal state, neutrons are captured by the nuclei of other atoms (Cl, H, B). The atom which captures the neutron becomes very excited and emits a gamma ray. The detectors on the tool may detect epithermal neutrons, thermal neutrons or high-energy gamma rays of capture. Compensated neutron tools (CNL) detect thermal neutrons and use a ratio of near-to-far detector counts to determine porosity. Sidewall neutron tools (SNP) detect epithermal neutrons and have less matrix effect (though they are affected by rough boreholes more than the CNL).

5.2.3.4.25 Interpretation

Neutron tools are seldom run alone. They are usually combined with a density-porosity tool. Older neutron logs are not presented as porosity but as count rates. Some logs do not specify a scale (Figure 5.2.32), but only which direction the count rate (or radiation) increases. An increase in radiation indicates lower porosity (less hydrogen). Newer logs present porosity (for a particular matrix, limestone, sandstone or dolomite) directly on the log. Most neutron logs are run on limestone matrix. Figure 5.2.33 corrects

the porosity for matrix effect if the log is run on limestone matrix [20]. Neutron logs exhibit “excavation effect” in gas-filled formations. The apparent decrease in porosity is due to the spreading out of hydrogen in gas molecules; gases have less hydrogen *per unit volume* than liquids. Thus the neutron tool sees less hydrogen and assumes less porosity. The magnitude of the effect depends on gas saturation, gas density, and pressure. Care should be taken in using correction charts for neutron tools; each service company has a slightly different design, and the correct chart for the particular tool and service company should be used.

5.2.3.4.26 Multiple-Porosity Log Interpretation

As mentioned earlier, the neutron, density, and sonic tools are lithology dependent. If the matrix is incorrectly selected, porosity may be off as much as 10 porosity units. If two lithology-dependent logs are run simultaneously on the same matrix and presented together, lithology and porosity can be determined. The most common and useful of combinations is the neutron and density. Figures 5.2.34 through 5.2.38 are crossplots of neutron, density, and sonic porosity. The charts are entered with the appropriate values on the ordinate and abscissa. The point defines porosity and gives an indication of matrix. If a point falls between two matrix lines, it is a combination of the two minerals

TABLE 5.2.8 Bulk Densities Commonly Used for Evaluating Porosity With a Density Log*

Material	ρ_{bulk}	ρ_{log} at 10% porosity (fresh water)
Unconsolidated sand	2.65 g/cc	2.48 g/cc
Silica cemented sand	2.65 g/cc	2.48 g/cc

or the neutron-density crossplots. Gas moves the points up and to the left. To correct for the gas effect, move parallel to the gas correction arrow to the assumed lithology. Note that a gassy limestone may look like a sandstone. Shales tend to bring points down and to the right depending on the shale composition. Typically, shaly sandstone will look like a limestone. The sonic-density crossplot is not very helpful in determining porosity or lithology but is extremely useful for determining evaporite mineralogy.

In some areas, neutron and density tools are run on sandstone porosity and therefore cannot be entered in the charts directly. To use the neutron-density crossplots when the matrix is not limestone, another method must be applied. Remember that the vertical lines are constant neutron-porosity and the horizontal lines are constant density-porosity. Instead of entering the bottom or sides of the chart, select the appropriate lithology line in the interior of the chart. Draw a horizontal line through the density-porosity and a vertical line through the neutron-porosity. Lithology and porosity are determined at the intersection of these two lines.

Another device that provides good lithology and matrix control is the Lithodensity tool (LDT). It combines a density tool with improved detectors and a P_{ef} curve (photoelectric

effect). Combining the P_b and P_{ef} curve values, an accurate 3- or 4-mineral composition can be determined from the charts in Figures 5.2.39 to 5.2.42. This also provides an excellent way to confirm neutron-density cross-plot interpretations.

5.2.3.4.27 Nuclear Magnetic Resonance (NMR)

This log examines the nucleus of certain atoms in the formation. Of particular interest are hydrogen nuclei (protons) since these particles behave like magnets rotating around each other [23]. Hydrogen is examined because it occurs in both water and hydrocarbons.

The log measures fluid by applying a magnetic field, greater in intensity than the earth field, to the formation. Hydrogen protons align themselves with the induced field and when the field is suddenly removed, the protons precess about the earth's magnetic field much like a gyroscope. The nucleus of hydrogen has a characteristic precession rate called the Larmor frequency ($\sim 2,100$ Hz), and can be identified by sensors on the tool [24]. The nuclei contributing to the total signal occur in the free fluid in the pores; fluid adsorbed on the grains makes no contribution. The signals are then processed in a computer and printed out onto a log.

FIGURE 5.2.39 Chart for finding apparent matrix density or apparent matrix transit time from bulk density or interval transit time and apparent total porosity [20].

FIGURE 5.2.40 Chart for finding porosity and matrix composition from a lithodensity log in fresh water [20].

FIGURE 5.2.41 Chart for determining apparent matrix volumetric cross section from bulk density and photoelectric cross section [20].

FIGURE 5.2.42 Matrix identification crossplot chart for finding matrix composition from apparent matrix density and apparent matrix volumetric cross section [20].

Normally, proton precession decays along a time constant, T_2 . This is a result of each proton precession falling out of phase with other protons due to differences in the local magnetic fields. Moreover, each proton precesses at a slightly different frequency, depending on the kind of fluid it occurs in. This disharmonic relationship makes it possible to differentiate between free water and free oil in a reservoir [34].

Three log modes can be presented:

1. Normal mode—consists of the free fluid index (FFI) in percent obtained from a polarization time of two seconds, the Larmor proton frequency (LFRE), the decay-time constant (or longitudinal relaxation time) of the signal (T_2) and a signal-to-noise ratio (STNR).
2. Continuous mode—gives three free fluid index (FFI) readings taken at polarization times of 100, 200, and 400 ms, respectively, two longitudinal relaxation times (T_1 and T_2), and a signal-to-noise ratio (STNR).
3. Stationary display mode—a signal-stacking mode where eight signals are stacked from each of six polarization times to obtain precise T_1 , T_2 , and FFI values.

FFI readings yield porosity that is filled with moveable fluid and is related to irreducible water saturation (S_{iw}). Addition of paramagnetic ions to the mud filtrate will disrupt the water portion of the signal and residual oil saturation (S_{or}) can be determined.

Desbrandes [33] summarized the following uses for the NML:

1. Measuring free fluid volume in the pores (ϕ_F).
2. Evaluating permeability by comparing ϕ_F with ϕ_T (total porosity from a neutron-density log combination).
3. Locating intervals at irreducible water saturation by comparing ϕ_F with ϕ_T and R_t , determined with other logs.
4. Determining residual oil saturation by adding paramagnetic ions to the mud filtrate to cancel the water signal and leave the oil signal.

5.2.3.4.28 Dielectric Measurement Tools

Dielectric measurement tools examine the formation with high frequency electromagnetic waves (microwaves) rather than high-frequency sound waves (as in the sonic or acoustic logging tools). The way the electromagnetic wave passes through a given formation depends on the dielectric constants (ϵ) of the minerals and fluids contained in the rock.

Two types of tools are available [33]:

1. VHF sondes that have frequencies of 20–47 MHz (found in the deep propagation tool [Schlumberger],

and dielectric tools [Dresser-Atlas and Gearhart-Owen], and

2. UHF sondes that have a frequency of 1.1 GHz (found in the electromagnetic propagation tool [Schlumberger]).

The only tool that is currently available is Schlumberger's electromagnetic propagation tool (EPT); the others are still experimental [33].

5.2.3.4.29 Theory

The EPT is a sidewall tool that measures the dielectric properties of a formation by passing spherically propagated microwaves into the rock. The tool consists of 2 transmitters (T_1 , and T_2) and 2 receivers (R_1 , and R_2) mounted in an antenna pad assembly. Its basic configuration is that of a borehole compensation array (much like the borehole compensated sonic (BHC) log). The transmitter fires a 1.1 GHz electromagnetic wave into the rock around the well-bore. As the wave passes through the rock and fluid there, it is attenuated, and its propagation velocity is reduced. The wave then refracts to the borehole where it is sequentially detected by the two receivers. How much the wave is attenuated is a function of the dielectric permittivity of the formation. Rocks and oil have similar permittivities while water has a very different permittivity. Therefore, the wave responds to the water-filled porosity in the formation, and the response is a function of formation temperature.

Since the wave is attenuated by water (and is not too bothered by oil), the log response indicates either R_{xo} (in water-based mud systems) or bulk volume water (in oil-based mud systems).

In order to provide usable values, the velocity of the returning wave is measured and compared to the wave-propagation velocity in free space. The propagation velocity of the formation is then converted into propagation time (T_{p1}). A typical log presentation includes a T_{p1} curve (in nanoseconds/meter), an attenuation curve (EATT) in decibels/meter, and a small-arm caliper curve (which measures borehole rugosity) recorded in tracks 2 and 3. Figure 5.2.43 shows the basic antenna configuration [35]. Figure 5.2.44 is an example of an EPT log presentation.

The depth of investigation of the tool varies between one and three inches and depends on formation conductivity; high conductivity reduces depth of investigation.

The tool is affected primarily by hole roughness (rugosity) and mud cakes $> \frac{3}{8}$ in. thick. These effects reduce depth of investigation and in extreme situations (i.e., very rough holes and/or very thick mud cakes) keep the tool from reading the formation at all.

FIGURE 5.2.43 Diagram showing antenna-transmitter configuration for an EPT sonde and microwave ray paths through the mudcake and formation adjacent to the borehole [35].

5.2.3.4.30 Interpretation

The most common way to interpret EPT logs is called the *T_{po} method* [35]. *T_{po}* in a clean formation is given by:

$$T_{po} = (\phi S_{xo} T_{pfo}) + \phi(1 - S_{xo})T_{phyd} + (1 - \phi)T_{pma} \quad (5.2.29)$$

Rearranging terms and solving for *S_{xo}*:

$$S_{xo} = \frac{(T_{po} - T_{pma}) + \phi(T_{pma} - T_{phyd})}{\phi(T_{pfo} - T_{phyd})} \quad (5.2.30)$$

where *T_{po}* = *T_{pl}* corrected for conductivity losses, nanosecs/m

T_{pma} = the matrix propagation time, nanosecs/m

T_{phyd} = the hydrocarbon propagation time, nanosecs/m

T_{pfo} = the fluid propagation time, nanosecs/m

T_{po} can be calculated by

$$T_{po} = T_{pl}^2 - \left(\frac{A_c}{60.03} \right)^2 \quad (5.2.31)$$

where

$$A_c = A_{log} - 50 \quad (5.2.32)$$

(*A_{log}* = EATT curve reading in dB/m)

T_{pfo} is a function of formation temperature (*T*) and can be found from:

$$T_{pfo} = \frac{20(710 - T/3)}{(440 - T/3)} \quad (5.2.33)$$

T_{pma} is taken from Table 5.2.9 and ϕ is taken from a neutron-density log (ϕ_{ND}). Equation 5.2.30 can be rearranged to find ϕ for a quick-look comparison with other porosity devices (specifically the neutron-density log). By assuming *T_{phyd}* ≈ *T_{pfo}*, *T_{phyd}* can be eliminated and

FIGURE 5.2.44 EPT log presentation.

$$S_{xo} = \frac{1}{\phi} \frac{(T_{po} - T_{pma})}{(T_{pfo} - T_{pma})} \quad (5.2.34)$$

Since the EPT log measures water-filled porosity, by definition

$$\phi = \phi_{EPT} \frac{(T_{po} - T_{pma})}{(T_{pfo} - T_{pma})} \quad (5.2.35)$$

in a water zone ($R_t = R_o$; $S_w = 100\%$)

So, in hydrocarbon zones:

$$S_{xo} = \frac{\phi_{EPT}}{\phi_{ND}} \quad (5.2.36)$$

Figure 5.2.45 is a quick look at ϕ_{EPT} response compared to FDC, CNL, and induction-log resistivity in gas, oil, fresh water, and saltwater-bearing formations [25]. These

responses also indicate moveable oil saturation ($1 - S_{xo}$) and, therefore permeability.

5.2.3.5 Special Openhole Logs and Services

5.2.3.5.1 Dipmeter

The dipmeter is a four-armed device with pads that read resistivity of thin zones. These four resistivity curves are analyzed by computer and correlated to determine formation dip and azimuth. The dips are presented on a computer-produced log. In addition to dip, hole deviation, borehole geometry, and fracture identification are also presented.

5.2.3.5.2 Repeat Formation Tester

The repeat formation tester measures downhole formation pressures. The tool is operated by an electrically driven hydraulic system so that several zones may be pressure

TABLE 5.2.9 Matrix Propagation Times with the Electromagnetic Propagation Tool for Various Minerals

Mineral	T_{pma} , nanosec/m
Sandstone	7.2

tested on the trip into the hole. Once the drawdown pressure and the pressure buildup have been recorded, they can be processed by a computer at the well-site to provide Horner plots from which permeabilities are calculated. Permeabilities from the drawdown test often vary considerably from measured permeabilities and should be considered an order-of-magnitude estimate. This is usually due to a very shallow depth of investigation associated with drawdown tests [33]. The pressure buildup has a better depth of investigation than the drawdown pressure test. Accuracy depends on what type of pressure-wave propagation model is chosen [[33],[35],[36]] as well as the compressibility and viscosity of the formation fluids.

5.2.3.5.3 Sidewall Cores

After drilling, cores from the side of the borehole can be taken by wireline core guns or drills. Guns are less expensive but do not always recover usable cores. Sidewall

drilling devices have become quite common in the last few years. Up to 20 cores may be cut and retrieved on one trip into the hole.

5.2.3.5.4 Cased Hole Logs

Cased hole logs are run to evaluate reservoir performance, casing/cement bond quality, and to check flow rates from producing intervals. The reader is referred to Bateman's book [38] on cased hole logging which provides a more detailed discussion than is possible in this summary.

Cased hole logs can be broadly divided into two classes:

1. Logs that measure formation parameters through the casing.
2. Logs that measure the parameters within and immediately adjacent to the casing.

These logs are all combined to monitor fluids being produced, monitor reservoir performance, and monitor producing-string deterioration with time. They differ from open-hole logs in that the majority of cased hole logs merely monitor fluid production rather than provide extensive data on formation characteristics.

Following recent developments in cased hole logging technology, the following measurements can be made:

- Formation resistivity through casing: Although the concept of measuring resistivity through casing is not new, but it is only recent break throughs in downhole electronics and electrode design that have made the measurements possible [Schlumberger tool: CHFR].
- Formation porosity through casing: Measurements are based on an electronic neutron source instead of a chemical source, and it uses borehole shielding and focusing to obtain porosity measurements that are affected only minimally by borehole environment, casing standoff, and formation characteristics such as lithology and salinity [Schlumberger tool: CHFP].
- Formation acoustics: This technique measures formation compressional and shear slowness in cased wells [Schlumberger tool: DSI].
- Fluid identification: This tool provides a technique for determining formation pressures in old or new cased wells, and it enables efficient fluid sampling without the inherent risks of conventional or standard sampling techniques [Schlumberger tool: CHDT].

5.2.3.5.5 Cased Hole Formation Evaluation

Two tools are currently being used to provide formation evaluation in cased holes:

1. Pulsed neutron logs.
2. Gamma spectroscopy tools (GST) logs.

FIGURE 5.2.45 EPT quicklook chart comparing curve response of induction resistivity, neutron porosity, density porosity and EPT porosity in water bearing and hydrocarbon-bearing zones [35].

5.2.3.5.6 Pulsed Neutron Logs

Pulsed neutron logs are used to monitor changes in fluid content and water saturation with respect to time. Current tools also provide a means of estimating porosity. They are particularly valuable for [38]:

1. Evaluating old wells when old open-hole logs are poor or nonexistent.
2. Monitoring reservoir performance over an extended period of time.
3. Monitoring the progress of secondary and tertiary recovery projects.
4. Formation evaluation through stuck drill pipe (generally a last resort).

5.2.3.5.7 Theory

A neutron generator that consists of an ion accelerator fires deuterium ions at tritium targets. This produces a burst of 14 keV neutrons which pass through the borehole fluid (must be fresh water), casing, and cement. The burst then forms a cloud of neutrons in the formation which are

rapidly reduced to a thermal state by collisions with the atoms in fluids in the rock (made up primarily of hydrogen atoms). Once in a thermal state, they are most liable to be captured by chlorine (or boron). The capture process will produce a gamma ray of capture which is then detected by a scintillometer in the tool. The time it takes for the neutron cloud to die during the capture process is a function of the chlorine concentration in the formation fluid. This is then related to water saturation. Rapid disappearance of the thermal neutron cloud indicates high water saturation. Slower disappearance of the cloud indicates low water saturation (i.e., high hydrocarbons saturations). The rate of cloud decay is exponential and can be expressed by:

$$N = N_0 e^{(-t/\tau)} \quad (5.2.37)$$

where N = number of gamma rays observed at time t
 N_0 = number of gamma rays observed at $t = 0$
 t = elapsed time (microseconds)
 τ = time constant of the decay process, microseconds

Of most interest is τ since it is strictly a function of the decay rate of the neutron cloud (or rather the slope of the exponential function). From τ the capture cross section, Σ , can be calculated:

$$\Sigma = 4,550/\tau \quad (5.2.38)$$

The tools that are available to measure τ include:

1. TDT-K (with 3 moveable gates or detectors)
2. DNLL (dual neutron lifetime log) (which uses 2 gates),
3. TDT-M (with 16 fixed gates), and
4. TMD (thermal multigate decay) (which uses 6 gates).

In general, these tools all perform the same function: they measure the decay rate of the neutron cloud in the

formation. This is accomplished by using a series of windows to measure near and far-spacing counting rates, as well as background gamma ray rates. The first gates are not triggered until all neutrons in the cloud in the formation are thermalized. At this point neutron capture has started. By using certain gating times and gate combinations, the slope of the straight portion of the decay curve is measured and related to Σ . In addition, the ratio between the short-space-detector and long-space-detector counting rates is also calculated and is related to porosity. (It is similar in principle to the CNL porosity device used in openhole logging).

5.2.3.5.8 Log Presentations

Figure 5.2.46 is an example of a DNLL log presentation. Most other TDT logs are presented in a similar way, except

FIGURE 5.2.46 Dual neutron lifetime log (DNLL) presentation.

that the number of curves varies from company to company. The log shown in this figure consists of 5 curves:

1. Gamma ray curve (Track 1).
2. Gate 1 counting rate (CPM).
3. Gate 2 counting rate (CPM).
4. Ratio curve (\approx CNL ratio).
5. Sigma curve (Σ).

In addition, the pips located on the left side of track 2 are the corrected casing collar locations.

Gate 1 and Gate 2 show the raw data from the detectors, the ratio curve shows relative hydrogen concentration (\approx water-filled porosity), and the σ curve shows the capture cross-section. Some logs also show a τ curve, but it is normally omitted [38].

5.2.3.5.9 Interpretation

Interpretation of pulsed neutron logs is very straightforward. It relies on knowledge of three parameters (four in hydrocarbon-bearing zones):

1. Σ_{\log} (capture units).
2. Σ_{matrix}

3. Σ_{water}
4. $\Sigma_{\text{hydrocarbon}}$

According to Schlumberger [41] the log response may be described as:

$$\Sigma_{\log} = \Sigma_{\text{ma}}(1 - \phi) + \Sigma_{\text{w}}\phi S_{\text{w}} + \Sigma_{\text{hy}}\phi(1 - S_{\text{w}}) \quad (5.2.39)$$

Solving for S_{w} :

$$S_{\text{w}} = \frac{(\Sigma_{\log} - \Sigma_{\text{ma}}) - \phi(\Sigma_{\text{hy}} - \Sigma_{\text{ma}})}{\phi(\Sigma_{\text{w}} - \Sigma_{\text{hy}})} \quad (5.2.40)$$

Porosity (ϕ) can be found either from an openhole porosity log or by combining the ratio curve and Σ_{\log} . Figures 5.2.47 to 5.2.50 are charts to find porosity, apparent water salinity, and Σ_{w} , using this combination. By selecting the chart for the appropriate borehole and casing diameter, these values are easy to determine. Simply enter the proper axes with the log-derived values, and find porosity and Σ_{w} at the intersection of the two lines. If water salinity and formation temperature are known, use Figure 5.2.50 to find Σ_{w} .

FIGURE 5.2.47 Chart for determining porosity and apparent water salinity from Σ log and ratio curves in 5 1/2-in. casing and an 8-in. borehole [20].

Sandstone, 7-in. Casing, 10-in. Borehole, Fresh Water Cement, Tool Eccentered

Example: Ratio = 3.1
 $\Sigma_{LOG} = 20$ cu
 Borehole fluid salinity = 80,000 ppm
 5 1/2-in. casing cemented in 8 3/4-in. borehole

Thus, from Chart Tcor-3
 $\phi = 30\%$
 Apparent water salinity = 50,000 ppm
 $\Sigma_{wa} = 40$ cu

If this were a clean formation and connate water salinity was known to be 150,000 ppm, then

$$S_w = \frac{50,000}{150,000} = 33\%$$

FIGURE 5.2.48 Chart for determining porosity and apparent water salinity from Σ log and ratio curves in 7-in. casing and a 9-in. borehole [20].

Estimating Σ_{hy} is another matter. You must first know if the hydrocarbons are oil, methane, or heavier hydrocarbon gases (i.e., propane, butane, pentane). For oil, solution gas-oil ratio and oil gravity ($^{\circ}$ API) are needed. If the gas is methane, reservoir pressure and temperature are required. For gases other than methane, the specific gravity of the gas can be converted to equivalent methane using Figure 5.2.51, and then Figure 5.2.52 can be entered. Once all of the parameters have been found, Equation 5.2.40 is used to find S_w .

5.2.3.5.10 Applications

Pulsed neutron logs are most useful for monitoring changes in water saturation over time while a reservoir is produced. Initially, these logs are run prior to perforating a zone. Subsequent logs are run every few months (or years) depending on production rate and the amount of control desired. Water saturation is calculated for each run using Equation 5.2.40 and subtracted from saturations determined from earlier runs. These values (ΔS_w) show the change in the position of the water table (hydrocarbon-water contact) versus time.

Sandstone, 7- to 9-in. Casing, 12-in. Borehole, Fresh Water Cement, Tool Eccentered

FIGURE 5.2.49 Chart for determining porosity and apparent water salinity from $\Sigma \log$ and ratio curves in 7- to 9-in. casing and a 12-in. borehole [20].

Example: A reservoir section at 90°C temperature and 25 MPa pressure contains water of 175,000 ppm (NaCl) salinity: 30°API oil with a GOR of 2000 cu ft/bbl, and methane gas.

Thus, $\Sigma_w = 87$ cu ($\tau = 52 \mu\text{s}$)
 $\Sigma_o = 19$ cu ($\tau = 240 \mu\text{s}$)
 $\Sigma_g = 6.9$ cu ($\tau = 660 \mu\text{s}$)

FIGURE 5.2.50 Chart for finding Σ_w from equivalent water salinity and formation temperature [20].

FIGURE 5.2.51 Chart for converting Σ_{gas} to Σ_{methane} [38].

FIGURE 5.2.52 Charts for finding Σh (for methane and liquid hydrocarbons) from reservoir pressure and formation temperature (gas) or solution gas-oil ratio (GOR) and API gravity (liquid 7 hydrocarbons) [20].

Another application is monitoring residual oil saturation in waterflood projects. The procedure outlined by Bateman [38] involves first running a base log (prior to injection). Next, salt water is injected and another log is run. Then fresh water is injected and another log run. If Σ_{brine} and Σ_{fresh} are known, Bateman [38] suggests using:

$$S_o = 1 - \frac{\Sigma_{\text{log(brine)}} - \Sigma_{\text{log(fresh)}}}{\phi(\Sigma_{\text{brine}} - \Sigma_{\text{fresh}})} \quad (5.2.41)$$

to find residual oil saturation (S_{or}). Additional details of estimating S_{or} are given later.

The main problem with using these logs is the presence of shale. Shale normally appears wet, and shale will make a reservoir look like it has higher S_w . Openhole logs and an NGS log are needed to confirm this interpretation although shaly sand corrections can easily be made [38].

5.2.3.5.11 Gamma Spectroscopy Tools (GST)

Also known as the carbon-oxygen log, this device has been incorporated into pulsed neutron tools to aid in differentiating oil and gas from water. GST tools operate with the same neutron generator as the pulsed neutron devices, but gamma rays returning from the formation are measured.

Two types of gamma rays are produced when neutrons are fired into a formation:

1. Those that result from neutron capture by chlorine and boron.
2. Those that result from inelastic collisions with atoms.

The detector on this tool has energy windows set to receive certain returning gamma rays [39]. The detectors are protected from the fast neutron source by an iron shield, and from returning thermal neutrons by a boron shield.

The energy of the returning gamma rays depends on the atom involved in the collisions. The atoms of interest include carbon, oxygen, silicon, and calcium. Carbon-oxygen ratio is a carbon indicator and when combined with porosity, gives an estimate of water saturation if matrix lithology is known. Figure 5.2.53 is used for this determination. Silicon-calcium ratio is an indicator of matrix and is used to distinguish oil-bearing rock from calcareous rocks (such as limy sands and limestones) [39,40]. Figure 5.2.54 is an example of a carbon-oxygen log.

If capture gamma rays are also detected with separate energy windows, chlorine and hydrogen content can be determined and related to formation water salinity. Figures 5.2.55 and 5.2.56 are used for this purpose. All that is required to estimate salinity of formation waters is knowledge of borehole fluid salinity, Cl/H ratio, and response mode of the tool. These devices should *not* be confused with the natural gamma spectroscopy log which only measures naturally-occurring gamma rays.

The readings on the GST log are not affected by shale although carbonaceous shales can cause trouble because of the sensitivity to carbon. Usually, however, these effects can be calibrated for or taken into account when this log is interpreted. Much of the interpretation of this type of log is based in regional experience; the analyst should have a good idea of the types of rocks present before trying to make an interpretation. No lithology crossplot charts are presently available to estimate lithology with these logs.

5.2.3.5.12 Natural Gamma Spectroscopy

This log operates in the same manner as its openhole counterpart. The main difference is that the log should be calibrated prior to being run in cased holes. No correction charts are currently available for cased hole applications with this device. Curve presentations are the same as for the open-hole version. Refer to the open-hole section for a discussion of this log.

5.2.3.5.13 Cased-Hole Completion Tools

These tools examine cement bond and casing quality. They assure that no leakage or intercommunication will occur between producing horizons, or between water-bearing horizons and producing horizons. The most common completion tools include:

1. Cement bond logs (CBL).
2. Multifingered caliper logs.
3. Electromagnetic inspection logs.
4. Electrical potential logs.
5. Borehole viewers.

5.2.3.5.14 Cement bond logs (CBL-VDL)

Cement bond logs are used to check cement bond quality behind the casing and to estimate compressive strength of the cement. It can also be used to locate channeling in the cement or eccentric pipe and to check for microannulus.

5.2.3.5.15 Theory

The cement bond tool is the same as a conventional sonic tool except that the receiver spacings are much larger. It consists of a transmitter and two receivers. The near receiver is 3 ft below the transmitter and is used to find Δt for the casing. The far receiver is 5 ft below the transmitter and is used for the variable density log (VDL) sonic-wave-form output. The operation is the same as a conventional sonic except that the transmit time (one way) is measured. The transmitter is fired and a timer is triggered in both receivers. The wave passes through the fluid in the casing, the casing, and the cement, and into the formation. The near receiver measures the first arrival of the compressional wave and the timer is shut off. This Δt is a function of whether the casing has cement behind it or not.

FIGURE 5.2.53 Chart for finding water saturation using the carbon-oxygen ratio curve and porosity if matrix lithology is known [20].

The sound wave is then picked up by the lower receiver which recognizes refracted compressional wave arrivals from the casing, cement, and formation, as well as Rayleigh, Stonely, and mud-wave arrivals. Figure 5.2.57 shows the basic tool configurations.

The most important parameter measured by this tool is compressive-wave attenuation-rate. This parameter is a function of the amount of cement present between the pipe and formation. Typically, cement must be at least 3/4 in. thick on the casing in order for attenuation to be constant [38]. Each part of the log reads different attenuations. The CBL registers attenuation of the compressional wave in the cement and casing which gives an indication of the cement-casing bond-quality. The VDL registers the attenuation of the compressional wave through casing, cement, and formation which gives an indication of acoustic coupling between casing, cement, and surrounding rock. This indicates not

only the casing bond quality but also the cement-formation-bond quality.

The basic parameter used to evaluate cement bonds is called the *bond index* and can be calculated by

$$\text{bond index} = \frac{\text{attenuation in zone of interest (db/ft)}}{\text{attenuation in a well cemented section (db/ft)}} \tag{5.2.42}$$

Bond index gives a relative way to determine bond quality through any given section of pipe. The minimum value of bond index necessary for a good hydraulic seal varies from region to region, and depends on hole conditions and type of cement used. Ideally, an index of 1.0 indicates excellent pipe-cement bonding; decreasing values show deteriorating conditions which may require squeezing to bring bonding up to acceptable standards. A bond index curve may be presented in track 2.

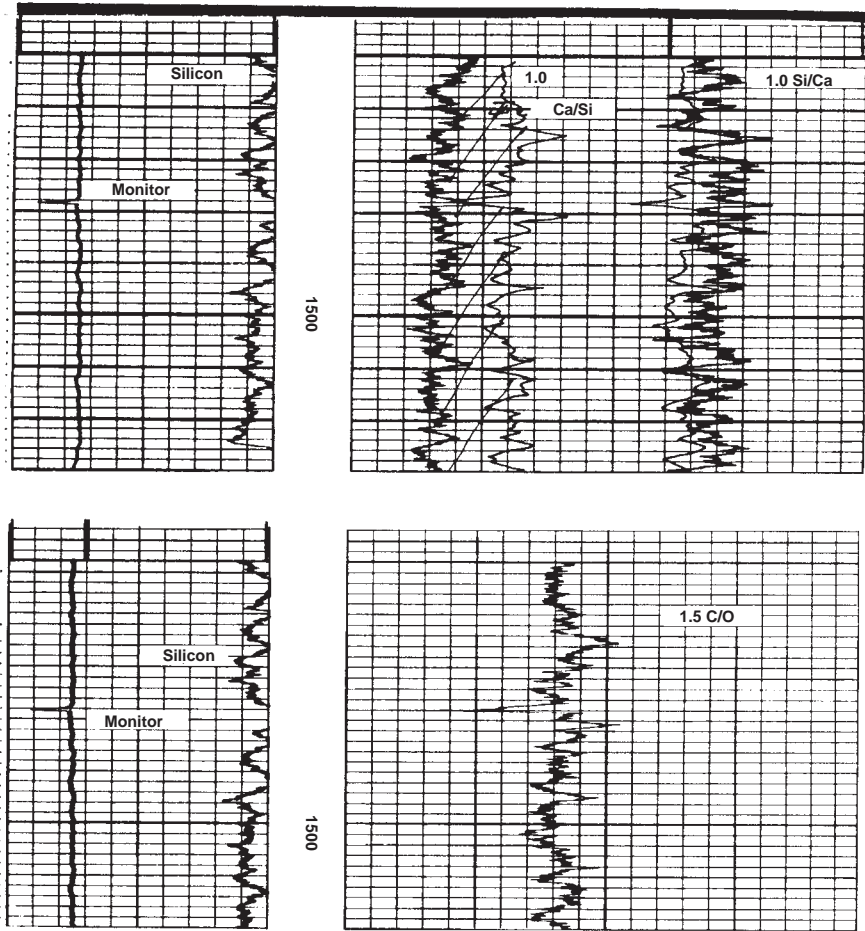

FIGURE 5.2.54 Carbon-oxygen and silicon-calcium ratio curves on a carbon-oxygen log.

FIGURE 5.2.56 Chart for finding apparent water salinity from chlorine-hydrogen ratio and borehole fluid salinity derived from a GST log (Tau-capture mode) [20].

FIGURE 5.2.57 Transmitter-receiver arrangement and surface equipment for cement bond log-variable density log combination [41].

5.2.3.5.16 Log Presentations

Figure 5.2.58 shows a CBL-VDL log. Typically, three curves (and sometimes more, depending on the service company) are presented on the log. Track 1 contains total travel time. This is total one-way travel time and is a function of the casing size and tool centering. Other curves may be presented in this track, including gamma ray, neutron, and casing collar locator logs. Track 2 contains the cement bond logs amplitude curve. The log is scaled in millivolts and is proportional to the attenuation of the compressional-wave first-arrivals. High attenuation produces low-amplitude values; low attenuation produces high-amplitude values. The higher the amplitude, the poorer is the casing-to-cement bond. Direction of increasing amplitude is normally indicated by an arrow. Some presentations also include a bond index curve in track 2. Track 3 contains the variable density log (VDL) display. The most common presentation is dark- and light-colored bands that represent the peaks and valleys

of the wave train. Figure 5.2.58 shows two possible types of arrivals:

1. Those from the casing which appear as straight, parallel light and dark bands intermittently broken by small V-shaped spikes which indicate the position of casing collars.
2. Those from the formation which appear as wavy, irregular, and intermittent light and dark bands which represent curve attenuation in the rock surrounding the borehole.

5.2.3.5.17 Interpretation

Interpretation of CBL-VDL logs involves recognition of basic curve pattern for determining whether casing is properly bonded or not. These curve patterns are presented in Figures 5.2.59 to 5.2.62. Four basic types of patterns are apparent:

FIGURE 5.2.58 Basic CBL-VDL log presentation [41].

FIGURE 5.2.59 CBL-VDL log run in free pipe [41].

FIGURE 5.2.60 CBL-VDL log run in casing eccentric in borehole making contact with the formation [41].

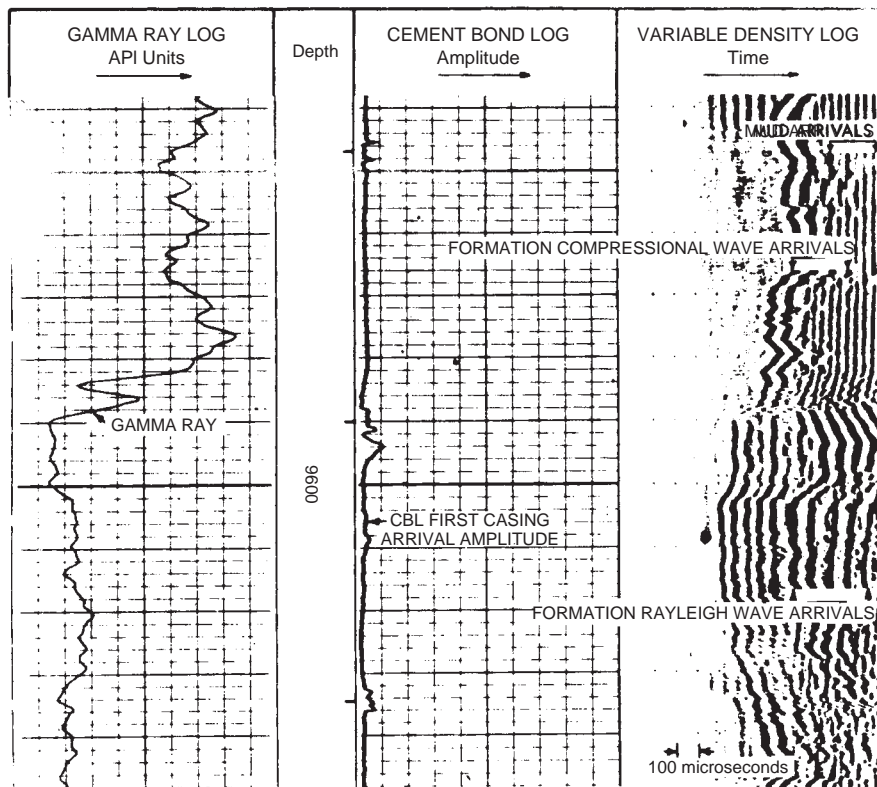

FIGURE 5.2.61 CBL-VDL log run in well-bonded casing [41].

FIGURE 5.2.62 CBL-VDL log run in casing with a good cement-casing bond and a poor cement-formation bond [41].

1. Those that show strong casing arrivals only.
2. Those that show strong casing and formation arrivals.
3. Those that show weak casing arrivals and strong formation arrivals.
4. Those that show both weak casing and weak formation arrivals.

Strong casing arrivals are shown in Figure 5.2.59 and are characterized by the pronounced casing arrival pattern (straight, alternating light and dark bands). No formation arrivals are present and cement-bond log-amplitude is moderate to high. These indicate free pipe with no cement or cement-casing-formation coupling. A high amplitude curve reading indicates low attenuation, hence no cement in the annulus.

Strong casing and formation arrivals are shown in Figure 5.2.60. This pattern has both the clean, pronounced casing signature as well as a strong, wavy-formation signature. The lack of cement is indicated by the high cement bond log-amplitude (i.e., no cement attenuation). The combination of these signals is interpreted as eccentric casing in contact with the wall of the well-bore. In this situation, proper cementation may be impossible.

Weak-casing and strong-formation arrivals are shown in Figure 5.2.61. This pattern shows no apparent casing or very weak casing patterns and very strong formation-patterns nearly filling the VDL in track 3. This indicates good casing-cement formation bonding, confirmed by the low cement bond log amplitude (high attenuation). Rayleigh and mud wave arrivals are also apparent along the right side of track 3.

Weak-casing and weak-formation arrivals are shown in Figure 5.2.62. This pattern shows what appears to be a

slightly attenuated casing pattern but the cement bond log amplitude suggests otherwise. The curve indicates strong to very strong attenuation due to cement. Strongest attenuation occurs at "A" with a very weak formation pattern on the VDL. Comparison with the open-hole VDL (immediately to the right) shows no unusual attenuations of the formation signal. This also confirms poor acoustic coupling between cement and formation with good coupling between casing and cement.

Other possible interpretations for this type of pattern are possible.

1. Gas in the mud can be ruled out by examining long intervals of the log. Generally, this effect will occur over long rather than short sections in the well.
2. Eccentered tool in the casing, which causes destructive interference of compressive-wave first-arrivals, can be confirmed by checking for wiggly casing arrivals or a slight decrease in the casing-arrival time shown on the total-transit-time curve or VDL log [41].
3. Thin cement sheaths, caused by excessive mud cake thickness along a permeable formation, are a problem when cement sheaths are less than $\frac{3}{4}$ in. thick (which allows stronger casing arrivals). At times, the cement and formation have a slight acoustic coupling which gives the VDL a faint or weak formation signal.

5.2.3.5.18 Microannulus or Channeling in Cement

Microannulus occurs when the cement is emplaced and the casing is pressurized. When pressure is released after the cement has set, the casing "pops" away from the cement sheath. This generates a gap or microannulus between the

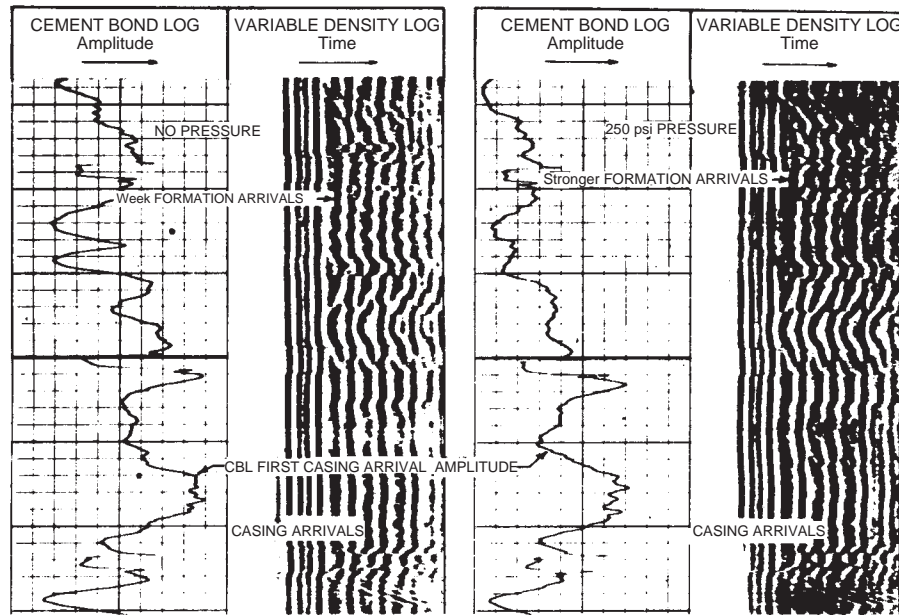

FIGURE 5.2.63 CBL-VDL log showing effects of microannulus and the change in signal strength on VDL in pressured and nonpressured pipe [41].

casing and the cement. This can also occur if excessive pipe dope or varnish is present on the pipe. Microannulus due to pressurization primarily occurs opposite washed out portions of the borehole.

Channeling occurs when cement is in the annulus but does not completely surround, or is not bonded to, the pipe. This condition will not have proper fluid seal which allows oil, gas or water to pass up the hole outside the casing. Microannulus, on the other hand, may have a proper seal even though a small gap exists. It is very important to be able to distinguish between microannulus and channeling; squeezing may eliminate the channel altogether.

Figure 5.2.63 shows a case of microannulus. Figure 5.2.63a shows strong to weak casing-bond on the CBL amplitude and weak formation-arrivals on the VDL. This indicates poor acoustic coupling between casing, cement, and formation. The weaker the formation signal, the more pronounced the microannulus.

Microannulus can be easily differentiated from channeling by:

1. Pressurizing the pipe and rerunning the CBI-VDL. Microannulus conditions are confirmed by strengthened formation signals on the VDL and decreased CBL amplitude indicating better casing-cement acoustic coupling. Typically, channeling will produce little or no improvement in the signal when the casing is pressurized. Figure 5.2.63b shows a case of stronger formation arrivals indicating the presence of microannulus rather than channeling.
2. Microannulus tends to occur over long intervals of the log; channeling is a localized phenomena. This is a result

of microannulus being directly related to pipe expansion during cementing operations.

Once the log has been interpreted, remedial measures can be applied as necessary.

5.2.3.5.19 Multifingered Caliper Logs

These logs incorporate up to 64 feelers or scratchers to examine pipe conditions inside the casing. Specifically, they can be combined with other logs to check:

1. Casing collar locations.
2. Corroded sections of pipe.
3. Casing wear.
4. Casing cracks or burstings.
5. Collapsed or crushed casing.
6. Perforations.
7. Miscellaneous breaks.

The number of feelers is a function of pipe diameter; smaller diameter pipe requires fewer feelers on the tool.

5.2.3.5.20 Electromagnetic Inspection Logs

This device induces a magnetic field into the casing and measures the returning magnetic flux. In general any disturbance in the flux from readings in normal pipe can be used to find:

1. Casing collars.
2. Areas of corroded pipe.
3. Perforations.
4. Breaks or cracks in the pipe.

This tool only records if corrosion has occurred on the pipe, not whether it is currently taking place. It does give an

indication of casing quality and integrity without removing the pipe from the hole. The principle behind this tool is the same as the magna flux device used to detect flaws in metals in a machine shop.

5.2.3.5.21 Electrical Potential Logs

Similar in some respects to an SP log, this tool measures the potential gradient of a DC current circulating through a string of casing. This current is applied to provide the casing with cathodic protection thereby preventing casing corrosion; any deviation from a negative field suggests that the pipe is not receiving proper protection and is probably being corroded. Combined with an electromagnetic inspection log, areas currently undergoing corrosion as well as having a relative amount of damage can be determined with ease.

5.2.3.5.22 Borehole Televiewers

This tool incorporates an array of transmitters and receivers to scan the inside of the casing. The signals are sent to the surface where they are analyzed and recorded in a format that gives a picture of the inside of the casing. Any irregularities or cracks in the pipe are clearly visible on the log presentation. This allows engineers to fully scan older pipe and get an idea of the kind and extent of damage that might not otherwise be readable from multifinger caliper, electromagnetic inspection, or electrical potential logs. The main drawback to this device is that it must be run in a liquid-filled hole to be effective.

5.2.3.5.23 Production Logs

Production logs are those devices used to measure the nature and behaviour of fluids in a well during production or injection. A Schlumberger manual [42] summarizes the potential benefits of this information:

1. Early evaluation of completion efficiency.
2. Early detection of disturbances which are not revealed by surface measurements (thief zones, channeled cement, plugged perforations, etc.).
3. Detailed information on which zones are producing or accepting fluid.
4. More positive monitoring of reservoir production.
5. Positive identification of encroachment, breakthrough, coring, and mechanical leaks.
6. Positive evaluation of injection efficiency.
7. Essential guidance for remedial workover and secondary or tertiary recovery projects.

The reader is referred to the Schlumberger volume [42] on production log interpretation for examples of various cased-hole-log situations. It is still free upon request.

The types of logs run include

1. Temperature
2. Manometer and gradiomanometer

3. Flow meters
4. Radioactive tracers

Devices that measure water-holdup are also available. These logs can be run singly or in combination on a production combination tool so that a number of parameters may be recorded on the same log sheet.

5.2.3.5.24 Temperature Log

A thermometer is used to log temperature anomalies produced by the flow or fluid inside the casing or in the casing annulus. It is used to help determine flow-rates and points of fluid entry or exit, and is, perhaps, most useful for finding fluid movement behind the casing.

5.2.3.5.25 Injection Wells

Figure 5.2.64 is the response of the temperature log when fluid is being injected into a reservoir. The sloping portion defines the geothermal gradient the vertical portion defines the zone tasking the water and is a function of the geothermal gradient as well as the injection fluid temperature. Below the sloping position, the temperature/curve rapidly returns to normal formation temperature and the geothermal gradient. The vertical portion of the log clearly indicates where the fluid is leaving the casing.

5.2.3.5.26 Production Wells

Figure 5.2.65 is the response of the temperature log when fluid is flowing into a well from perforations in the casing. Three curves are presented. This figure shows that curve response depends on whether the fluid produced is hotter, the same as, or cooler than the geothermal gradient. If the fluid is hotter or cooler, then the entry point is obvious. If the fluid temperature is the same as the geothermal gradient, the change is so subtle that recognition of the entry point may be very difficult. In this case, a high resolution thermometer may be necessary to pinpoint the fluid entry location.

5.2.3.5.27 Flow Behind Casing (Annular Flow)

Figure 5.2.66 is a typical response to annular flow down the outside of the casing in a shut-in well. The figure shows water entering the annulus at about 6,500 ft. Perforations are at ~ 8,500 ft.

In a producing well, the shape of the curve defines the top of the annular space and its relationship to the perforations.

5.2.3.5.28 Manometers and Gradiomanometers

Manometers are pressure-sensitive devices used to measure changes in pressure that result from:

FIGURE 5.2.64 The effect of water injection on a temperature log for several injection water temperatures [42].

1. Leaks in tubing or casing.
2. Fluid inflow through perforations.
3. Gradient measurements in a static mud column.

They are particularly useful for determining pressure opposite a gas-bearing horizon. This value is vital for calculating open-flow potentials in gas wells.

Gradiomanometers are used to check the difference in pressure over a 2-in. interval in a producing well. This is then related to water-holdup in polyphase fluid flow within the casing.

The pressure difference is converted to density and is used to interpret two-phase flow (usually consisting of water as the heavy component and oil as the lighter component). At any given level, the gradiomanometer measures the

specific gravity (density) of any fluids entering the borehole. The log reading is related to water holdup and specific gravity by:

$$\rho_{\text{gradiomanometer}} = Y_w \rho_w + (1 - Y_w) \rho_o \quad (5.2.43)$$

where $\rho_{\text{gradiomanometer}}$ = specific gravity reading of the gradiomanometer, g/cc

ρ_w = specific gravity of the formation water, g/cc

ρ_o = specific gravity of the oil being produced with the water, g/cc

Y_w = water holdup (or holdup of the heavy phase)

FIGURE 5.2.65 Temperature logs in a producing interval for formation fluids with different temperatures [42].

FIGURE 5.2.66 Temperature log showing water flow behind the casing. Water is flowing down to the producing interval [42].

The specific gravity reading is not exclusively dependent on fluid density. Since the fluids are also flowing while measurements are being made, other terms must be added:

$$\rho_{\text{gradiomanometer}} = \rho_f(1.0 + K + F) \quad (5.2.44)$$

where $\rho_{\text{gradiomanometer}}$ = specific gravity reading of the instrument, g/cc
 ρ_f = specific gravity of the fluid in the casing (oil + water + gas), g/cc
 K = a kinetic term
 F = a friction term from fluid flowing around the tool

At flow rates less than 2,000 bopd, F is negligible and $\rho_{\text{grad}} \approx \rho_f$ [42]. The kinetic term is important when logging from tubing into the casing. Fluid velocity changes become significant at the change in hole diameter. The change causes a sharp pressure increase on the log. The friction term is important at high flow rates in casing and when logging in small-diameter tubing or casing [42].

Another log similar to the gradiomanometer is the water-holdup meter. The main limitation is that it only reads water holdup and cannot be used if water is not present. It has the advantage over the gradiomanometer where sensitivity is required; small differences in density may not be seen by the gradiomanometer.

5.2.3.5.29 Flowmeters

Flowmeters are designed to measure fluid flow in the casing. This measurement is then related to volume of fluid being produced. Three types of flowmeters are available:

1. Fullbore-spinner flowmeter.
2. Continuous flowmeter.
3. Packer flowmeter.

Each is used in certain circumstances and is combinable with other devices so that improved flow rates can be obtained.

5.2.3.5.30 Fullbore-Spinner Flowmeter

This device measures velocities of fluid moving up the casing. These velocities are then related to volume of fluid moved with charts available from the various service companies. In general, this tool can be used at flow rates as low as 20 barrels per day in monophasic flow situations (usually water). Polyphase flow raises this minimum to 300 barrels per day if gas is present (i.e., oil and water) in $5\frac{1}{2}$ in. casing. This tool is used in wells with hole diameters ranging from $5\frac{1}{2}$ to $9\frac{5}{8}$ in.

5.2.3.5.31 Continuous Flowmeter

This tool is similar to the fullbore-spinner flowmeter except that it can be applied to hole diameters between $3\frac{1}{2}$ in. and $6\frac{5}{8}$ in. It has a higher flow threshold (in barrels per day) and should be restricted to use in monophasic flow situations (i.e., waterfloods, high-flow-rate gas wells, and

high-flow-rate oil wells) [42]. It can be combined with a spinner flowmeter for better flow measurements.

5.2.3.5.32 Packer Flowmeter

This is a small spinner-flowmeter with an inflatable packer that can be used in small-diameter tubing ($1\frac{1}{16}$ to $2\frac{1}{8}$ in.). It has an operable flow range from 10 to 1,900 barrels per day and can be applied in low-flow wells as long as measurements are made in the tubing at a sufficient distance above the perforations. Flow measurements are related to volume of fluid flowing the same way found with the other spinner flowmeters.

5.2.3.5.33 Radioactive Tracers

Radioactive tracers are combined with cased hole gamma-ray logs to monitor:

1. Fluid velocities in monophasic fluid flow situations where flow velocity is at or near the threshold for spinner flowmeters.
2. Fluid movement behind the casing or to locate channeling in the cement.

Fluid velocity is measured by velocity-shot analysis. A shot of radioactive fluid is injected into the flow stream above two detectors located on a stationary mammary tool. As the radioactive pulse moves down the hole, the amount of time required to move past the two detectors is measured. This travel time is then related to flow rate in the casing by:

$$q(B/D) = \frac{\text{spacing(in.)} \times \frac{1(\text{ft})}{12(\text{in.})} \times \frac{\pi}{4} (d_h - d_{\text{tool}})(\text{in.}^2) \times \frac{1(\text{ft.}^2)}{144(\text{in.}^2)} \times 256.5 \frac{B/D}{\text{ft}^3/\text{min}}}{\text{time(sec)} \times \frac{1(\text{min})}{60(\text{sec})}} \quad (5.2.45)$$

where q is flow rate in barrels per day, the spacing between detectors is in inches, the time between detector responses is in seconds, d_h is the hole diameter in in., and d_{tool} is the tool diameter in in.

The main limitation is that slippage and water-holdup factors seriously affect the time reading so this technique cannot be applied in production wells. Moreover, the production of radioactive material is not desirable; therefore, use is mainly restricted to water- or gas-injection wells [42].

Fluid movement behind the casing can be measured with a timed-run radio-active survey. A slug of radioactive fluid is introduced at the bottom of the tubing, and movement is then monitored by successive gamma-ray log runs. Unwanted flow up any channels in the cement can be easily determined and remedial action taken. Again, this technique is mainly applied to water injection wells to monitor flood operations and injection-fluid losses. Figure 5.2.67 is an example of this type of application.

5.2.4 Determination of Initial Oil & Gas in Place

5.2.4.1 Initial Oil in Place

For undersaturated crude, the reservoir contains only connate water and oil with their respective solution gas contents. The initial or original oil in place can be estimated from the volumetric equation:

$$N = \frac{7,758 V_b \phi (S_{oi})}{B_{oi}} = \frac{7,758 Ah \phi (1 - S_{wi})}{B_{oi}} \quad (5.2.46)$$

The constant 7,758 is the number of barrels in each acre-ft, V_b is bulk volume in acre-ft, ϕ is the porosity (ϕV_b is pore volume), S_{oi} is the initial oil saturation, B_{oi} is the initial oil formation volume factor in reservoir barrels per stock tank barrel, A is area in ft^2 , h is reservoir thickness in ft, and S_{wi} is the initial water saturation.

In addition to the uncertainty in determining the initial water saturation, the primary difficulty encountered in using the volumetric equation is assigning the appropriate porosity-feet, particularly in thick reservoirs with numerous non-productive intervals. One method is to prepare contour maps of porosity-feet that are then used to obtain areal extent. Another method is to prepare isopach maps of thickness and porosity from which average values of each can be obtained. Since recovery of the initial oil can only occur from permeable zones, a permeability cutoff is used to obtain the net reservoir thickness. Intervals with permeabilities lower than the cutoff value are assumed to be nonproductive. The absolute value of the cutoff will depend on the average or maximum permeability, and can depend on the relationship between permeability and water saturation. A correlation between porosity and permeability is often used to determine a porosity cutoff. In cases in which reservoir cores have been analyzed, the net pay can be obtained directly from the permeability data. When only logs are available, permeability will not be known; therefore a porosity cutoff is used to select net pay. These procedures can be acceptable when a definite relationship exists between porosity and permeability. However, in very heterogeneous reservoirs (such as some carbonates), estimates of initial oil in place can be in error. A technique [43] has been proposed in which actual pay was defined using all core samples above a specific permeability cutoff and apparent pay was defined using all core samples above a specific porosity cutoff; the relationship between these values was used to find a porosity cutoff.

5.2.4.2 Initial Gas In Place

For the foregoing case of an undersaturated oil (at the bubble point with no free gas), the gas in solution with the oil is:

FIGURE 5.2.67 Radioactive tracer survey in an injection well where water is flowing behind the casing into another zone [42].

$$G = \frac{7,758 Ah\phi(1 - S_{wi})R_s}{B_{oi}} \quad (5.2.47)$$

where G is the initial gas in solution in standard cubic feet (scf), R_s is gas solubility in the oil or solution gas-oil ratio (dimensionless), and the other terms are as defined in Equation 5.2.46.

5.2.4.3 Free Gas In Place

Free gas within a reservoir or a gas cap when no residual oil is present can be estimated:

$$G = \frac{7,758 V_g\phi(1 - S_{wi})}{B_{gi}} \quad (5.2.48)$$

where 7,758 is the number of barrels per acre-ft, V_g is the pore volume assigned to the gas-saturated portion of the

reservoir in acre-ft, B_{gi} is the initial gas formation volume factor in RB/scf, and the other terms are as already defined. (Note: If the formation volume factor is expressed in ft^3/scf , 7,758 should be replaced with $43,560 \text{ ft}^3/\text{acre-ft}$).

5.2.5 Productivity Index

The productivity index, J , is a measure of the ability of a well to produce hydrocarbon liquids:

$$J_o = \frac{q_o}{p_e - p_{wf}} \quad (5.2.49)$$

where q_o is the flow rate of oil in stock-tank barrels of oil per day, p_e is the external pressure in psi, p_{wf} is the flowing bottomhole pressure in psi, and the quantity $(p_e - p_{wf})$ is referred to as the pressure drawdown. Because the flow rate

in this case is in STB/D, the oil productivity index (J_o) has units of STB/D/psi. Since only q and p_{wf} can be measured directly, p_e is commonly replaced with \bar{p} which can be determined from pressure transient testing.

After the well has been shut in for a period of time (usually at least 24 to 72 hours or longer depending on reservoir characteristics), the well is put on production at a low rate with a small choke. The rate of production is recorded as a function of flow time. When the production rate has stabilized, the flow rate is increased by increasing the choke, and flow rate is monitored with time. This process is repeated until a series of measurements has been recorded [19].

In order to attain a stabilized productivity index, a minimum time is required after each individual flow-rate change. This time can be approximated by two equations [18,66]:

$$t_s \cong \frac{380\phi\mu c_t A}{k} \quad (5.2.50)$$

$$t_s \cong \frac{0.04\phi\mu c_t r_e^2}{k} \quad (5.2.51)$$

where t_s is the stabilization time in hours, k is the permeability in md, ϕ is the porosity as a fraction, μ is viscosity in cp, c_t is total compressibility in psi^{-1} , A is area in ft^2 , and r_e is the external radius in feet which should be based on the distance to the farthest drainage boundary for the well. For large systems or reservoirs with low permeability, very long stabilization times may be required.

Equation 5.2.49 assumes that productivity index does not change with flow rate of time, and in some wells the flow rate will remain proportional to the pressure drawdown over a wide range of flow rates. However, in many wells, the direct relationship is not linear at high flow rates as shown in Figure 5.2.68. The causes for the deviation in the straight-line behavior can include insufficient producing times at each rate, an increase in gas saturation near the wellbore caused by the pressure drop in that region, a decrease in permeability of oil due to the presence of gas, a reduction in permeability due to changes in formation compressibility, an increase in oil viscosity with pressure drop below the bubble point, and possible turbulence at high rates of flow.

A plot of oil production rate versus bottomhole pressure, termed the inflow performance relationship (IPR), was

FIGURE 5.2.68 Productivity index [18].

FIGURE 5.2.69 Vogel IPR curve [45].

proposed as a method of analysis of flowing and gas-lift wells [44]. Vogel [45] calculated dimensionless IPR curves for solution gas reservoirs that covered a wide range of oil PVT and relative permeability characteristics. From computer simulations, Vogel [45] showed that any solution gas drive reservoir operating below the bubble point could be represented as shown by Figure 5.2.69 or by the following relationship:

$$\frac{q_o}{(q_o)_{\max}} = 1 - 0.2 \frac{P_{wf}}{\bar{p}} - 0.8 \left(\frac{P_{wf}}{\bar{p}} \right)^2 \quad (5.2.52)$$

where q_o is the oil flow rate in STB/D occurring at bottomhole pressure p_{wf} , $(q_o)_{\max}$ is the maximum oil flow rate in STB/D, p_{wf} is the flowing bottomhole pressure, and \bar{p} is the average reservoir pressure. From the well pressure and average reservoir pressure, the ratio of producing rate to maximum oil rate can be obtained; then from the measured production rate, the maximum oil production can be calculated.

Vogel's method handles the problem of a single well test when the permeability near a wellbore is the same as the permeability throughout the reservoir. When a zone of

altered permeability exists near the wellbore, the degree of damage (or improvement) is expressed in terms of a "skin effect" or "skin factor." (Skin effect will be discussed in more detail later.) A modification to Vogel's IPR curves has been proposed by Standing [45] for situations when a skin effect is present (see Figure 5.2.70). In this figure, Standing has provided a series of IPR curves for flow efficiencies between 0.5 and 1.5, where flow efficiency (FE) is defined as:

$$FE = \frac{\bar{p} - p_{wf} - \Delta p_s}{\bar{p} - p_{wf}} \quad (5.2.53)$$

where \bar{p} is the average reservoir pressure, P_{wf} is the flowing bottomhole pressure, and Δp_s is the pressure drop in the skin region. Thus, the Vogel curve is for a flow efficiency of 1.0.

For reservoir systems operating below the bubble point when fluid properties and relative permeabilities vary with distance from the wellbore, Fetkovich [47] has proposed an empirical equation which combines single-phase and two-phase flow:

$$q_o = J'_o (p_b^2 - p_{wf}^2)^n + J_o (p_e - p_b) \quad (5.2.54)$$

FIGURE 5.2.70 Standing's modification to IPR curves [46].

where p_b is the bubble-point pressure in psia, \bar{p} may be substituted for p_e , J'_o is a form of productivity index and n is an exponent; both J'_o and n are determined from individual well multirate and pressure tests, or isochronal tests. For cases where the data required by the Fetkovich procedure are not available, a method for shifting the axes of the Vogel plot has been proposed [48]. In this latter method, only one set of production test data (rate and bottomhole flowing pressure) together with the shut-in bottomhole pressure (or average reservoir pressure) and bubble-point pressure are required to construct a reliable IPR.

5.3 PRESSURE TRANSIENT TESTING OF OIL AND GAS WELLS

Section reviewed by Heru Danardatu

Production rates depend on the effectiveness of the well completion (skin effect), the reservoir permeability, the reservoir pressure, and the drainage area. Pressure transient analysis is a powerful tool for determining the reservoir characteristics required to forecast production rates. Transient pressure data are generated by changing the producing rate and observing the change in pressure with time. The transient period should not exceed 10% of the previous flow or shut-in period. There are a number of methods to generate the transient data available to the reservoir engineer.

Single-well tests such as buildup, falloff, drawdown, injection, and variable-rate describe the isotropic reservoir adjacent to the test well while multiple well tests such as long term interference or short term pulse describe the characteristics between wells. Buildup and falloff tests are most popular because the zero flow rate is readily held constant. Drawdown and injection tests are run less frequently due to problems with maintaining a constant rate. Variable rate tests are useful when wellbore storage is a problem. Multiwell testing for characterizing anisotropic reservoirs has been popularized by the increased use of sophisticated simulation software.

5.3.1 Definitions and Concepts

Several excellent references on well test analyses are available [1.13, 1.66], and a good discussion of difficulties in interpretation of data is available in a recent text. From information in these references several definitions will be given, and the basic concepts of well test analysis will be summarized. More advanced concepts can be found in the foregoing references or in the extensive literature on this subject that has appeared in recent years.

5.3.1.1 Definitions

5.3.1.1.1 Transient Region

Flow regimes that occur at different flow times are shown in [Figure 5.3.1](#) for a well flowing at a constant rate. The flowing bottomhole pressure is shown as a function of time

FIGURE 5.3.1 Flow regimes [1, 13].

on both linear and semilog plots. In the transient region, the reservoir is infinite-acting, and the flowing bottomhole pressure is a linear function of $\log \Delta t$. This region is amenable to analysis by transient methods, and occurs for radial flow at flow times up to approximately $t = \phi \mu c r_e^2 / 0.00264k$, where field units are used: t is time in hours, ϕ is porosity as a fraction, μ is viscosity in cp, c is compressibility in psi^{-1} , r_e is the external radius in ft, and k is permeability in md [1.13].

5.3.1.1.2 Late-Transient Region

At the end of the transient region and prior to the semisteady-state period, there is a transitional period called the late-transient region (see Figure 5.3.1). There are no simple equations that define this region, but the late-transient period may be very small or practically nonexistent.

5.3.1.1.3 Semisteady-State Region

If there is no flow across the drainage boundary and compressibility is small and constant, a semisteady- or pseudosteady-state region is observed in which the pressure declines linearly with time (see Figure 5.3.1). Pressures in the drainage area decrease by the same amount in a given time, and the difference between reservoir pressure and wellbore pressure remains constant during this period. For

radial flow, semisteady-state flow conditions start at a flow time of about $t = \phi \mu c r_e^2 / 0.00088k$, in field units as already specified [13]. This region is suitable for reservoir limit tests in which reservoir size and distance to boundaries can be estimated. The most useful test to estimate reservoir limits is the drawdown test [2.18]; interpretation of reservoir limit tests can be difficult as discussed in the literature [2.18].

5.3.1.1.4 Steady-State Flow

At a constant flow rate for steady-state flow, the pressure at every point in the reservoir will remain constant with time. This condition is rarely encountered in most well test analyses; steady-state flow may be approached in reservoirs with strong water drives or in cases where reservoir pressure is maintained by gas injection or waterflooding.

5.3.1.1.5 Buildup Tests

Pressure buildup tests are conducted by (1) producing an oil or gas well at a constant rate for sufficient time to establish a stabilized pressure distribution, (2) ceasing production by shutting in the well, and (3) recording the resulting increase in pressure. In most cases, the well is shut in at the surface and the pressure is recorded downhole. In pumping wells, buildup tests can be made by: (1) pulling the rods and running a pressure bomb in the tubing, (2) by measuring pressure in the annulus from sonic measurements obtained with an echo-device, or (3) occasionally by using surface-indicating gauges. The pressure buildup curve is analyzed for wellbore conditions such as damage or stimulation and for reservoir properties such as formation permeability, pressure in the drainage area, reservoir limits or boundaries, and reservoir heterogeneities.

5.3.1.1.6 Drawdown Tests

Pressure drawdown tests are conducted by: (1) having an oil or gas well shut in for sufficient time to establish a stabilized pressure distribution, (2) putting the well on production at a constant rate, and (3) recording the resulting decrease in bottomhole pressure. An ideal time to run a drawdown test is when the well is initially put on production because in addition to obtaining information on wellbore conditions and formation permeability, estimates of reservoir volume can be made also. A long, constant flow rate is required.

5.3.1.1.7 Falloff Tests

Pressure falloff tests are conducted in injection wells and are analogous to the pressure buildup tests in producers. A falloff test consists of (1) injecting fluid at a constant rate, (2) shutting in the well, and (3) recording the decrease in pressure. As long as the mobility ratio between the injected fluid and in-situ fluids is near unity, the analysis of pressure transient tests in injection wells is relatively simple. The equations used in producing well tests are applicable with the exception that the flow is taken to be negative for injection whereas flow is positive for production.

5.3.1.1.8 Multiple-Rate Tests

The preceding tests apply to conditions in which the flow rate either has been or is constant. In some cases, maintaining a constant flow rate may not be possible or practical. In other cases, regulatory agencies may require that wells, especially gas wells, be tested at various flow rates. Multiple-rate tests may be conducted at variable flow rates or a series of constant rates, and are applicable to buildup or drawdown tests in producers or falloff tests in injectors. If accurate flow rate and pressure data are obtained, information on permeability, skin, and reservoir pressure can be deduced.

5.3.1.1.9 Interference Tests

In the prior tests, the pressure and flow rate applied to only one well at a time. With interference tests, two wells are involved. Interference tests are conducted by producing from or injecting into at least one well and observing the pressure response in at least one shut-in observation well. A change in rate (pressure) at the active producer or injector will cause a pressure interference at the observation well. A special form of multiple-rate testing is the pulse test in which the pressure caused by alternating periods of production (or injection) and shut-in periods is monitored at one or more observation wells. Multiple-rate tests are used to determine if wells are in communication with each

other in the same reservoir as well as to provide estimates of formation permeability and the product of porosity and total compressibility.

5.3.1.1.10 Miller-Dyes-Hutchinson (MDH) Plot

One of the most useful methods of pressure test analysis is that of Miller, Dyes, and Hutchinson [2]. The MDH method is a plot of bottomhole pressure versus log time on semilog paper. A schematic of an MDH plot for a pressure buildup test is depicted in Figure 5.3.2; the region is identified where MDH and Horner plots are applicable.

5.3.1.1.11 Horner Plot

In the Horner plot [3] bottomhole pressure is plotted against $\log(t + \Delta t)/\Delta t$. The Horner method should be applied only to infinite-acting reservoirs; for radial flow, the Horner plot will be a straight line. Several conditions such as boundaries or changes in fluids or fluid properties, can cause the Horner plot to deviate from a straight line (see Figures 5.3.3 and 5.3.4).

5.3.1.1.12 Skin Factor

The skin effect refers to a zone of altered formation permeability near a wellbore as a result of drilling, completion, or stimulation [4, 5]. The extent of altered permeability is expressed in terms of a skin factor, s , which is positive for damage and negative for improvement. Skin factor can

FIGURE 5.3.2 MDH plot [66].

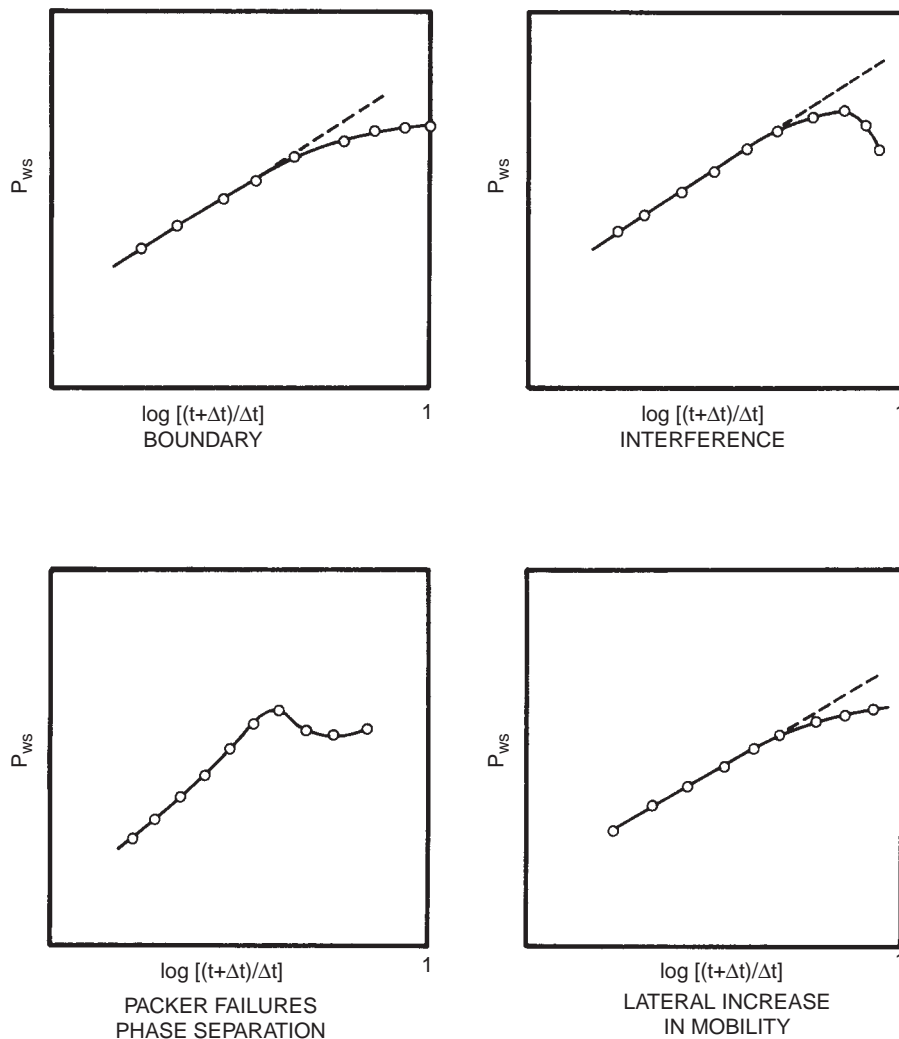

FIGURE 5.3.3 Downtrending Horner plots [1,13].

range from about -5 for a hydraulically fractured well to a theoretical limit of infinity for a severely damaged or plugged well. A schematic diagram of the pressure distribution near the wellbore of a damaged well is given in Figure 5.3.5. Effects of positive and negative skin are shown for the MDH plot in Figure 5.3.2.

5.3.1.1.13 Wellbore Storage

Wellbore storage, also referred to as after flow, wellbore loading or unloading, after production, and after injection, will affect short-time transient pressure behavior. This phenomenon has more of an effect on pressure buildup than drawdown tests, and can be especially important in low-permeability formations or in gas wells. During a buildup test, a well is closed in at the surface, but fluid may continue to flow into the wellbore for some time which causes a lag in the buildup at early times. Various levels of wellbore storage are shown in the MDH buildup plot in Figure 5.3.2. Storage

can obscure the transient period thus negating the value of a semi log plot.

5.3.1.2 Concepts

Most techniques used in the analysis of transient tests assume a single well operating at a constant flow rate in an infinite reservoir. At early times, a well transient is like a single well in an infinite reservoir, but at late times, effects of other wells aquifers, or reservoir boundaries can cause the pressure behavior to deviate from the infinite-acting assumption. Other common assumptions include: horizontal flow, negligible gravity effects, a single fluid of small and constant compressibility, a homogeneous and isotropic porous medium, the Darcy equation is obeyed, and several parameters (including porosity, permeability, viscosity, and compressibility) are independent of pressure.

Pressure transients arriving at the well following a rate change move through three regions on their way to the

FIGURE 5.3.4 Uptrending Horner plots [1, 13].

FIGURE 5.3.5 Skin region [1].

wellbore. Nearest the wellbore is the early-time region, ETR, where storage and skin effects dominate; next is the middle-time region, MTR, where the formation permeability is determined, and most distant is the late-time region, LTR, where drainage boundaries are sometimes observed (see Figure 5.3.6a for examples of a buildup test and Figure 5.3.6b for a drawdown test) [1]. As discussed earlier, the transient flow region (see Figure 5.3.1) is amenable to analysis by transient flow methods; this region consists of both the ETR and the MTR. The LTR can include the late-transient and the pseudosteady-state or semisteady-state

regions. The crux of the analysis involves selecting the proper data to analyze.

Middle-time data will plot as a straight line on semilogarithmic paper. The slope and the intercept of the MTR straight line are used to calculate reservoir permeability, skin factor, and average reservoir pressure. Semilogarithmic straight lines can occur in the ETR and the use of their slopes and intercepts results in unrealistic reservoir characteristics. Typically, improper use of injection well ETR data indicates a tight, fractured reservoir while use of producing well ETR data indicates damaged permeable rock when that is not at all the case.

Flow conditions in the pseudosteady-state LTR occur when transients reach the no-flow drainage boundary during producing-well transient-tests. Flow conditions in the steady-state LTR occur when transients reach the constant pressure boundary in secondary recovery operations. The slope of a Cartesian plot of an LTR drawdown can be useful in determining reservoir limits. Care should be taken to ensure that LTR data are not included in the MTR analysis.

The ETR region is dominated by skin and storage effects close to the wellbore. Storage effects occur when surface and sandface flow rates are unequal such as an injection well that goes on vacuum when shut in or a gas well where gas compresses in the tubing due to afterflow following surface shut in. Conventional pressure transient analysis is dependent on a constant sandface flow rate during the

FIGURE 5.3.6 Early-, middle-, and late-time regions [1].

test period and since zero is an easy constant flow rate to maintain, wellbore storage is a frequent problem. The length of the storage period is increased by skin damage since damage acts as an area of reduced permeability around the wellbore.

A logarithmic plot of the change in pressure, $p_i - p_{wf}$, versus the test time, dT , provides a practical means of determining the end of the ETR and the beginning of the MTR semilogarithmic straight line. A logarithmic plot with a unit-slope line (a line with 45° slope) indicates storage effects. The proper MTR semilogarithmic straight line begins at 50 times the end of the unit slope, that is, wellbore storage effects cease at about one and a half log cycles after the disappearance of the unit-slope line.

A logarithmic plot that exhibits a half-slope line (a line with a slope of 26.6°) indicates a fractured wellbore. The proper straight line begins at 10 times the end of the half-slope line if the fractures are unpropped. Pressure drop at the start of the straight line is twice that at the end of the unit-slope line. Injection wells, acid jobs, or naturally fractured reservoirs are typical examples of the uniform flux, unpropped fractures.

A well that has short, propped (infinite capacity) hydraulically induced fractures will exhibit the proper straight line at 100 times the end of the half-slope line. The pressure drop will be about 5 times that at the end of the half-slope line.

Hydraulically stimulated wells in tight formations (< 0.01 md) with long (finite conductivity) fractures never exhibit the proper straight line during a conventional transient test time period. As a practical matter, all production from tight gas wells occurs during the ETR. Type curves or computer simulation are required to successfully analyze this type of ETR data. The ETR can range to hundreds of years in tight gas wells with finite-conductivity fractures.

Use of the logarithmic data plot to determine the start of the semilogarithmic straight line of course means that the ETR data must be recorded. Pressure changes need to be monitored by the minute and bottomhole pressure at the time of shut-in must be precisely determined. Occasionally a great deal of emphasis is placed on the accuracy of the pressure-measuring equipment when the emphasis should be on the clock.

A problem in determining the initial pressure frequently arises when pressure buildup data from pumping wells are analyzed. A Cartesian plot of the early-time bottomhole pressure versus shut-in time should result in a straight line with the proper initial pressure at the intercept.

5.3.1.3 Important Pressure Transient Analysis Equations

$$\text{permeability, } k = 162.6 \frac{q\mu B}{mh}, \text{ md} \quad (5.3.1)$$

$$\text{radius of investigation, } r_i = \left[\frac{kt}{948\phi\mu C_t} \right]^{1/2}, \text{ ft} \quad (5.3.2)$$

skin factor (buildup),

$$s = 1.151 \left[\frac{p_{1hr} - p_{wf}}{m} - \log \left(\frac{k}{\phi\mu C_t r_w^2} \right) + 3.23 \right] \quad (5.3.3)$$

skin factor (drawdown),

$$s = 1.151 \left[\frac{p_i - p_{1hr}}{m} - \log \left(\frac{k}{\phi\mu C_t r_w^2} \right) + 3.23 \right] \quad (5.3.4)$$

$$\text{preressure drop due to skin, } (\Delta p)_s = 0.869 ms \quad (5.3.5)$$

average drainage area pressure,

$$\bar{p} = p_{wf} + \frac{141.2q\mu B \left(\ln \frac{r_e}{r_w} - \frac{3}{4} - s \right)}{kh} \quad (5.3.6)$$

average pressure (steady-state),

$$\bar{p} = p_{wf} + \frac{141.2q\mu B \left(\ln \frac{r_e}{r_w} - \frac{1}{2} - s \right)}{kh} \quad (5.3.7)$$

flow efficiency,

$$FE = \frac{\bar{p} - p_{wf} - \Delta p_s}{\bar{p} - p_{wf}} \quad (5.3.8)$$

For these equations, the following nomenclature is applicable:

Rate	q, B/D
Time	t, hr
formation volume factor	B, RB/STB
Viscosity	μ , cp
Thickness	h, ft
Porosity	ϕ , fraction

total compressibility	c_t , psi^{-1}
external drainage radius	r_e , ft
wellbore radius	r_w , ft
semilogarithmic MTR slope	m, psi/cycle
initial reservoir pressure	p_i , psi
flowing bottomhole pressure	p_{wf} , psi
shut-in bottomhole pressure	p_{ws} , psi
pressure drop across skin region	Δp_s , psi
MTR semilog intercept	p_{1hr} , psi

In the equation for skin factor during the pressure buildup, p_{ws} is measured just before shutting in the well, and p_{1hr} is obtained from the straight-line portion (extrapolated if necessary) of the buildup curve one hour after shut-in (see Figure 5.3.7a). Similarly, the straight-line portion of the

FIGURE 5.3.7 Extrapolation of MTR straight line [13].

drawdown data must be extrapolated to one hour if the data do not fall on the semilog straight-line (see Figure 5.3.7b).

5.3.1.4 Type-Curves

While at least one author [2.18] questions the uniqueness of pressure-transient type-curves and others [1.66,2.1] state that type-curves should only be used when conventional techniques cannot be used, curve-matching techniques have received more widespread use. In some cases where conventional analyses fail such as when wellbore storage distorts most or all of the data, type-curves may be the only means of interpretation of the pressure data. Type-curves developed by Ramey et al. [6–8] and McKinley [9, 10] for pressure buildup and constant-rate drawdown tests and by Gringarten [11] for vertically fractured wells are discussed in a recent monograph [1]. Type-curves are used to estimate formation permeability, damage, and stimulation of the tested well as well as to identify the portion of the data that should be analyzed by conventional techniques. Families of type-curves for various conditions are available from the SPE book order department in Dallas.

5.4 MECHANISMS & RECOVERY OF HYDROCARBONS BY NATURAL MEANS

Section reviewed by Heru Danardatu

5.4.1 Petroleum Reservoir Definitions [1.17]

Accumulations of oil and gas occur in underground traps that are formed by structural and/or stratigraphic features. A reservoir is the portion of the trap that contains the oil and/or gas in a hydraulically connected system. Many reservoirs are hydraulically connected to water-bearing rocks or aquifers that provide a source of natural energy to aid in hydrocarbon recovery. Oil and gas may be recovered by: fluid expansion, fluid displacement, gravitational drainage, and/or capillary expulsion. In the case of a reservoir with no aquifer (which is referred to as a volumetric reservoir), hydrocarbon recovery occurs primarily by fluid expansion, which, in the case of oil, may be aided by gravity drainage. If there is water influx or encroachment from the aquifer, recovery occurs mainly by the fluid displacement mechanism which may be aided by gravity drainage or capillary expulsion. In many instances, recovery of hydrocarbon occurs by more than one mechanism.

At initial conditions, hydrocarbon fluids in a reservoir may exist as a single phase or as two phases. The single phase may be a gas phase or a liquid phase in which all of the gas present is dissolved in the oil. When there are hydrocarbons vaporized in the gas phase which are recoverable as liquids at the surface, the reservoir is called gas-condensate, and the produced liquids are referred to as condensates or distillates. For two-phase accumulations, the vapor phase is termed the gas cap and the underlying liquid phase is called the oil zone. In the two-phase case, recovery of hydrocarbons includes the free gas in the gas cap, gas evolving from the oil (dissolved gas), recoverable liquid from the gas cap, and crude oil from the oil zone. If an aquifer or region of high water saturation is present, a transition zone can exist in which the water saturation can vary as a function of vertical depth and formation permeability. Water that exists in the oil- or gas-bearing portion of the reservoir above the transition zone is called connate or interstitial water. All of these factors are important in the evaluation of the hydrocarbon reserves and recovery efficiency.

5.4.2 Natural Gas Reservoirs [1.17]

For reservoirs where the fluid at all pressures in the reservoir or on the surface is a single gaseous phase, estimates of reserves and recoveries are relatively simple. However, many gas reservoirs produce some hydrocarbon liquid or condensate. In the latter case, recovery calculations for the single-phase case can be modified to include the condensate if the reservoir fluid remains in a single phase at all pressures encountered. However, if the hydrocarbon liquid phase develops in the reservoir, additional methods are necessary to handle these retrograde, gas-condensate reservoirs.

5.4.3 Primary Recovery of Crude Oil

Initial crude oil production often takes place by the expansion of fluids which were trapped under pressure in the rock. The expanding fluids may be gas evolving from the oil, an expanding gas cap, a bottom- or edge-water drive, or a combination of these mechanisms. After the initial pressure in the reservoir falls to a low value, the oil no longer flows to the wellbore, and pumps are installed to lift the crude oil to the surface. This mode of oil production is referred to as primary production. Recovery of oil associated with natural reservoir energy varies with producing mechanisms that are broadly classified as: solution-gas or depletion drive, gas cap drive, natural water drive, gravity drainage, and

compaction drive. In some reservoirs, production can be attributed mainly to one of the mechanisms; in other cases, production may result from more than one mechanism, and this is referred to as a combination drive.

5.4.3.1 Statistical Analysis of Primary Oil Recovery

Most of the producing mechanisms are sensitive to the rate of oil production; only the solution gas drive mechanism is truly rate-insensitive [2.1]. Primary recoveries are usually reported [2.1] to be less than 25% of the original oil in place by solution gas drive, 30% to 50% of OOIP for water drive, and can exceed 75% of OOIP for gravity drainage in thick reservoirs with high vertical permeabilities. For water drive reservoirs, primary recovery efficiency can be low if the initial water saturation is more than 50%, if permeability is low, or if the reservoir is oil-wet [2.1]. From a recent statistical analysis [1], primary recovery from carbonate reservoirs tends to be lower than for sandstones (see Table 5.4.1 for recoveries by different drive mechanisms). Since primary recoveries tend to be lower for solution gas drive, these reservoirs are usually better candidates for waterflooding and will represent the bulk of the prospective candidates for enhanced oil recovery.

In the United States, much of the primary production involves solution gas reservoirs. Thus, this mechanism will

TABLE 5.4.1 Primary Recovery Efficiencies

be emphasized in this chapter, but non-U.S. production may involve other mechanisms. The differences in recovery mechanisms are important if an engineer is to avoid misapplication of methods; this subject has been addressed in Reference 2.18.

5.4.3.2 Empirical Estimates of Primary Oil Recovery

Several attempts have been made to correlate primary oil recovery with reservoir parameters [1-4]. Based on field data [3] from water-drive reservoirs, a statistical study [4] yielded the following empirical relationship for primary oil recovery:

$$N_p = (0.2719 \log k + 0.25569 S_w + 0.1355 \log \mu_o) \quad (5.4.1)$$

$$- 15,380\phi - 0.00035 h + 0.11403) \quad (5.4.2)$$

$$\times \left[7,758 Ah\phi \frac{(1 - S_w)}{B_{oi}} \right] \quad (5.4.3)$$

where N_p is oil production in STB, k is permeability in md, S_w is fractional water saturation, μ_o is oil viscosity in cp, ϕ is fractional porosity, h is pay thickness in ft, A is a real extent in ft^2 , and B_{oi} is the initial formation volume factor of oil in reservoir barrels per STB. Based on the first API study [2], correlations were developed for recoverable oil.

For solution gas drive reservoirs, the recoverable oil (RO) in stock tank barrels per net acre-ft was:

$$RO = 3,244 \left[\frac{\phi(1 - S_w)}{B_{ob}} \right]^{1.1611} \left[\frac{k}{\mu_{ob}} \right]^{0.0979} \times [S_w]^{0.3722} \left[\frac{p_b}{p_a} \right]^{0.174} \quad (5.4.4)$$

For water drive reservoirs, the correlation was:

$$RO = 4,259 \left[\frac{\phi(1 - S_w)}{B_{oi}} \right]^{1.0422} \left[\frac{k\mu_{wi}}{\mu_{oi}} \right]^{0.0770} \quad (5.4.5)$$

$$\times [S_w]^{-0.1903} \left[\frac{p_i}{p_a} \right]^{-0.2159} \quad (5.4.6)$$

In the second API study [1], analysis of 116 solution gas drive reservoirs gave the following equation:

$$RO = 6,533 \left[\frac{\phi(1 - S_w)}{B_{ob}} \right]^{1.312} \left[\frac{k}{\mu_{ob}} \right]^{0.0816} \quad (5.4.7)$$

$$\times [S_w]^{0.463} \left[\frac{p_b - p_a}{p_b} \right]^{0.249} \quad (5.4.8)$$

However, the second study concluded that none of the equations developed in either study was statistically appropriate to provide a valid correlation. Furthermore, no statistically valid correlation was found between oil recovery and definable reservoir parameters. The second study found that

FIGURE 5.4.1 Correlation of primary oil recovery for water-drive reservoirs [1].

when reservoirs were separated by lithology, geographical province, and producing mechanism, the only reasonable correlations that could be developed were between recoverable oil and original oil in place. Even then, the correlations were of poor quality as indicated by Figure 5.4.1 which presents the best correlation for Texas sandstone natural-water-drive reservoirs. The average primary recovery for various groups of reservoirs at the average value of OOIP for each group is listed by production mechanism in Table 5.4.1 [1,5].

In view of the lack of suitable correlations, primary oil recovery for an individual reservoir must be estimated by one of three methods: (1) material balance equations in conjunction with equations for gas-oil ratio and fluid saturations, (2) volumetric equations if residual oil saturation and oil formation volume factor at abandonment are known or estimated, and (3) decline curve analysis, if production history is available. Each of these methods for estimating primary oil recovery and gas recovery, when appropriate, will be discussed in the following sections.

5.4.4 Primary Recovery Factors in Solution-Gas-Drive Reservoirs

Primary recovery from solution-gas-drive reservoirs depends on: type of geologic structure, reservoir pressure, gas solubility, fluid gravity, fluid viscosity, relative permeabilities, presence of connate water, rate of withdrawal, and pressure drawdown. From a statistical study [6,7] the primary recovery factors in Table 5.4.2 were obtained for different oil gravities and solution gas-oil ratios in sands sandstones, limestones, dolomite, and chert. Based on work of the same type in 135 reservoir systems, Wahl [8] presented a series of figures that can be used to estimate primary recovery. One of these figures, for a condition of a 2 cp reservoir oil and a 30% connate water saturation, is reproduced in Figure 5.4.2. To use these figures the following is required: oil viscosity at reservoir conditions, interstitial water saturation, bubble-point pressure, solution gas-oil ratio at the bubble-point pressure, and formation volume factor.

TABLE 5.4.2 Primary Recovery in Percent of Oil in Place for Depletion-Type Reservoirs

Oil solution GOR ft ³ /bbl	Sand or sandstones			Limestone, Dolomite or Chert

5.5 MATERIAL BALANCE AND VOLUMETRIC ANALYSIS

Section reviewed by Heru Danardatu

Methods of estimating hydrocarbons in place by volumetric methods were discussed. These estimates can be confirmed and future reservoir performance can be predicted with the use of material balance equations. In the most elementary form the material balance equation states that the initial

volume in place equals the sum of the volume remaining and the volume produced [1.19]. Material balance equations [1.19] will be given for different reservoir situations. Nomenclature used in these equations is listed below [1.19, 2.18, 1].

B_o = oil formation volume factor = volume at reservoir conditions per volume at stock-tank conditions, dimensionless (reservoir barrel per stock-tank barrel, RB/STB)

B_g = gas formation volume factor = volume at reservoir conditions per volume at standard conditions, RB/scf (Note: if the gas formation volume factor is expressed in cu ft/scf, divided by 5.615 or multiply by 0.1781 to get RB/scf)

B_w = factor = volume at reservoir conditions per volume at standard conditions, dimensionless (RB/STB)

$B_t = B_o + (R_{si} - R_s)B_g$ = composite oil or total oil formation volume factor = volume at reservoir conditions per volume at standard conditions

c_f = formation (rock) compressibility = pore volume per pore volume per psi

c_w = water compressibility = pore-volume per pore-volume per psi

G = total initial gas in place in reservoir, scf

G_e = cumulative gas influx (encroachment), scf

ΔG_e = gas influx (encroachment) during an interval, scf

G_i = cumulative gas injected, scf

G_p = cumulative gas produced, scf

k_{rg} = relative permeability to gas, dimensionless

k_{ro} = relative permeability to oil, dimensionless

$m = GB_{gi}/NB_{oi}$ = ratio of initial gas-cap/gas-reservoir volume to initial reservoir oil volume

N = initial oil in place, STB

N_p = cumulative oil produced, STB

ΔN_p = oil produced during an interval, STB

p = reservoir pressure, psia

p_i = initial reservoir, pressure, psia

p_r = reduced pressure, dimensionless

R_s = solution-gas-oil ratio (gas solubility in oil), scf/STB

R_{si} = initial solution-gas-oil ratio, scf/STB

R_{sw} = gas solubility in water, scf/bbl at standard conditions

R_p = cumulative gas-oil ratio, scf/STB

S_o = oil saturation, fraction of pore space

S_g = gas saturation, fraction of pore space

S_{iw} = irreducible or connate water saturation, fraction of pore space

S_w = water saturation, fraction of pore space

S_{wi} = initial water saturation, fraction of pore space

W = initial water in place, reservoir bbl

W_e = cumulative water influx, bbl at standard conditions

W_p = cumulative water produced, bbl at standard conditions

W_i = cumulative water injected, bbl at standard conditions

μ_g = gas viscosity, cp

μ_o = oil viscosity, cp

z = gas deviation factor (compressibility factor), $z = pV/nRT$, dimensionless

i = subscript, initial or original conditions

1 = subscript for conditions at p_1

2 = subscript for conditions at p_2

5.5.1 Material Balance for Gas Reservoirs

5.5.1.1 Material Balance Equations

Reservoirs that contain only free gas are called gas reservoirs. These reservoirs contain a mixture of gaseous hydrocarbons, which may be dry, wet, or condensate gas. Gas reservoirs may be volumetric with no water influx. For such reservoirs, the material balance is:

$$GB_{gi} = (G - G_p)B_g \quad (5.5.1)$$

where all terms have been defined earlier in the notation. In the case of a gas reservoir with water encroachment and water production, the material balance equation is:

$$GB_{gi} = (G - G_p)B_g + (W_e - W_p) \quad (5.5.2)$$

In either equation, the gas formation volume factor can be obtained, as a function of pressure and temperature, as outlined earlier. A schematic representation [2.18] of the material balance equations for dry-gas reservoirs is depicted in Figure 5.5.1.

5.5.1.2 Graphical Form of Material Balance (p/z Plots)

For volumetric gas reservoirs in which there is no water influx and negligible water production, the definition of gas formation volume factor (Equation 5.1.3) can be substituted into Equation 5.5.1, and the resulting equation can be rearranged to give [2.18]:

$$G_p = G - \frac{p}{z} \frac{Gz_i}{p_i} \quad (5.5.3)$$

where all terms are as defined previously and the subscript i refers to initial conditions. This equation indicates that for a volumetric gas reservoir a plot of cumulative gas production (G_p) in standard cubic feet versus the ratio p/z is a straight line. Within limits of error for average reservoir pressure and cumulative production, this plot is linear as shown in Figure 5.5.2. The straight line can be extrapolated to zero pressure to find the initial gas in place, or can be extrapolated to predict the cumulative production at any future average reservoir pressure. A plot of pressure versus cumulative production is not a straight line because the produced gas is not a perfect gas. Since the gas deviation factor, z , is a function of pressure, the ratio of p/z can be obtained conveniently from plots of p/z versus p , p_r/z versus z for different reduced temperature, or from computer programs that have gas deviation factors in storage [2.18]. Other graphical interpretations have been suggested [2].

A plot of p/z versus G_p may not be a straight line for several reasons: an unexpected water drive may exist, average reservoir pressure may be inaccurate, or the reservoir pore volume may be changing unpredictably as a result of abnormally high reservoir pressures [2.18]. A water drive reduces relative permeability to gas and increases pressure at abandonment [2.1]. For reservoirs at moderate to high pressure in the absence of a water drive, the recovery efficiency under pressure depletion may range from about 80% to more than 90%; a water drive can reduce recovery to about 60%. To maximize efficiency, water-bearing zones should not be perforated if the water is movable, and production should be at a high rate since water entry is time dependent [2.1].

5.5.2 Material Balance Equations in Oil or Combination Reservoirs

When discovered, a reservoir may contain oil, gas and water that can be intermingled or segregated into zones. As

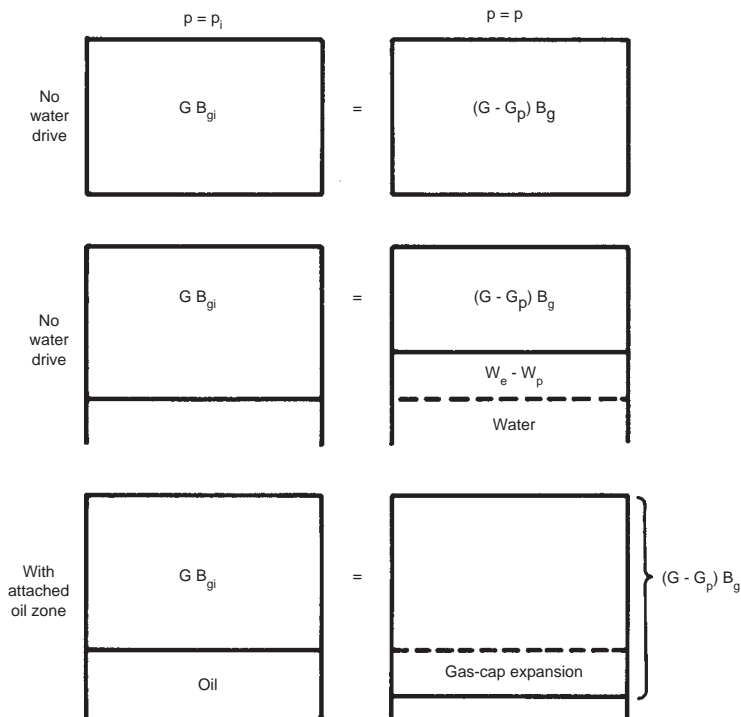

FIGURE 5.5.1 Schematic of material balance equations for a dry-gas reservoir [2.18].

FIGURE 5.5.2 A p/z plot [1.17].

described earlier, recovery may be caused by solution gas drive, water drive, gas cap drive, or a combination of these mechanisms. A general material balance equation should be capable of handling any type of fluid distribution and any drive mechanism.

From the compressibilities given in the first section, water and formation compressibilities are less significant where there is appreciable gas saturation such as in gas reservoirs, gas cap reservoirs, and in undersaturated reservoirs below the bubble point. Because of this and because of

the complications they would introduce in already complex equations, water and formation compressibilities are generally neglected, except in undersaturated reservoirs producing above the bubble point. Gas in solution in the formation is small and also generally neglected. One general material balance equation, the Schilthuis equation, is a volumetric balance stating that the sum of the volume changes in oil, gas, and water must be zero because the reservoir volume is constant.

$$\begin{aligned}
 & \text{oil zone} \quad \text{gas cap} \quad \text{water} \quad \text{cumulative oil} \\
 & [\text{expansion}] + [\text{expansion}] + [\text{influx}] = [\text{zone production}] \\
 & N(B_t - B_{ti}) + \frac{NmB_{ti}(B_g - B_{gi})}{B_{gi}} + W_e = N_p B_t \\
 & + \left[\begin{array}{c} \text{cumulative gas cap} \\ \text{gas production} \end{array} \right] + \left[\begin{array}{c} \text{cumulative water} \\ \text{production} \end{array} \right] \\
 & + N_p(R_p - R_{si})B_g + B_w W_p \quad (5.5.4)
 \end{aligned}$$

All symbols have been defined earlier. Rearranging terms, Equation 5.5.4 can be written:

$$\begin{aligned}
 & N \left[B_t - B_{ti} + \frac{mB_{ti}(B_g - B_{gi})}{B_{gi}} \right] \\
 & = N_p[B_t + (R_p - R_{si})B_g] - W_e + B_w W_p \quad (5.5.5)
 \end{aligned}$$

Material balance equations are often expressed in terms of the initial oil in place, N :

$$N = \frac{N_p[B_t + (R_p - R_{si})B_g] - (W_e - B_w W_p)}{B_t - B_{ti} + \frac{mB_{ti}}{B_{gi}}(B_g - B_{gi})} \quad (5.5.6)$$

This equation applies to a reservoir under any drive mechanism or to fields under the simultaneous influence of dissolved gas drive, water drive, or gas cap drive.

If there is no water drive, $W_e = 0$; therefore:

$$N = \frac{N_p[B_t + (R_p - R_{si})B_g] + B_w W_p}{B_t - B_{ti} + \frac{mB_{ti}}{B_{gi}}(B_g - B_{gi})} \quad (5.5.7)$$

When there is no original free gas, $m = 0$; therefore:

$$N = \frac{N_p[B_t + (R_p - R_{si})B_g] - (W_e - B_w W_p)}{B_t - B_{ti}} \quad (5.5.8)$$

When there is neither an original gas cap nor any water drive, $m = 0$ and $W_p = 0$; therefore:

$$N = \frac{N_p[B_t + (R_p - R_{si})]B_g}{B_t - B_{ti}} \quad (5.5.9)$$

Although connate water and formation compressibilities are quite small, relative to the compressibility of reservoir fluids above their bubble points they are significant and account for an appreciable fraction of the production above

the bubble point. In cases when compressibilities can be important, Equation 5.5.6 can be written as:

$$N = \frac{N_p[B_t + (R_p - R_{si})B_g] - (W_e - B_w W_p)}{B_t - B_{ti} + (c_f + c_w S_{iw})\Delta p B_{ti}/(1 - S_{iw}) + mB_{ti}(B_g - B_{gi})/B_{gi}} \quad (5.5.10)$$

Material balance equations for various drive mechanisms and different initial conditions are summarized in Table 5.5.1. Note that in this table B_g is expressed in ft^3/scf , and the conversion factor, 0.1781, is the reciprocal of 5.615 ft^3 per barrel.

5.5.3 Generalized Material Balance Equation

Many forms of the so-called general material balance equation have appeared in the literature. In the most general form, the material balance equation, expressed in terms of the initial oil in place, is:

$$N = \frac{N_p B_o + B_g(G_p - N_p R_s) - G(B_g - B_{gi}) - (W_e - W_p)}{B_o - B_{oi} + (R_{si} - R_s)B_g + (c_f + c_w S_{iw})\Delta p B_{oi}/(1 - S_{iw})} \quad (5.5.11)$$

This equation can be obtained by substituting in Equation 5.5.10 the following terms:

$$B_i = B_o + (R_{si} - R_s)B_g; \quad B_{ti} = B_{oi}; \quad \text{and} \quad G_p = N_p R_p.$$

A schematic representation [1.19] of the possible changes in fluid distribution is presented in Figure 5.5.3. In order to not omit any of the significant reservoir energies, Slider [2.18] suggests beginning all material balance applications with Equation 5.5.11. With the use of Equation 5.5.11, it is not necessary to list separate equations for the various drive mechanisms and conditions since this one equation can be reduced to any of the individual cases. For reservoirs above the bubble point, some of the terms in Equation 5.5.11 become zero or else cancel out: $G = 0$ since there is no free gas, G_p , and $N_p R_s$ cancel out since the gas production term is equal to the total gas produced, $R_{si} - R_s$ is zero since the gas in solution at any pressure is equal to the gas originally in solution.

For a reservoir with no initial free gas saturation or no initial gas cap, $G = 0$. If there is no water encroachment, $W_e = 0$; however, the water production term should remain, even if there is no water drive, because connate water may be produced when the reservoir pressure declines.

When a reservoir contains free gas, the pore volume expansion or compressibilities of the formation and water are insignificant compared to the free gas terms. Since the gas compressibility is about 100 times the compressibility of the water and formation, a gas saturation of only 1% may provide as much energy as the water and formation compressibility terms. Thus, when the gas saturation is substantial the change in pore volume is insignificant.

TABLE 5.5.1 Material Balance Equations

Gas reservoir with active water drive

$$G = \frac{C_p B_g - 5.615(W_e - W_p)}{B_g - B_{gi}}$$

Gas reservoir; no active water drive ($W_e = 0$)

$$G = \frac{C_p B_g + 5.615 W_p}{B_g - B_{gi}}$$

Oil reservoir with gas cap and active water drive

$$N = \frac{N_p [B_t + 0.1781 B_g (R_p - R_{si})] - (W_e - W_p)}{m B_{oi} \left(\frac{B_g}{B_{gi}} - 1 \right) + (B_t - B_{oi})}$$

Oil reservoir with gas cap; no active water drive ($W_e = 0$)

$$N = \frac{N_p [B_t + 0.1781 B_g (R_p - R_{si})] + W_p}{m B_{oi} \left(\frac{B_g}{B_{gi}} - 1 \right) + (B_t - B_{oi})}$$

Initially undersaturated oil reservoir with active water drive ($m = 0$)

1. Above bubble point

$$N = \frac{\left[N_p (1 + \Delta p c_o) - \frac{W_e - W_p}{B_{oi}} \right] (1 - S_w)}{\Delta p [c_o + c_t - S_w (c_o - c_w)]}$$

2. Below bubble point

$$N = \frac{N_p [B_t + 0.1781 B_g (R_p - R_{si})] - (W_e - W_p)}{B_t - B_{oi}}$$

Initially undersaturated oil reservoir; no active water drive

($m = 0, W_e = 0$)

1. Above bubble point

$$N = \frac{\left[N_p (1 + \Delta p c_o) - \frac{W_p}{B_{oi}} \right] (1 - S_w)}{\Delta p [c_o + c_t - S_w (c_o - c_w)]}$$

2. Below bubble point

$$N = \frac{N_p [B_t + 0.1781 B_g (R_p - R_{si})] + W_p}{B_t - B_{oi}}$$

From Reference 2.1.

Note: In this table, B_g is expressed in ft^3/SCF .

FIGURE 5.5.3 Schematic representation of fluid distributions [1.19].

5.5.4 Material Balance for Solution-Gas Drive Reservoirs

A schematic representation of material balance equations for solution-gas reservoirs, when the change in pore volume is negligible, is shown in Figure 5.5.4. When these reservoirs are producing above the bubble point or saturation pressure, no gas is liberated and production occurs by expansion of liquids in the reservoir. When reservoir pressure drops below the bubble point, gas is liberated in the reservoir and will be produced with the oil.

5.5.4.1 Liquid Expansion

For some very large reservoirs (often with limited permeability), production may occur for extended periods by expansion of liquids in the reservoir. If production is caused only by liquid expansion, the material balance equation obtained from Figure 5.5.4 for pressures above the bubble point is:

$$N = \frac{(N - N_p) B_o}{B_{oi}} \tag{5.5.12}$$

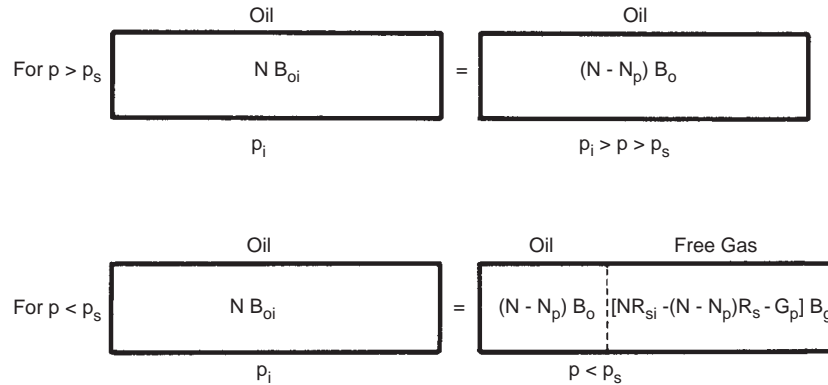

FIGURE 5.5.4 Schematic of material balance equations for a solution-gas drive reservoir [2.18].

5.5.4.2 Gas Liberation

When reservoir pressure declines below the bubble-point pressure, the original gas in solution has either been produced as G_p , is still in solution in the oil, $(N - N_p)R_s$, or exists as free gas. For this condition as shown in Figure 5.5.4, the material balance is:

$$N = \frac{N_p B_o + B_g (G_p - N_p R_s)}{B_o - B_{oi} + (R_{si} - R_s) B_g} \quad (5.5.13)$$

5.5.5 Predicting Primary Recovery in Solution-Gas Drive Reservoirs

Several methods for predicting performance of solution-gas behavior have appeared in the literature. These methods relate pressure decline to gas-oil ratio and oil recovery. Because neither water influx nor gravity segregation is considered, time is not a factor with solution-gas reservoirs, and time must be inferred from the oil in place and production rate [1.17]. The following assumptions are generally made: uniformity of the reservoir at all times regarding porosity, fluid saturations, and relative permeabilities; uniform pressure throughout the reservoir in both the gas and oil zones (which means the gas and oil volume factors, the gas and oil viscosities, and the solution gas will be the same throughout the reservoir); negligible gravity segregation forces; equilibrium at all times between the gas and the oil phases; a gas liberation mechanism which is the same as that used to determine the fluid properties, and no water encroachment and negligible water production.

5.5.5.1 The Schilthuis Method [3]

For solution-gas drive reservoirs where the reservoir pressure is about equal to the saturation pressure and for gas cap drive reservoirs, Equation 5.5.11 can be written [2.18]:

$$N = \frac{N_p B_o + (G_p - N_p R_s) B_g - G (B_g - B_{gi})}{B_o - B_{oi} + (R_{si} - R_s) B_g} \quad (5.5.14)$$

If this equation is rearranged and solved for cumulative oil produced:

$$N_p = \frac{N [B_o - B_{oi} + (R_{si} - R_s) B_g] + G (B_g - B_{gi}) - B_g G_p}{B_o - B_g R_s} \quad (5.5.15)$$

In order to predict the cumulative oil production at any stage of depletion, the original oil and gas in place and the initial reservoir pressure must be known. The original pressure establishes values for B_{oi} , B_{gi} , and R_{si} , and the pressure at the given level of depletion establishes values of B_o , B_g , and R_s . Cumulative gas production can be obtained from:

$$G_p = \sum R_s \Delta N_p \quad (5.5.16)$$

A procedure for using this method is [2.18]:

1. At a set value of reservoir pressure, assume the cumulative amount of gas produced, G_p .
2. Calculate N_p by Equation 5.5.15.
3. Calculate S_o using Equation 5.5.31.
4. Determine the relative permeability ratio based on the liquid saturation from data such as that in Figure 5.1.55.
5. Calculate G_p using Equations 5.5.16 and 5.5.17.
6. Compare the calculated G_p with the assumed G_p from Step 1.
7. If the assumed and calculated values do not agree to a satisfactory degree, repeat the calculations from Step 1 for another value of G_p .
8. If the assumed and calculated G_p values agree, return to Step 1 and set a new pressure.

5.5.5.2 The Tarnier Method

This [4] is a trial-and-error procedure based on the simultaneous solution of the material balance equation and the instantaneous gas-oil ratio equation. For a pressure drop from p_1 to p_2 , the procedure involves a stepwise calculation of cumulative oil produced $(N_p)_2$ and of cumulative gas produced $(G_p)_2$. Several variations in the procedure and equations are possible; the straightforward procedure outlined by Timmerman [2.1] is reproduced here.

1. During the pressure drop from p_1 to p_2 , assume that the cumulative oil production increases from $(N_p)_1$ to $(N_p)_2$. At the bubble point pressure, N_p should be set equal to zero.
2. By means of the material-balance equation for $W_p = 0$, compute the cumulative gas produced $(G_p)_2$ at pressure p_2 :

$$(G_p)_2 = (N_p)_2(R_p)_2 = N \left[(R_{si} - R_s) - \frac{B_{oi} - B_o}{B_g} \right] - (N_p)_2 \left(\frac{B_o}{B_g} - R_s \right) \quad (5.5.17)$$

3. Compute the fractional total liquid saturation $(S_L)_2$ at pressure p_2 :

$$(S_L)_2 = S_w + (1 - S_w) \frac{B_o}{B_{oi}} \left[1 - \frac{(N_p)_2}{N} \right] \quad (5.5.18)$$

4. Determine the k_{rg}/k_{ro} ratio corresponding to the total liquid saturation $(S_L)_2$ and compute the instantaneous gas-oil ratio at p_2 :

$$R_2 = R_s + \frac{B_o}{B_g} \frac{\mu_o}{\mu_g} \frac{k_{rg}}{k_{ro}} \quad (5.5.19)$$

5. Compute the cumulative gas produced at pressure p_2 :

$$(G_p)_2 = (G_p)_1 + \frac{R_1 + R_2}{2} [(N_p)_2 - (N_p)_1] \quad (5.5.20)$$

where R_1 is the instantaneous gas-oil ratio computed at pressure p_1 .

Usually three judicious guesses are made for the value $(N_p)_2$ and the corresponding values of $(G_p)_2$ computed by both step 2 and step 5. When the values for $(G_p)_2$ are plotted against the assumed values for $(N_p)_2$, the intersection of the curve indicates the cumulative gas and oil production that will satisfy both equations. In actual application the method is usually simplified further by equating the incremental gas production $(G_p)_2 - (G_p)_1$ rather than $(G_p)_2$ itself. This equality signifies that at each pressure step the cumulative gas, as determined by the volumetric balance is the same as the quantity of gas produced from the reservoir, as controlled by the relative permeability ratio of the rock, which in turn depends on the total liquid saturation.

5.5.5.3 The Muskat Method

The Schilthuis and Tarnier forms of material balance have been expressed in integral form. An approach presented by Muskat [5] expresses the material balance in terms of finite pressure differences in small increments. The changes in variables that affect production are evaluated at any stage of depletion or pressure. The assumption is made that values of the variables will hold for a small drop in pressure, and the incremental recovery can be calculated for the small pressure drop. The variables are recalculated at the lower pressure, and the process is continued to any desired abandonment pressure. If the PVT data and the gas-oil relative permeabilities are known at any liquid saturation, the unit recovery by pressure depletion can be computed from a differential form of the material balance equation:

$$\frac{dS_o}{dp} = \frac{\frac{S_o B_g}{B_o} \frac{dR_s}{dp} + \frac{S_o k_{rg} \mu_o}{B_o k_{ro} \mu_g} \frac{dB_o}{dp} + (1 - S_o - S_w) B_g \frac{d(1/B_g)}{dp}}{1 + \frac{k_{rg} \mu_o}{k_{ro} \mu_g}} \quad (5.5.21)$$

From the change in saturation at any pressure, the reservoir saturation at that time can be related to the change in oil production and the instantaneous gas-oil ratio. Calculations can be facilitated if the terms in the numerator that are functions of pressure only (B_g , B_o , B_s) are determined for various depletion pressures. Pressure increments of 10 psi or less may be necessary for acceptable accuracy [2.1].

5.5.6 Predicting Primary Recovery in Water-Drive Reservoirs

In the prediction of performance caused by water influx, predictions of water encroachment are made independent of material balance. The extent of water encroachment depends on the characteristics of the aquifer and is a function of the pressure history and time [6]. While several methods are available to predict water drive performance, some [2.18] feel that the theory of unsteady-state compressible flow should be used, and that water encroachment generally follows the constant pressure solution to the radial diffusivity equation. Solutions to the radial diffusivity equation have been provided by van Everdingen and Hurst [7] in terms of dimensionless time, t_D , and a dimensionless fluid flow function, Q_{tD} , which is determined at t_D :

$$t_D = \frac{6.323 \times 10^{-3} kt}{\phi \mu c r^2} \quad (5.5.22)$$

where k is permeability in md, t is time in days, ϕ is the fractional porosity, c is the compressibility in psi^{-1} , and r is the reservoir radius in ft. Values of Q_{tD} are given in tabular form as a function of t_D in the paper by van Everdingen and Hurst [7] and have been reproduced in several texts [1.17, 2.18]. Because of the length of the tables, they will not be reproduced in this section. The water encroachment, W_e in barrels, can be estimated from:

$$W_e = B\Sigma(dp)(Q_{tD}) \quad (5.5.23)$$

where dp is the pressure drop in psi, and the constant B is:

$$B = 1.12\phi hcr^2 \frac{\theta}{360} \quad (5.5.24)$$

where h is the reservoir thickness in ft, θ is the angle subtended by the reservoir circumference (θ is 360° for a circular reservoir and θ is 180° for a semicircular reservoir against a fault), and the other terms are as defined above [1.17]. From the slope of cumulative water influx at various times versus the summation term at those times, the aquifer constant, B , can be obtained, and the cumulative water influx for any pressure history can be estimated from Equation 5.5.23. Plots of Q_{tD} versus t_D for various dimensionless reservoir sizes are also available [1.17,7] and extensions of these data are available as well [2.18].

5.5.7 Volumetric Calculations for Recovery of Gas and Oil

The volumetric equations for original oil and gas in place were given earlier. In this section, volumetric equations will be given for the recovery of gas and oil reservoirs under several common instances.

5.5.7.1 Recovery of Gas

The volume of gas recovered, G_p in scf, from a dry-gas reservoir is:

$$G_p = 7,758 Ah\phi(1 - S_w) \left(\frac{1}{B_{gi}} - \frac{1}{B_g} \right) \quad (5.5.25)$$

where 7,758 is the number of barrels per acre-ft, A is the areal extent in acres, h is the reservoir thickness in ft, ϕ is the fractional porosity, S_w is the fractional water saturation, B_{gi} is the initial gas formation volume factor in reservoir barrels per scf, and B_g is the gas formation volume factor in RB/scf at the abandonment pressure. (Note: if the formation volume factors are expressed in ft^3/scf , 7,758 should be replaced with $43,560 \text{ft}^3$ per acre-ft.

If Equation 5.5.1 is rearranged in terms of the initial gas in place:

$$G = \frac{G_p B_g}{(B_g - B_{gi})} \quad (5.5.26)$$

The recovery efficiency, E_R , which is the volume of gas recovered divided by the volume of gas initially in place, can be found from:

$$E_R = \frac{B_{gi} - B_g}{B_{gi}} \quad (5.5.27)$$

For volumetric gas reservoirs (which assumes no change in S_w) recoveries may range from 80% to 90% of the initial gas in place.

For gas reservoirs under water drive, recovery efficiency is:

$$E_R = \frac{(1 - S_{wi})B_{gi} - (S_{gr}B_g)}{(1 - S_{wi})B_{gi}} \quad (5.5.28)$$

where S_{gr} is the residual gas saturation and the other terms are as defined above.

5.5.7.2 Recovery of Oil

5.5.7.2.1 Solution-Gas or Depletion Drive

Oil recovery by depletion or solution-gas drive is:

$$N_p = 7,758 Ah\phi \left[\frac{(1 - S_w)}{B_{oi}} - \frac{(1 - S_w - S_{gr})}{B_o} \right] \quad (5.5.29)$$

where B_{oi} is the initial oil formation volume factor and B_o is the oil formation volume factor at abandonment, and the other terms are as previously defined. The ultimate free gas saturation is often estimated from the old data of Arps [4.7] and Craze and Buckley [4.3] in which the average S_g was 30% for a 2.2 cp oil with $400 \text{ft}^3/\text{bbl}$ of solution gas. A general rule suggests that for each doubling of solution gas, S_g should be increased 3%; and for each doubling of oil viscosity, S_g should be decreased by 3% [1.14]. As a first approximation, S_{gr} can be taken to be about 0.25 [8].

For a volumetric, undersaturated reservoir,

$$N_p = \frac{N(B_o - B_{oi})}{B_o} \quad (5.5.30)$$

where N_p is the oil produced in stock tank barrels, N is the initial oil in place in STB and the other terms are as already given. In this case, the oil saturation after any stage of primary production, S_o , can be obtained from:

$$S_o = \frac{(N - N_p)B_o(1 - S_w)}{NB_{oi}} \quad (5.5.31)$$

If calculations are made at the abandonment of primary production, S_o will represent the oil saturation after primary. The gas saturation at any time, S_g , can be found from:

$$S_g = 1 - S_o - S_w \quad (5.5.32)$$

For a solution-gas drive reservoir with water encroachment [1.73]:

$$N_p = N \left[\frac{B_o - B_{oi}}{B_o} + \frac{W_e}{B_o} \right] \quad (5.5.33)$$

where W_e is the cumulative water influx in barrels and all other terms are consistent with the prior definitions.

5.5.7.2.2 Water-Drive Reservoir

Recovery from a water-drive reservoir (which assumes no appreciable decline in pressure) can be calculated from [1.14]:

$$N_p = 7,758(Ah\phi) \left[\frac{(1 - S_w)}{B_{oi}} - \frac{S_{or}}{B_o} \right] \quad (5.5.34)$$

where S_{or} is the residual oil saturation as a fraction of pore volume. Residual oil saturation can be obtained from cores taken with water base mud or from logs as described earlier. Methods of estimating residual oil saturation after water injection are discussed later. In the absence of data, residual oil saturations are sometimes obtained from the empirical data of Arps [4.7] and Craze and Buckley [4.3]

which are given in Table 5.5.2. However, the caution given earlier is repeated here: from a more recent study [4.1] *no statistically valid correlation was found between oil recovery and definable reservoir parameters.*

The recovery efficiency is the case of water influx is given by:

$$E_R = \frac{(1 - S_w - S_{or})}{(1 - S_w)} \quad (5.5.35)$$

5.5.7.2.3 Gravity Drainage

For segregation drive reservoirs, Equation 5.5.35 can be used. Residual oil saturations for gravity drainage reservoirs tend to be low (possibly on the order of 0.10) [1.14].

5.5.7.2.4 Gas-Cap Drive

For a gas-cap drive reservoir with no water influx, the oil saturation can be estimated from [1.73]:

$$S_o = \left(\frac{N - N_p}{NB_{oi}} \right) (1 - S_w) \left[\frac{1}{1 - m(B_g - B_{gi})/B_{gi}} \right] \quad (5.5.36)$$

where m is the ratio of original gas zone to original oil zone in the reservoir and all other quantities have been defined.

TABLE 5.5.2 Approximation of Residual Oil Saturation

Reservoir oil viscosity, cp	Residual oil saturation, % PV
0.2	30
0.5	32
1.0	34.5
2.0	37
5.0	40.5
10.0	43.5
20.0	46.5
Average reservoir permeability,	Deviation of residual oil saturation from viscosity trend, md
	% PV
50	+12
100	+9
200	+6
500	+2
1,000	-1
2,000	-4.5
5,000	-8.5

5.6 DECLINE CURVE ANALYSIS

Section reviewed by Heru Danardatu

The conventional analysis of production decline curves for oil or gas production consists of plotting the log of flow rate versus time on semilog paper. In cases for a decline in rate of production, the data are extrapolated into the future to provide an estimate of expected production and reserves.

The empirical relationships for the analysis of production decline curves were first proposed by Arps [1] in which a decline rate, a , was defined as the fractional change in the flow rate, q , with time, t :

$$a = \frac{-dq/dt}{q} \quad (5.6.1)$$

If time is in days, flow rate in this equation is expressed in terms of stock tank barrels per day in the case of oil and scf per day for gas. Other consistent units of flow rate and time can be used. As shown in Figure 5.6.1, three types of decline can occur: a constant percentage or exponential decline, a hyperbolic decline, and a harmonic decline [4.7]. For the semilog plot, the exponential decline is a straight line whereas the slopes of the hyperbolic and harmonic decline curves decrease with time. For the exponential decline, the drop in production per unit time is a constant fraction of the production rate. For a hyperbolic decline, the decrease in production per unit time as a fraction of the production rate is proportional to a fractional power (between 0 and 1) of the production rate. For a harmonic decline, the decrease in production per unit time as a fraction of the production rate is directly proportional to the rate. Slider [2] presented an equation for the hyperbolic decline that will reduce to the other types under certain circumstances:

$$\frac{a}{a_i} = \frac{q^n}{q_i^n} \quad (5.6.2)$$

where a is the decline rate when the production rate is q , and a_i and q_i are the decline rate and production at an initial time. As mentioned above, the exponent, n , is a number between, but not including zero and one for the hyperbolic decline. When n is zero, the decline rate is constant which is the exponential decline. When n is one, the decline rate is proportional to the rate which is the harmonic decline. Several early publications related to decline-curve analysis have appeared in the literature [3–8].

The exponential and hyperbolic types of decline curves are more common than the harmonic decline. The exponential or constant percentage decline is indicative of a homogeneous producing interval where the pressure response has been affected by the outermost reservoir limits [9–10]. The exponential decline may apply to pumping wells that are kept pumped off or gas wells and many oil wells that produce at a constant bottomhole pressure. The hyperbolic decline is indicative of either unsteady-state conditions or pressure response from a variable permeability reservoir [11]. Although frequently encountered, the harmonic decline may be observed with reservoirs that are dominated by gravity drainage [2.18]. Equations for each type of decline-curve are given in Table 5.6.1, and will be discussed for each case.

5.6.1 Exponential Decline

For the exponential or constant percentage decline, the nominal or instantaneous decline rate is:

$$a = \frac{\ell n(q_i/q)}{t} \quad (5.6.3)$$

and as shown in Table 5.6.1, the rate-time relationship is:

$$q = q_i e^{-at} \quad (5.6.4)$$

and the relationship between flow rate and cumulative production is:

$$N_p = \frac{q_i - q}{a} \quad (5.6.5)$$

The annualized (effective) or continuous decline rate, d , is:

$$d = \frac{q_i - q}{q} \quad (5.6.6)$$

from which the cumulative production, N_p , is:

$$N_p = \frac{q_i - q}{-\ell n(1 - d)} \quad (5.6.7)$$

and the flow rate at time, t , is:

$$q = q_i + N_p \ell n(1 - d) \quad (5.6.8)$$

5.6.2 Hyperbolic Decline

As shown in Table 5.6.1, the time-rate relationship for the hyperbolic decline is:

$$q = \frac{q_i}{(1 + na_i t)^{1/n}} \quad (5.6.9)$$

If h is substituted for $1/n$, the time-rate relationship is:

$$q = \frac{q_i}{\left(1 + \frac{a_i t}{h}\right)^h} \quad (5.6.10)$$

where h is the hyperbolic decline constant.

For the hyperbolic decline, the rate-cumulative production relationship is:

$$N_p = \frac{q_i^n}{a_i(1 - n)} (q_i^{1-n} - q^{1-n}) \quad (5.6.11)$$

and if h is substituted into this equation:

$$N_p = \left[\frac{h}{(h - 1)} \right] \left(\frac{1}{a_i} \right) \left[q_i - q \left(1 + \frac{a_i t}{h} \right) \right] \quad (5.6.12)$$

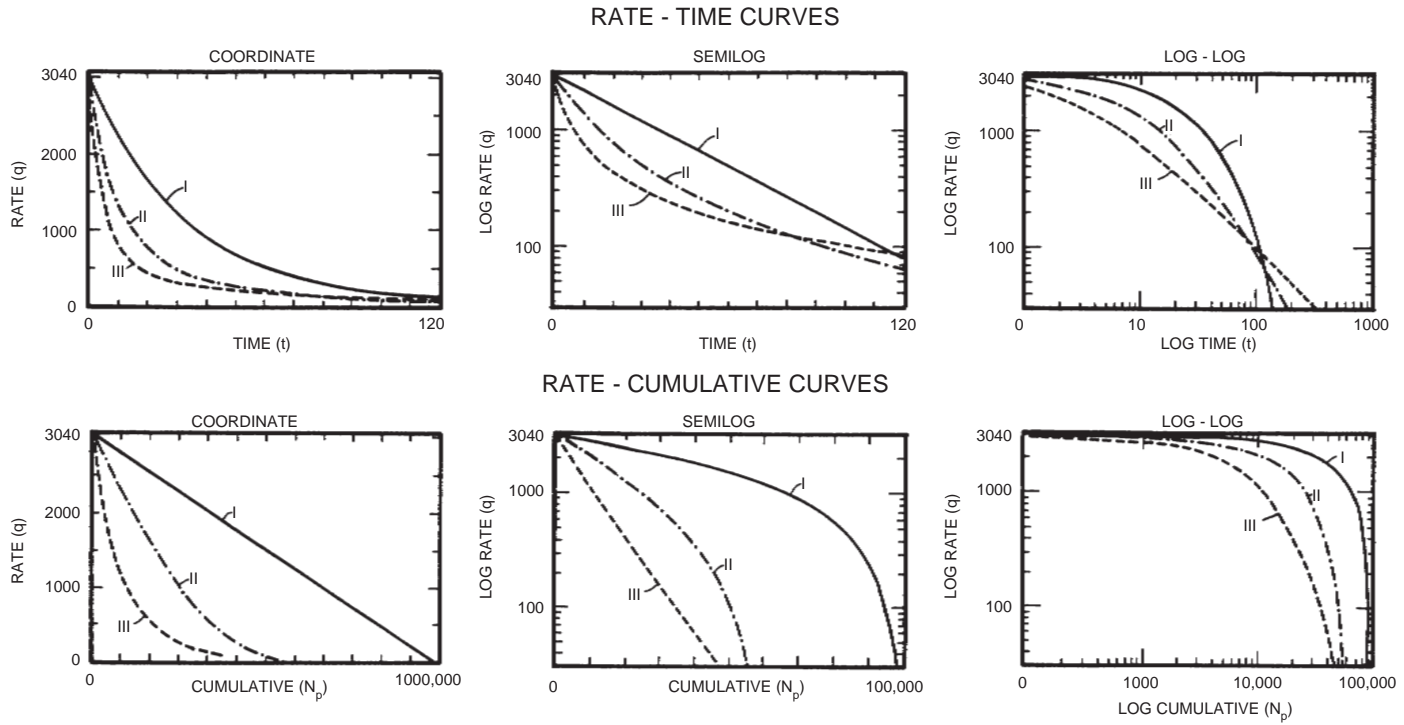

Figure 5.6.1 Decline curves [4.7].

TABLE 5.6.1 Classification of Production Decline Curves

Decline type	I. Constant percentage decline	II. Hyperbolic decline	III. Harmonic decline
Basic characteristic	Decline is constant $n = 0$	Decline is proportional to a fractional power (n) of the production rate $0 < n < 1$	Decline is proportional to a production rate $n = 1$
Rate-time relationship	$q = q_i e^{-at}$	$q = \frac{q_i}{(1 + na_i t)^{1/n}}$	$q = \frac{q_i}{1 + na_i t}$
Rate-cumulative relationship	$N_p = \frac{(q_i - q)}{a}$	$N_p = \frac{q_i n}{a_i(1-n)} (q_i^{1-n} - q^{1-n})$	$N_p = \frac{q_i}{a_i} \ln \left(\frac{q_i}{q} \right)$
	$q = \frac{q_i}{\left(1 + \frac{a_i t}{h}\right)^h}$		
	$N_p = \left[\frac{h}{(h-1)} \right] \left(\frac{1}{a_i} \right) \left[q_i - q \left(1 + \frac{a_i t}{h} \right) \right]$		
From Reference 1. $a =$ decline as a fraction of production rate $t =$ time $a_i =$ initial decline $N_p =$ cumulative oil production at time t $q_i =$ an initial production rate $n =$ exponent $q =$ production rate at time t $h = 1/n$			

Equation 5.6.10 can be rearranged to:

$$\frac{1}{a} = \frac{1}{a_i} + \frac{t}{h} \quad (5.6.13)$$

which represents a straight line. If the decline rate, $1/a$, is plotted on the y-axis versus the time interval on the x-axis, the intercept at $t = 0$ will yield $1/a_i$, and the slope will yield $1/h$. These values can be substituted into Equation 5.6.10 to give any future estimates of production rates [10].

5.6.3 Harmonic Decline

For a harmonic decline, the time-rate relationship is:

$$q = \frac{q_i}{(1 + na_i t)} \quad (5.6.14)$$

and the rate-cumulative production relationship as shown in Table 5.6.1 is:

$$N_p = \frac{q_i}{a_i} \ln \left(\frac{q_i}{q} \right) \quad (5.6.15)$$

5.6.4 Production Type-Curves

5.6.4.1 Semilog Plots

The complexity of the analysis of hyperbolic decline-curves led to the development of curve-matching techniques. One of the simpler techniques was proposed by Slider [2] with the development of an overlay method to analyze rate-time data. The actual decline-curve data are plotted on

transparency paper and compared to a series of semilog plots that represent different combinations of a_i and n . Tabular values needed to plot the hyperbolic type-curves are available [2.18] for values of n from 0.1 to 0.9, in increments of 0.1.

Gentry [12] prepared a series of plots of q_i/q versus $N_p/q_i t$ for different values of n from 0 to 1.0 in increments of 0.1. Using two rates, the cumulative production, and the intervening time, the value of n for a particular hyperbolic decline-curve can be obtained. Gentry provided other curves to estimate a_i , or Equation 5.6.9 can be rearranged:

$$a_i = \frac{(q_i/q)^n - 1}{nt} \quad (5.6.16)$$

With the use of the semilog type-curves, caution must be exercised to ensure that the interval being analyzed is indeed a hyperbolic curve [2.18]. Another problem with the semilog plots is that an exact fit of the data may not be possible; however, the techniques are relatively rapid.

5.6.4.2 Log-log (Fetkovich) Type-Curves

Conventional decline-curve analysis should be used only when mechanical conditions and reservoir drainage remain constant and the well is producing at capacity [2.18]. An advanced approach for decline-curve analysis, which is applicable for changes in pressure or drainage, has been presented by Fetkovich [13, 14]. This technique, which is similar to the approach used in pressure testing, involves log-log plots of q/q_i (or q_{Dd}) versus $a_i t$ (or t_{Dd}) for different values of n (see Figure 5.6.2). As shown in this figure, a

Figure 5.6.2 Log-log type curves [14].

log-log plot of the dimensionless rate and dimensionless time can identify transient data and/or depletion data, the Arps' equations given in Table 5.6.1 must only be applied to rate-time data that indicate depletion [14]. Use of transient data in the Arps' equations will result in incorrect forecasts that are overly optimistic.

The full-size Fetkovich type-curves can be ordered from the book order department of SPE. The field data are plotted on tracing paper that has the same log-log scale as the full-size type-curves. The log-log plot of flow rate and time can be in terms of barrels/day versus days, barrels/month versus months, or barrels/year versus years, depending on the time interval being studied. Using the best fit on the appropriate type-curve, a match point can be used to obtain q_i and a_i for the actual data. The appropriate equation can then be used to analyze the rate, time, and cumulative production behavior.

5.7 RESERVE ESTIMATES

Section reviewed by Heru Danardatu

5.7.1 Definition and Classification of Reserves

5.7.1.1 Definitions [1–3]

5.7.1.1.1 Crude Oil

This is defined technically as a mixture of hydrocarbons that existed in the liquid phase in natural underground reservoirs and remains liquid at atmospheric pressure after passing through surface facilities. For statistical purposes, volumes reported as crude oil include: (1) liquids technically defined as crude oil; (2) small amounts of hydrocarbons that existed in the gaseous phase in natural underground reservoirs but are liquid at atmospheric pressure after being recovered from oilwell (casing head) gas in lease separators¹; and (3) small amounts of nonhydrocarbons produced with the oil.

5.7.1.1.2 Natural Gas

This is a mixture of hydrocarbons and varying quantities of nonhydrocarbons that exist either in the gaseous phase or in solution with crude oil in natural underground reservoirs. Natural gas may be subclassified as follows.

Associated gas is natural gas, commonly known as gas-cap gas, that overlies and is in contact with crude oil in the reservoir.²

Dissolved gas is natural gas that is in solution with crude oil in the reservoir.

Nonassociated gas is natural gas that is in reservoirs that do not contain significant quantities of crude oil.

Dissolved gas and associated gas may be produced concurrently from the same wellbore. In such situations, it is not feasible to measure the production of dissolved gas and associated gas separately; therefore, production is reported under the heading of associated-dissolved or casinghead gas. Reserves and productive capacity estimates for associated and dissolved gas also are reported as totals for associated-dissolved gas combined.

-
1. From a technical standpoint, these liquids are termed "condensate"; however, they are commingled with the crude stream and it is impractical to measure and report their volumes separately. All other condensate is reported as either "lease condensate" or "plant condensate" and included in natural gas liquids.
 2. Where reservoir conditions are such that the production of associated gas does not substantially affect the recovery of crude oil in the reservoir, such gas may be classified as nonassociated gas by a regulatory agency. In this event, reserves and production are reported in accordance with the classification used by the regulatory agency.

5.7.1.1.3 Natural Gas Liquids (NGLs)

There are those portions of reservoir gas that are liquefied at the surface in lease separators, field facilities, or gas processing plants. Natural gas liquids include but are not limited to ethane, propane, butanes, pentanes, natural gasoline, and condensate.

5.7.1.1.4 Reservoir

A reservoir is a porous and permeable underground formation containing an individual and separate natural accumulation of producible hydrocarbons (oil and/or gas) which is confined by impermeable rock and/or water barriers and is characterized by a single natural pressure system. In most situations, reservoirs are classified as oil reservoirs or as gas reservoirs by a regulatory agency. In the absence of a regulatory authority, the classification is based on the natural occurrence of the hydrocarbon in the reservoir as determined by the operator.

5.7.1.1.5 Improved Recovery

This includes all methods for supplementing natural reservoir forces and energy, or otherwise increasing ultimate recovery from a reservoir. Such recovery techniques include (1) pressure maintenance, (2) cycling, and (3) secondary recovery in its original sense (i.e., fluid injection applied relatively late in the productive history of a reservoir for the purpose of stimulating production after recovery by primary methods of flow or artificial lift has approached an economic limit). Improved recovery also includes the enhanced recovery methods of thermal, chemical flooding, and the use of miscible and immiscible displacement fluids.

5.7.1.1.6 Reserves [3]

These are estimated volumes of crude oil, condensate, natural gas, natural gas liquids, and associated substances anticipated to be commercially recoverable and marketable from a given data forward, under existing economic conditions, by established operating practices, and under current government regulations. Reserves do not include volumes of crude oil, condensate, or natural gas liquids being held in inventory.

Reserve estimates are based on interpretation of geologic and/or engineering data available at the time of the estimate. Existing economic conditions are prices, costs, and markets prevailing at the time of the estimate. Other assumed future economic conditions may lead to different estimates of recoverable volumes; these volumes are not considered reserves under existing economic conditions constraints, but may be identified as resources.

Marketable means that facilities to process and transport reserves to market are operational at the time of the estimate, or that there is a commitment to install such

facilities in the near future, and there is a readily definable market or sales contract. Reserve estimates generally will be revised as reservoirs are produced, as additional geologic and/or engineering data become available, or as economic conditions change.

Natural gas reserves are those volumes which are expected to be produced and that may have been reduced by onsite usage, by removal of nonhydrocarbon gases, condensate or natural gas liquids.

Reserves may be attributed to either natural reservoir or improved recovery methods. Improved recovery includes all methods for supplementing natural reservoir energy to increase ultimate recovery from a reservoir. Such methods include (1) pressure maintenance, (2) cycling, (3) waterflooding, (4) thermal methods, (5) chemical flooding, and (6) the use of miscible and immiscible displacement fluids. Reserves attributed to improved recovery methods usually will be distinguished from those attributed to primary recovery.

All reserve estimates involve some degree of uncertainty, depending chiefly on the amount and reliability of geologic and engineering data available at the time of the estimate and the interpretation of these data. The relative degree of uncertainty may be conveyed by placing reserves in one of two classifications, either proved or unproved. Unproved reserves are less certain to be recovered than proved reserves and may be subclassified as probable or possible to denote progressively increasing uncertainty.

5.7.1.2 Classification of Reserves

5.7.1.2.1 Proved Reserves

Attributed to known reservoirs, proved reserves can be estimated with reasonable certainty. In general, reserves are considered proved if commercial producibility of the reservoir is supported by actual production or formation tests. The term proved refers to the estimated volume of reserves and not just to the productivity of the well or reservoir. In certain instances, proved reserves may be assigned on the basis of a combination of core analysis and/or electrical and other type logs that indicate the reservoirs are analogous to reservoirs in the same areas that are producing, or have demonstrated the ability to produce in a formation test. The area of a reservoir considered proved includes (1) the area delineated by drilling and defined by fluid contacts, if any, and (2) the undrilled areas that can be reasonably judged as commercially productive on the basis of available geological and engineering data. In the absence of data on fluid contacts, the lowest known structural occurrence of hydrocarbons controls the proved limit unless otherwise indicated by definitive engineering or performance data.

In general, proved undeveloped reserves are assigned to undrilled locations that satisfy the following conditions: (1) the locations are direct offsets to wells that have indicated commercial production in the objective formation, (2) it is reasonably certain that the locations are within the known proved productive limits of the objective formation, (3) the locations conform to existing well spacing regulation, if any, and (4) it is reasonably certain that the locations will be developed. Reserves for other undrilled locations are classified as proved undeveloped only in those cases where interpretation of data from wells indicates that the objective formation is laterally continuous and contains commercially recoverable hydrocarbons at locations beyond direct offsets.

Reserves that can be produced through the application of established improved recovery methods are included in the proved classification when: (1) successful testing by a pilot project or favorable production or pressure response of an installed program in that reservoir, or one in the immediate area with similar rock and fluid properties, provides support for the engineering analysis on which the project or program is based and (2) it is reasonably certain the project will proceed.

Reserves to be recovered by improved recovery methods that have yet to be established through repeated commercially successful application are included in the proved category only after a favorable production response from the reservoir from either (1) a representative pilot or (2) an installed program that provides support for the engineering analysis on which the project or program is based.

5.7.1.2.2 Unproved Reserves

These are based on geologic and/or engineering data similar to that used in estimates of proved reserves, but technical, contractual, or regulatory uncertainties preclude such reserves being classified as proved. Estimates of unproved reserves may be made for internal planning of special evaluations, but are not routinely compiled.

Unproved reserves are not to be added to proved reserves because of different levels of uncertainty. Unproved reserves may be divided into two subclassifications: probable and possible.

5.7.1.2.3 Probable Reserves

These reserves are attributed to known accumulations and are less certain to be recovered than proved reserves. In general, probable reserves may include (1) reserves that appear to exist a reasonable distance beyond the proved limits of productive reservoirs, where fluid contacts have not been determined and proved limits are established by the lowest known structural occurrence of hydrocarbons, (2) reserves

in formations that appear to be productive from core and/or log characteristics only, but that lack definitive tests or analogous producing reservoirs in the area, (3) reserves in a portion of a formation that has been proved productive in other areas in a field, but that is separated from the proved area by faults, (4) reserves obtainable by improved recovery methods and located where an improved recovery method (that has yet to be established through repeated commercially successful operation) is planned but not yet in operation, and where a successful pilot test has not been performed but reservoir and formation characteristics appear favorable for its success, (5) reserves in the same reservoir as proved reserves that would be recoverable if a more efficient primary recovery mechanism were to develop than that assumed in estimating proved reserves, (6) incremental reserves attributable to infill drilling where closer statutory spacing had not been approved at the time of the estimate, and (7) reserves that are dependent for recovery on a successful workover, treatment, retreatment, change of equipment, or other mechanical procedures, when such procedures have not been proved successful in wells exhibiting similar behavior in analogous formations.

5.7.1.2.4 Possible Reserves

These are associated with known accumulations and are less certain to be recovered than probable reserves. In general, possible reserves may include (1) reserves indicated by structural and/or stratigraphic extrapolation from developed areas, (2) reserves located where reasonably definitive geophysical interpretations indicate an accumulation larger than could be included within the proved and probable limits, (3) reserves in formations that have favorable log characteristics but questionable productivity, (4) reserves in untested fault segments adjacent to proved reservoirs where a reasonable doubt exist as to whether such fault segment contains recoverable hydrocarbons, (5) incremental reserves attributable to infill drilling that are subject to technical or regulatory uncertainty, and (6) reserves from a planned improved recovery program that is not in operation and that is in a field in which formation, fluid, or reservoir characteristics are such that a reasonable doubt exists to its success.

5.7.1.2.5 Reserve Status Categories

These define the development and producing status of wells and/or reservoirs. They may be applied to proved or unproved (probable or possible) reserves.

5.7.1.2.6 Developed Reserves

These are expected to be recovered from existing wells (including reserves behind pipe). Improved recovery

reserves are considered developed only after the necessary equipment has been installed, or when the costs to do so are relatively minor. Developed reserves may be subcategorized as producing or nonproducing.

5.7.1.2.7 Producing Reserves

These are expected to be recovered from completion intervals open at the time of the estimate and producing to market. Improved recovery reserves are considered to be producing only after an improved recovery project is in operation. Unproved (probable or possible) producing reserves are in addition to proved producing reserves, such as (1) reserves that may be recovered from portions of the reservoir down-dip from proved reserves or (2) reserves that may be recovered if a higher recovery factor is realized than was used in the estimate of proved reserves.

5.7.1.2.8 Nonproducing Reserves

These include shut-in and behind-pipe reserves. Shut-in reserves are expected to be recovered from completion intervals open at the time of the estimate, but which have not started producing, or were shut in for market conditions of pipeline connection, or were not capable of production for mechanical reasons, and the time when sales will start is uncertain. Behind-pipe reserves are expected to be recovered from zones behind casing in existing wells, which will require additional completion work or a future recompletion prior to the start of production.

5.7.1.2.9 Undeveloped Reserves

These are expected to be recovered: (1) from new wells on undrilled acreage, (2) from deepening existing wells to a different reservoir, or (3) where a relatively large expenditure is required to (a) recomplete an existing well, or (b) install production or transportation facilities for primary or improved recovery projects. Undeveloped reserves usually will be distinguished from developed reserves. The ownership status of reserves may change due to the expiration of a production license or contract; when relevant to reserve assignment, such changes should be identified for each reserve classification.

5.7.2 Methods of Estimating Reserves

Method of determining reserves progress from analogy, before a well is drilled, to history after it is plugged and abandoned. The accuracy with which reserves can be estimated progresses along the same path from speculation to history.

5.7.2.1 Analogy

The decision to drill a well is based upon the potential reserves that it will recover. This means that an engineer must be able to predict reserves before a well is drilled. The lack of information about the reservoir restricts the engineering methods available.

Analogy is the only method which can be used without specific well information such as porosity, reservoir thickness, and water saturation. Because analogy employs no specific information about a well, it is the least accurate method of determining reserves. Methods of analogous reserve determination depend on the proximity of similar reserves. The best analogy can be made by taking the median ultimate recovery of a number of wells that are closest and have the same formation and characteristics expected in the proposed well. When ultimate recovery data are not available, volumetric, decline curve or other methods of estimating ultimate recovery may be used.

Unless values of ultimate recovery figures for the group are relatively close, the median ultimate recovery should be calculated by making a normal probability plot. This plot is made by graphing estimated ultimate recovery against the cumulative percent of samples. A best-fit line is drawn through the points and the median is read where the line intersects fifty percent. A straight line indicates a normal distribution; if the line is not straight the distribution is skewed. If there are no similar wells in the area, data from those less similar may be used, but confidence goes down as similarity decreases.

5.7.2.2 Volumetric

If a well is drilled after reserves are determined by analogy, factual information becomes available and reserves can then be determined volumetrically. From log analysis the porosity, water saturation, and productive formation thickness are estimated. A reasonable drainage area is assigned and total hydrocarbons in place are then calculated. When enough wells have been drilled to delineate the field, a subsurface geological contour map showing the subsea sand top and bottom depth, oil-water contact, and gas-oil contact can be prepared. From this map the total areas in acre-feet of each contour are planimetered and graphed as the abscissa against the subsea depth as the ordinate. Lines are then drawn to connect the sand-top points and the sand-bottom-points, the area bounded by the oil-water-contact depth, the sand-top line, the sand-bottom line and the gas-oil-contact line. This area is the gross oil-bearing sand-volume in acre-feet. The area, if present, that is bounded by the gas-oil contact depth, the sand-top-line, the sand-bottom-line and the abscissa is the gross gas-bearing sand-volume in acre-feet. The engineer must determine from core data and/or electric logs the percentage of the gross sand volume

that is productive and must then reduce the total acre-foot by that percentage. If there is no subsurface contour map available or if the reservoir is very heterogeneous, an isopach or an isovol map should be constructed. An isopach map is constructed by contouring net sand thickness. This kind of map works well when the reservoir is uniform and when porosity and water saturation are relatively constant. When the water saturation and porosity vary widely from well to well, an isovol map that indicates hydrocarbon thickness is useful. This map is constructed by contouring the value of net pay height multiplied by porosity and by one minus the water saturation. Care should be taken not to rely on the scale provided on the map especially when using xeroographed copies, as this and other methods of reproduction can distort one or both axes as much as five percent. A known area such as a section should be measured to calibrate the instrument. Once the contour areas have been planimetered, the net pay volume can be calculated in several ways. If the number of contour intervals is even, the volume can be calculated by Simpson's rule [4]:

$$V_R = 1/3h[(y_0 + y_n) + 4(y_1 + y_3 + \dots + y_{n-1}) + 2(y_2 + y_4 + \dots + y_{n-2})] \quad (5.7.1)$$

where V_R = reservoir volume, acre-ft
 h = contour interval, ft
 y_0 = area on top of sand minus area on base of sand at the highest contour
 y_n = area on top of sand minus area on base of sand at the lowest contour

When the number of contours is uneven, the volume can be found using the slightly less accurate trapezoidal method:

$$V_R = h[1/2(y_0 + y_n) + y_1 + y_2 + \dots + Y_{n-1}] \quad (5.7.2)$$

Once the reservoir volume is known, the oil in place, N , in stock tank barrels is calculated by an equation similar to that given earlier:

$$N = \frac{7,758 V_o(1 - S_w)}{B_o} \quad (5.7.3)$$

where N = reservoir oil initially in place, STB
 $7,758$ = number of barrels/acre-ft
 V_o = net producing reservoir volume, acre-ft
 B_o = oil formation volume factor, RB/STB
 S_w = interstitial water saturation, fraction
 ϕ = formation porosity, fraction

Similarly gas-in-place, G , in thousands of standard cubic feet, is estimated by an expression similar to that given earlier:

$$G = \frac{43,560 V_g \phi (1 - S_w) p T_s}{z T p_s} \quad (5.7.4)$$

where G = gas in place, scf

V_g = gas bearing volume of reservoir, acre-ft

p_s = standard pressure, psia

T = reservoir temperature, degrees absolute

T_s = standard temperature base, degrees absolute

z = gas deviation factor at reservoir conditions

Volumetric analysis yields the total hydrocarbon content of the reservoir; this figure must be adjusted by a recovery factor to reflect the ultimate recoverable reserves. Recovery factors are based upon empirical correlations, experience, or analogy.

5.7.2.3 Material Balance

If a field development program has been well planned and executed, enough information should be available to calculate reserves by the material balance equation. The material balance equation is derived on the assumption that the reservoir is a homogeneous vessel with uniform porosity, permeability, and fluid properties. The equation accounts for all quantities of materials that enter or leave the vessel. The simplest form of the equation is that initial volume is equal to the volume remaining plus the volume removed. As material is withdrawn from a constant-volume reservoir the pressure declines and remaining material expands to fill the reservoir. Laboratory PVT analysis of the reservoir fluid defines the change in volume per unit pressure drop. Knowing the amount of fluid withdrawn from the reservoir and the drop in pressure one can calculate the corresponding volume of fluid at the original reservoir pressure. The calculated reservoir size should remain constant as fluid is withdrawn and pressure drops. If the calculated reservoir size changes constantly in one direction as the field is produced the assumed production mechanism is probably wrong. Calculations should be repeated assuming different mechanisms until one is found that yields a constant reservoir size. Since Schilthuis [5.3] developed the original material balance equation in 1936 it has been rearranged to solve almost any unknown. The most frequently used forms of the equation are for these types of recovery mechanisms [4]:

1. Oil reservoir with gas cap and active water drive.
2. Oil reservoir with gas cap and no active water drive.
3. Initially undersaturated oil reservoir with active water drive: A. Above bubble point. B. Below bubble point.
4. Initially undersaturated oil reservoir with no active water drive: A. Above bubble point. B. Below bubble point.
5. Gas reservoir with active water drive.
6. Gas reservoir with no active water drive.

The material balance equation, when combined with reliable relative permeability data, can be used to predict future reservoir performance. Many times, reservoirs do not conform to the assumptions made in the material balance equation. Few reservoirs are homogeneous and no reservoirs respond instantaneously to changes in pressure. The precision with which reserves can be calculated or predicted with the material balance equation is affected by the quality of data available and the degree of agreement between the assumptions made in the equation and the actual reservoir conditions.

5.7.2.4 Model Studies

Predicting reservoir performance with the Turner [5.4] or the Muskat [5.5] method is a long and tedious process and, even with a programmable calculator, the process takes several hours. To resolve the problems caused by the assumptions inherent in the material balance equation, a reservoir would have to be broken up into parts small enough to be considered homogeneous. The material balance equation would then have to be calculated for each part and for each increment of production. This would entail thousands of calculations performed thousands of times and would drastically limit the number of reservoir simulations an engineer could run. Fortunately, computers have cut the required time to a few minutes. Numerical simulators divide the reservoir up into discreet elements, each having the properties and spatial orientation of the associated blocks of a physical reservoir [5]. The simulator treat each block as a small reservoir, and keeps track of fluid entering or leaving the block. When a change in pressure due to injection or withdrawal of fluid occurs, the simulator solves the material balance equation for a number of time steps for each block until equilibrium is reached. Blocks are usually configured so that each well is in an individual block. Time steps are picked so that the required information is resolved without using excessive computer time. Since the simulator keeps track of fluid movement through the reservoir, the output can include a wide variety of parameters. Fluid fronts, saturation changes, pressure distribution, and oil-water contact

movement are a few of the things that can be plotted. The three general classifications of simulators are gas, black oil, and compositional. Gas simulators model one or two phases (gas or gas and water). Black oil simulators are designed to model any proportion of gas, oil, and water, and they account for gas going into or out of solution. Compositional simulators are used when PVT data does not adequately describe reservoir behavior such as in condensate reservoirs. These simulators calculate the mass fraction of individual components in each phase and mass transfer between phases as each phase flows at different rates. Most models are run with limited information and must be tuned to properly predict actual reservoir performance. This is done by changing parameters such as relative permeability, porosity, and permeability data until the simulator matches the field history.

5.7.2.5 Production Decline Curves

The most widely used method of estimating reserves is the production rate decline-curve. This method involves extrapolation of the trend in performance. If a continuously changing continuous function is plotted as the dependent variable against an independent variable, a mathematical or graphical trend can be established. Extrapolation of that trend can then permit a prediction of future performance. For an oil reservoir, the plot of the logarithm of production rate against time is most useful. Although decline-curve analysis is empirical, if care is taken to ensure that production rates are not being affected by such things as the mechanical degradation of equipment or the plugging of the formation by fines or paraffin, the method is reasonably accurate. As discussed, there are three major types of decline curves: constant percentage or exponential, hyperbolic, and harmonic. Although analysis of a large number of actual production decline curves indicates that most wells exhibit a hyperbolic decline with an n value falling between 0 and 0.4, the constant-percentage exponential decline-curve is most widely used. The exponential decline curve is most popular because, when plotted on semilog paper the points make a straight line which is easiest to extrapolate to the economic limit. Now that programmable calculators and personal computers reside at most every engineer's desk, it is easy to punch in the production data and decide which decline curve is best.

5.7.3 Quality of Reserve Estimates

If reserve estimates contained no risk, no dry holes would be drilled. Unfortunately, risk is inversely proportional to knowledge and the least is known before a well is drilled.

FIGURE 5.7.1 Quality of reserves [6].

Hudson and Neuse [6] presented a graphical representation (reproduced in Figure 5.7.1) of reserve estimate quality throughout the life of a property. Section 1 shows the production history of the property. Section 2 indicates the probable risk factor associated with each stage of production from completion to depletion. Section 3 shows the range of possible reserve estimates through the life of the property. Section 4 shows at what stage of the life of the property each method of reserve estimate method becomes available. The solid line indicates for what period each method is most applicable. Section 5 names the depletion stage of the reservoir.

The quality of reserve estimates throughout the industry should improve now that the SPE definitions for proved reserves are being accepted. When the definitions for probable and possible reserves are approved, uniform factors for risk analysis can be made [7].

5.8 SECONDARY RECOVERY

Section reviewed by Heru Danardatu

5.8.1 Definitions

5.8.1.1 Secondary and Tertiary Recovery

Primary recovery, as already discussed, refers to the recovery of oil and/or gas that is recovered by either natural flow or artificial lift through a single wellbore. Thus, primary

recovery occurs as a result of the energy initially present in the reservoir at the time of discovery. When the initial energy has been depleted and the rate of oil recovery declines, oil production can be increased by the injection of secondary energy into the reservoir. Secondary recovery is the recovery of oil and/or gas that involves the introduction of artificial energy into the reservoir via one wellbore and production of oil and/or gas from another wellbore. Conventional means of secondary recovery include the immiscible processes of waterflooding and gas injection. Currently in the United States, waterflooding is the dominant secondary recovery method in that about half of the oil production is recovered from waterflood projects. After secondary recovery, a substantial amount of oil may remain, and attempts to recover oil beyond primary and secondary recovery are referred to as tertiary recovery. Any method that recovers oil more effectively than plain waterflooding or gas injection is defined as enhanced recovery. The more sophisticated enhanced methods may be initiated as a tertiary process if they follow waterflooding or gas injection, or they may be a secondary process if they follow primary recovery directly. Many of the enhanced recovery projects are implemented after water-flooding. (Enhanced recovery methods are discussed later.)

5.8.1.2 Pressure Maintenance

Pressure maintenance is a secondary recovery process that is implemented early during the primary producing phase before reservoir energy has been depleted. Pressure maintenance projects, which can be accomplished by the injection of either gas or water, will almost always recover more oil reserves than are recoverable by primary producing mechanisms. For example, the return of gas to the formation early in the primary producing history of a field will permit higher rates of oil production.

5.8.2 Gas Injection

Historically, both natural gas and air have been used in gas injection projects, and in some cases nitrogen and flue gases have been injected. Many of the early gas injection projects used air to immiscibly displace crude oil from reservoirs. The injection of hydrocarbon gas may result in either a miscible or immiscible process depending on the composition of the injected gas and crude oil displaced, reservoir pressure, and reservoir temperature. Hydrocarbon miscible injection is considered as an enhanced recovery process and is discussed later.

Although the ultimate oil recovered from immiscible gas injection projects will normally be lower than for waterflooding, gas injection may be the only alternative for secondary recovery under certain circumstances. If permeability is very low, the rate of water injection may be so low that gas injection is preferred. In reservoirs with swelling clays, gas injection may be preferable. In steeply-dipping reservoirs, gas that is injected updip can very efficiently displace crude oil by a gravity drainage mechanism; this technique is very effective in low-permeability formations such as fractured shales. In thick formations with little dip, injected gas (because of its lower density) will tend to override and result in vertical segregation if the vertical permeability is more than about 200 md [5.8]. In thin formations especially if primary oil production has been by solution-gas drive, gas may be injected into a number of wells in the reservoir on a well pattern basis; this dispersed gas injection operation attempts to bank the oil in a frontal displacement mechanism. In addition to the external gas injection into reservoirs with dip as just described (which may be into a primary or secondary gas cap), a variation called attic oil recovery involves injection of gas into a lower structural position. If there is sufficient vertical permeability, the injected gas will migrate upward to create a secondary gas cap that can displace the oil downward where it is recovered in wells that are already drilled.

Volumetric calculations for gas injection are given in Table 5.8.1. The material balance equation for dispersed gas injection in a solution-gas-drive reservoir where there is no water influx, no water production, and no gas cap can be expressed in terms of the oil produced during an interval [5.8]:

$$\Delta N_p = \frac{(1 - N_{p1}) \left(\frac{dB_o}{dB_g} - dR_s \right) - d \left[\left(\frac{1}{B_g} \right) B_{ob} \right]}{\left(\frac{B_o}{B_g} - R_s \right)_2 + R_{avg}(1 - I)} \quad (5.8.1)$$

where I is the constant fraction of the produced gas which is reinjected into the oil reservoir, B_{ob} is the oil formation volume factor at bubble-point conditions, R is the producing gas-oil ratio, the subscripts 1 and 2 refer to the time increments at p_1 and p_2 , the other standard terms are as already defined, and R_{avg} is $(R_1 + R_2)/2$. As given in Table 5.8.1, the instantaneous gas-oil ratio, R , is:

$$R = R_s + \frac{B_o k_g \mu_o}{B_g k_o \mu_g} \quad (5.8.2)$$

TABLE 5.8.1 Volumetric Calculations for Gas Injection

<i>Gas drive field with gas cap</i>	
$\frac{dB_o}{dp} = \frac{\frac{B_g S_o}{B_o} \frac{dR_s}{dp} + \frac{k_g \mu_o S_o}{k_o \mu_g B_o} \frac{dB_o}{dp} - \frac{(1 - S_o - S_w) + m(1 - S_w)}{B_g} \frac{dB_g}{dp}}{1 + \frac{k_g \mu_o}{k_g \mu_g}}$

<i>Reinjection of all produced gas-pressure maintenance</i>	
$\frac{dB_o}{dp} = \frac{\frac{B_g S_o}{B_o} \frac{dR_s}{dp} - \frac{R_s B_g S_o}{B_o^2} \frac{dB_o}{dp} - \frac{(1 - S_o - S_w)}{B_g} \frac{dB_g}{dp}}{1 - \frac{R_s B_g}{B_o}}$	
<i>Gas reinjection</i>	
Producing GOR $R = \frac{k_g \mu_o B_o}{k_o \mu_g B_g} + R_s$	
Net GOR $R = \left(\frac{k_g \mu_o B_o}{k_o \mu_g B_g} + R_s \right) (1 - I)$	
I = fraction of gas that is reinjected	
$\frac{dB_o}{dp} = \frac{\frac{B_g S_o}{B_o} \frac{dR_s}{dp} + \left[(1 - I) \frac{k_g \mu_o S_o}{k_o \mu_g B_o} - \frac{I R_s B_g S_o}{B_o^2} \right] \frac{dB_o}{dp} - \left[\frac{(1 - S_o - S_w) + m(1 - S_w)}{B_g} \frac{dB_g}{dp} \right]}{1 + (1 - I) \left(\frac{k_g \mu_o}{k_o \mu_g} \right) - \frac{I R_s B_g}{B_o}}$	
m = ratio of gas-cap volume to oil-zone volume	
<i>From References 1.14 and 5.8.</i>	

where R_s is the solution gas-oil ratio, B is formation volume factor, k is permeability, μ is viscosity, and the subscripts o and g refer to oil and gas, respectively. The relative permeabilities are determined at the total liquid saturation, S_L :

$$S_L = S_w + S_o = S_w + (1 - S_w) \frac{(N - N_p) B_o}{N B_{ob}} \quad (5.8.3)$$

The simultaneous solution of these three equations will provide estimates of oil produced at any chosen conditions for a dispersed-gas-drive injection project. Additional details can be found in Reference 5.8.

Many of the flow equations and concepts for immiscible gas displacement are similar to those that will be presented later for waterflooding. Because of the importance of water

injection processes in U.S. operations, waterflooding concepts will be emphasized.

5.8.3 Water Injection

Water injection processes may be designed to: (1) dispose of brine water, (2) conduct a pressure maintenance project to maintain reservoir pressure when expansion of an aquifer or gas cap is insufficient to maintain pressure, or (3) implement a water drive or waterflood of oil after primary recovery. As mentioned before, waterflooding is the dominant secondary recovery process which accounts for about 50% of the current oil production in U.S. operations. Because of the importance of waterflooding, fluid displacement in waterflooded reservoirs is covered as a separate discussion in a later section.

5.8.4 Spacing of Wells and Well Patterns

5.8.4.1 Spacing of Wells

One section (one sq mile or 5,280 ft by 5,280 ft) is 640 acres. If wells are drilled evenly such that each well is theoretically assigned to drain 40 acres, the 16 wells per section would be as spaced as in Figure 5.8.1. Each 40 acres ($\frac{1}{4}$ mile by $\frac{1}{4}$ mile or 1,320 ft by 1,320 ft) would contain $40 \times 43,560$ or 1,742,400 ft². The 10-acre region in Figure 5.8.1 would measure 660 ft by 660 ft and would contain 435,000 ft². Similarly, a 20-acre region would contain 871,200 ft² and would measure $[20 \times 871,200]^{1/2}$ or 933.4 ft by 933.4 ft.

In many parts of the United States, 40-acre spacing or less is common for oil wells, and 160-acre or 320-acre spacing is common for gas wells. Because drilling costs increase considerably with depth, deeper wells may be on larger spacing.

5.8.4.2 Injection Well Placement

Wells may be spaced evenly or unevenly from each other based on surface topology, lease boundaries, regulations, or

other factors. Many older fields were developed on irregular spacing. In more recent times, more uniform drilling patterns and well spacing have been used.

In most cases when an injection project is started, primary recovery has been implemented and producing wells will already be in place. For some projects, a number of existing wells will be converted from producers to injectors, and in other cases, new injection wells will be drilled. In either event, the injection well placement must be compatible with the existing wells and should [1.133]: (1) take advantage of known reservoir uniformities or nonuniformities (fractures, directional permeability, regional permeabilities, dip, etc.), (2) provide sufficient fluid injection rate to yield the desired production rate, (3) maximize recovery with a minimum of production of the injected fluid, and (4) in most cases, require a minimum of new wells. Two general types of well locations are common: (1) peripheral or central flooding where the injectors are grouped together, and (2) pattern flooding where certain patterns are repeated throughout the field. The relative location of injectors and producers depends on the geology and type of reservoir, the volume of reservoir swept, and the time limitations that affect economics. When possible, the injection scheme

FIGURE 5.8.1 Well locations for 40-acre spacing.

should take advantage of gravity, i.e., dipping or inclined reservoirs, gas caps, or underlying aquifers.

5.8.4.3 Peripheral or Central Flooding

In peripheral flooding, the injectors are located around the periphery so that the flood progresses toward the center as shown in Figure 5.8.2. When the first row of producers flood out, they are converted to injection status. This type of flood can result in maximum oil recovery with a minimum of produced injectant, and less injectant is required for a given amount of production, but a peripheral flood usually takes longer than a pattern flood. In general, adequate permeability is required to permit movement of fluids at an acceptable rate with the available well spacing. Central flooding is the opposite case in which injectors are located in the center of the field, and the flood progresses outward (see Figure 5.8.2).

A form of peripheral flooding is an end-to-end flood such as that shown in Figure 5.8.2. This type of injection could include the injection of gas into a gas cap or the injection of water into an aquifer. The choice of peripheral or repeating pattern flood is usually made on the basis of: formation permeability, formation dip, area and dimensions of the reservoir, and the initial production response that is acceptable.

FIGURE 5.8.2 Peripheral and central flooding.

5.8.4.4 Pattern Flooding

In pattern flooding, the injectors are distributed among the producers in some repeating fashion. Examples of the common repeating patterns are shown in Figure 5.8.3. Pattern flooding is very common, and the selection of the type of pattern will depend on circumstances in a given field. If existing wells were drilled on square patterns, 5-spots and 9-spots are common, and both yield similar oil recovery and water-oil ratio performance. If the injected fluid is more mobile than the displacing fluid (which is often the case, especially when oil viscosity is high), a pattern having more producers than injectors may be desired to balance the injection and production rates. In cases where the injected fluid is less mobile or when the formation permeability is low, a pattern having more injectors than producers may be desired. From an inspection of Figure 5.8.3, the ratio of producers to injectors for the various patterns can be determined as given in Table 5.8.2. For either the normal (or regular) 5-spot or the inverted 5-spot (inverted means one injector per pattern), the ratio of producers to injectors is 1:1; in this case, the distinction between normal and inverted is only important if a few patterns are involved, such as for a small pilot flood.

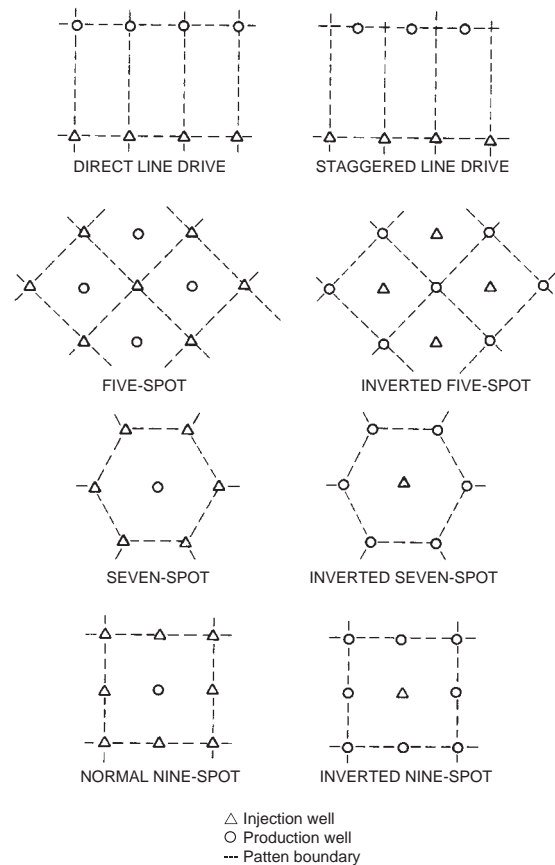

FIGURE 5.8.3 Well locations in pattern floods.

TABLE 5.8.2 Well Patterns

Pattern	Ratio of producers to injectors	Drilling pattern
Direct line drive	1	Rectangle
Staggered line drive	1	Offset line of wells
5-spot	1	Square
Normal 7-spot	1/2	Equilateral triangle
Inverted 7-spot	2	Equilateral triangle
Normal 9-spot	1/3	Square
Inverted* 9-spot	3	Square

From Reference 1.133.

**Inverted: One injection well per pattern.*

For the 7-spot and 9-spot patterns, the distinction between normal and inverted patterns is more important.

There is often confusion between well spacing (or density) and pattern size. As shown in [Figure 5.8.4](#), the pattern area for a 5-spot is twice the well spacing or well density, and the pattern area for a 9-spot is four times the well spacing. When information is given concerning patterns of a given size, the reader is cautioned to find out if well spacing or pattern size is intended.

Dimensions of various distances for 5-spot patterns and 9-spot patterns with different well spacings are given in [Table 5.8.3](#). For the 9-spot pattern, s refers to the shortest distance from a side injection well and the central producer (the opposite for an inverted pattern), and

l refers to the longest or lateral distance from injector to producer. For the 5-spot pattern, l is the lateral or straight-line distance from injector to producer, a refers to the distance between wells that are alike, and d refers to the distance between the dissimilar wells. Distances of d and a for the line drive pattern and staggered line drive pattern are shown in [Figure 5.8.5](#), the 5-spot pattern is a special case of the staggered line drive when d/a is 0.5.

Pattern selection is important because it can affect the area swept by the injected fluid. Areal or pattern sweep efficiency is discussed in the section under fluid movement in waterflooded reservoirs, but the principles apply to either water or gas injection.

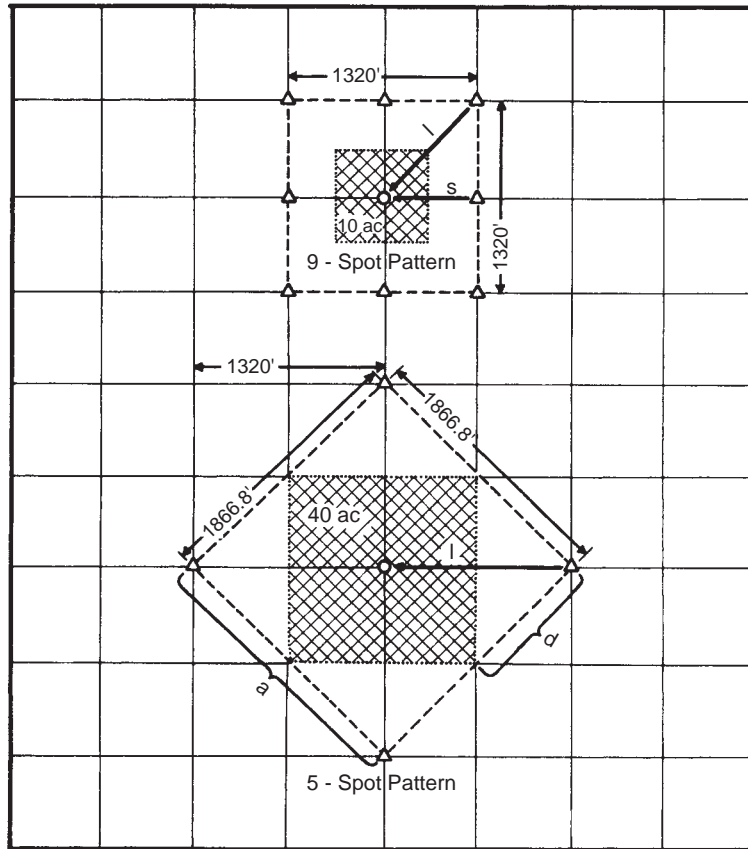

FIGURE 5.8.4 Pattern size for 9-spot and 5-spot patterns.

TABLE 5.8.3 Well Distance in 5-Spot and 9-Spot Patterns				
5-spot pattern				
Well spacing	Pattern size	a (ft)	d (ft)	l (ft)
5 acres	10 acres	660	330	467
10 acres	20 acres	933	467	660
20 acres	40 acres	1,320	660	933
40 acres	80 acres	1,867	933	1,320
9-spot pattern				
Well spacing	Pattern size	s (ft)	l (ft)	
5 acres	20 acres	467	660	
10 acres	40 acres	660	933	
20 acres	80 acres	933	1,320	
40 acres	160 acres	1,320	1,867

5.9 FLUID MOVEMENT IN WATERFLOODED RESERVOIRS

Section reviewed by Heru Danardatu

Many of the principles discussed in this section also apply to immiscible gas injection, primary recovery by gravity drainage, and natural bottom-water drive. However, because of the importance of waterflooding in the United States, the emphasis is placed on fluid movement in waterflooded reservoirs.

The importance of various factors that affect displacement of oil by water were discussed in the first section. In particular, the discussion on the effect of wettability on relative permeability characteristics is important in the understanding of oil displacement during waterflooding.

Several textbooks on waterflooding are available [1.133,5.8, 1–3]. The source most often referred to in this section is the excellent SPE monograph by Craig [1.133]; many of the principles in this monograph are summarized in the Interstate Oil Compact Commission text [2] and in an SPE paper [4]. The text by Smith [5.8] contains many useful aspects of waterflooding, and the recent SPE text [3] contains a more thorough and mathematical treatment of the subject.

5.9.1 Displacement Mechanisms

Under ideal conditions, water would displace oil from pores in a rock in a piston-like manner or at least in a manner representing a leaky piston. However, because of various wetting conditions, relative permeabilities of water and oil are important in determining where flow of each fluid occurs, and the manner in which oil is displaced by water. In addition, the higher viscosity of crude oil in comparison to water will contribute to nonideal displacement behavior. Several concepts will be defined in order that an understanding of displacement efficiencies can be achieved.

5.9.1.1 Buckley–Leverett Frontal Advance

By combining the Darcy equations for the flow of oil and water with the expression for capillary pressure, Leverett [1.100] provided an equation for the fractional flow of water, f_w at any point in the flow stream:

$$f_w = \frac{1 + \frac{kk_{ro}}{v_t \mu_o} \left(\frac{\partial P_c}{\partial L} - g \Delta \rho \sin \alpha_d \right)}{1 + \frac{\mu_w k_o}{\mu_o k_w}} \quad (5.9.1)$$

where f_w = fraction of water in the flowing stream passing any point in the rock (i.e., the water cut)
 k = formation permeability

k_{ro} = relative permeability to oil
 k_o = effective permeability to oil
 k_w = effective permeability to water
 μ_o = oil viscosity
 μ_w = water viscosity
 v_t = total fluid velocity (i.e., q_t/A)
 P_c = capillary pressure = $p_o - p_w$ = pressure in oil phase minus pressure in water phase
 L = distance along direction of movement
 g = acceleration due to gravity
 $\Delta \rho$ = water-oil density differences = $\rho_w - \rho_o$
 α_d = angle of the formation dip to the horizontal.

This equation is derived in an appendix in the monograph by Craig [1.133]. Because relative permeabilities and capillary pressure are functions of only fluid saturation, the fractional flow of water is a function of water saturation alone. In field units, Equation 5.9.1 becomes [1.133]:

$$f_w = \frac{1 + 0.001127 \frac{kk_{ro}}{\mu_o} \frac{A}{q_t} \left(\frac{\partial P_c}{\partial L} - 0.433 \Delta \rho \sin \alpha_d \right)}{1 + \frac{\mu_w k_o}{\mu_o k_w}} \quad (5.9.2)$$

where permeability is in md, viscosities are in cp, area is in sq ft, flow rate is in B/D, pressure is in psi, distance is in ft, and densities are in g/cc.

In practical usage, the capillary pressure term in Equation 5.9.1 is neglected [1.133]:

$$f_w = \frac{1 - \frac{k k_{ro}}{v \mu_o} (g \Delta \rho \sin \alpha_d)}{1 + \frac{\mu_w k_o}{\mu_o k_w}} \quad (5.9.3)$$

and for a horizontal displacement of oil by water, the simplified form of this equation is [1.133]:

$$f_w = \frac{1}{1 + \frac{\mu_w k_{ro}}{\mu_o k_{rw}}} \quad (5.9.4)$$

Examples of idealized fractional flow curves, f_w vs. S_w , are given in Figure 5.9.1 for strongly water-wet and strongly oil-wet conditions [1.133].

Based on the initial work of Leverett [1.100], Buckley and Leverett [1.152] presented equations to describe an immiscible displacement in one-dimensional flow. For incompressible displacement, the velocity of a plane of constant water saturation traveling through a linear system was given by:

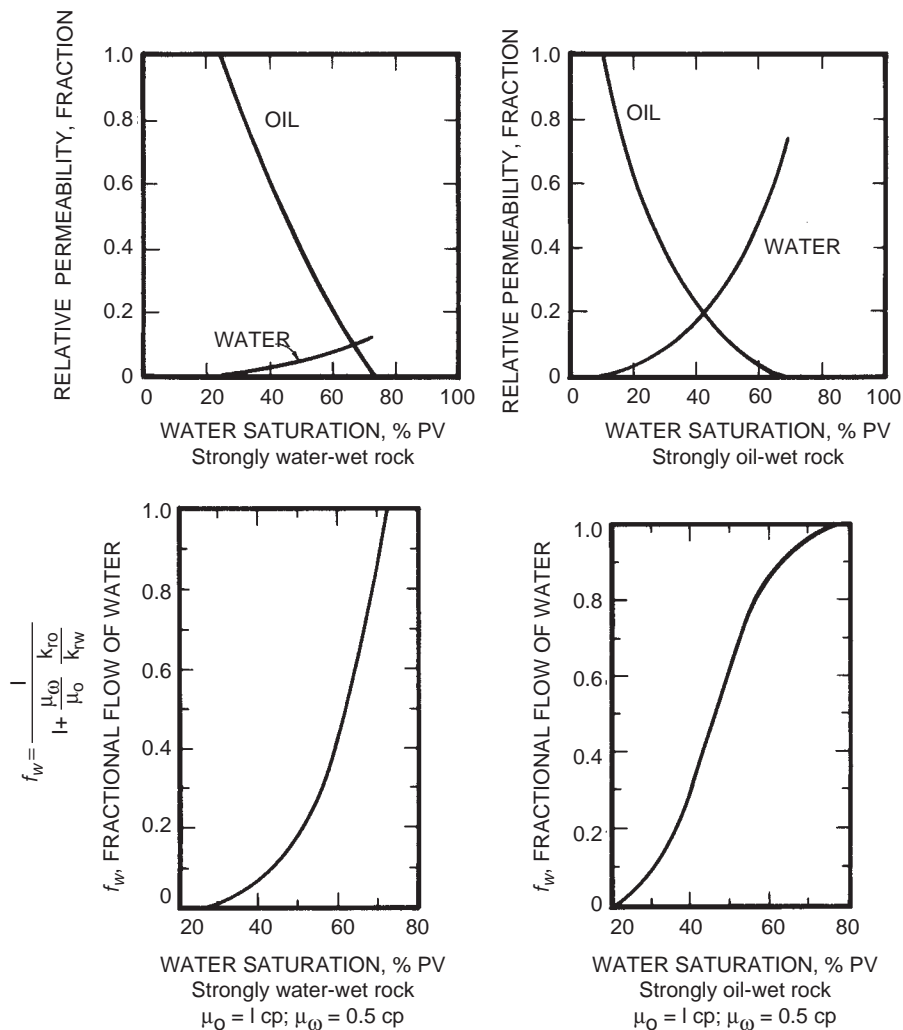

FIGURE 5.9.1 Effect of water saturation on relative permeabilities and fractional flow of water [1.133].

$$v = \frac{q}{A\phi} \left(\frac{\partial f_w}{\partial S_w} \right) \tag{5.9.5}$$

where q is the flow rate in cc/sec (or ft³/D), A is the cross-sectional area in cm² (or ft²), ϕ is the fractional porosity, v is the velocity or rate of advance in cm/sec (or ft/D), and $(\partial f_w / \partial S_w)$ is the slope of the curve of f_w vs. S_w . This equation states that the rate of advance or velocity of a plane of constant water saturation is directly proportional to the derivative of the water cut at that water saturation. By integrating Equation 5.9.5 for the total time since the start of injection, the distance that the plane of given water saturation moves can be given by:

$$L = \frac{W_i}{A\phi} \left(\frac{\partial f_w}{\partial S_w} \right) \tag{5.9.6}$$

where W_i is the cumulative water injected and L is the distance that a plane of given saturation has moved.

If L is the distance from injector to producer, the time of water breakthrough, t_{bt} , is given by:

$$t_{bt} = \frac{L}{\frac{q}{A\phi} \left(\frac{\partial f_w}{\partial S_w} \right)} \tag{5.9.7}$$

Equation 5.9.6 can be used to calculate the saturation distribution in a linear waterflood as a function of time. According to Equation 5.9.6, the distance moved by a given saturation in a given time interval is proportional to the slope of the fractional flow curve at the saturation of interest. If the slope of the fractional flow curve is graphically obtained at a number of saturations, the saturation distribution in the reservoir can be calculated as a

function of time. The saturation distribution can then be used to predict oil recovery and required water injection on a time basis. A typical plot of df_w/dS_w vs. S_w will have a maximum as shown in Figure 5.9.2. However, a problem is that equal values of the slope, df_w/dS_w , can occur at two different saturations which is not possible. To overcome this difficulty, Buckley and Leverett [1.152] suggested that a portion of the saturation distribution curve is imaginary, and that the real curve contains a saturation discontinuity at the front. Since the Buckley-Leverett procedure neglects capillary pressure, the flood front in a practical situation will not exist as a discontinuity, but will exist as a stabilized zone of finite length with a large saturation gradient.

5.9.1.2 Welge Graphical Technique

A more simplified graphical technique was proposed by Welge [153] which involves integrating the saturation distribution from the injection point to the front. The graphical interpretation of this equation is that a line drawn tangent to the fractional flow curve from the initial water saturation (S_{wi}) will have a point of tangency equal to water saturation at the front (S_{wf}). Additionally, if the tangent line is extrapolated to $f_w = 1$, the water saturation will correspond to the average water saturation in the water bank, \bar{S}_w . Construction of a Welge plot is shown in Figure 5.9.3. The tangent line

FIGURE 5.9.2 Change in fractional flow of water with change in water saturation [1.133].

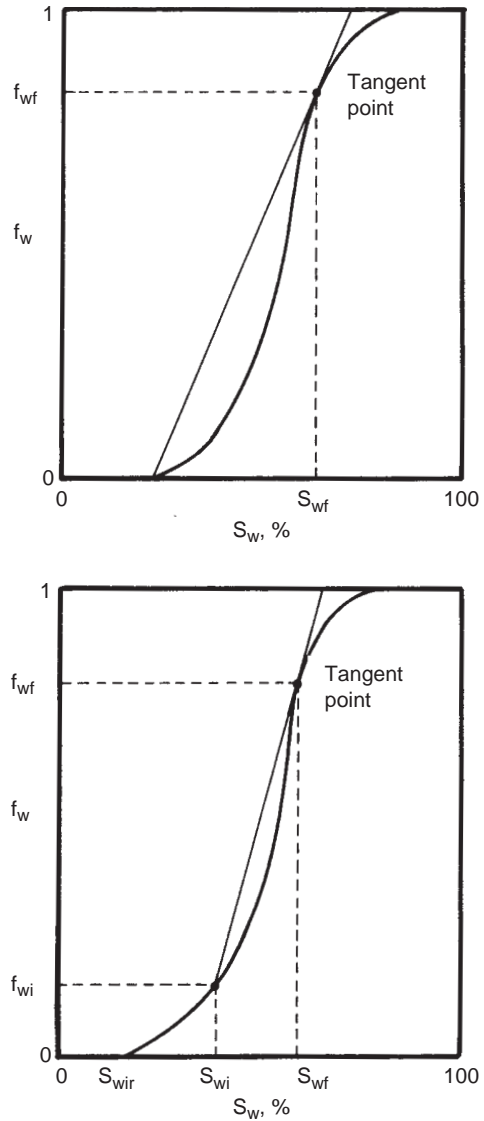

FIGURE 5.9.3 Welge graphical plot [1.153].

should be drawn from the initial water saturation even if that saturation is greater than the irreducible saturation.

Welge derived an equation that relates the average displacing fluid saturation to the saturation at the producing end of the system:

$$\bar{S}_w - S_{w2} = Q_i f_{o2} \tag{5.9.8}$$

where \bar{S}_w = average water saturation, fraction of PV

S_{w2} = water saturation at the producing end of the system, fraction of PV

Q_i = pore volumes of cumulative injected fluid, dimensionless

f_{o2} = fraction of oil flowing at the outflow end of the system

Equation 5.9.8 is important because it relates to three factors of prime importance in waterflooding [1.133]: (1) the average water saturation and thus the total oil recovery, (2) the cumulative injected water volume, and (3) the water cut and hence the oil cut.

Welge also related the cumulative water injected and the water saturation at the producing end:

$$Q_t = \frac{1}{\left(\frac{df_w}{dS_w}\right)_{S_{w2}}} \quad (5.9.9)$$

Thus, the reciprocal of the slope of the tangent line gives the cumulative water influx at the time of water breakthrough. When a value of Q_i and the injection rate are known, the time to reach that stage of the flood can be computed.

For a liquid-filled, linear system, the average water saturation at breakthrough, \bar{S}_{wbt} , is:

$$\bar{S}_{wbt} = S_{iw} + \frac{W_i}{A\phi L} \quad (5.9.10)$$

where S_{iw} is the irreducible or connate water saturation. If Equation 5.9.6 is substituted into Equation 5.9.10:

$$\bar{S}_{wbt} - S_{iw} = \frac{1}{\left(\frac{df_w}{dS_w}\right)} = \frac{S_{wf} - S_{iw}}{f_{wf}} \quad (5.9.11)$$

where S_{wf} is the water saturation at the flood front and f_{wf} is the water cut at the flood front. After breakthrough, water saturation is obtained from Equations 5.9.8 and 5.9.9 where, as mentioned earlier: (1) the tangent point, S_{w2} , represents the water saturation at the producing end of the system, (2) the value of f_w at the point of tangency is the producing water cut, (3) the saturation at which the tangent intersects $f_w = 1.0$ is the average water saturation, and (4) the inverse of the slope of the tangent line is equal to the cumulative injected fluid in pore volumes (Q_i). If connate water is mobile, appropriate corrections need to be made [1.133].

Oil production at breakthrough can be computed from [3]:

$$N_{pbt} = \frac{\phi AL}{B_o} (\bar{S}_{wbt} - S_{iw}) \quad (5.9.12)$$

After water breakthrough, a number of saturation greater than S_{wf} are selected; the slope of the tangent line and average water saturation are determined for each value of S_w chosen. Oil production after breakthrough is then determined by observing the change in water saturation [3]:

$$\Delta N_p = \frac{\phi AL}{B_o} (\bar{S}_w - \bar{S}_{wbt}) \quad (5.9.13)$$

The incremental oil production from Equation 5.9.13 can be added to the breakthrough production from Equation 5.9.12, and the resulting total production for the linear system can be listed as a function of S_w , time, or other parameters. If the pore volumes in these equations are in ft^3 , divide by 5.615 to get barrels.

5.9.2 Viscous Fingering

A problem often encountered in the displacement of oil by water is the viscosity contrast between the two fluids. The adverse mobility ratios that result promote fingering of water through the more viscous crude oil and can reduce the oil recovery efficiency. An example of viscous fingering is shown in Figure 5.9.4.

5.9.3 Mobility and Mobility Ratio

Mobility of a fluid is defined as the ratio of the permeability of the formation to a fluid, divided by the fluid viscosity:

$$\lambda = \frac{k}{\mu} \quad (5.9.14)$$

where λ = mobility, md/cp
 k = effective permeability of reservoir rock to a given fluid, md
 μ = fluid viscosity, cp

When multiple fluids are flowing through the reservoir, relative permeabilities must be used along with viscosities of the fluids. By convention, the term mobility ratio is defined as the mobility of the displacing fluid divided by the mobility of the displaced fluid. For waterfloods, this is the ratio of water to oil mobilities. Thus the mobility ratio, M , for a waterflood is:

FIGURE 5.9.4 Viscous fingering.

$$M = \frac{k_{rw}/\mu_w}{k_{ro}/\mu_o} = \frac{k_{rw}\mu_o}{k_{ro}\mu_w} \quad (5.9.15)$$

where k_{rw} and k_{ro} , are relative permeabilities to water and oil, respectively, μ_o is oil viscosity and μ_w is water viscosity. Prior to 1957, there was no accepted definition, and many workers defined mobility ratio as oil to water mobility; in this case, the reciprocal of mobility ratio (as now accepted) must be used. The oil mobility used in Equation 5.9.10 refers to the location in the oil bank ahead of the flood front. For the water mobility, there are several possibilities regarding the location at which the relative permeability should be chosen: at the flood front, at residual oil saturation where only water is flowing (end point), or at some intermediate saturation. Craig [1.133] found a better correlation if the water mobility was determined at the average water saturation behind the flood front at water breakthrough. Thus for the mobility ratio expression, the relative permeability of water is found at the average water saturation at water break-through as determined by the Welge graphical approach. As Craig notes, the mobility ratio of a waterflood will remain constant before breakthrough, but it will increase after water breakthrough corresponding to

the increase in water saturation and relative permeability to water in the water-contacted portion of the reservoir. Unless otherwise specified, the term mobility ratio is taken to be the value prior to water breakthrough. As will be discussed later in this section, mobility ratio is important in determining the volume of reservoir contacted by the waterflood.

5.9.4 Recovery Efficiency

Recovery efficiency is the fraction of oil in place that can be economically recovered with a given process. The efficiency of primary recovery mechanisms will vary widely from reservoir to reservoir, but the efficiencies are normally greatest with water drive, intermediate with gas cap drive, and least with solution gas drive. Results obtained with waterflooding have also varied. The waterflood recovery can range from less than the primary recovery to as much as 2.5 times the recovery obtained in some solution-gas drive reservoirs. A recent statistical analysis by the API [4.1] provided the average primary and secondary recovery efficiencies in Table 5.9.1. Generally, primary and ultimate recoveries from carbonate reservoirs tend to be

TABLE 5.9.1 Ultimate Recovery (Primary Plus Secondary)

lower than from sandstones. For pattern waterfloods, the average ratio of secondary to primary recovery ranges from 0.33 in California sandstones to greater than one in Texas carbonates. For edge water injection, the secondary-to-primary ratio ranged from an average of 0.33 in Louisiana to 0.64 in Texas. By comparison, secondary recovery for gas injection into a gas cap averaged only 0.23 in Texas sandstones and 0.48 in California sandstones. Ultimate primary and secondary recovery performance for different drive mechanisms are given in Table 5.9.2. Solution-gas-drive reservoirs will generally have higher oil saturations after primary recovery, and are usually the better candidates for waterflooding.

Displacement of oil by waterflooding is controlled by fluid viscosities, oil-water relative permeabilities, nature of the reservoir rock, reservoir heterogeneity, distribution of pore sizes, fluid saturations (especially the amount of oil present), capillary pressure, and the location of the injection wells in relation to the production wells. These factors contribute to the overall process efficiency. Oil recovery efficiency (E_R) of a waterflood is the product of displacement efficiency (E_D) and volumetric efficiency (E_V), both of which can be correlated with fluid mobilities:

$$E_R = E_D E_V = E_D E_P E_I \quad (5.9.16)$$

where E_R = overall reservoir recovery or volume of hydrocarbons recovered divided by volume of hydrocarbons in place at start of project

E_D = volume of hydrocarbons (oil or gas) displaced from individual pores or small groups of pores divided by the volume of hydrocarbons in the same pores just prior to displacement

E_P = pattern sweep efficiency (developed from areal efficiency by proper weighting for variations in net pay thickness, porosity, and hydrocarbon saturation): hydrocarbon pore space enclosed behind the injected-fluid front divided by total hydrocarbon pore space of the reservoir or project.

E_I = hydrocarbon pore space invaded (affected, contacted) by the injection fluid or heat-front divided by the hydrocarbon pore space enclosed in all layers behind the injected fluid

5.9.5 Displacement Sweep Efficiency (E_D)

Factors affecting the displacement efficiency for any oil recovery process are pore geometry, wettability (water-wet, oil-wet, or intermediate), distribution of fluids in the reservoir, and the history of how the saturation occurred. Results are displayed in the relative permeability curves

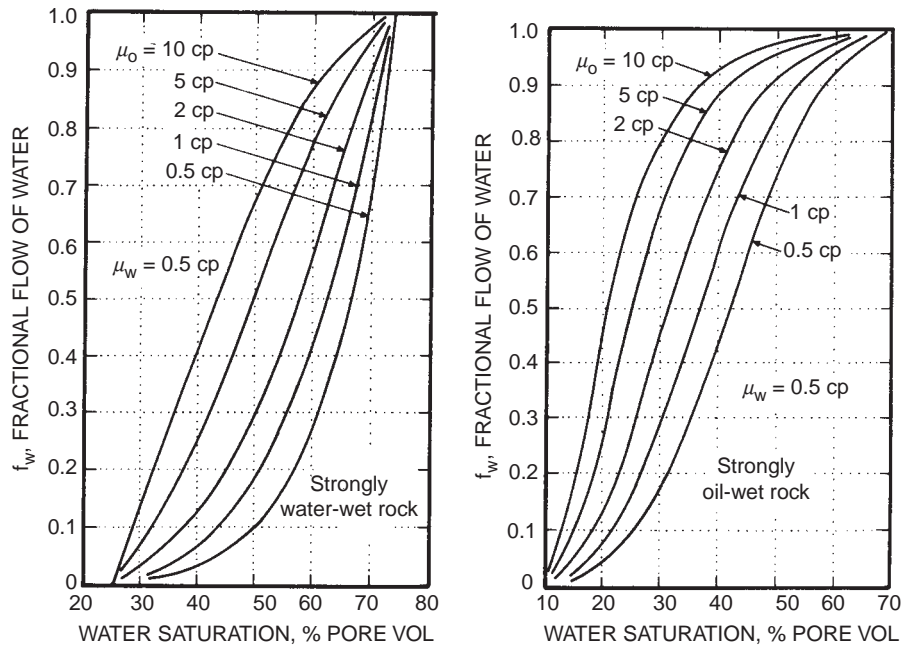

FIGURE 5.9.5 Effect of oil viscosity on fractional flow of water [1.133].

(Figure 5.9.1) from which the flowing water saturation (or conversely the oil saturation) can be obtained at any total fluid saturation. As shown in Figure 5.9.5, displacement efficiencies decrease as oil viscosities increase [1.133].

5.9.6 Volumetric Sweep Efficiency (E_V)

Whereas displacement efficiency considers a linear displacement in a unit segment (group of pores) of the reservoir, macroscopic or volumetric sweep takes into account that fluid (i.e., water) is injected at one point in a reservoir and that other fluids (i.e., oil, water) are produced from another point (Figure 5.9.6). Volumetric sweep efficiency, the percentage of the total reservoir contacted by the injected fluid (often called fluid conformance), is composed of areal (or pattern) efficiency and vertical sweep.

5.9.7 Areal or Pattern Sweep Efficiency (E_P)

Areal sweep efficiency of an oil recovery process depends primarily on two factors: the flooding pattern and the mobilities of the fluids in the reservoir. In the early work on sweep efficiency and injectivity, Muskat and coworkers [1.25,5] presented analytical solutions for direct line drive, staggered line drive, 5-spot, 7-spot, and 9-spot patterns (patterns were discussed earlier; see Figure 5.8.3). Experimental studies on the effect of mobility ratio for different patterns were presented by Dyes, Caudle, and Erickson [6] (5-spot and line drives); Craig, Geffen, and Morse [7], Prats et al. [8], Caudle and Witte [9], and Haberman [10] (5-spot);

and Kimbler, Caudle, and Cooper [11] (9-spot). The effect of sweepout beyond the pattern area was studied as well [12,13]. From a mathematical study the breakthrough sweep efficiency of the staggered line drive was presented by Prats [14]. A comparison of the areal sweep efficiency and the ratio d/a is shown in Figure 5.9.7 for direct and staggered line drives [1.25,14], and a review of the early work was provided by Crawford [15].

Areal sweep efficiency at breakthrough for a 5-spot pattern is shown in Figure 5.9.8, and the effect of mobility ratio on areal sweep is shown in Figure 5.9.9. These figures show that areal sweep efficiency is low when mobility ratio is high (note that the data in Figure 5.9.9 from Dyes, Caudle and Erickson are plotted in terms of the reciprocal of mobility ratio as currently defined). Areal sweep efficiencies at breakthrough, for different patterns and a mobility ratio of one, are summarized in Table 5.9.3 [1.133,2,4].

Areal sweep efficiency is more important for considering rate vs. time behavior of a waterflood rather than ultimate recovery because, at the economic limit, most of the interval flooded has either had enough water throughout to provide 100% areal sweep or the water bank has not yet reached the producing well so that no correction is needed for areal sweep [1.133].

When waterflooding calculations are performed, especially with computers or programmable calculators, the use of equations with adjustable coefficients are very useful. Recently, Fassihi [16] provided correlations for the calculation of areal and vertical sweep efficiencies. For these correlations of areal sweep, the data of Dyes, Caudle, and

FIGURE 5.9.6 Sweep efficiencies.

FIGURE 5.9.9 Effect of mobility ratio on areal sweep efficiency after breakthrough for a 5-spot pattern [6].

Erickson [6] were curve-fitted and the resulting equation was:

$$\frac{1 - E_p}{E_p} = [a_1 \ln(M + a_2) + a_3]f_w + a_4 \ln(M + a_5) + a_6 \quad (5.9.17)$$

where E_p is the areal sweep efficiency which is the fraction of the pattern area contacted by water, M is the mobility ratio, and the coefficients are as listed in Table 5.9.4 for the 5-spot, direct line drive, and staggered line drive. These

coefficients are valid both before and after breakthrough, and apply to mobility ratios between zero and ten, which is within the range observed in many waterfloods. For the 5-spot pattern, these values of E_p are generally higher than in later experiments, and a correction has been suggested by Claridge [17] that should be multiplied by the E_p from the Dyes et al. data:

$$E_v = \frac{E_p/V_d}{\{M^{0.5} - [(M - 1)(1 - E_p/V_d)]^{0.5}\}^2} \quad (5.9.18)$$

where E_V is the volumetric sweep efficiency in a linear displacement, V_d is the displaceable pore volumes injected, and the other terms are as already defined.

5.9.8 Vertical or Invasion Sweep Efficiency (E_i)

For well-ordered sandstone reservoirs, the permeability measured parallel to the bedding planes of stratified rocks is generally larger than the vertical permeability. For carbonate reservoirs, permeability (and porosity) may have developed after the deposition and consolidation of the formation; thus the concept of a stratified reservoir may not be valid. However, in stratified rocks, vertical sweep

efficiency takes into account the inherent vertical permeability variations in the reservoir. Vertical sweep efficiency of a waterflood depends primarily upon the vertical distribution of permeabilities within the reservoir, on the mobility of fluids involved, and on the density differences between flowing fluids. As a result of nonuniformity of permeabilities in the vertical direction, fluid injected into an oil-bearing formation will seek the paths of least resistance and will move through the reservoir as an irregular front. Consequently, the injected fluid will travel more rapidly in the more permeable zones and will travel less rapidly in the tighter zones. With continued injection, and displacement of some of the resident fluids, the saturation of the injected fluid will become greater in the more permeable areas than in the low-permeability strata. This can cause early breakthrough of injected fluid into the producing wells before the bulk of the reservoir has been contacted. In addition, as the saturation of the injected fluid increases in the highly permeable zones, the relative permeability to that fluid also increases. All of these effects can lead to channeling of the injected fluid, which is aggravated by the unfavorable viscosity ratio common in waterflooding. In many cases, permeability stratification has a dominant effect on behavior of the waterflood.

5.9.9 Permeability Variation

Two methods of quantitatively defining the variation in vertical permeabilities in reservoirs are commonly used. The extent of permeability stratification is sometimes described with the Lorenz coefficient [18] and is often described with the Dykstra–Parsons [19] coefficient of permeability variation.

5.9.9.1 Lorenz Coefficient

Schmalz and Rahme [18] suggested arranging the vertical distribution of permeabilities from highest to lowest, and plotting the fraction of total flow capacity (kh) versus the fraction of total volume ($h\phi$). To obtain the Lorenz coefficient (see Figure 5.9.10), the area ABCA is divided by the area ADCA. Values of the Lorenz coefficient can range from zero for a uniform reservoir to a theoretical maximum value of one. However, the Lorenz coefficient is not a unique measure of stratification, and several different permeability distributions can give the same Lorenz coefficient [1.133].

5.9.9.2 Dykstra–Parsons Coefficient of Permeability Variation

The coefficient of permeability variation described by Dykstra and Parsons [19] is also referred to as the permeability variation or permeability variance. This method assumes that vertical permeabilities in a reservoir will have

FIGURE 5.9.10 Lorenz coefficient plot [1.133].

a log-normal distribution. The procedure outlined by Dykstra and Parsons was to: (1) divide permeabilities (usually from core analysis) so that all samples are of equal thickness (often 1 ft), (2) arrange the permeabilities in descending order from highest to lowest, (3) calculate for each sample the percent of samples that have a higher permeability (see example in Table 5.9.5), (4) plot the data from Step 3 on log-probability paper (see Figure 5.9.11) (5) draw the best straight line through data (with less emphasis on points at the extremities, if necessary), (6) determine the permeability at 84.1% probability ($k_{84.1}$) and the mean permeability at 50% probability (k_{50}), and (7) compute the permeability variation, V :

$$V = \frac{k_{50} - k_{84.1}}{k_{50}} \quad (5.9.19)$$

As with the Lorenz coefficient, the possible values of the Dykstra–Parsons permeability variation range from zero for a uniform reservoir to a maximum value of 1. In some cases, there may be a direct relation between the Lorenz and Dykstra–Parsons coefficients [20], but in many instances a direct relationship with field data will not be observed. Often, insufficient data are available to provide

enough samples for adequate analysis, and in some cases, the data may not provide a log-normal distribution. In the remainder of this chapter, the term permeability variation will refer to the Dykstra–Parsons coefficient of permeability variation.

Increasing values of permeability variation indicate increasing degrees of vertical heterogeneity in a reservoir. Permeability variations often range from about 0.5 to 0.8; lower numbers may be observed for relatively uniform reservoirs, and higher numbers may be calculated for very nonuniform reservoirs. Using the data from Dykstra and Parsons, Johnson [21] provided a graphical technique to estimate recovery during an immiscible displacement. One of Johnson's plots is reproduced in Figure 5.9.12 for a producing water-oil ratio (WOR) of 100 which could represent the economic limit for many waterfloods. Lines of constant recovery are given as functions of permeability variation and mobility. Johnson also provided plots for WOR = 1, WOR = 5, and WOR = 25. At any WOR, an increase in vertical permeability variation yielded a lower recovery. As will be discussed later under prediction methods, the Dykstra–Parsons fractional recovery, R , as a percent of oil in place, must be multiplied by the areal sweep efficiency, E_p , to obtain an estimate of the oil recovered.

TABLE 5.9.5 Data for Permeability Variation plot

Permeability (md)	Percent of samples with greater than stated permeability
950	0
860	5

160	35
135	40
130	45
110	50
78	55
65	60
63	65
54	70
40	75
27	80
21	85
20	90
15	95

As mentioned earlier, correlations for calculating vertical and areal sweep efficiencies were provided by Fassihi [16]. The correlating parameter, Y , for vertical coverage, C , is:

$$Y = a_1 C^{a_2} (1 - C)^{a_3} \quad (5.9.20)$$

where $a_1 = 3.334088568$
 $a_2 = 0.7737348199$
 $a_3 = -1.225859406$

where the equation for Y was given by deSouza and Brigham [22] in terms of water-oil ratio (WOR), mobility ratio (M), and permeability variation (V):

$$Y = \frac{(\text{WOR} + 0.4)(18.948 - 2.499 V)}{(M + 1.137 - 0.8094 V)^{f(V)}} \quad (5.9.21)$$

where $f(V) = -0.6891 + 0.9735 V + 1.6453 V^2$.

These equations are valid for mobility ratios ranging from 0 to 10 and for permeability variations ranging from 0.3 to 0.8.

Based on calculations of WOR vs. oil recovery for a 5-spot pattern, Craig [23] found that there was a minimum number of equal thickness layers required to obtain the same performance as with 100 layers. Table 5.9.6 shows the effect of permeability variation and mobility ratio on the minimum number of layers for WORs above 10. Craig [23] presented similar tables for lower WORs.

A recent analytical extension [24] of the Dykstra-Parsons method allows calculations of total flow rates and flow rates in each layer for both a constant injection rate and for a constant pressure drop. The ability to calculate cumulative injection into a layer allows the incorporation of sweep efficiency of each layer as a function of mobility ratio and displaceable pore volumes injected for the pattern used in the waterflood.

5.9.9.3 Crossflow

In the usual cases where there is vertical communication between the different layers of varying permeabilities, the effect of vertical crossflow must be considered [25, 26]. Goddin et al. [26] performed a numerical simulation in a 2-D, 2-layer, water-wet system. For mobility ratios ranging from 0.21 to 0.95, oil recovery with crossflow was between that computed for a uniform reservoir and that for a layered reservoir with no crossflow. Goddin et al. [26] defined a crossflow index, which is a measure of the extent the performance varies from that of a uniform permeability system:

$$\text{crossflow index} = \frac{N_{\text{pcf}} - N_{\text{pnfcf}}}{N_{\text{pu}} - N_{\text{pnfcf}}} \quad (5.9.22)$$

where N_{pu} = oil recovery from uniform system with the average permeability

N_{pcf} = oil recovery from layered system with crossflow

N_{pnfcf} = oil recovery from stratified system with no crossflow

Of the variables investigated, mobility ratio and the permeability ratio of the two layers had the largest effect on crossflow (see Figures 5.9.13 and 5.9.14, respectively). Crossflow was more pronounced at lower mobility ratios or at high ratios of layer permeabilities. The crossflow index of one means that the performance of the layered system with crossflow is identical to the performance of the system with uniform permeability.

Still at issue is the relative importance of mobility ratio and gravity in waterflooding stratified reservoirs [27–31]. For wetting conditions that are not strongly water-wet, additional complications will arise.

FIGURE 5.9.13 Influence of mobility ratio on vertical crossflow [26].

5.9.9.4 Estimates of Volumetric Sweep Efficiency

Volumetric sweep efficiency ranges from about 0.1 for very heterogeneous reservoirs to greater than 0.7 for homogeneous reservoirs with good flooding characteristics [3]. For a liquid-filled, 5-spot pattern, Craig [23] found that the volumetric sweep efficiency (E_V) at breakthrough decreases sharply as the permeability variation increases

(see Figure 5.9.15). Similar trends were observed for initial gas saturations of 10% and 20%. These data indicated that the major effect of mobility ratio on E_V at breakthrough occurs for mobility ratios ranging from 0.1 to 10.

More recent simulations [32] of 5-spot patterns with a streamtube model yielded the volumetric sweep efficiencies shown in Figures 5.9.16 and 5.1.17 for WORs of 25 and 50, respectively. Mobility ratios of 0.1, 1, 10, 30, and 100

FIGURE 5.9.14 Effect of layer permeability ratio on crossflow [26].

FIGURE 5.9.15 Effect of permeability variation and mobility ratio on volumetric sweep at breakthrough [23].

were used. The permeabilities in the 100-layer model were assumed to have a log-normal distribution, and pseudo-relative permeability expressions were used. In a companion paper [33] the streamtube model (no crossflow) was compared to the Dykstra–Parsons method (no crossflow) and with a model having the assumption of equal pressure gradient in each layer (with crossflow). The streamtube model was more closely described by the model with vertical communication for unfavorable (high) mobility ratios and by the Dykstra–Parsons model for favorable (low) mobility ratios.

5.9.10 Estimation of Waterflood Recovery by Material Balance

Oil recovered by waterflooding, N_{pw} , in STB, can be estimated from [3]:

$$N_{pw} = \frac{7,758 Ah\phi[S_{op} - E_v S_{or} - (1 - E_v)S_{oi}]}{B_o} \quad (5.9.23)$$

where 7,758 is the number of barrels per acre-ft, A is areal extent of the reservoir in acres, h is reservoir thickness in ft, ϕ is the fractional porosity, S_{op} is the oil saturation at

FIGURE 5.9.16 Effect of permeability variation and mobility ratio on volumetric sweep at breakthrough [32].

FIGURE 5.9.17 Effect of permeability variation and mobility ratio on volumetric sweep at WOR = 50 [32].

the start of waterflooding, S_{or} is the waterflood residual oil saturation, S_{oi} is the initial oil saturation, B_o is the oil formation volume factor, and E_v is the volumetric sweep or fraction of the reservoir volume swept by the injected water when the economic limit has been reached. In terms of the original oil in place, the waterflood recovery is [3]:

$$N_{pw} = (N - N_p) - N \frac{B_{oi}}{B_o} \left[1 + E_v \left(\frac{S_{or}}{S_{oi}} - 1 \right) \right] \quad (5.9.24)$$

where N_{pw} = oil potentially recoverable by waterflooding, STB

N = initial oil in place, STB

N_p = oil produced during primary operations, STB

B_{oi} = initial FVF

These equations can be altered to include a residual gas saturation, if present. The volumetric sweep efficiency can be estimated from one of the correlations given previously or can be obtained from an analogy from similar water-flood projects.

5.9.11 Prediction Methods

An extensive survey on prediction of waterflood performance was provided by Craig [1.133]. Of the methods reviewed, three appeared most promising: (1) the Higgins-Leighton streamtube model [34], (2) the Craig, Geffen, and Morse model [7], and (3) the Prats et al. method [8]. Discussion of the various prediction methods is beyond the scope of this text, and only two very simple methods will be presented for illustrative purposes. Both the Dykstra-Parsons [19] and Stiles [35] methods are very cursory and, if used, they are normally followed by more extensive evaluations, usually by computer simulation.

For either the Dykstra-Parsons or Stiles methods, the permeabilities are arranged in descending order. For the Dykstra-Parsons method, the permeability variation is determined as described earlier. Two options are then possible: a program [36] for hand-held calculators can be used, or the graphical technique presented by Johnson [21] can be used. The fractional recovery, R , (see Figure 5.9.12 for example) expressed as a fraction of the oil in place when the waterflood is started, must be multiplied by the areal sweep efficiency (for example from Figure 5.9.9) to obtain the waterflood recovery.

For the Stiles technique, a program [37] for hand-held calculators is available or the procedure summarized in Table 5.9.7 can be used. A straightforward presentation of the Stiles method is in the text by Craft and Hawkins [1.17]. The fractional recovery obtained with the Stiles method is a fraction of the recoverable oil ($S_{op} - S_{or}$) that has been

TABLE 5.9.7 Stiles Method of Calculating Waterflood Performance in Stratified Reservoirs

$R = \frac{[k_j h_j + (c_t - c_j)]}{k_j h_t}$	
R = fraction of recoverable oil that has been produced	
c_t = total capacity of formation (md-ft)	
c_j = md-ft which have been completely flooded with water	
h_t = total net thickness of formation (ft)	
h_j = total net thickness flooded (ft)	
k_j = permeability of layer just flooded out	
<i>Reservoir conditions at P.W.</i>	<i>Surface conditions</i>
$f_w = \frac{M c_j}{[M c_j + (c_t - c_j)]}$	$f'_w = \frac{A c_j}{[A c_j + (c_t - c_j)]}$
f_w = fractional flow of water	$A = \frac{k_{rw} \mu_o B_o}{k_{ro} \mu_w B_w}$
$M = \frac{k_{rw} \mu_o}{k_{ro} \mu_w}$	B_o = oil formation volume factor
	B_w = water formation volume factor
<i>From Reference 1.17.</i>	

recovered at a given reservoir water cut. Since a water-oil ratio (WOR) is measured at surface conditions, the fractional water cut at reservoir conditions, f_w , is obtained (assuming $B_w = 1.0$) from:

$$f_w = \frac{WOR}{WOR + B_o} \quad (5.9.25)$$

where B_o is the oil formation volume factor.

5.9.12 Performance Evaluation

Monitoring waterflood performance is crucial to the success of the flood. From a reservoir engineering standpoint, the primary concerns are water injectivity and oil productivity. A few important factors related to these concerns will be summarized.

5.9.13 Injectivity and Injectivity Index

Whereas productivity index was the ability of a well to produce hydrocarbons, injectivity index, I , in B/D/psi, is a measure of the ability of a well to accept fluids [1.17]:

$$I = \frac{q_{sc}}{P_{iwf} - P_e} \quad (5.9.26)$$

where q_{sc} is the flow rate in B/D at surface conditions, P_{iwf} is the flowing bottomhole pressure in psi, and P_e is the external pressure in psi. Some engineers express injectivity in terms of q_{sc}/p_{iwf} so that when injectivity is given, the reader is cautioned to understand what base pressure was intended. By dividing I by reservoir thickness, a specific injectivity index (specific to one well) can be obtained in B/D/psi/ft. In addition to expressing injectivity in terms of fluid injection rate in B/D, injectivity also is given as B/D/ac-ft and B/D/net ft of producing interval. Values of injectivity depend on properties of the reservoir rock, well spacing, injection water quality, fluid-rock interactions, and pressure drop in the reservoir. Typical values of injectivity are in the range of 8–15 B/D/net ft or 0.75 – 1.0 B/D/net ac-ft. In waterflooding operations, water injection may begin into a reservoir produced by solution-gas-drive in which a mobile gas saturation exists, or injection may begin prior to the development of a mobile gas saturation. In the latter case, the system can be considered filled with liquid.

5.9.13.1 Injectivities for Various Flood Patterns

Analytical expressions for liquid-filled patterns were given by Muskat [1.25] and Deppe [38] for a mobility ratio of one (see Table 5.9.8). While these exact analytical solutions can be developed for steady-state pressure distributions,

the equations in Table 5.9.8 cannot be used directly if the mobility is not one. However, the equations are useful in estimating injectivity in limiting conditions. For example, if k and μ are selected for oil at the connate water saturation, an estimate of initial injection rate can be obtained. Then if k and μ are selected for water at residual saturation, an estimate can be made of injectivity at 100% sweep. (These estimates can be useful when equipment is sized for a waterflood). If data on skin factor are available, suitable corrections [2.18,5.8,3] can be inserted in the logarithm term in the denominator in these equations. For unit mobility ratio, the injection rate will remain constant during the flood. If the mobility ratio is more than one, the injection rate increases as more water is injected; if the mobility ratio is less than one, the injection rate decreases. Figure 5.9.18 shows for different mobility ratios, the change in relative injectivity as the water bank extends radially from the injector [23]. Figure 5.9.19 shows, for different mobility ratios, the change in relative injectivity as a 40-acre 5-spot is swept [23].

For water injection into a depletion drive reservoir, several stages can describe the progress of the flood [2.1]. The first stage is the period of radial flow from the start of infection until interference of oil banks from adjacent injectors occurs. The second stage is the period from interference until fill-up of the pre-existing gas space; after fill-up, production response begins. The third stage is the period from fill-up to water breakthrough into the producing

TABLE 5.9.8 Injection Rates in Fully Developed Patterns at Unit Mobility Ratio

Direct line drive $\frac{d}{a} \geq 1$	Staggered line drive

$i = \frac{0.003541 kh(\Delta p)}{\mu \left[\ln \left(\frac{d}{r_w} \right) - 0.619 \right]}$	$i = \frac{0.00472 kh(\Delta p)}{\mu \left[\ln \left(\frac{d}{r_w} \right) - 0.569 \right]}$
Nine-spot	Nine-spot
$i = \frac{0.003541 kh(\Delta p)_{i,c}}{\left(\frac{1+R}{2+R} \right) \left[\ln \frac{d}{r_w} - 0.272 \right] \mu}$	$i = \frac{0.00782 kh(\Delta p)_{i,s}}{\left(\frac{3+R}{2+R} \left[\ln \frac{d}{r_w} - 0.272 \right] - \frac{0.693}{2+R} \right) \mu}$

R = ratio of producing rate of corner well to side well

$(\Delta p)_{i,c}$ = pressure difference between injection well and corner well, and

$(\Delta p)_{i,s}$ = pressure difference between injection well and side well.

From References 1.25 and 38.

*Units in these equations are B/D, md, ft, psi, and cp.

FIGURE 5.9.18 Change in injectivity at varying radial distances for different mobility ratios [23].

FIGURE 5.9.19 Change in injectivity as a function of area swept for different mobility ratios [23].

wells; water production begins at breakthrough. The fourth and final stage is the period from water breakthrough until floodout. For a 5-spot pattern, the injection rate during fill-up and to the time of interference can be estimated by [3]:

$$i = \frac{0.007082 k_w \left(\frac{k_{ro}}{\mu_o} \right) h (p_{iwf} - p_{wf})}{\frac{1}{M} \ln \frac{r_f}{r_w} + \ln \frac{r_{ob}}{r_f}} \quad (5.9.27)$$

where oilfield units of B/D, md, cp, ft, and psi are used, and

r_{ob} = radius of the oil bank, $r_w \leq r_{ob} \leq d/\sqrt{2}$

r_f = radius of the flood-front saturation

Both r_{ob} and r_f can be obtained by a material balance on the injected water:

$$W_i = \pi(r_f^2 - r_w^2)(\bar{S}_w - S_{iw})h\phi \quad (5.9.28)$$

$$r_f = \sqrt{\frac{W_i}{\pi\phi h(\bar{S}_w - S_{iw})} + r_w^2} \quad (5.9.29)$$

Since the volume of water injected to fill-up is equal to the volume of gas displaced by the oil bank as the initial gas saturation, S_{gi} , is reduced to the trapped-gas saturation, S_g , a material balance for r_{ob} , is:

$$r_{ob} = \sqrt{\frac{W_i}{\pi\phi h(S_{gi} - S_{gt})} + r_w^2} \quad (5.9.30)$$

At interference, $r_{ob} = d/\sqrt{2}$, and Equation 5.9.30 can be used to compute the volume of water required to reach interference. Usually, fill-up occurs in a relatively short time after interference, and the volume of water injected at fill-up is:

$$W_{if} = 2d^2\phi h S_{gi} \quad (5.9.31)$$

At fill-up, r_f is obtained by:

$$r_f = \sqrt{\frac{2d^2 S_{gi}}{\pi(\bar{S}_w - S_{iw})} + r_w^2} \quad (5.9.32)$$

After interference, the equation in Table 5.9.8 for the 5-spot pattern can be used to estimate injectivity. Additional details of estimating injectivity can be found in several good texts on this subject [2.18,5.8,3].

5.9.13.2 Monitoring Injectivity

Injection well performance can be analyzed and monitored by several means. During and after a period of injection, the pressure transient methods discussed earlier can be used. Additionally, several bookkeeping methods of monitoring injection rates and pressures are quite useful.

Hearn [39] proposed a method to analyze injection well pressure and rate data. Permeability is obtained from the

FIGURE 5.9.20 Hall plot [40].

slope of a plot of $\Delta p/q_w$ versus the logarithm of cumulative water injected. However, the method can only be used during the initial injection period. After fill-up, $\Delta p/q$, the reciprocal of injectivity index, will cease to be a function of cumulative water injected unless the well experiences damage or is stimulated. In these cases, the plots suggested by Hall [40] are convenient for analysis of the data.

A Hall plot is a graph of cumulative pressure-time versus cumulative water injection. Such plots are useful in observing injection well plugging or any beneficial results of stimulation procedures. An improvement in injectivity is indicated if the slope decreases, whereas plugging is suspected if the slope steepens. Figure 5.9.20 shows an improvement in water injectivity that resulted from a surfactant treatment [41].

The reciprocal of the Hall plot slope is the injectivity index in bbl/D/psi. Effective pressures are obtained by subtracting the static reservoir pressure from the flowing bottomhole pressures [40]:

$$\text{effective pressure} = P_{iwf} - \bar{p} = (p_{wh} + 0.45 D - \Delta p_t) - \bar{p} \quad (5.9.33)$$

where p_{wh} is the wellhead pressure, 0.45 is the hydrostatic pressure gradient in psi/ft, D is the depth to the midpoint of the reservoir, and Δp_t is the pressure drop in the tubing. Although the Hall method assumes that only the wellhead pressure changes with cumulative water injected, the effective pressure drop should be used if permeability capacity, or transmissibility changes, are desired [40]. If the difference between reservoir pressure and the hydrostatic head is more than 15% of the wellhead pressure, serious

quantitative errors can result when wellhead pressures are used in the construction of Hall plots; if the difference is less than 15%, only slight errors are caused [1.66].

Earlougher has presented a modified version of the Hall technique in which the slope, m' , is defined as [1.66]:

$$m' = \frac{141.2 \mu}{kh} \left[\ln \left(\frac{r_e}{r_w} \right) + s \right] \quad (5.9.34)$$

The improvement in overall flow efficiency, E_f , can be obtained from [1.66]:

$$\frac{E_f \text{ after}}{E_f \text{ before}} = \frac{m' \text{ before}}{m' \text{ after}} = \frac{I \text{ after}}{I \text{ before}} \quad (5.9.35)$$

where the injectivity index, I , or Hall slopes are calculated using the pressure difference between the flowing bottom-hole pressure and the formation pressure.

5.9.13.3 Production Curves

Plots of waterflood injection and production performance can be presented in a number of ways. For the history of the project, water injection rate, oil production rate, and water-oil ratio or water cut can be plotted vs. time (usually months). The actual water injection and oil production rates can be compared to the predicted rates on a time basis.

Future oil production and ultimate recovery are often extrapolated from graphical methods. One of the more popular methods is a plot of the WOR on a log scale vs. cumulative oil production on a linear scale or a linear plot of the fractional water cut (or percent water produced) vs. cumulative oil produced. Alternatively, the oil-water ratio

TABLE 5.9.9 Waterflood Parameters

Waterflood residual oil saturations measured in core test samples

can be plotted on a log scale vs. the cumulative production on a linear scale. One of the purposes of these plots is to predict the ultimate oil recovery by extrapolating the curve to some economic limit at which time it becomes no longer profitable to continue the flood. If the operating methods remain relatively unchanged, a method [42] has been proposed for a fully developed waterflood that permits an easy extrapolation of recovery to a given water cut. This latter method consists of a linear plot of E_R , fractional recovery of oil in place, vs. the term $-[(1/f_w) - 1] - (1/f_w)$. This method also provides an estimate of water-oil relative permeabilities.

5.9.13.4 Waterflood Parameters

Important parameters in waterflood operations are the water residual oil saturation, S_{Or} , and the relative permeability to water, k_{rw} . A statistical study of these parameters, as well as peak oil rates, was provided by Felsenthal [43]. Data on S_{Or} and k_{rw} from core data are listed in Table 5.9.9. Endpoint k_{rw} values were higher in carbonates than in sandstones; for

a given lithology, k_{rw} decreased as the absolute permeability decreased.

5.10 ESTIMATION OF WATERFLOOD RESIDUAL OIL SATURATION

Section reviewed by Heru Danardatu

It is recognized throughout the industry that there is no single generally accepted method of measuring residual oil [1]. The available methods should be considered on their merits and some combination of methods should always be used as a cross-check. Each method provides somewhat different information about the amount and distribution of residual oil. This section discusses the various methods that are in current use, and recommendations are made as to how residual oil should be measured [2].

5.10.1 Material Balance

Material balance was one of the first and is the most widely used technique employed in estimating oil reserves and depletion. Overall estimates of the amount of in-place

and recoverable oil are based mainly on material balance. These calculations are also used as a first screening point to determine if sufficient oil remains after waterflooding for application of tertiary recovery. The quantity of oil remaining in the reservoir, having pore volume V_p , in stock tank barrels, is given by the difference between the initial oil-in-place, N , and the amount of oil produced, N_p . The overall residual saturation $(S_{or})_{MB}$ is based on the volume of oil relative to the reservoir pore space [1].

$$(S_{or})_{MB} = \frac{(N - N_p)B_{or}}{V_p} \quad (5.10.1)$$

where B_{or} is the oil formation volume factor after waterflooding.

Many of the projects currently being evaluated as tertiary prospects were initially developed twenty to thirty years ago or longer. At that time, methods for estimating hydrocarbon content were not as accurate as methods presently available. In addition, adequate information relating to hydrocarbon volumes may be limited to only a few wells in a field and production data for the field may not always be reliable. In any event, even where material balance might yield a reasonable estimate of the amount of residual oil-in-place, it does not indicate the distribution of oil within the reservoir.

The value of $(S_{or})_{MB}$ will be dependent on both the microscopic displacement efficiency in swept zones and the vertical and horizontal sweep efficiency. It has been suggested that a high ratio of $(S_{or})_{MB}$ to S_{or} , determined by methods applying to the swept zone, indicates that the reservoir still contains an unusually high amount of oil in the unswept region. The reservoir should then receive special consideration as a candidate for obtaining additional oil recovery through infill drilling [1].

In application of tertiary recovery, the residual oil remaining in the swept zone is of most interest because this is the region that will most likely be contacted by a tertiary process. Thus, the material balance, even in more sophisticated forms than the foregoing simple volumetric balance, should only be used for rough screening in evaluating prospects for tertiary recovery. Furthermore, because of the many uncertainties in the measurements used to obtain a material balance, an enhanced recovery prospect should not be discounted on the basis of material balance alone.

When the volume of oil produced is known with reasonable precision, the accuracy of this method depends mainly on the reliability of the original oil-in-place estimate.

5.10.2 Well Test Analyses

In-situ oil saturations can be estimated by combining relative permeability data determined in the laboratory with field well test data such as:

Production data

Single well transient tests in producing wells

Pressure buildup

Pressure drawdown

Multiple-rate testing

Multiple-well transient tests

Interference tests

Pulse tests

Details of the methods for developing the well test data can be found in the literature [1.13,1.66,3.1], and were summarized earlier. If sufficient, good quality relative permeability data are available from laboratory tests that simulate downhole conditions, the techniques of correlating well test analyses can give some indication of the reservoir oil saturation. For these techniques to be applicable, numerous assumptions are made: the reservoir interval is homogeneous, horizontal, and isotropic with a small and constant compressibility; fluid properties and saturations are uniform in the formation; relative permeabilities are constant throughout the test area; there are no oil-water or gas-oil contacts; and the tested wells are not affected by other wells outside the test area [1]. The following discussion applies to waterflooded reservoirs with no free gas saturation, but could be extended to more complex systems.

5.10.2.1 Production Data

When the producing oil and water flow rates, formation volume factors, and viscosities are known, relative permeability ratios can be determined:

$$\frac{k_{rw}}{k_{ro}} = \frac{q_w B_w \mu_w}{q_o B_o \mu_o} \quad (5.10.2)$$

where k_r = relative permeability

q = flow rate

B = formation volume factor

μ = viscosity

and the subscripts w and o refer to water and oil, respectively. Thus, the relative permeability ratio between water and oil can be estimated from the producing water-oil ratio (WOR).

Relative permeabilities determined in the laboratory may be based on any one of the following measures of core permeability: air, water at 100% S_w , or oil at irreducible water saturations. Laboratory-derived permeability ratios can be used to find the water saturation at which the field-derived permeability ratio would occur. In the absence of gas saturation,

$$S_o = 1 - S_w \quad (5.10.3)$$

Provided core analysis data are available, this method is easy and rapid. However, no information is obtained regarding wellbore damage or specific permeabilities to the flowing fluids. This important information can be obtained from the transient well tests.

5.10.2.2 Transient Tests

Whereas the producing well production data can only provide a relative permeability ratio, transient well testing can provide estimates of reservoir permeabilities to both oil and water (and free gas, if present):

$$k_o = \frac{162.6 q_o B_o \mu_o}{mh} \quad (5.10.4)$$

$$k_w = \frac{162.6 q_w B_w \mu_w}{mh} \quad (5.10.5)$$

where k , q , B , and μ are as previously defined and have units of millidarcies, barrels per day, reservoir barrels per stock tank barrel, and centipoise, respectively. The thickness of the interval, h , is in ft and m is the appropriate slope from the Miller-Dyes-Hutchinson (MDH) plot or the Horner plot.

Multiple well or single well tests can be used to estimate the effective permeability to oil by using type-curve matching:

$$k_o = \frac{141.2 q_o B_o \mu_o (P_D)_M}{h \Delta P_M} \quad (5.10.6)$$

where $(P_D)_M$ is the dimensionless pressure at the match point for type-curve matching, ΔP_M is the pressure change from transient test data at the match point for type-curve matching, and the previously defined terms are in field units. Laboratory relative permeability curves are then used to find the saturations that correspond to the relative permeabilities obtained from the transient tests.

Multiple well testing can also be used to estimate oil saturation by using the total compressibility from the match point data and:

$$c_t = c_w S_w + c_o S_o + c_g S_g + c_f \quad (5.10.7)$$

where c_t is system total compressibility; C_f is the formation or pore volume compressibility; c_w , c_o , and c_g are compressibilities of water, oil and gas, all with units of psi^{-1} ; and S is the corresponding saturation [3]. Since the gas term is assumed to be zero for the waterflooded case and since $S_w = (1 - S_{or})$,

$$c_t = c_w(1 - S_o) + c_o S_o + c_f \quad (5.10.8)$$

By rearranging,

$$S_o = \frac{c_t - c_w - c_f}{(c_o - c_w)} \quad (5.10.9)$$

With a knowledge of oil, water, and formation pore volume compressibilities, and the total compressibility determined from the type-curve matching, reservoir oil saturation can be estimated [1]. Oil saturation based on compressibility is generally less accurate than saturations determined from field relative permeability data and is normally regarded as an approximation.

5.10.2.3 Applicability

Because of the rigid requirements of the assumptions made, and the problems with interpreting the field data, oil saturations obtained from well test analyses are considered rough estimates. The saturation estimate is an overall average for the region of the reservoir influenced by the test. If permeability variations or other conditions cause a variation in the vertical saturation distribution, these techniques will not yield meaningful data. For these techniques to be considered for oil saturation determinations, good laboratory core analysis data are essential. However, because of the low costs and relative ease in conducting the tests, plus the additional important information obtained, well test analyses should be developed along with the other more direct methods of determining residual oil saturations.

5.10.3 Coring and Core Testing

5.10.3.1 Well Coring

Well coring is the process of obtaining representative samples of the productive formation. The choice of depth at which to begin coring can often be a problem. Cores from the regions of interest may not be obtained because of unexpected changes in stratigraphy. There is also the possibility that the region cored will be a nonproductive region which did not contain significant hydrocarbon content initially. However, analysis and testing of core samples continues to be an important method of determining residual oil [4,5].

Various techniques are used to obtain core samples: conventional diamond-bit coring, rubber-sleeve coring, pressure coring, sidewall coring, and recovery of cuttings generated from the drilling operation. The last two methods are not used for residual oil measurements. Conventional coring is normally done in competent formations to obtain full-diameter cores. In unconsolidated, or poorly consolidated formation, a core barrel containing a rubber sleeve is used. The core sample is held together by the sleeve and its properties during laboratory tests remain reasonably representative of conditions in the formation [4].

Two main problems in coring for determination of residual oil are that further flushing of oil to below-normal waterflood residual can take place around the core bit, and that loss of oil occurs, due mainly to gas expansion, as the core is lifted to the surface.

5.10.3.1.1 Flushing During Coring

For a condition where the in-place oil saturation is at its waterflood residual value, no more oil can be produced at normal flow rates. During the coring operation, it is important to avoid extreme flushing conditions that could cause part of the residual oil to be mobilized [2.15]. Some of the variables that control the amount of residual oil flushed from a core by mud filtrate are: borehole-to-formation differential pressure (overbalance), interfacial tension, wettability (the following discussion applies principally to water-wet rocks), core permeability, coring penetration rate, core diameter, type of drill bit, drilling mud composition (including particle size distribution), depth of invasion of mud particles into the core, rate of filtrate production (both spurt loss and total fluid loss), permeability of the formation, and nature of the reservoir (uniformity, texture etc.) [6]. In one type of system investigated in the laboratory, the amount of oil stripped from cores varied directly with the overbalance pressure, filtration production rate, and core permeability; it varied inversely with penetration rate and core diameter. The overbalance pressure is usually the critical variable [2.16].

5.10.3.1.2 Overbalance Pressure

Unintentional displacement of residual oil may occur in coring operations when large pressure gradients exist near the core bit. In this region when fluid velocities are high, the resulting viscous forces may become sufficient to overcome the capillary forces that hold the residual oil in place.

Results from an extensive laboratory coring program [2.16] showed a reduction in pre-test residual oil saturation

of almost 20 percent to about 60 percent as the pressure gradients varied from about 350 to 1,700 psi/ft. In an evaluation of the same data, other authors [1.123] contend that when analyzing larger diameter cores (4-in. diameter) and considering radial flow, the estimated penetration would result in only a 10% change in residual oil. In addition, they contend that core samples used in retort analysis are usually taken from the center of the core where mud solid penetration into the core would be minimal. However, it is generally recognized that residual oil, which is immobile after normal waterflood operations, can become mobile and be stripped from the core, especially in the region adjacent to the core bit.

The ratio of viscous to capillary forces has been expressed as $\Delta P/L\sigma$, where $\Delta P/L$ is the pressure drop per unit length, and σ is the interfacial tension. In water-wet cores, at least, a critical value of $\Delta p/L\sigma$ must be exceeded before production of residual oil occurs [2.15]. In coring, the overbalance pressure must be kept low in order to minimize flushing. Furthermore, the drilling mud should not contain additives that cause significant reduction in interfacial tension that could mobilize residual oil. The use of dispersants, emulsifiers, lubricants, lost circulation materials, and oil should be avoided. If the overbalance pressure causes the critical displacement ratio to be exceeded, then there will be some displacement of residual oil. Linear displacement tests run in the laboratory show the critical displacement pressure to vary from about 1 (psi/ft)/(dyne/cm) for a 1,000 md sandstone to about 25 for a 100 md sandstone [2.15]. Thus, the permissible overbalance pressure will have significant dependence on the properties of the formation that is being cored (Figure 5.10.1).

FIGURE 5.10.1 Critical capillary number as a function of permeability [2.15].

5.10.3.1.3 Drilling Mud Properties

At bottomhole conditions, API filter loss for water-base muds is often in the range of 5 to 10 cc for 30 minutes, which is sufficient to drive most 3-in. to 4-in. diameter cores to the equivalent of the waterflood residual oil saturation if the region being cored is not already at this condition [1.123]. Higher mud water loss or smaller core diameters can lead to displacement of some of this residual oil. However, only general agreement has been found between API filter loss and the amount of oil stripped from cores. More consistent agreement has been observed between the amount of mobilized residual oil and spurt loss (the rapid fluid loss to the formation that occurs before an effective mud filter cake has built up). Spurt loss has been shown to correlate with solids content and particle size distribution which also influence filtration rates and amount of oil-stripping [2.16]. In general, when taking cores it is always preferable to use a bland water base drilling fluid which contains no oil or surface active materials [1].

5.10.3.1.4 Shrinkage and Bleeding

In reservoirs which have been depleted to low pressures and waterflooded to high water-oil ratios, changes in residual saturation in bringing the core to the surface should be fairly minimized. However, in most cases, as the core is raised, gases will come out of solution and can cause residual oil to bleed from the core. The loss of gas causes the oil to shrink.

5.10.3.1.5 Corrections for Shrinkage and Bleeding

Shrinkage of residual oil can be estimated from laboratory measurements of shrinkage when the pressure of bottomhole oil samples is lowered. Reduction of temperature will also contribute to shrinkage. The following corrections have been proposed for the effects of shrinkage and bleeding [1.123].

$$(S_{or})_R = (S_{or})_c B_o E \quad (5.10.10)$$

where $(S_{or})_R$ = average post-waterflood residual oil saturation in the flooded region of the reservoir

$(S_{or})_c$ = average oil saturation from cores

B_o = oil formation volume factor at the time of coring

E = bleeding factor (in the absence of specific bleeding measurements, a value of 1.11 is assumed)

A modification to this calculation has been suggested [7] to compensate for waterflood displacement efficiency by dividing the reservoir residual oil saturation by the conformance factor. In the absence of a reservoir simulator that accounts for reservoir heterogeneity, capillary effects, mobility of oil, and mobility of water, it was suggested the conformance factor be estimated by $(1 - V^2)/M$

where M = mobility ratio or the ratio of the mobility of water at the average water saturation in the reservoir at breakthrough to the mobility of oil in the oil bank ahead of the displacing front

V = the Dykstra-Parsons permeability variation

Thus, the modified calculation would be

$$(S_{or})_R = (S_{or})_c B_o E \frac{M}{1 - V^2} \quad (5.10.11)$$

However, these corrections, particularly the one for bleeding factor, are only approximate at best and considerable attention has been given to recovering cores at reservoir pressure.

5.10.3.1.6 Pressure Core Barrel

Considerable development work has gone into developing a core barrel that will bring cores to the surface without major reduction in reservoir pressure, and thus prevent shrinkage and bleeding. The pressure core barrel is designed to cut the core and seal it within a cylinder before retrieval. Although the cores obtained are small in diameter ($\sim 2\frac{1}{2}$ -in.), pressure coring has gained acceptance as one of the best methods of determining residual oil, particularly when information on the vertical profile of the oil saturation is wanting. Success in application of the core barrel depends to a great extent on the skill and experience of the personnel running the operation. The main criterion for success is retrieving cores at or close to formation pressure. Improvements over the years have led to the present success level of about 70% to 80% in consolidated formations [2.3,1,8-13].

5.10.3.1.7 Sponge Cores

A recent modification [14] to a conventional core barrel is the incorporation of a porous sponge to collect oil that bleeds from the core. The oil saturation measured by conventional techniques is corrected for the bleeding of oil as measured in the sponge. Oil saturations measured with this technique have approximated the values determined by pressure coring but at a cost that is closer to conventional coring.

5.10.3.2 Core Testing

Laboratory tests to estimate reservoir residual oil can be performed on cores that have been preserved at the well-site or cores which are extracted with solvent and subsequently restored to reservoir conditions. Cores obtained with drilling muds that minimize wettability alteration, and that are protected at the wellsite to prevent evaporation or oxidation are called preserved cores. Cores that are cleaned with solvents and resaturated with reservoir fluids are called restored-state cores or extracted cores. The restoring process is often performed on nonpreserved or weathered cores,

but the same technique could apply to cores that had been preserved.

5.10.3.2.1 Core Handling

Conventional Cores. The precautions taken in handling cores once they have been recovered depends mainly on the measurements and tests that are to be performed on them. If the measurements are routine and can be run within a day or two, it is generally considered sufficient to wipe the cores, wrap them in plastic and protect them from exposure to the sun. However, it is better to keep the wrapped cores inside ice boxes to minimize evaporation, especially when longer transit times are anticipated. When maintenance of wettability conditions as they exist in the reservoir is attempted, the most widely preferred method of preservation is to wrap the core in thin sheets of plastic followed by aluminum foil and then isolate the wrapped core from the atmosphere by a coating of wax or plastic. An alternative method of preservation is to store the cores in deoxygenated aqueous solution. This may be formation brine, synthetic brine or mud filtrate [1, 15].

5.10.3.2.2 Pressure Cores

Special handling is needed for cores obtained using the pressure core barrel. This is normally carried out by the trained crew which assembled the barrel prior to testing. After retrieving the core barrel, drilling fluid is displaced at pressure by gelled kerosene. The complete barrel is then chilled in dry ice for several hours in order to freeze the water in the core sample. The pressure in the core barrel can then be released and an inner metal sleeve containing the core is removed. The core is cut into convenient lengths, of about three to four feet, and kept frozen by means of dry ice during transportation [1].

5.10.3.2.3 Measurement of Residual Oil in Recovered Cores

Various techniques are available for determining the oil content of cores. Examples that involve removal of the oil are vacuum distillation, a combination of distillation and solvent extraction (Dean Stark), and high temperature retorting. The Dean Stark method with toluene as solvent is normally used when displacement tests are to be carried out on the extracted cores. In this method, the oil saturation is determined by difference from the amount of water removed from the core [2, 12, 15, 16].

In general, cores obtained with the pressure core barrel under conditions of minimal flushing are needed in order to obtain residual saturations that can be treated with reasonable confidence. Special analytical methods have evolved for treatment of pressure cores. The frozen cores are removed from the metal-containing sleeve and dressed while still frozen. The pressure cores are then allowed to thaw in an inert atmosphere, and volumes of evolved gases are recorded. Next, the free water is distilled from the core. Any remaining oil is removed by a toluene-CO₂

leaching. The amount of oil in the core is determined by adding the volume obtained by distillation to the volume removed during extraction and then making a correction for evolved gas. As a check on extent of penetration of mud filtrate into the core, a tracer can be added to the drilling mud which permits the radial depth of invasion to be estimated. However, filtrate invasion does not necessarily imply flushing of residual oil [1].

5.10.3.2.4 Residual Oil from Laboratory Core Floods

Most cores are subjected to cleaning before measurement of permeability and porosity. However, when the preservation of wetting properties is of main interest, displacement tests are run on the cores prior to cleaning.

Another approach to the problem of reservoir wettability is the restored state method. Cleaned cores are saturated with reservoir brine or brine of similar composition. The brine is displaced by reservoir crude to an equivalent connate water saturation. Recontacting the reservoir rock with the reservoir crude is believed to result in adsorption of those components from the crude oil which determined the in-situ wettability and hence restore the system to its original wetting condition.

Relatively little is known about the causes of reservoir wettability and its sensitivity to the numerous variables that may cause the wettability of recovered cores to be changed. It has been shown that wettability can have significant effect on residual oil [1, 121, 1, 25]. This is the main reason why values of residual oil saturation determined by laboratory core flooding tests are treated with caution. Residual saturations determined by laboratory flooding tests are often used in estimating the amount of oil that will be recovered by waterflooding. However, when residual oil saturation is to be determined for evaluation of a tertiary recovery prospect, laboratory flooding tests do not seem to be in favor. In a recent monograph on residual oil determination, results of such tests received a rating of only poor to fair [1]. Nevertheless, there seems to be consensus view in the industry that the problem of wettability as it relates to residual oil has been satisfactorily resolved. However, little attention appears to have been given to restoring cores to their in-situ residual oil saturation at wetting conditions which are representative of the reservoir even though this may be critical to proper laboratory testing of a tertiary process [17, 18].

Even though laboratory flooding of reservoir cores may not be a generally acceptable method of determining residual oil, it is considered vital that tertiary processes be tested in the laboratory using these cores.

5.10.4 Tracer Tests for Determining Residual Oil

5.10.4.1 How Tracer Tests Work

The tracer test was conceived by applying principles of chromatographic separation to fluid movement in the

reservoir. The outstanding advantage of the tracer test is its ability to investigate a relatively large volume of the formation. It was first suggested that the method could be applied to flow between two wells [19]. The method depends on the effect which the relative solubility of a tracer between oil and water has on the rate at which a pulse of low concentration tracer passes through the formation.

The condition where the reservoir has been flooded out and the oil is immobile is considered later, but the theory can also be applied where both oil and water are flowing, or where the water phase is immobile. If a formation containing residual oil is flooded with a bank of water containing a tracer which is mutually soluble in oil and water, part of the tracer will pass into the oil phase. If there is local equilibrium, the concentration of the tracer in the oil, C_{to} , is related to the concentration in the aqueous phase, C_{tw} , by the distribution coefficient, K_1 .

$$K_1 = \frac{C_{to}}{C_{tw}} \quad (5.10.12)$$

As a result of partitioning, part of the tracer temporarily resides in the immobile residual oil, and the overall velocity of the tracer is less than that of the flowing aqueous phase. The concentration of tracer in the oil together with the oil volume determines the fraction of tracer resident in the oil phase. Since oil volume is directly proportional to oil saturation, the rate at which a pulse of tracer concentration passes through the formation depends on the oil saturation in regions swept by the tracer.

Equilibration of the tracer between the residual oil and water following the tracer bank coupled with dispersion effects determines the shape of a peaked concentration distribution of tracer. Ahead of the peak there is net movement of tracer into the residual oil. Behind the peak there is net movement of tracer molecules from the residual oil back into the water.

From consideration of the way the tracer divides itself between the oil and water phases and the effect of the magnitude of the residual oil saturation on residence time of the tracer, the velocity of the tracer, v_t , is related to the velocity of the associated water, v_w , by

$$v_t = \frac{(1 - S_{or})v_w}{(1 - S_{or}) + K_1 S_{or}} \quad (5.10.13)$$

from which residual oil is given by

$$S_{or} = \frac{v_w - v_t}{v_w v_t + v_t K_1} \quad (5.10.14)$$

The long time needed for tracer to move between wells and the broad and uninterpretable residence time distribution that would arise because of streamline and heterogeneity effects for normal well spacings are cited as reasons why the well tracer test may be impractical as a between-well

test, although there is still some interest in applying this method to small pilot areas [1].

5.10.4.2 Single-Well Tracer Technique

The single-well or backflow tracer technique to determine residual oil saturation is a recent innovation. Patents [19,20] assigned to Exxon Production Research Company in 1971 described the injection of tracers to measure in-situ oil saturation at distances of typically 10 to 30 ft away from the wellbore of a producing well. The single-well tracer test overcomes many of the difficulties that, in general, make the two-well test impractical.

5.10.4.2.1 Test Procedure

The method involves injection of a bank of water containing an alkyl ester as the tracer. The selection of the ester will depend on temperature of the reservoir. For example, ethyl acetate is used in higher temperature reservoirs and n-propyl formate is used at lower temperatures [21]. These tracers are suitable for reservoirs with bottomhole temperatures ranging from about 80°F to 200°F. The ester partially hydrolyzes within the formation to form an acetate and an alcohol, the latter serving as a secondary tracer. Methanol is also added as a material balance tracer to the injected bank and also to the water which is used to push the bank into the formation [21–24].

A desirable volume for the slug is 50–90 barrels per foot of formation. Injection and production rates may limit the size of test that can be conducted in a reasonable period of time. Primary tracer volumes have varied from 40–1,000 barrels while total water volumes have ranged from 175–2,000 barrels [21–24]. Primary tracer concentration has normally been between 0.5–1 volume percent. In an example given by Deans [20], 500 barrels of 1% ethyl acetate and 0.5% methanol in brine is followed by 1,500 barrels of brine containing 0.5% methanol. These quantities are determined by simple volumetric balance based on the desired depth of invasion.

Depending on formation permeability, injection may normally require 1 to 3 days and shut-in time will be 3 to 12 days. After allowing a suitable time period for hydrolysis of about 10% of the ester (usually about 3–12 days), the well is put on production and tracer concentration in the produced water is monitored. Because the alcohol formed by hydrolysis is much more soluble in the aqueous phase than its parent ester, the alcohol is produced ahead of the ester. The greater this separation between the two tracers, the higher the residual oil saturation. The methanol tracer, which is soluble only in water, determines the drift rate in the reservoir and also indicates the fraction of chemical slug that is produced during the test [21–24].

5.10.4.2.2 Interpretation

Computer simulation is used to model the injection, reaction, partitioning, production of the tracers and to correct

for overall drift of fluids past the wellbore [22]. Fluid drift is mainly caused by injection or production of fluids in the vicinity of the test well. A best fit is obtained for the injected and produced ester and methanol, and parameters given by this fit are used to model the alcohol production for a range of assigned values of residual saturation. The measured alcohol production curve is then compared with the simulated results in order to estimate the residual saturation in the formation. Reservoir heterogeneity and loss of tracer can present problems in interpretation.

5.10.4.2.3 Reservoir Heterogeneity

Although the tracer test samples a relatively large pore volume, results will be weighted towards the higher permeability zones. However, this may not be a disadvantage because these zones will normally be swept preferentially by tertiary processes.

The single-well tracer method is not recommended for fractured reservoirs. Fractures cause nonradial flow, which results in tracer profiles that are almost impossible to simulate [23]. Severe permeability variations are also difficult to interpret. Where gross permeability variations exist, it may be necessary to conduct frequent injection profile tests to determine the intervals that are experiencing high-rate fluid flow [24].

5.10.4.2.4 Loss of Tracer

When the chemical tracer is injected into zones that do not subsequently produce fluids, tracer will be lost to the reservoir. In one field test, loss of tracer was estimated at 15% of the injected amount [21]. Conversely, dilution of produced fluids by water from zones that did not receive tracer injection will also present interpretation problems. If high drift-rates cannot be controlled, the slug of water containing chemicals can move so far from the wellbore that tracer profiles may not be well defined. Drift-rate should be less than 1 ft/day [24].

In some cases, it may not be practical to perform tests in wells with large intervals open or in wells with large holdup volumes in the wellbore. In such instances, well workovers may be required [22].

With wells produced by gas lift, corrections are required to account for the loss of part of the more volatile tracers to the gas by stripping action in the wellbore. Tests conducted [23] with ethyl acetate in gas lift wells indicate a loss of about 30%. Appreciable gas accompanying crude oil lifted by other production methods may cause loss of tracer by stripping.

5.10.4.2.5 Accuracy

Success in application of the tracer test depends to a considerable extent on the skill and experience of those conducting the test. While there is no absolute measure of success, comparison of measurements with simulated results pro-

vides a useful guide as to the reliability and tolerance of the results. In about 10% of the early tests conducted, residual oil saturation could not be determined from results. Oil saturations of 10% to 20% pore volume have been measured with reported accuracies of $\pm 2\%$ to $\pm 4\%$. Although conventional methods of estimating residual oil cannot be considered an acceptable standard for determining absolute accuracy of the tracer technique, measurements obtained from tracer tests have generally agreed with values obtained from pressure core tests [1, 21–24].

5.10.4.2.6 Field Application

Logistic considerations require adequate preplanning which means it may be difficult to schedule tests on quick notice [21]. As compared to well logging techniques, considerable time is required to obtain and interpret the data.

5.10.5 Geophysical Well Logging Techniques

Geophysical well logging has the advantage of being an in-situ measurement and is able to give a continuous estimate of residual oil saturation versus depth [25, 26]. These features allow the calibration of the measurements in known water-saturated formations. A more detailed discussion of well logging is given earlier. An evaluation of logging techniques for measurement of S_{or} was provided by Fertl [26].

5.10.5.1 Logging Devices

Five measurements that have potential application are:

1. *Electrical resistivity.* Many devices of different depths of investigation are available [1.58, 27]. These devices cannot be used in cased holes unless one uses some nonconducting casing.
2. *Pulsed neutron capture.* This name (PNC) covers logs commercially available such as the Dresser Atlas Neutron Lifetime Log (NLL) and the Schlumberger Thermal Decay Time (TDT). The PNC has the virtue of being useful in cased holes.
3. *Carbon-oxygen.* This measurement has the virtues of being directly sensitive to carbon and of working in cased holes.
4. *Nuclear magnetism.* This service is not routinely used but has the unique virtue of being sensitive only to formation fluids.
5. *Dielectric constant.* This service is now routine but is limited to open holes. Its main advantage over resistivity measurements is that water salinity need not be known.

5.10.5.1.1 Electrical Resistivity

Resistivity measurements provide a great range of choice as to the volume of formation to be sampled, ranging from a few cubic inches to many cubic feet. Interpretation of the measurements for residual oil saturation requires a

determination of the relation between water saturation and resistivity. If the true formation resistivity R_t and the water resistivity R_w are known, then for clean sandstones [1.42],

$$R_t = F_R R_w S_w^n \quad (5.10.15)$$

where F_R is the formation factor. If after measuring R_t , the fluid around the hole is replaced by water of resistivity R'_w (through chemical flushing followed by displacement with water of resistivity R'_w), then from Equation 5.10.15 it follows that

$$S_w = 1 - S_{or} = \left[\frac{R_t R'_w}{R'_t R_w} \right]^{1/n} \quad (5.10.16)$$

Clearly, n , the saturation exponent, must also be known. It is often taken to be $n = 2$. If cores or other logs are available, better estimates of n can be made.

Relations other than Equation 5.10.16 are required for carbonates and shaly sands [28,29].

Resistivity measurements cannot be made in cased holes. This may explain the limited documentation of such methods for residual oil determination in the literature.

5.10.5.1.2 Pulsed-Neutron-Capture

The device used for this measurement periodically emits brief bursts of high energy neutrons. Between bursts these neutrons are rapidly reduced in energy and then more slowly absorbed by formation nuclei. It is the rate of this relatively slow absorption that is measured.

Upon neutron absorption most formation nuclei are left in high energy states that decay to ground states through the emission of a characteristic set of gamma rays. That is, the gamma rays emitted have various energies and numbers at these energies that are unique to the capturing nucleus. However, carbon does not participate in this process.

The gamma rays emitted above a fixed energy (the fixed energy used in commercial tools varies from 50 kev to 200 kev) are detected and counted as a function of time. The analysis of this counting rate yields the apparent thermal decay time or equivalently the apparent capture cross-section of the formation. The apparent cross-section can be corrected to true formation cross-section through computation. Certain modes of operation [30] can yield results requiring little or no correction.

The formation capture cross-section Σ_t is related to the cross-sections of the constituents of the fluid-saturated rock (see Equation 5.2.39) by the formula [30,31]:

$$\Sigma_t = \Sigma_{ma}(1 - \phi) + \Sigma_w \phi S_w + \Sigma_h \phi (1 - S_w) \quad (5.10.17)$$

where Σ_{ma} is the capture cross-section of the rock (including clay or shale), ϕ is the porosity, Σ_w is the cross-section for the water, Σ_h is the cross-section of the hydrocarbons, and S_w is the water saturation. Thus $(1 - S_w)\phi$ is the oil volume per unit volume of formation.

Of course, the desire is to determine the residual oil saturation $(1 - S_w)$ or the residual oil per unit volume, $\phi(1 - S_w)$. Because many of the quantities on the right hand side of Equation 5.10.17 may be unknown, one employs the so-called log-inject-log technique [32–35].

In the porosity is known in addition to Σ_w , then the simplest form of the log-inject-log technique can be used. Here two successive logs are run. In the first, the normal formation water of cross-section Σ_w occupies the pores. The section of interest is then flushed (at low injection rate) with water of cross-section Σ'_w as different from Σ_w as possible, Σ_t and Σ'_t for these two conditions are measured. Then from Equation 5.10.17 it follows that $S_{or} = 1 - S_w$ is

$$S_{or} = 1 - \frac{\Sigma'_t - \Sigma_t}{\phi(\Sigma'_w - \Sigma_w)} \quad (5.10.18)$$

To obtain accurate values of Σ_t and Σ'_t one should use a very low logging speed, or stationary measurements, or repeat passes that can be averaged.

If porosity is not known, the water flush can be followed by a flush with chlorinated oil [34]. Here the chlorination is adjusted so that the oil has cross-section Σ''_w . Then from the viewpoint of the PNC response, it is just as if we had $S_w = 100\%$. Then Equation 5.10.17 yields

$$\phi = \frac{\Sigma''_t - \Sigma_t}{\Sigma''_w - \Sigma_w} \quad (5.10.19)$$

where Σ''_t is the measured value after the chlorinated oil flush.

The technique just outlined will suffer if Σ_w is small corresponding to low chloride concentration (below 30,000 parts per million). If Σ_w is unknown, it can be controlled by an initial water flush with water of known cross-section.

The most common practice has been to run a PNC log, inject fresh water, and run a second PNC log. Excellent results have been reported for initial water salinities in excess of 30,000 part per million.

5.10.5.1.3 Carbon-Oxygen

The oil industry has long sought a logging method that directly measures oil saturation. The carbon-oxygen (C/O) log is the most recent method in this continuing effort. Since the method is sensitive to formation carbon and since oil is largely carbon, the ideal result would yield directly formation oil content [2.39,2.40, 36–39].

The C/O log utilizes apparatus similar to that of the PNC log; namely, a pulsed neutron source and a gamma ray detector. The neutron bursts and the detector device are timed to emphasize gamma rays produced by high-energy neutrons scattering off of carbon and oxygen. The gamma rays are not simply counted but are also analyzed

for their energy. The gamma rays produced during the neutron burst are primarily inelastic gamma rays, and it is in this time period that carbon contributes gamma rays to the detector. When the neutron source is off, capture gamma rays are detected and analyzed. Carbon does not contribute to the capture-gamma-ray spectrum. The capture gamma-ray spectrum is used to correct for interference in the carbon region of the inelastic spectrum due to calcium, silicon, and oxygen [37].

The device has serious limitations. These include problems with counting statistics, interfering gamma rays, carbonate rocks, and perturbations caused by casing and borehole. Best results are obtained when the tool is stationary for several minutes to overcome counting statistics, and when the formation porosity and oil saturation are high. The measurement may be improved using log-flush-log techniques, but only a few efforts have been documented at this time [26].

5.10.5.1.4 Nuclear Magnetism

This method has been thoroughly discussed in the literature [40–42]. The technique involves a polarization of the hydrogen magnetic moments via a large coil (3 ft long and 3½ in. in diameter) carrying a large direct current. The idea is to align the hydrogen magnetic moments along the field created by the coil. This field ideally is at right angles to the earth's magnetic field. After a few seconds (up to about four), this coil-produced field is reduced to zero as quickly as possible. The polarized hydrogen moment then precesses about the earth's field at about 2,200 Hz. This includes a voltage into the coil which is detected and processed to yield a measure of the total number of hydrogen nuclei in the formation fluid. This number or concentration is called the free fluid index (FFI). Since oil and water have about the same concentration of hydrogen nuclei, FFI is a measure of porosity as given by the fluid contributing to the signal.

For the detection of residual oil saturation, one relies on the fact that the addition of paramagnetic ions to the formation water will cause the signal from the water to be annulled. The measurement thus utilizes the log-flush technique. A first measurement is made of FFI. The formation is then flushed with water containing paramagnetic ions so that FFI is sensitive only to residual oil. The result is that S_{or} can be estimated from:

$$S_{or} = \frac{FFI'}{FFI} \quad (5.10.20)$$

This technique requires signal averaging over many repetitions of the basic measurement in order to compensate for the very poor signal to noise ratio.

The method cannot be used in cased holes and requires a fairly large (> 7 in.) open hole. It has a very shallow penetration and highly viscous oils will not contribute to FFI. In this latter case, a separate measure of porosity will be needed. The service is still not widely available but in principle it is the most promising of all logging methods for the determination of S_{or} [43,44].

5.10.5.1.5 Dielectric Constant

The dielectric constants of rock and oil are distinctly different from that of water. The dielectric constant of bulk water is about 80 while those of oil and rock are 4 or less. In practice, however, due to polarization effects on heterogeneous media, this difference in dielectric properties is masked unless very high frequencies are employed in the measurement. One study shows that results of the expected order are obtained with use of very high frequencies and, furthermore, the measurements are unaffected by water salinity [45]. Several devices designed in accordance with these ideas have been designed and successfully field tested [46–56].

The use of this measurement for S_{or} determination could also benefit from the log-inject-log procedure. For example, after logging initially, one could displace the water with a fluid having about the same dielectric constant as oil. A further flush with a fluid removing all oil and of known dielectric constant could be made.

To interpret the measurements, one can use an equation similar to Equation 5.10.17:

$$\Delta t_t = \Delta t_{ma}(1 - \phi) + \Delta t_w \phi S_w + \Delta t_H(1 - \phi) S_H \quad (5.10.21)$$

where the Δt_t refers to travel time of the electromagnetic energy between the two receivers of the device. Δt_t is the measured parameter while the other Δt symbols refer to formation and fluid travel times. After the first flush, S_{or} is found from:

$$\phi S_{or} = \phi(1 - S_w) = \frac{\Delta t_t - \Delta t'_t}{(\Delta t_w - \Delta t'_w)} \quad (5.10.22)$$

After a second flush, ϕ could be determined from an equation similar to Equation 5.10.19. Equation 5.10.22 can be used to obtain the amount of oil per unit volume. If S_{or} is required, a porosity derived from a neutron-density log could be used.

5.10.5.2 Volume of Reservoir Sampled

It is important to know how large a volume of the reservoir is investigated by a given logging method. This is determined by the vertical resolution and depth of investigation, which have been estimated as follows:

Pulsed neutron capture	
Depth of investigation	~ 6 in.
Vertical resolution	~ 1½ ft
Resistivity	
Depth of investigation	~ 1 in. to 5 ft
Vertical resolution	~ 1 in. to 5 ft

This large range reflects the large number of resistivity devices available.

Carbon-oxygen	
Depth of investigation	~ 2 in.
Vertical resolution	~ 1 ft
Nuclear magnetism	
Depth of investigation	~ 11/2 in.
Vertical resolution	~ 3 ft
Dielectric constant	
Depth of investigation	~ 11/2 in.
Vertical resolution	~ 11/2 in.

These measurements are bulk measurements of the formation sampled. Thus, if there are heterogeneities due to fractures, permeability variations, etc., these will result in errors for elemental volumes. However, since for example, a low permeability zone may not contribute to a tertiary recovery process, this feature of the measurements may be an asset rather than a liability.

5.10.5.3 Accuracy of Logging Methods

The estimated uncertainty in residual oil saturations from electric logs is 5% to 10% under optimum conditions and could easily exceed 10% under less favorable conditions [31]. Accuracy of saturations derived from electric logs is generally in the range of ± 15 saturation percent [6], which is clearly inadequate for residual oil determinations.

From the laboratory measurements of the C/O ratio, it is known that the accuracy of this technique is poor when porosity is low [2.39]. Oil saturation probably cannot be reliably determined at porosities less than 15%. However, even in a 30% porosity sand, the accuracy of oil saturation measurements would only be $\pm 12.5\%$. While this uncertainty could be reduced by taking repeated measurements at the same depth, stability of resolution may still be a problem.

The accuracy requirement for the determination of residual oil is so great that the use of the log-inject-log technique is often required. Although this technique is applicable to various logging methods, practical application has been limited to the PNC and NML. The term log-inject-log (L-I-L) refers basically to the fact that the measurements are made with control over the properties of the fluid saturating the rock volume under study. Assumptions with this technique are that the formation is at residual oil saturation; no oil is displaced from the formation during injection the true total cross-section is measured; the formation water is completely displaced within the radius of investigation by

the tool; and that shrinkage of oil due to gas stripping during injection is negligible.

With the pulsed-neutron-capture L-I-L technique, accuracy of $\pm 5\%$ oil saturation is obtainable [31, 34]. For best results, the contrast in salinities of the two waters should be as great as possible. While this technique has been successfully used, a test in a 100% water saturated formation yielded oil saturations of 40%–60% [35]. These obviously incorrect values may have resulted from incomplete displacement of formation water close to the wellbore by the injected low salinity water.

Accuracy of the nuclear magnetism log depends largely on the signal-to-noise ratio which can be improved by making repeated readings. Newer versions of the NML tool have improved signal-to-noise characteristics. As with other log-inject-log techniques, the possibility of fluid drift in the formation should be considered. Fluid drift should not be sufficient to move injected paramagnetic ions away from the wellbore which would cause erroneously high values of S_{or} [31].

5.10.6 Summary of Methods for Estimating Residual Oil

Economics of primary and secondary recovery processes are usually sufficiently attractive to permit considerable error in the estimation of recoverable reserves. However, for tertiary recovery the amount of oil remaining in a reservoir and its distribution must be known with reasonable confidence. Firstly, a reliable estimate of residual content is extremely important to technical evaluation of field tests. Secondly, the high front-end costs of tertiary processes are such that overestimates of residual oil saturation could have disastrous economic consequence. Thus, a well-planned effort to measure residual oil saturation is a necessity before any tertiary recovery application. Under favorable circumstances, accuracies of $\pm 2\%$ of reservoir pore space can be achieved. In general, accuracies will not be this good, but values within $\pm 5\%$ are considered necessary.

There is no absolute measure of residual oil saturation for a reservoir. When evaluating a tertiary prospect, a combination of methods should be used which provide information on both amount and distribution. Evaluation will normally begin with material balances using information that is already available. Frequently quoted nation-wide estimates of the amount of residual oil that is potentially available for tertiary recovery are based mainly on material balance. Comparisons of material balance with other methods of determining residual show unacceptable scatter, and on average, the material balance gives saturations which are too high by about 9% (by pore volume). This corresponds to about a 30%–50% overestimate in amount of residual oil. It has been suggested that a much higher ratio (say 2 to 1 or more) in residual oil determined by material balance to that

given by other methods is an indication that the reservoir contains extensive regions of high oil saturation and may, therefore, be a good prospect for infill drilling.

In addition to material balance, other estimates of residual oil from resistivity logs and laboratory waterflood tests may also be available. However, in general, none of the conventional methods of determining residual oil saturation—analysis of conventional cores, laboratory displacement tests, conventional logging, material balance—are considered sufficiently reliable in themselves. They can provide useful guides as to whether a tertiary prospect should be investigated further.

Over the past 15–20 years there has been increased field testing of a number of more sophisticated techniques: pressure coring, tracer tests, and the various types of log-inject-log procedures. These methods vary in the conditions under which they can be applied and the type of information they provide.

Pressure coring and the sponge core technique provide information on the vertical distribution of residual oil and also have the advantage that the core analysis procedures directly demonstrate the presence of oil. Because of the possibility of flushing, results may tend to be conservatively low. For pressure coring, the time taken to obtain results tends to be longer than other methods because of transportation and the specialized core analysis work that is needed.

After determining residual oil, the extracted cores are used to obtain needed information on reservoir properties, in particular vertical heterogeneity, and they also can be used in laboratory displacement tests. The reduced diameter ($\sim 2\frac{1}{2}$ in.) of pressure cores compared to those obtained by conventional coring is a disadvantage with respect to making laboratory displacement studies. The use of the sponge coring technique has increased because of the lower coring costs, reduced analysis costs, and, since larger diameter cores are obtained, core plugs can be obtained for subsequent conventional or specialized core testing.

The tracer test samples about a half million times more pore volume than the pressure core barrel. Results with the tracer test will be conservatively low because they are usually weighted towards the more permeable zones, where residual oil will tend to be lower. On balance this is probably an advantage because these zones will also tend to be swept more readily during a tertiary process. The tracer test can be used in old wells, but it is important that the well has not been fractured or stimulated severely.

Of the various log-inject-log procedures, the pulsed-neutron-capture method is the most widely tested. It has the advantage that it can be used in cased holes. Problems can arise with borehole rugosity effects and high values of residual oil if displacements are incomplete during the log-inject-log procedure. Results can be affected by flushing because of the small depth of investigation. The method can give accurate results under favorable circumstances. Stabilization of capture-cross-section values for the log-inject-

log procedure can take unexpectedly long times and can present problems in interpretation. The nuclear magnetic log has been rated highly as to accuracy, but cannot be used in cased holes and it still has limited commercial availability. Log-inject-log resistivity measurements can give good results under favorable circumstances but are not applicable to cased holes.

5.10.7 Recommended Methods for Assessing Residual Oil

In determining residual oil saturation, at least two reliable methods should be compared. In most cases, a tracer test combined with injectivity profiles should be run in all situations unless there are clear reasons, such as excessive drift, why the tracer test would fail. The second method selected should provide information on vertical distribution of residual oil. The situations of old and new holes will be considered separately.

5.10.7.1 Existing Wells

Considerable cost can be saved if first measurements can be made on existing, preferably watered-out, producing wells. These wells will usually be cased. Old resistivity logs and core analysis data may be of value in estimating oil distribution and related heterogeneity. For more accurate determination of residual oil, the tracer test should be run together with the pulsed neutron capture log. However careful consideration must first be given to the past history to the well. There is no reliable method for determining residual oil if the well has been fractured or subjected to excessive stimulation. Inadvertent fracturing could have occurred during stimulation. Various forms of acidizing can have serious effects on near-borehole rock properties. The operator must also be sure that any injected chemicals which could affect results are absent from the test region, and that the well is clean and can be put on injection.

5.10.8 New Wells

When drilling new wells for residual oil determination, special attention should be given to using a bland drilling mud that contains no additives likely to alter interfacial tension or wetting properties. If full-diameter cores are obtained (which is desirable if economics permit), the sponge coring technique should be used with precautions being taken to ensure that flushing is minimal during coring. It is also recommended that the vertical distribution of residual oil be determined with a suite of open-hole logs that can include resistivity and dielectric constant. In cases where good data on capture cross-section are available, residual oil saturation can be obtained with a pulsed-neutron-capture log. If a log-inject-log scheme is used (for example, with PNC), this should not involve chemical

flushing. The tracer test should be run after completion of logging measurements. All of these measurements can be packed up by laboratory displacement tests which should be carried out on preserved cores.

5.11 ENHANCED OIL RECOVERY METHODS

Section reviewed by Heru Danardatu

5.11.1 Definition

Tom Wynn

A general schematic of the enhanced oil recovery (EOR) process is depicted in [Figure 5.11.1](#). The more common techniques that are currently being investigated include:

Enhanced Oil Recovery

Chemical Oil Recovery or Chemical Flooding

Polymer-augmented waterflooding

Alkaline or caustic flooding

Surfactant flooding

—Low tension waterflooding

—Micellar/polymer (microemulsion) flooding

Hydrocarbon or Gas Injection

Miscible solvent (LPG or propane)

Enriched gas drive

High-pressure gas drive

Carbon dioxide flooding

Flue gas

Inert gas (nitrogen)

Thermal Recovery

Steamflooding

In-situ combustion

FIGURE 5.11.1 General schematic of enhanced oil recovery.

These procedures are discussed in several texts on the subject [9.2,1–5]. Two studies by the National Petroleum Council [6, 7] and several papers summarizing the later study are available [8–11]. The extensive literature on enhanced recovery will not be cited, and the reader is referred to Reference 12 which provides numerous citations and is the basis of the following discussion.

5.11.2 Chemical Flooding

Chemical oil recovery methods include polymer, surfactant/polymer (variations are called micellar-polymer, microemulsion, or low tension waterflooding), and alkaline (or caustic) flooding. All of these methods involve mixing chemicals (and sometimes other substances) in water prior to injection. Therefore, these methods require conditions that are very favorable for water injection: low-to-moderate oil viscosities, and moderate-to-high permeabilities. Hence, chemical flooding is used for oils that are more viscous than those oils recovered by gas injection methods but less viscous than oils that can be economically recovered by thermal methods. Reservoir permeabilities for chemical flood conditions need to be higher than for the gas injection methods, but not as high as for thermal methods. Since lower mobility fluids are usually injected in chemical floods, adequate injectivity is required. If previously waterflooded, the chemical flood candidate should have responded favorably by developing an oil bank. Generally, active water-drive reservoirs should be avoided because of the potential for low remaining oil saturations. Reservoirs with gas caps are ordinarily avoided since mobilized oil might resaturate the gas cap. Formations with high clay contents are undesirable since the clays increase adsorption of the injected chemicals. In most cases, reservoir brines of moderate salinity with low amounts of divalent ions are preferred since high concentrations interact unfavorably with the chemicals that are injected.

5.11.2.1 Polymer-Augmented Waterflooding

High mobility ratios cause poor displacement and sweep efficiencies, and result in early breakthrough of injected water. By reducing the mobility of water, water breakthrough can be delayed by improving the displacement, areal, and vertical sweep efficiencies; therefore more oil can be recovered at any given water cut. Thus, the ultimate oil recovery at a given economic limit may be 4%–10% higher with a mobility-controlled flood than with plain water. Additionally, the displacement is more efficient in that less injection water is required to produce a given amount of oil.

The need to control or reduce the mobility of water led to the advent of polymer flooding or polymer-augmented waterflooding. Polymer flooding is viewed as an improved waterflooding technique since it does not ordinarily recover residual oil that has been trapped in pore spaces and iso-

lated by water. However, polymer flooding can produce additional oil over that obtained from waterflooding by improving the displacement efficiency and increasing the volume of reservoir that is contacted. Dilute aqueous solutions of water-soluble polymers have the ability to reduce the mobility of water in a reservoir thereby improving the efficiency of the flood. Partially hydrolyzed polyacrylamides (HPAM) and xanthan gum (XG) polymers both reduce the mobility of water by increasing viscosity. In addition, HPAM can alter the flow path by reducing the permeability of the formation to water. The reduction in permeability to water that is achieved with HPAM solution can be fairly permanent while the permeability to oil can remain relatively unchanged. The resistance factor is a term that is commonly used to indicate the resistance to flow that is encountered by a polymer solution as compared to the flow of plain water. For example, if a resistance factor of 10 is observed, it is 10 times more difficult for the polymer solution to flow through the system, or the mobility of water is reduced 10-fold. Since water has a viscosity of about 1 cp, the polymer solution, in this case, would flow through the porous system as though it had an apparent or effective viscosity of 10 cp even though a viscosity measured in a viscometer could be considerably lower.

The improvement in areal sweep efficiency resulting from polymer treatment can be estimated from Figure 5.9.9. For example, if the mobility ratio for a waterflood with a 5-spot pattern is 5, the areal sweep efficiency is 52% at breakthrough. If the economic limit is a producing water-oil ratio of 100:1 ($f_w \cong 100/101 = 0.99$), the sweep efficiency at floodout is about 97%. If the polymer solution results in the mobility ratio being lowered to 2, sweep efficiencies are 60% at breakthrough and 100% at the same economic water-oil ratio.

A simplified approach to qualitatively observing the improvement with polymers in a stratified system is illustrated in Figure 5.9.12. For example, if the permeability variation is 0.7, the waterflood mobility ratio is 5, and the initial water saturation is 0.3, the fractional recovery of oil-in-place can be estimated. From the plot, $R(1 - 0.4S_w) = 0.29$, and the fractional recovery, R , is $0.29/[1 - (0.4)(0.3)] = 0.33$. This R needs to be multiplied by the areal sweep efficiency of 0.97 to yield a recovery of 32% of the oil-in-place. If polymers again reduce the mobility ratio to 2 (and if no improvement in permeability variation occurs), a fractional recovery of 0.375 is obtained. Since the areal sweep with the polymer flood is 100%, a recovery of 37.5% of the oil-in-place is estimated. Thus the improvement with polymers is estimated at 0.375–0.32 or 5.5% of the oil-in-place. If the flow distribution with polymer solution lowered the permeability variation (which is not likely), the incremental production could be higher. These calculations are gross oversimplifications of actual conditions and only serve as a tool to show that

reducing mobility ratio with polymers can improve the sweep efficiencies.

A properly sized polymer treatment may require the injection of 15%–25% of a reservoir pore volume; polymer concentrations may normally range from 250 to 2,000 mg/L. For very large field projects, millions of pounds of polymer may be injected over a 1–2 year period of time; the project then reverts to a normal waterflood. The polymer flooding literature was reviewed in the late 1970s [13]. Recommendations on the design of polymer floods were made available by Martin [14].

5.11.2.2 Variations in the Use of Polymers

5.11.2.2.1 In-Situ Polymerization

A system is available in which acrylamide monomer is injected and polymerized in the reservoir. Both injection wells and producing wells have been treated.

5.11.2.2.2 Crosslinked or Gelled Polymers

Several methods are available for diverting the flow of water in reservoirs with high permeability zones or fracture systems. Some methods are only effective near the injection well while others claim the treatment can be effective at some depth into the reservoir. Both producing wells and injection wells can be treated.

One method is the aluminum citrate process which consists of the injection of a slug of HPAM polymer solution, aluminum ion chelated with citrate ion, and a second slug of polymer. Some of the polymer in the first slug adsorbs or is retained on the surfaces of the reservoir. The aluminum ion attaches to the adsorbed polymer and acts as a bridge to the second polymer layer. This sequence is repeated until the desired layering is achieved. The transport of aluminum ions through the reservoir may be a problem in certain cases, so the effects of the treatment may be limited to near the wellbore.

Another method is based on the reduction of chromium ions to permit the crosslinking of HPAM or XG polymer molecules. A polymer slug containing Cr^{+6} is injected followed by a slug of polymer containing a reducing agent. When the Cr^{+6} is reduced to Cr^{+3} , a gel is formed with the polymer. The amount of permeability reduction is controlled by the number of times each slug is injected, the size of each slug, or the concentrations used. An alternate treatment involves placing a plain water pad between the first and second polymer slugs.

In another variation of the above two methods for HPAM, a cationic polymer is injected first. Since reservoir surfaces are often negatively charged, the cationic polymer is highly adsorbed. When the foregoing sequential treatments are injected, there is a strong attraction between the adsorbed cationic polymer and the anionic polymers that follow.

Polymer concentrations used in these variations are normally low, on the order of 250 mg/L. With low molecular weight polymers or if a very stiff gel is desired, polymer concentrations of 1–1.5% are common. The type of polymers are similar to those used in conventional polymer flooding, but the products used for gelation command a higher price.

Methods have been developed, especially for fracture treatments, include Cr^{3+} (acetate)-polyacrylamide, colloidal silica, and resorcinol-formaldehyde.

5.11.2.3 Surfactant and Alkaline Flooding

Both alkaline flooding and surfactant flooding improve oil recovery by lowering the interfacial tension between crude oil and the displacing water. With alkaline flooding, the surfactants are generated in situ when the alkaline materials react with crude oil—this technique is normally only viable when the crude oil contains sufficient amount of organic acids to produce natural surfactants. Other possible mechanisms with the caustic materials include emulsification of the oil and alteration in the preferential wettability of the reservoir rock.

With surfactant flooding, surface-active agents are mixed with other compounds (such as alcohol and salt) in water and injected to mobilize the crude oil. Polymer-thickened water is then injected to push the mobilized oil-water bank to the producing wells. Water-soluble polymers can be used in a similar fashion with alkaline flooding. For micellar/polymer flooding, the concentration of polymer used may be similar to the value given for polymer flooding, but the volume of polymer solution may be increased to 50% or more of a reservoir pore volume.

5.11.2.3.1 Alkaline Flooding

Alkaline or caustic flooding consists of injecting aqueous solutions of sodium hydroxide, sodium carbonate, sodium silicate or potassium hydroxide. The alkaline chemicals react with organic acids in certain crude oils to produce surfactants in situ that dramatically lower the interfacial tension between water and oil. The alkaline agents also react with the reservoir rock surfaces to alter wettability—either from oil-wet to water-wet, or vice versa. Other mechanisms include emulsification and entrainment of oil or emulsification and entrapment of oil to aid in mobility control. Since an early patent in the 1920s described the use of caustic for improved recovery of oil, much research and some field tests have been conducted. Slug size of the alkaline solution is often 10%–15% PV, concentrations of the alkaline chemical are normally 0.2% to 5%. Recent tests are using large amounts of relatively high concentrations. A preflush of fresh or softened water often precedes the alkaline slug, and a drive fluid (either water or polymer-thickened water) follows the alkaline slug.

5.11.2.3.2 Surfactant/Polymer Flooding

Surfactant use for oil recovery is not a recent development. Patents in the late 1920s and early 1930s proposed the use of low concentrations of detergents to reduce the interfacial tension between water and oil. To overcome the slow rate of advance of the detergent, Taber [15] proposed very high concentrations ($\sim 10\%$) of detergent in aqueous solution.

During the late 1950s and early 1960s, several different present-day methods of using surfactants for enhanced recovery were developed. A review of these methods is beyond the scope of this chapter and is available in the literature [16–19]. In some systems, a small slug ($>$ about 5% PV) was proposed that included a high concentration of surfactant (normally 5%–10%). In many cases, the microemulsion includes surfactant, hydrocarbon, water, an electrolyte (salt), and a cosolvent (usually an alcohol). These methods ordinarily used a slug (30%–50% PV) of polymer-thickened water to provide mobility control in displacing the surfactant and oil-water bank to the producing wells. The polymers used are the same as those discussed in the previous section. In most cases, low-cost petroleum sulfonates or blends with other surfactants have been used. Intermediate surfactant concentrations and low concentration systems (low tension waterflooding) have also been proposed. The lower surfactant concentration systems may or may not contain polymer in the surfactant slug, but will utilize a larger slug (30%–100% PV) of polymer solution.

5.11.2.3.3 Alkaline/Surfactant/Polymer Flooding

A recent development uses a combination of chemicals to lower process costs by lowering injection cost and reducing surfactant adsorption. These mixtures, termed alkaline/surfactant/polymer (ASP), permit the injection of larger slugs of injectant because of the lower cost.

5.11.3 Gas Injection Methods

5.11.3.1 Hydrocarbon Miscible Flooding

Gas injection is certainly one of the oldest methods utilized by engineers to improve recovery, and its use has increased, although most of the new expansion has been coming from the nonhydrocarbon gases [20]. Because of the increasing interest in CO_2 and nitrogen or flue gas methods, they are separated from the hydrocarbon miscible techniques.

Hydrocarbon miscible flooding can be subdivided further into three distinct methods, and field trials or extensive operations have been conducted in all of them. For LPG slug or solvent flooding, enriched (condensing) gas drive and high pressure (vaporizing) gas drive, a range of pressures (and therefore, depths) are needed to achieve miscibility in the systems.

Unless the reservoir characteristics were favorable, early breakthrough and bypassing of large quantities of oil have

plagued many of the field projects. In addition, the hydrocarbons needed for the processes are valuable, and there is increasing reluctance to inject them back into the ground when there is some question about the percentage that will be recovered the second time around. Therefore, in the U.S. in recent years the emphasis has been shifting to less valuable nonhydrocarbon gases such as CO_2 , nitrogen, and flue gases. Although nitrogen and flue gases do not recover oil as well as the hydrocarbon gases (or liquids), the overall economics may be somewhat more favorable.

5.11.3.2 Nitrogen and Flue Gas Flooding

As previously mentioned, nitrogen and flue gas (about 87% N_2 and 12% CO_2) are sometimes used in place of hydrocarbon gases because of economics. Nitrogen also competes with CO_2 in some situations for the same reason. The economic appeal of nitrogen stems not only from its lower cost on a standard Mcf basis, but also because its compressibility is much lower. Thus, for a given quantity at standard conditions, nitrogen will occupy much more space at reservoir pressures than CO_2 or even methane at the same conditions. However, both nitrogen or flue gas are inferior to hydrocarbon gases (and much inferior to CO_2) from an oil recovery point of view. Nitrogen has a lower viscosity and poor solubility in oil and requires a much higher pressure to generate or develop miscibility. The increase in the required pressure is significant compared to methane and very large (4–5 times) when compared to CO_2 . Therefore, nitrogen will not reduce the displacement efficiency too much when used as a chase gas for methane, but it can cause a significant drop in the effectiveness of a CO_2 flood if the reservoir pressures are geared to the miscibility requirements for CO_2 displacements. Indeed, even methane counts as a desirable “light end” or “intermediate” in nitrogen flooding, but methane is quite deleterious to the achievement of miscibility in CO_2 flooding at modest pressures.

5.11.3.3 Carbon Dioxide Flooding

CO_2 is effective for recovery of oil for a number of reasons. In general, carbon dioxide is very soluble in crude oils at reservoir pressures; therefore, it swells the net volume of oil and reduces its viscosity even before miscibility is achieved by the vaporizing gas drive mechanism. As miscibility is approached, both the oil phase and the CO_2 phase (which contains many of the oil’s intermediate components) can flow together because of the low interfacial tension and the relative increase in the total volumes of the combined CO_2 and oil phases compared to the water phase. However, the generation of miscibility between the oil and CO_2 is still the most important mechanism, and it will occur in CO_2 –crude oil systems as long as the pressure is high enough. This so-called “minimum miscibility pressure” or MMP has been the target of several laboratory investigations

and is no longer a mystery. The 1976 NPC report [6] showed that there is a rough correlation between the API gravity and the required MMP, and that the MMP increased with temperature. Some workers have shown that a better correlation is obtained with the molecular weight of the C_5^+ fraction of the oil than with the API gravity. In general the recent work shows that the required pressure must be high enough to achieve a minimum density in the CO_2 phase [21,22]. At this minimum density, which varies with the oil composition, the CO_2 becomes a good solvent for the oil, especially the intermediate hydrocarbons, and the required miscibility can be generated or developed to provide the efficient displacement normally observed with CO_2 . Therefore, at higher temperatures, the higher pressures are needed only to increase the CO_2 density to the same value as observed for the MMP at the lower temperature. Figure 5.11.2 shows the variation of minimum miscibility pressure with temperature and oil composition [23].

Although the mechanism for CO_2 flooding appears to be the same as that for hydrocarbon miscible floods, CO_2 floods may give better recoveries even if both systems are above their required miscibility pressures, especially in tertiary floods. Compared to hydrocarbons, CO_2 has a much higher solubility in water, and it has been observed in laboratory experiments to diffuse through the water phase to swell bypassed oil until the oil is mobile. Thus, not only are the oil and depth screening criteria easier to meet in CO_2 flooding, but the ultimate recovery may be better

than with hydrocarbons when above the MMP. It must be noted, however that this conjecture has not been proved by rigorous and directly comparable experiments.

5.11.4 Thermal Recovery

5.11.4.1 In-Situ Combustion

The theory and practice of in-situ combustion or fireflooding is covered comprehensively in the recent SPE monograph on thermal recovery by Prats [4]. In addition, the continuing evolution of screening criteria for fireflooding [24, 25] and steamflooding [26] have been reviewed and evaluated by Chu. A recent appraisal of in-situ combustion was provided by White [27] and the status of oxygen fireflooding was provided by Garon [28].

Part of the appeal of fireflooding comes from the fact that it uses the world's cheapest and most plentiful fluids for injection: air and water. However, significant amounts of fuel must be burned, both above the ground to compress the air, and below ground in the combustion process. Fortunately, the worst part of the crude oil is burned; the lighter ends are carried forward in advance of the burning zone to upgrade the crude oil.

5.11.4.2 Steam Flooding

Of all of the enhanced oil recovery processes currently available, only the steam drive (steamflooding) process is routinely used on a commercial basis. In the United States, a

FIGURE 5.11.2 Correlations for CO_2 minimum miscibility pressure [23].

majority of the field testing with this process has occurred in California, where many of the shallow, high-oil-saturation reservoirs are good candidates for thermal recovery. These reservoirs contain high-viscosity crude oils that are difficult to mobilize by methods other than thermal recovery.

In the steam drive process, steam is continuously introduced into injection wells to reduce the viscosity of heavy oil and provide a driving force to move the more mobile oil towards the producing wells. In typical steam drive projects, the injected fluid at the surface may contain about 80% steam and 20% water (80% quality) [6]. When steam is injected into the reservoir, heat is transferred to the oil-bearing formation, the reservoir fluids, and some of the adjacent cap and base rock. As a result, some of the steam condenses to yield a mixture of steam and hot water flowing through the reservoir.

The steam drive may work by driving the water and oil to form an oil bank ahead of the steamed zone. Ideally this oil bank remains in front, increasing in size until it is produced by the wells offsetting the injector. However, in many cases, the steam flows over the oil and transfers heat to the oil by conduction. Oil at the interface is lowered in viscosity and dragged along with the steam to the producing wells. Recoverability is increased because the steam (heat) lowers the oil viscosity and improves oil mobility. As the more mobile oil is displaced the steam zone expands vertically, and the steam-oil interface is maintained. This process is energy-intensive since it requires the use of a significant fraction (25%–40%) of the energy in the produced petroleum for the generation of steam.

In steamflooding, the rate of steam injection is initially high to minimize heat losses to the cap and base rock. Because of reservoir heterogeneities and gravity segregation of the condensed water from the steam vapor, a highly permeable and relatively oil-free channel often develops between injector and producer. Many times this channel occurs near the top of the oil-bearing rock, and much of the injected heat is conducted to the caprock as heat loss rather than being conducted to oil-bearing sand where the heat is needed. In addition, the steam cannot displace oil efficiently since little oil is left in the channel. Consequently, neither the gas drive from the steam vapor nor the convective heat transfer mechanisms work as efficiently as desired. As a result, injected steam will tend to break through prematurely into the offset producing wells without sweeping the entire heated interval.

5.11.5 Technical Screening Guides

In some instances, only one type of enhanced recovery technique is applicable for a specific field condition but, in many instances, more than one technique is possible. The selection of the most appropriate process is facilitated by matching reservoir and fluid properties to the requirements

necessary for the individual EOR techniques. A summary of the technical screening guides for the more common EOR processes is given in Table 5.11.1. A distinction is made between the oil properties and reservoir characteristics that are required for each process. Generally, steamflooding is applicable for very viscous oils in relatively shallow formations. On the other extreme, CO₂ and hydrocarbon miscible flooding work best with very light oils at depths that are great enough for miscibility to be achieved. Both steamflooding and in-situ combustion require fairly high permeability reservoirs. Chemical flooding processes (polymer, alkaline, or surfactant) are applicable in low to medium viscosity oils; depth is not a major consideration except, at great depths, the higher temperature may present problems in the degradation or consumption of some of the chemicals.

Screening guides or criteria are among the first items considered when a petroleum engineer evaluates a candidate reservoir for enhanced oil recovery. A source often quoted for screening criteria is the 1976 National Petroleum Council (NPC) report on Enhanced Recovery [6], which was revised by the NPC in 1984 [7]. Both reports list criteria for six enhanced recovery methods.

Some reservoir considerations apply to all enhanced recovery methods. Because drilling costs increase markedly with depth, shallow reservoirs are preferred, as long as all necessary criteria are met. For the most part, reservoirs that have extensive fractures, gross heterogeneities, thief zones, or are highly faulted should be avoided. Ideally, relatively uniform reservoirs with reasonable oil saturations, minimum shale stringers, and good areal extent are desired.

Implementation of enhanced recovery projects is expensive, time-consuming, and people-intensive. Substantial costs are often involved in the assessment of reservoir quality, the amount of oil that is potentially recoverable, laboratory work associated with the EOR process, computer simulations to predict recovery, and the performance of the project. One of the first steps in deciding to consider EOR is, of course, to select reservoirs with sufficient recoverable oil and areal extent to make the venture profitable.

With any of the processes, the nature of the reservoir will play a dominant role in the success or failure of the process. Many of the failures with EOR have resulted because of unknown or unexpected reservoir problems. Thus, a thorough geological study is usually warranted.

The technique of using cursory screening guides is convenient for gaining a quick overview of all possible methods before selecting the best one for an economic analysis. Common sense and caution must be exercised since the technical guides are based on laboratory data and results of enhanced recovery field trials, and are not rigid guides for applying certain processes to specific reservoirs. Additionally, the technical merits of recent field projects are clouded by various incentive programs that make it difficult to discern true technical applications. Some projects

TABLE 5.11.1 Summary of Screening Criteria for Enhanced Recovery Methods

may have been technical misapplications or failures, but economic successes. Certainly, there have been enough technical successes, but economic failures.

Nevertheless, some EOR processes can be rejected quickly because of unfavorable reservoir or oil properties, so the use of preferred criteria can be helpful in selecting methods that may be commercially attractive. If the criteria are too restrictive, some feasible method may be rejected from consideration. Therefore, the guidelines that are adopted should be sufficiently broad to encompass essentially all of the potential methods for a candidate reservoir.

For convenience, brief descriptions of the eight most common enhanced recovery methods are provided in the following sections. These descriptions list the salient features of each method along with the important screening guides. A few general comments are offered here on the relative importance of some individual screening guides to the overall success of the various methods. In addition, we will make some observations on the method itself and its relationship to other enhanced recovery choices that may be available.

5.11.5.1 Hydrocarbon Miscible Flooding [12]

5.11.5.1.1 Description

Hydrocarbon miscible flooding consists of injecting light hydrocarbons through the reservoir to form a miscible flood. Three different methods are used. One method uses about 5% PV slug of liquidified petroleum gas (LPG) such as propane, followed by natural gas or gas and water. A second method, called enriched (condensing) gas drive, consists of injecting a 10%–20% PV slug of natural gas that is enriched with ethane through hexane (C_2 to C_6), followed by lean gas (dry, mostly methane) and possibly water. The enriching components are transferred from the gas to the oil. The third method, called high pressure (vaporizing) gas drive, consists of injecting lean gas at high pressure to vaporize C_2 – C_6 components from the crude oil being displaced.

5.11.5.1.2 Mechanisms

Hydrocarbon miscible flooding recovers crude oil by:

- Generating miscibility (in the condensing and vaporizing gas drive)
- Increasing the oil volume (swelling)
- Decreasing the viscosity of the oil

Technical Screening Guides

Crude oil

Gravity	> 35° API
Viscosity	< 10 cp
Composition	High percentage of light hydrocarbons (C_2 – C_7)

Reservoir

Oil saturation	> 30% PV
Type of formation	Sandstone or carbonate with a minimum of fractures and high permeability streaks
Net thickness	Relatively thin unless formation is steeply dipping
Average permeability	Not critical if uniform
Depth	> 2,000 ft (LPG) to > 5000 ft (high pressure gas)
Temperature	Not critical

5.11.5.1.3 Limitations

- The minimum depth is set by the pressure needed to maintain the generated miscibility. The required pressure ranges from about 1,200 psi for the LPG process to 3,000–5,000 psi for the high pressure gas drive, depending on the oil.
- A steeply dipping formation is very desirable to permit some gravity stabilization of the displacement which normally has an unfavorable mobility ratio.

5.11.5.1.4 Problems

- Viscous fingering results in poor vertical and horizontal sweep efficiency.
- Large quantities of expensive products are required.
- Solvent may be trapped and not recovered.

5.11.5.2 Nitrogen and Flue Gas Flooding [12]

5.11.5.2.1 Description

Nitrogen and flue gas flooding are oil recovery methods which use these inexpensive nonhydrocarbon gases to displace oil in systems which may be either miscible or immiscible depending on the pressure and oil composition. Because of their low cost, large volumes of these gases may be injected. Nitrogen or flue gas are also considered for use as chase gases in hydrocarbon-miscible and CO_2 floods.

5.11.5.2.2 Mechanisms

Nitrogen and flue gas flooding recover oil by:

- Vaporizing the lighter components of the crude oil and generating miscibility if the pressure is high enough.
- Providing a gas drive where a significant portion of the reservoir volume is filled with low-cost gases.

Technical Screening Guides

Crude oil

Gravity	> 24° API (> 35° for nitrogen)
Viscosity	< 10cp
Composition	High percentage of light hydrocarbons (C_1 – C_7)

Reservoir

Oil saturation	> 30% PV
Type of formation	Sandstone or carbonate with few fractures and high permeability streaks
Net thickness	Relatively thin unless formation is dipping
Average permeability	Not critical
Depth	>4,500 ft
Temperature	Not critical

5.11.5.2.3 Limitations

- Developed miscibility can only be achieved with light oils and at high pressures; therefore, deep reservoirs are needed.
- A steeply dipping formation is desired to permit gravity stabilization of the displacement which has a very unfavorable mobility ratio.

5.11.5.2.4 Problems

- Viscous fingering results in poor vertical and horizontal sweep efficiency.
- Corrosion can cause problems in the flue gas method.
- The nonhydrocarbon gases must be separated from the saleable produced gas.

5.11.5.3 Carbon Dioxide Flooding [12]**5.11.5.3.1 Description**

Carbon dioxide flooding is carried out by injecting large quantities of CO₂ (15% or more of the hydrocarbon PV) into the reservoir. Although CO₂ is not truly miscible with the crude oil, the CO₂ extracts the light-to-intermediate components from the oil, and, if the pressure is high enough, develops miscibility to displace the crude oil from the reservoir.

5.11.5.3.2 Mechanisms

CO₂ recovers crude oil by:

- Generation of miscibility
- Swelling the crude oil
- Lowering the viscosity of the oil
- Lowering the interfacial tension between the oil and the CO₂-oil phase in the near-miscible regions.

*Technical Screening Guides**Crude oil*

Gravity	> 26°API (preferably > 30°)
Viscosity	< 15 cp (preferably < 10 cp)
Composition	High percentage of intermediate hydrocarbons (C ₅ –C ₂₀), especially C ₅ –C ₁₂

Reservoir

Oil saturation	> 30% PV
Type of formation	Sandstone or carbonate with a minimum of fractures and high permeability streaks
Net thickness	Relatively thin unless formation is steeply dipping.
Average permeability	Not critical if sufficient injection rates can be maintained.
Depth	Deep enough to allow high enough pressure (> about 2,000 ft), pressure required for optimum production (sometime called minimum miscibility pressure) ranges from about 1,200 psi for a high gravity (> 30° API) crude at low temperatures to over 4,500 psi for heavy crudes at higher temperatures.
Temperature	Not critical but pressure required increases with temperature.

5.11.5.3.3 Limitations

- Very low viscosity of CO₂ results in poor mobility control.
- Availability of CO₂.

5.11.5.3.4 Problems

- Early breakthrough of CO₂ causes several problems: corrosion in the producing wells; the necessity of separating CO₂ from saleable hydrocarbons; repressuring of CO₂ for recycling; and a high requirement of CO₂ per incremental barrel produced.

5.11.5.4 Surfactant/Polymer Flooding**5.11.5.4.1 Description**

Surfactant/polymer flooding, also called micellar/polymer or microemulsion flooding, consists of injecting a slug that contains water, surfactant, electrolyte (salt), usually a cosolvent (alcohol), and possibly a hydrocarbon (oil). The size of the slug is often 5%–15% PV for a high surfactant concentration system and 15%–50% PV for low concentrations. The surfactant slug is followed by polymer-thickened water. Concentrations of the polymer often range from 500–2,000 mg/L; the volume of polymer solution injected may be 50% PV, more or less, depending on the process design.

5.11.5.4.2 Mechanisms

Surfactant/polymer flooding recovers crude oil by:

- Lowering the interfacial tension between oil and water
- Solubilization of oil

- Emulsification of oil and water
- Mobility enhancement

Technical Screening Guides

Crude oil

Gravity	> 25° API
Viscosity	< 30 cp
Composition	Light intermediates are desirable

Reservoir

Oil saturation	> 30% PV
Type of formation	Sandstone preferred
Net thickness	> 10 ft
Average permeability	> 20 md
Depth	< about 8,000 ft (see temperature)
Temperature	< 175°F

5.11.5.4.3 Limitations

- An areal sweep of more than 50% on waterflood is desired.
- Relatively homogeneous formation is preferred.
- High amounts of anhydrite, gypsum, or clays are undesirable.
- Available systems provide optimum behavior over a very narrow set of conditions.
- With commercially available surfactants, formation water chlorides should be < 20,000 ppm and divalent ion (Ca^{++} and Mg^{++}) < 500 ppm.

5.11.5.4.4 Problems

- Complex and expensive system.
- Possibility of chromatographic separation of chemicals.
- High adsorption of surfactant.
- Interactions between surfactant and polymer.
- Degradation of chemicals at high temperature.

5.11.5.5 Polymer Flooding [12]

5.11.5.5.1 Description

The objective of polymer flooding is to provide better displacement and volumetric sweep efficiencies during a waterflood. Polymer augmented waterflooding consists of adding water soluble polymers to the water before it is injected into the reservoir. Low concentrations (often 250–2,000 mg/L) of certain synthetic or biopolymers are used; properly sized treatments may require 15%–25% reservoir PV.

5.11.5.5.2 Mechanisms

Polymers improve recovery by:

- Increasing the viscosity of water
- Decreasing the mobility of water
- Contacting a large volume of the reservoir

Technical Screening Guides

Crude oil

Gravity	> 25° API
Viscosity	< 150 cp (preferably < 100)
Composition	Not critical

Reservoir

Oil saturation	> 10% PV mobile oil
Type of formation	Sandstones preferred but can be used in carbonates
Net thickness	Not critical
Average permeability	> 10 md (as low as 3 md in some cases)
Depth	< about 9,000 ft (see temperature)
Temperature	< 200°F to minimize degradation

5.11.5.5.3 Limitations

- If oil viscosities are high, a higher polymer concentration is needed to achieve the desired mobility control.
- Results are normally better if the polymer flood is started before the water-oil ratio becomes excessively high.
- Clays increase polymer adsorption.
- Some heterogeneities are acceptable, but for conventional polymer flooding, reservoirs with extensive fractures should be avoided. If fractures are present, the crosslinked or gelled polymer techniques may be applicable.

5.11.5.5.4 Problems

- Lower injectivity than with water can adversely affect oil production rate in the early stages of the polymer flood.
- Acrylamide-type polymers lose viscosity due to shear degradation or increases in salinity and divalent ions.
- Xanthan gum polymers cost more, are subject to microbial degradation, and have a greater potential for well-bore plugging.

5.11.5.6 Alkaline Flooding [12]

5.11.5.6.1 Description

Alkaline or caustic flooding involves the injection of chemicals such as sodium hydroxide, sodium silicate or sodium carbonate. These chemicals react with organic petroleum acids in certain crudes to create surfactants in situ. They also react with reservoir rocks to change wettability. The concentration of the alkaline agent is normally 0.2 to 5%; slug size is often 10% to 50% PV, although one successful flood only used 2% PV, (but this project also included polymers for mobility control). Polymers may be added to the alkaline mixture, and polymer-thickened water can be used following the caustic slug.

5.11.5.6.2 Mechanisms

Alkaline flooding recovers crude oil by:

- A reduction of interfacial tension resulting from the produced surfactants
- Changing wettability from oil-wet to water-wet

- Changing wettability from water-wet to oil-wet
- Emulsification and entrainment of oil
- Emulsification and entrapment of oil to aid in mobility control
- Solubilization of rigid oil films at oil-water interfaces (Not all mechanisms are operative in each reservoir.)

Technical Screening Guides

Crude oil

Gravity	> 13° to 35° API
Viscosity	< 200 cp
Composition	Some organic acids required

Reservoir

Oil saturation	Above waterflood residual
Type of formation	Sandstones preferred
Net thickness	Not critical
Average permeability	> 20 md
Depth	< about 9,000 ft (see temperature)
Temperature	< 200°F preferred

5.11.5.6.3 Limitations

- Best results are obtained if the alkaline material reacts with the crude oil: the oil should have an acid number of more than 0.2 mg KOH/g of oil.
- The interfacial tension between the alkaline solution and the crude oil should be less than 0.01 dyne/cm.
- At high temperatures and in some chemical environments, excessive amounts of alkaline chemicals may be consumed by reaction with clays, minerals, or silica in the sandstone reservoir.
- Carbonates are usually avoided because they often contain anhydrite or gypsum, which interact adversely with the caustic chemical.

5.11.5.6.4 Problems

- Scaling and plugging in the producing wells.
- High caustic consumption

5.11.5.7 In-Situ Combustion [12]

5.11.5.7.1 Description

In-situ combustion or fireflooding involves starting a fire in the reservoir and injecting air to sustain the burning of some of the crude oil. The most common technique is forward combustion in which the reservoir is ignited in an injection well, and air is injected to propagate the combustion front away from the well. One of the variations of this technique is a combination of forward combustion and waterflooding (COFCAW). A second technique is reverse combustion in which a fire is started in a well that will eventually become a producing well, and air injection is then switched to adjacent wells; however, no successful field trials have been completed for reverse combustion.

5.11.5.7.2 Mechanisms

In-situ combustion recovers crude oil by:

- The application of heat which is transferred downstream by conduction and convection, thus lowering the viscosity of the crude.
- The products of steam distillation and thermal cracking which are carried forward to mix with and upgrade the crude.
- Burning coke that is produced from the heavy ends of the crude oil
- The pressure supplied to the reservoir by the injected air.

Technical Screening Guides

Crude oil

Gravity	< 40° API (normally 10–25°)
Viscosity	< 1,000 cp
Composition	Some asphaltic components to aid coke deposition

Reservoir

Oil saturation	> 500 bbl/acre-ft (or > 40–50% PV)
Type of formation	Sand or sandstone with high porosity
Net thickness	> 10 ft
Average permeability	> 100 md
Transmissibility	> 20 mud ft/cp
Depth	> 500 ft
Temperature	> 150°F preferred

5.11.5.7.3 Limitations

- If sufficient coke is not deposited from the oil being burned, the combustion process will not be sustained.
- If excessive coke is deposited, the rate of advance of the combustion zone will be slow, and the quantity of air required to sustain combustion will be high.
- Oil saturation and porosity must be high to minimize heat loss to rock.
- Process tends to sweep through upper part of reservoir so that sweep efficiency is poor in thick formations.

5.11.5.7.4 Problems

- Adverse mobility ratio.
- Complex process, requiring large capital investment, is difficult to control.
- Produced flue gases can present environmental problems.
- Operational problems such as severe corrosion caused by low pH hot water, serious oil-water emulsions, increased sand production, deposition of carbon or wax, and pipe failures in the producing wells as a result of the very high temperatures.

5.11.5.8 Steamflooding [12]

5.11.5.8.1 Description

The steam drive process or steamflooding involves the continuous injection of about 80% quality steam to displace crude oil towards producing wells. Normal practice is to precede and accompany the steam drive by a cyclic steam stimulation of the producing wells (called huff and puff).

5.11.5.8.2 Mechanisms

Steam recovers crude oil by:

- Heating the crude oil and reducing its viscosity
- Supplying pressure to drive oil to the producing well

Technical Screening Guides

Crude oil

Gravity	< 25° API (normal range is 10°–25° API)
Viscosity	> 20 cp (normal range is 100–5,000 cp)
Composition	Not critical but some light ends for steam distillation will help

Reservoir

Oil saturation	> 500 bbl/acre-ft (or > 40%–50% PV)
Type of formation	Sand or sandstone with high porosity and permeability preferred
Net thickness	> 20 feet
Average permeability	> 200 md (see transmissibility)
Transmissibility	> 100 md ft/cp
Depth	300–5,000 ft
Temperature	Not critical

5.11.5.8.3 Limitations

- Oil saturations must be quite high and the pay zone should be more than 20 feet thick to minimize heat losses to adjacent formations.
- Lighter, less viscous crude oils can be steamflooded but normally will not be if the reservoir will respond to an ordinary waterflood.
- Steamflooding is primarily applicable to viscous oils in massive, high permeability sandstones or unconsolidated sands.
- Because of excessive heat losses in the wellbore, steamflooded reservoirs should be as shallow as possible as long as pressure for sufficient injection rates can be maintained.
- Steamflooding is not normally used in carbonate reservoirs.

- Since about one-third of the additional oil recovered is consumed to generate the required steam, the cost per incremental barrel of oil is high.
- A low percentage of water-sensitive clays is desired for good injectivity.

5.11.5.8.4 Problems

- Adverse mobility ratio and channeling of steam.

5.11.5.9 Criteria for Gas Injection

For LPG slug or solvent flooding, enriched (condensing) gas drive, and high pressure (vaporizing) gas drive, a range of pressures (and therefore, depths) are needed to achieve miscibility in the systems. Thus, there is a minimum depth requirement for each of the processes as shown earlier (see section on “Hydrocarbon Miscible Flooding”). The permeability is not critical if the structure is relatively uniform; permeabilities of the reservoirs for the current field projects range from less than 1 md to several darcies [29]. On the other hand, the crude oil characteristics are very important. A high-gravity, low-viscosity oil with a high percentage of the C₂–C₇ intermediates is essential if miscibility is to be achieved in the vaporizing gas drives.

As shown earlier under “Nitrogen and Flue Gas Flooding,” the screening criteria for flooding with nitrogen or flue gas are similar to those for the high pressure gas drive. Pressure and depth requirements, as well as the need for a very light oil, are even greater if full miscibility is to be realized in the reservoir. The nitrogen and flue gas method is placed between hydrocarbon miscible and CO₂ flooding because the process can also recover oil in the immiscible mode. It can be economic because much of the reservoir space is filled with low cost gas.

Because of the minimum pressure requirement, depth is an important screening criteria, and CO₂ floods are normally carried out in reservoirs that are more than 2,000 ft deep. The oil composition is also important (see section on “Carbon Dioxide Flooding”), and the API gravity exceeds 30° for most of the active CO₂ floods [29]. A notable exception is the Lick Creek, Arkansas, CO₂/waterflood project which was conducted successfully, not as a miscible project, but as an immiscible displacement [30].

5.11.5.10 Criteria for Chemical Methods

For surfactant/polymer methods, oil viscosities of less than 30 cp are desired so that adequate mobility control can be achieved. Good mobility control is essential for this method to make maximum utilization of the expensive chemicals. Oil saturations remaining after a waterflood should be more than 30% PV to ensure that sufficient oil is available for recovery. Sandstones are preferred because carbonate reservoirs are heterogeneous, contain brines with

high divalent ion contents, and cause high adsorption of commonly used surfactants. To ensure adequate injectivity, permeability should be greater than 20 md. Reservoir temperature should be less than 175°F to minimize degradation of the presently available surfactants. A number of other limitations and problems were mentioned earlier, including the general requirement for low salinity and hardness for most of the commercially available systems. Obviously, this method is very complex, expensive, and subject to a wide range of problems. Most importantly, the available systems provide optimum reduction in interfacial tension over a very narrow salinity range. Preflushes have been used to attempt to provide optimum conditions, but they have often been ineffective.

The screening guidelines and a description of polymer flooding are contained earlier in Section "Polymer Flooding." Since the objective of polymer flooding is to improve the mobility ratio without necessarily making the ratio favorable, the maximum oil viscosity for this method is 100 or possibly 150 cp. If oil viscosities are very high, higher polymer concentrations are needed to achieve the desired mobility control, and thermal methods may be more attractive. As discussed earlier, polymer flooding will not ordinarily mobilize oil that has been completely trapped by water; therefore, a mobile oil saturation of more than 10% is desired. In fact, a polymer flood is normally more effective when started at low producing water-oil ratios [31]. Although sandstone reservoirs are usually preferred, several large polymer floods have been conducted in carbonate reservoirs. Lower-molecular-weight polymers can be used in reservoirs with permeabilities as low as 10 md (and, in some carbonates, as low as 3 md). While it is possible to manufacture even lower-molecular-weight polymers to inject into lower permeability formations, the amount of viscosity generated per pound of polymer would not be enough to make such products of interest. With current polymers, reservoir temperature should be less than 200°F to minimize degradation; this requirement limits depths to about 9,000 ft. A potentially serious problem with polymer flooding is the decrease in injectivity which must accompany any increase in injection fluid viscosity. If the decreased injectivity is prolonged, oil production rates and project costs can be adversely affected. Injection rates for polymer solutions may be only 40%–60% of those for water alone, and the reduced injectivity may add several million dollars to the total project costs. Other problems common to the commercial polymers are cited earlier.

Moderately low gravity oils (13°–35° API) are normally the target for alkaline flooding (see section on "Alkaline Flooding"). These oils are heavy enough to contain the organic acids, but light enough to permit some degree of mobility control. The upper viscosity limit (< 200 cp) is slightly higher than for polymer flooding. Some mobile

oil saturation is desired, the higher the better. The minimum average permeability is about the same as for surfactant/polymer (> 20 md). Sandstone reservoirs are preferred since carbonate formations often contain anhydrite or gypsum which react and consume the alkaline chemicals. The alkaline materials also are consumed by clays, minerals, or silica; this consumption is high at elevated temperatures so the maximum desired temperature is 200°F. Caustic consumption in field projects has been higher than indicated by laboratory tests. Another potential problem in field applications is scale formation which can result in plugging in the producing wells.

5.11.5.11 Criteria for Thermal Methods

For screening purposes, steamflooding and fireflooding are often considered together. In general, combustion should be the choice when heat losses from steamflooding would be too great. In other words, combustion can be carried out in deeper reservoirs and thinner, tighter sand sections where heat losses for steamflooding are excessive. Screening guides for in-situ combustion are given earlier in Section "In-Situ Combustion." The ability to inject at high pressures is usually important so 500 ft has been retained as the minimum depth, but a few projects have been done at depths of less than 500 ft. Since the fuel and air consumption decrease with higher gravity oils, there is a tendency to try combustion in lighter oils if the fire can be maintained, but no projects have been done in reservoirs with oil gravities greater than 32° API [29].

In summary, if all screening criteria are favorable, fireflooding appears to be an attractive method for reservoirs that cannot be produced by methods used for the lighter oils. However, the process is very complicated and beset with many practical problems such as corrosion, erosion and poorer mobility ratios than steamflooding. Therefore, when the economics are comparable, steam injection is preferred to a combustion drive [4].

Screening criteria for steamflooding are listed earlier in section "Steamflooding". Although steamflooding is commonly used with oils ranging in gravity from 10°–25° API, some gravities have been lower, and there is recent interest in steamflooding light oil reservoirs. Oils with viscosities of less than 20 cp are usually not candidates for steamflooding because waterflooding is less expensive; the normal range is 100–5,000 cp. A high saturation of oil-in-place is required because of the intensive use of energy in the generation of steam. In order to minimize the amount of rock heated and maximize the amount of oil heated, formations with high porosity are desired; this means that sandstones or unconsolidated sands are the primary target, although a steam drive pilot has been conducted in a highly fractured carbonate reservoir in France. The product of oil saturation times porosity should be greater than about 0.08 [26].

The fraction of heat lost to the cap and base rocks varies inversely with reservoir thickness. Therefore, the greater the thickness of the reservoir, the greater the thermal efficiency. Steamflooding is possible in thin formations if the permeability is high. High permeabilities (> 200 md or preferably > 500 md) are needed to permit adequate steam injectivity; transmissibility should be greater than 100 md ft/cp at reservoir conditions. Depths shallower than about 300 ft may not permit good injectivity because the pressures required may exceed fracture gradients. Heat losses become important at depths greater than about 2,500 ft. and steamflooding is not often considered at depths greater than 5,000 ft. Downhole steam generators may have potential in deeper formations if operational problems can be overcome.

5.11.5.12 Graphical Representation of Screening Guides

From the summary of screening guides in Table 5.11.1, the viscosity, depth and permeability criteria are presented graphically in Figures 5.11.3 to 5.11.5. The figures have some features which permit the quick application of screening criteria but they cannot replace the table for detailed evaluations. In a sense, the figures present a truer picture than the table because there are few absolutes among the numbers presented as screening guides in the tables. Different authors and organizations may use different parameters for the same process, and most of the guidelines are subject to change as new laboratory and field information evolves.

In field applications, there are exceptions to some of the accepted criteria, and the graphs accommodate these nicely. The “greater than” and “less than” designations of the tables can also be displayed better graphically.

The range of values are indicated on the graphs by the open areas, and by cross-hatching along with general words such as “more difficult,” “not feasible,” etc. The “good” or “fair” ranges are those usually encompassed by the screening parameters in the table. However, the notation of “good” or “very good” does not mean that the indicated process is sure to work; it means simply that it is in the preferred range for that oil or reservoir characteristic.

The influence of viscosity on the technical feasibility of different enhanced recovery methods is illustrated in Figure 5.11.3. Note the steady progression, with increasing viscosity, from those processes that work well with very light oils (hydrocarbon miscible or nitrogen) to oils that are so viscous that no recovery is possible unless mining and extraction are employed.

For completeness, we have included the two “last resort” methods (special steamflooding techniques with shafts, fractures, drainholes, etc., and mining plus extraction) are listed in Figure 5.11.5. These methods are not included in Figures 5.11.4 and 5.11.5 because these unconventional techniques are not considered in most reservoir studies.

Figure 5.11.4 shows that those enhanced recovery processes that work well with light oils have rather specific depth requirements. As discussed, each gas injection method has a minimum miscibility pressure for any given

FIGURE 5.11.3 Viscosity ranges for EOR processes [12].

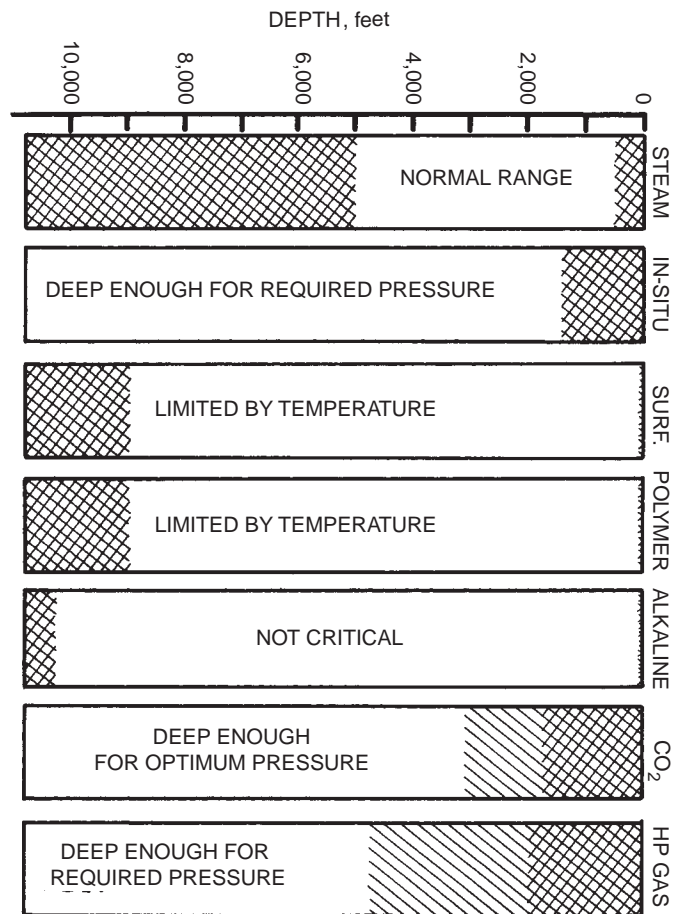

FIGURE 5.11.4 Depth requirements for EOR processes [12].

FIGURE 5.11.5 Permeability ranges for EOR methods [12].

oil, and the reservoir must be deep enough to accommodate the required pressure.

Figure 5.11.5 shows that the three methods that rely on gas injection are the only ones that are even technically feasible at extremely low permeabilities. The three methods that use backup waterflooding need a permeability of greater than 10 md in order to inject the chemicals or emulsions and to produce the released oil from the rock. Although most authors show a minimum permeability requirement of 20 md for polymers, we indicate a possible range down as low as 3 md for low molecular weight polymers, especially in some carbonate reservoirs.

The screening guides in the figures can perhaps be summarized by stating a fact well-known to petroleum engineers: oil recovery is easiest with light oil in very permeable reservoirs and at shallow or intermediate depths. Unfortunately, nature has not been kind in the distribution of hydrocarbons, and it is necessary to select the recovery method that best matches the oil and reservoir characteristics.

5.11.6 Laboratory Design for Enhanced Recovery

5.11.6.1 Preliminary Tests

5.11.6.1.1 Water Analysis

A complete water analysis is important to determine the effects of dissolved ions on the EOR processes (especially the chemical methods) or to ascertain any potential water problems such as scale or corrosion that may result when EOR processes are implemented. Water viscosity and density are also measured.

5.11.6.1.2 Oil Analysis

Oil viscosity and density are measured as well. A carbon number distribution of the crude may be obtained, especially if CO₂ flooding is being considered.

5.11.6.1.3 Core Testing

Routine core analyses, such as porosity, permeability, relative permeabilities, capillary pressure, and waterflood susceptibility tests are normally done by service companies that specialize in these types of tests. Specialized core tests, such as thin sections or scanning electron microscopy, are available to evaluate the relationship between pore structure and the process being considered. If required, stimulation or injectivity improvement measures can be recommended.

5.11.6.2 Polymer Testing

The desirability of adding polymers is determined by evaluating all available data to assess the performance of normal waterflooding. Any problems such as adverse viscosity ratios or large permeability variations should be identified. If the results of this study indicate that mobility control of the waterflood is warranted, the following laboratory tests are undertaken.

5.11.6.2.1 Viscosity Testing

Based on the permeability of the reservoir, relative permeability data, and the desired level of mobility control, polymers of certain molecular weights are selected for testing. Various concentrations of the polymers are dissolved in both the available injection water and in blends of the injection and formation waters. Polymer solutions may be non-Newtonian at certain shear rates, that is, the viscosity decreases at high shear rates (shear-thinning or pseudoplastic). This shear-thinning behavior is reversible and, if observed in the reservoir, is beneficial in that good injectivity can result from the lower viscosity observed at high shear rates near the injection well. At the lower shear rates encountered some distance from the injector, the polymer solution develops a higher viscosity. In this testing, it is important to consider not only the viscosity of the injected solution, but, more importantly, the in-situ viscosity that is achieved in the reservoir. Several things can happen that will reduce viscosity when the polymer solution is injected into the reservoir. Reduction in viscosity as a result of irreversible shear degradation is possible at the injection wellbore if the shear rates or shear stresses are large. Once in the reservoir, dilution with formation water or ion exchange with reservoir minerals can cause a reduction in viscosity, and the injected polymer concentration will need to be sufficiently high to compensate for all viscosity-reducing effects.

5.11.6.2.2 Polymer Retention

Retention of polymer in a reservoir can result from adsorption, entrapment, or, with improper application, physical plugging. Polymer retention tests are usually performed after a standard waterflood (at residual oil saturation) or during a polymer flood oil recovery test. If polymer retention tests are conducted with only water initially present in the core, a higher level of retention will result from the increased surface area available to the polymer solution in the absence of oil. Effluent samples from the core are collected during both the polymer injection and a subsequent water flush. These samples are analyzed for polymer content. From a material balance, the amount of polymer retained in the core is calculated. Results are usually expressed in lbs per acre-ft. Excessive retention will increase the amount of polymer that must be added to achieve the desired mobility control. The level of polymer retained in a reservoir depends on a number of variables: permeability of the rock, surface area, nature of the reservoir rock (sandstone, carbonate, minerals, or clays), nature of the solvent for the polymer (salinity and hardness), molecular weight of the polymer, ionic charge on the polymer, and the volume of porosity that is not accessible to the flow of polymer solution. Polymer retention levels often range from less than 100 lb/acre-ft to several hundred lb/acre-ft.

5.11.6.3 Surfactant and Alkali Testing

Laboratory tests consist of measuring the interfacial tension (IFT) between the crude oil and the injected solution (alkaline or surfactant additive). This is usually done with a spinning drop interfacial tensiometer. With surfactants, the requirement for measuring tensions can be minimized by performing vial tests to determine solubilization parameters that can be correlated with IFT. Other tests include determining relative permeabilities, wettability, and total fluid mobilities. Once the optimum conditions are found, results of oil recovery tests with the chemical flood additives are conducted, usually at waterflood residual oil saturation.

5.11.6.4 CO₂ Flooding

For the gas injection projects, the trend in this country is toward the use of carbon dioxide although the full impact of CO₂ flooding will be felt in several years since construction of CO₂ pipelines into the west Texas area was completed in the 1980s. Carbon dioxide flooding is not a truly miscible process; that is, it does not dissolve in all proportions with crude oil. However, CO₂ can extract light to intermediate components out of the crude oil. This CO₂-rich mixture can develop miscibility and effectively displace additional crude oil. The main limitation involved is the very low viscosity of CO₂ that results in fingering of CO₂ through the more viscous crude oil. This causes premature breakthrough of the CO₂ and reduces the amount of oil recovered per unit volume of CO₂.

A prediction of the minimum pressure required to achieve miscibility can be made if the reservoir depth and basic properties of the crude oil are known. Laboratory tests often consist of some means of determining the minimum miscibility pressure, often by observing the oil displacement efficiency by CO₂ in a small-diameter tube (slim tube) packed with sand or glass beads. Carbon number distribution of the crude will be of value in determining if sufficient amounts of the C₅ to C₁₂ components are present.

5.11.6.5 Thermal Recovery

Viscosities of very viscous crude oils can be reduced by the use of thermal recovery methods. Fireflooding or in-situ combustion involves starting a fire in the reservoir and injecting air to sustain the burning of some of the crude oil. Heat that is generated lowers the viscosity of the crude oil and results in improved recovery. With the steam drive or steamflooding process, steam is generated on the surface and injected into the injection wells. Some companies are now exploring the use of downhole steam generators in deeper wells where heat loss can be a serious problem. A primary problem with steam flooding is the channeling of steam through thin sections of the reservoir. To combat this problem, several organizations are studying the use of

surfactants to create a foam in situ for improving sweep efficiency.

For steamflooding, the most important laboratory tests are, of course, viscosity of the crude oil and permeability of the reservoir core material. To be economically viable, steamfloods must be conducted in thick, very permeable, shallow reservoirs that contain very viscous crude.

5.12 NATURALLY FRACTURED RESERVOIRS

Section reviewed by Tom Wynn

5.12.1 Introduction

Naturally fractured reservoirs (NFRs) are defined as reservoirs where fractures created by geological processes have a significant impact on the migration, storage, and extraction of hydrocarbons (Table 5.12.1). NFRs can be split into three different types [1]:

Typical flow characteristics of Type I and Type II NFRs are listed below. A single fractured reservoir may not exhibit all of these behaviors. Type III NFRs usually display

TABLE 5.12.1 Naturally Fractured Reservoir Types.

Type	Description
Type I	All storage and flow in fracture system, no matrix contribution
Type II	Some or most storage in the matrix, virtually all permeability in the fractures
Type III	Most or all storage in the matrix, permeability in the matrix and the fractures

From Reference 1.

more subtle changes in comparison to an expected matrix response.

1. Well test permeabilities $\geq 10\times$ the matrix permeabilities.
2. Highly heterogeneous well test permeabilities if the fractures are heterogeneous or the wells are poorly connected to the fracture system.
3. Very low skin values unless the fractures are damaged during drilling or the well has missed the permeable fracture system.
4. Highly anisotropic permeability and or connectivity as interpreted from well test responses or observed from interference testing.
5. Linear late time well test responses where fractures are sparse and/or poorly connected to each other, radial late time responses if fractures have high intensities and are well connected in multiple directions.

5.12.2 Fracture Type and Distribution

5.12.2.1 Tensile fractures

Fractures are usually formed by tensile opening or shearing processes. Tensile fractures (joints or veins) are typically found as sets perpendicular to geological bedding and are usually confined to single beds of mechanically homogeneous material. They terminate vertically at thin bed parallel laminations or at major lithology changes, so vertical fracture permeability is usually very low. Joints and veins have lengths of tens to hundreds of meters and heights of centimeters to meters. For a single tensile fracture, permeability is usually enhanced parallel to the fracture within a bed and either unaffected or reduced perpendicular to the fracture. The distribution of joint lengths may be best described by log-normal or fractal distribution types. Their distributions are usually controlled by mechanical bed thickness, lithology, fold curvature, or structural position on a fold (Figure 5.12.1).

5.12.2.2 Shear fractures

Shear fractures (faults, shear bands, granulation seams, etc.) during faulting processes. Most faults are oriented at 60° – 80° to the horizontal but in fold and thrust belts they are oriented at 0° – 30° to the horizontal. The inner part of the fault (fault core) with the most displacement is usually comprised of brecciated or finely ground and altered host rock and may also be associated with halos of tensile fractures and smaller shear fractures (the damage zone). Faults usually cross lithologies unless an interval of ductile material such as shale or salt is present that is thicker than the fault displacement. Therefore, faults can form vertically extensive conduits that tap fluids from deep within a reservoir or the aquifer. This may mean that large faults are either not drilled or are cemented off whereas smaller fractures are targeted. For a single fault zone, permeability may be enhanced parallel to the fault in one or

FIGURE 5.12.1 Relationships for fracture spacing vs. mechanical bed thickness [2].

FIGURE 5.12.2 Distributions of fractures in various structural settings.

both directions but is usually reduced or completely sealed perpendicular to the fault. Fault sizes (length or throw) may range from centimeters to many kilometers and are usually best described by self-similar fractal relationships. Groups of faults formed during a single period of tectonic activity either terminate in space or form swarms of features that anastomose with one another. These multiple fault sets can form complex compartments and flow pathways (Figure 5.12.2).

5.12.3 Fracture Parameters

5.12.3.1 Fracture intensity

This is simply the fracture count per unit measure and can take a number of forms:

- Number of fractures per unit length (P_{10})
- Fracture length per unit area (P_{21})
- Fracture area per unit volume (P_{32})

Intensities are best defined for sets of fractures with similar orientations and origins (e.g., joints or veins or faults). The most common reported intensity values are P_{10} (expressed in #/ft) as these are easily measured from core or image logs. P_{10} values may be quoted as raw/uncorrected or corrected for borehole deviation [3]:

$$\text{Intensity}_{\text{corr}} = \text{Intensity} \frac{1}{\cos \delta} \quad (5.12.1)$$

where δ is the angle between the sample line (e.g., wellbore) and the normal to the fracture set. These corrected P_{10} values can be regarded as equivalent to the P_{32} true volumetric

intensity that is useful for reservoir models if all the fractures are assumed to exist over the volume of interest (e.g., a grid cell). Several different fracture sets may exist over the same interval in which case they will intersect or terminate on one another. Shear fractures usually offset earlier sets or terminate in the matrix. Tensile fractures usually abut onto earlier fractures, terminate at bed boundaries or terminate in matrix.

5.12.3.2 Fracture aperture

Fracture aperture governs the fracture porosity and is also related to fracture permeability, particularly in the simplified parallel plate (“cubic law”) single fracture permeability equations. Average open fracture apertures in the subsurface can be highly variable but are typically in the order of 0.004–0.118 in. depending on fracture type, host lithology, degree of mineral fill/dissolution and the in situ stress regime. Apertures are typically log normally distributed although accurate apertures are very hard to measure as they are very small and can be highly variable with parts of the fracture occluded by minerals or zero aperture areas where the opposing fracture walls touch.

Different types of aperture need to be considered for fracture porosity vs. fracture permeability. For fracture porosity (aperture times fracture area), the average physical or mechanical aperture (E) is required. For fracture permeability, the equivalent smooth-walled or hydraulic (e) aperture is required. The relationship between the two is not particularly straightforward, although a variety of correlations exist. A relatively simple one is defined below [4]:

$$\text{Hydraulic aperture } (e) = \text{Mechanical aperture } (E)^2 / \text{JRC}^{2.5} \quad (5.12.2)$$

where apertures (E and e) are in micrometers (μm) and JRC is the joint roughness coefficient. The JRC is an empirical number between 0 and 20 with increasing values defining increasing roughness of the fracture wall (Figure 5.12.3).

To measure actual apertures, the excess current method applied to electrical image log tools [5] allows a semi quantitative measure of fracture aperture from electrical image logs run in conductive muds.

$$W = cAR_m^b R_{X_0}^{(1-b)} \quad (5.12.3)$$

where A is the excess conductivity above a background value, R_m is mud resistivity, R_{X_0} the flushed zone resistivity, and W is the aperture. The b and c empirical factors to ensure W is reasonable are hard to constrain leading to a wide range of realistic values for W . However, the aperture distribution shapes obtained from this method are useful. Alternative methods of estimating aperture include analog field studies where aperture is related to fracture length or displacement and apertures measured from core.

FIGURE 5.12.3 Schematic of joint roughness coefficient fracture profiles [4].

Core-derived apertures are unconfined measurements and can only be done on the outer core surface or cut faces. However, they are useful where the fractures are partially cemented and the occluded sections bridge the fracture and prevent much closure in the subsurface. An equivalent mechanical aperture of a partly occluded single fracture can be defined by estimating the average aperture of the open parts multiplied by the estimated percentage of open aperture within the individual fracture.

Irrespective of the measurement or estimation method, deriving meaningful average apertures valid over many cubic feet or more is very difficult and best handled via alternate estimates covering a viable range.

Fracture apertures can be susceptible to changes due to changes in the reservoir stress system during production or injection operations. Typical fracture system compressibilities are 1–2 orders of magnitude greater than matrix pore system compressibilities. However, once the fracture system is related to a unit volume of rock, the total fracture plus matrix system compressibility is typically 2–3 times greater than the matrix only.

In terms of rock volume:

$$C_f = \frac{1}{\text{pore volume}} \frac{\Delta(\text{fracture volume})}{\Delta P} \quad (5.12.4)$$

In terms of fracture volume:

$$C_{ff} = \frac{1}{\text{fracture volume}} \frac{\Delta(\text{fracture volume})}{\Delta P} \quad (5.12.5)$$

Therefore the permeability reduction factor for a given pressure drop is as follows:

$$\frac{k_f}{k_{fi}} = (1 - C_f \Delta P)^3 \quad (5.12.6)$$

Measuring compressibility in the lab is difficult due to hysteresis effects (fracture face damage) during multiple loading cycles. In addition, fractures of different orientations will respond differently to the changing normal stress regime and shearing effects may counteract normal stress closure effects (Figure 5.12.4).

5.12.3.3 Fracture porosity

This is very difficult to measure directly as typical fracture porosities are usually less than 1% and are typically 0.1–0.3%. Therefore they are often at or below typical open-hole porosity tool measurement thresholds (e.g., density, neutron, sonic). For reservoirs with high-fracture intensities and large apertures formed from say dissolution then porosities may be as high as 3–5% and the openhole porosity tools may be adequate. Note that some fault zones can have porosities in the range of 10–20% due to the intense fracturing and brecciation. However, these intervals will usually form a small fraction of the total reservoir volume causing the reservoir average fracture fault-related porosity to be more like 1–2% or less.

In the absence of accurate measurements from traditional log porosity methods, fracture porosity can be estimated for a single orientation-based fracture set from the following equation;

$$\varphi_{\text{frac}} \% = 100 \times \text{Intensity}_{\text{Corr}} \times E \quad (5.12.7)$$

where Intensity_{Corr} and mechanical aperture (E) are #/ft and ft or #/m and meters, respectively.

Minimum fracture porosity can be estimated from well tests but this theoretical equation is rarely used in practice [6]. Equation 5.12.8 shows the formula for estimating fracture porosity in oil wells. A different one is required for gas wells.

$$\varphi_f = \frac{1}{577.9} \left(\frac{\text{PI} \mu_o B_o f_s^2 \log \left(\frac{r_e}{r_w} \right)}{h} \right)^{1/3} \quad (5.12.8)$$

where φ_f = fraction, $f_s = 1/a$ or $2/a$ (cm/cm²), PI = productivity index (m³/d/atm) $\mu = \text{cP}$ and $h = \text{meter}$.

Total fracture porosity in a reservoir, grid cell, or interval of interest on a well log is estimated by summing the fracture porosity for each set. A similar process can be adopted for estimating porosities in faults, where the fault core widths and porosities and damage zone widths and fracture intensities can be measured or estimated and integrated for the interval or volume of interest.

5.12.3.4 Fracture permeability

The basic equations for fracture permeability for a single-, smooth-, parallel-walled fracture are given below [6, 7]. Fracture permeability can be defined by combining Darcy’s and Poiseuille’s Laws.

FIGURE 5.12.4 Variation in fracture permeability with confining pressure for different JRC values.

Darcy's law is defined as:

$$q_D = \frac{A k \Delta P}{\mu L} \quad (5.12.9)$$

Poiseuille's law is defined as:

$$q_P = \frac{w e^3 \Delta P}{12 \mu L} \quad (5.12.10)$$

From combining these equations, the "cubic law" fracture permeability equation is found:

$$k = \frac{w e^3}{12 A} \quad (5.12.11)$$

Equation 5.12.11 is for the intrinsic fracture permeability defined within the fracture only. These values tend to be very large and can be tens of thousands or millions of Darcy's. It is essential to remember that fracture permeability is governed by a power term on the aperture. Of more relevance to well test matching and reservoir simulation are the effective permeabilities where the fracture permeability is defined over a unit volume of rock from multiplying it by the fracture porosity. The equations linking intrinsic and effective fracture permeability are shown below.

Intrinsic fracture permeability is given by Equation 5.12.11. Referring to Poiseuille's law and Figure 5.12.5, this can also be expressed as:

$$k_{ff} = \frac{w e^3}{12 w e} = \frac{e^2}{12} \quad (5.12.12)$$

Effective fracture permeability is then defined as:

$$k_f = \frac{w e^3}{12 w h} = \frac{e^2}{12 h} \quad (5.12.13)$$

where permeability is in m^2 and 1 Darcy is approximately $10^{-12} m^2$. Note that h is the fracture spacing and $1/h$ is the same as $Intensity_{Corr}$ defined in Equation 5.12.1.

Note that the relationship between fracture permeability and fracture porosity for a single simple fracture is not

straightforward because fracture porosity is governed by mechanical aperture and fracture intensity whereas fracture permeability is governed by a power term of hydraulic aperture and fracture intensity. For example, a set of 10 fractures with an aperture of e will have the same porosity as one fracture with an aperture of $10e$ but the single large aperture fracture will have a permeability 100 times larger than the set of 10 smaller fractures.

These permeability equations are valid for a single, smooth-walled fracture. For groups of parallel, regularly spaced fractures (i.e., single orientation sets) defined with respect to an arbitrary direction such as a modeling grid, the following equations are valid:

Two orthogonal intersecting fracture sets:

$$K_{fxy} = \left(K_f^2 / 2 \right)^{0.5} \quad (5.12.14)$$

For a resolved grid direction X that forms the acute angle to the fracture direction:

$$K_{fx} = \text{Abs}(\text{Cos}^2 \theta) \times K_f \quad (5.12.15)$$

For the orthogonal grid direction Y:

$$K_{fy} = \text{Abs}(\text{Sin}^2 \theta) \times K_f \quad (5.12.16)$$

where K_f is in millidarcies and θ = fracture angle to grid direction (X or Y) and is in degrees.

The permeability equations above are useful for desktop studies or model-based estimates of fracture permeability, where the fracture system only is important. For systems where the fractures and matrix are both relevant and to utilize real flow data, the classic dual porosity response from well tests is usually employed. This is governed by the Warren and Root equation [6, 8], which treats the fractured media as a series of matrix cubes bounded on all sides by open fractures (Figure 5.12.6).

Equation 5.12.17 provides the pressure drop associated with steady state flow in a fractured reservoir. It combines the dimensionless radial diffusivity equation for a pressure drop at constant terminal rate [9] with the Warren and Root

FIGURE 5.12.5 Graphical illustrations of the difference between Darcy's and Poiseuille's laws. Parameters relate to equations 5.X.9 and 5.X.10. Courtesy AGR TRACS Training.

FIGURE 5.12.6 Graphical representation of a realistic fracture matrix system (left) and the Warren and Root approximation (right). Courtesy AGR TRACS Training.

FIGURE 5.12.7 Warren and Root type pressure vs. time response. Courtesy of AGR TRACS Training.

terms for dimensionless pressure in a fractured reservoir with steady state flow [6].

$$\Delta P(t_D) = \frac{q_0 \mu B}{4 \mu h k_f} \left[\ln(t_D) + 0.81 + E_i \left(\frac{\lambda t_D}{\omega(1-\omega)} \right) - E_i \left(\frac{\lambda t_D}{1-\omega} \right) + 2s \right] \quad (5.12.17)$$

where:

$$\omega = \frac{\phi_f c_f}{\phi_f c_f + \phi_m c_m} \quad (5.12.18)$$

$$\lambda = \alpha \frac{k_m r_w^2}{k_f} \quad (5.12.19)$$

and C_f = fracture compressibility, C_m = matrix compressibility, K_m = matrix permeability, and K_f = fracture permeability. The plot of pressure vs. time response for dual porosity system is shown below (Figure 5.12.7). The first segment of the slope is proportional to the fracture

permeability, the second portion of the slope related to the fracture plus matrix permeability. Usually the slopes are very similar as the fracture system permeability dominates.

The well test response derivative curves in a dual porosity system should exhibit these characteristic troughs where the horizontal position and depth of the trough are related to λ and ω respectively (Figure 5.12.8).

In reality, the dual porosity response is very hard to accurately define from actual well test data. This may be due to wellbore storage masking or from complexities of fracture system connectivity and many different matrix block sizes obscuring the derivative trough. Note the dual layer response where the layers communicate with each other away from the well has an identical mathematical formulation.

Real well test responses in fractured reservoirs often display late time radial or linear flow (half slope) behavior. These can be interpreted as representing well-connected (e.g., multiple sets) or poorly connected fracture systems (e.g., single sets) respectively away from the wellbore [10].

FIGURE 5.12.8 Typical Warren and Root derivative responses showing the influence of changes in the λ and ω parameters. Courtesy of AGR TRACS Training.

5.12.4 Fractured Reservoir Recovery Processes

For fractured reservoirs with most or all the storage in the fracture system, recovery is generally via depletion plus/minus fracture compressibility plus/minus aquifer or injection water ingress. Hydrocarbon saturations can be close to 100% with little or no transition zone due to the very high intrinsic permeabilities. Recovery is limited by the effectiveness of the depletion mechanism vs. water ingress and the connectivity of the fracture system to the well stock. Horizontal wells drilled across multiple fracture trends usually do best.

Recovery processes in fractured reservoirs where some or all of the storage is in the matrix can be defined by two main types:

Gas-oil gravity drainage. This is a relatively slow, low-recovery process that occurs in oil wet reservoirs with

primary or secondary gas caps. Only higher values of the uncontrollable parameter of matrix block height can help improve recovery as gravity is required to drain the oil into the fracture system (Figure 5.12.9).

Oil-water imbibition. This can be a moderate to slow process but recovery efficiencies can be high in water wet reservoirs if offtake rate is matched to the injection/aquifer water ingress rate. Increased oil wettability will reduce the recovery (Figure 5.12.10).

5.13 SHALE RESERVOIRS

Section reviewed by PK Pande and Tom Blasingame

5.13.1 Locations of Unconventional Reservoirs

In [Figure 5.13.1](#) a summary map is presented for the active and potential shale plays in the world. The most interesting aspect of this map is that, with the exception of North America (i.e., Canada and the United States), there

are relatively few commercial successes in unconventional (shale) plays at present (2015). Emerging plays in Argentina and Russia have some historical success in terms of production, but economic success is limited—most likely due to the lack of available services, as well as a restricted economic environment (in some countries the internal prices for oil and gas are not sufficient to yield economic success).

In [Figure 5.13.2](#), a map is presented for the currently active and emerging shale plays in the United States as of April 2015. The most striking feature of this map is the number of plays and expectation that other plays will be developed in essentially every major geologic basin.

The most active plays at present are the so-called “liquids-rich” plays that produce significant liquid streams (e.g., the Eagle Ford Shale (Texas), the Niobrara Shale (Colorado and Wyoming), the Bakken Shale (North Dakota), and the Utica Shale (Ohio)). The major shale gas plays are the Barnett Shale (Texas), the Haynesville Shale (Louisiana and Texas), the Marcellus Shale (Pennsylvania, Ohio, West Virginia, New York), and the Eagle Ford (Texas). These plays constitute a major portion of the gas production in the United States at present, and the contribution of “shale gas” is expected to continue to increase over the next 30–40 years.

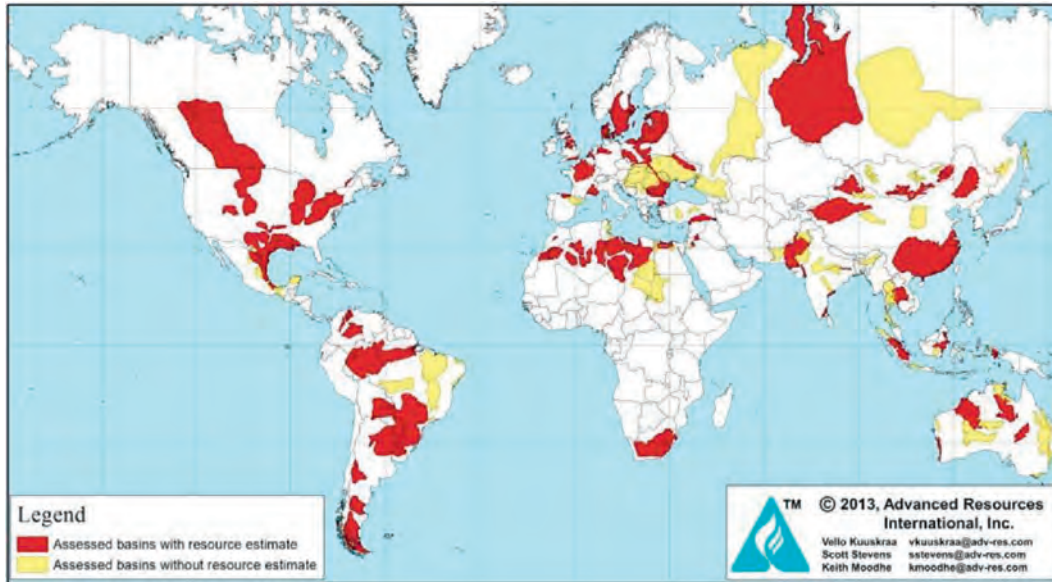

FIGURE 5.13.1 Global shale plays [1].

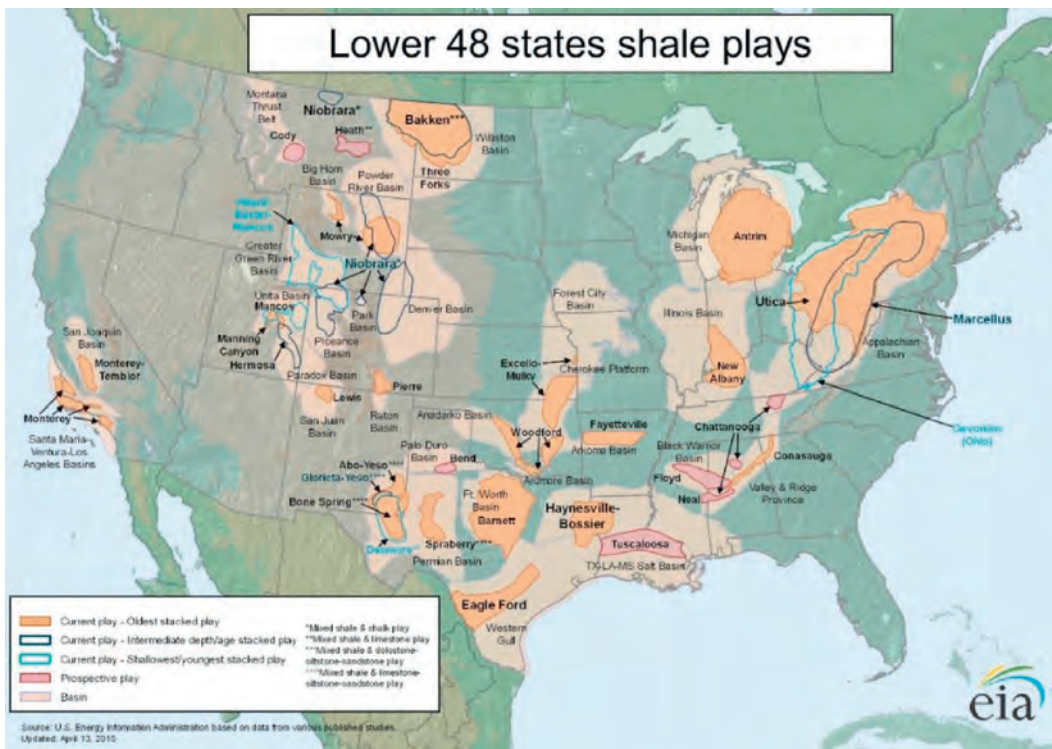

FIGURE 5.13.2 North American shale plays [2].

Considering the commercially successful Eagle Ford Shale (Texas), Figure 5.13.3 was obtained from the Texas Railroad Commission (RRC) which is the regulatory body for oil and gas in Texas. By the coloration of the wells on this map (oil wells are green, gas wells are red), it is immediately noted that the Eagle Ford shale has a complete

hydrocarbon sequence, from dry gas to black oil. There are geologic factors that influence and even control production in the Eagle Ford Shale—including thermal maturity, depth of burial, and geologic features such as faults and regional highs/lows. The clearest message from Figure 5.13.3 is that in terms of oil and gas production, the Eagle Ford Shale

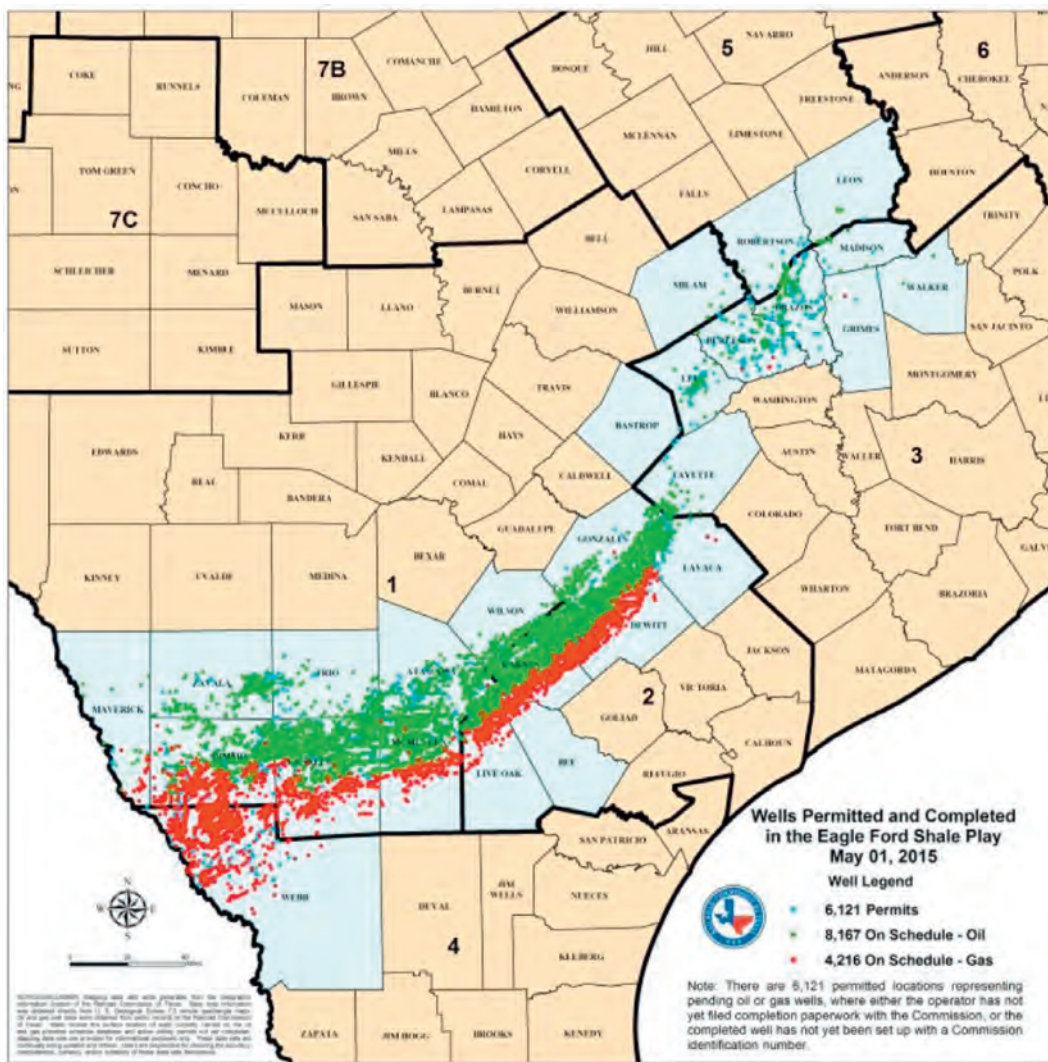

FIGURE 5.13.3 Eagle Ford map—Completions [3].

is clearly successful in terms of well completions and is economic in most producing areas. In the long term, the major challenge for plays such as the Eagle Ford Shale, the Niobrara Shale, and the Bakken Shale are to improve the recovery (less than 10%) in the oil-prone areas of these plays.

In Figure 5.13.4, the specific production metric being shown on this map of the Eagle Ford Shale is the initial producing gas–oil ratio (or GOR) and it is noted that the initial GOR is tied to both production *and* recovery. A similar map could be constructed for other “liquids-rich” plays (e.g., the Niobrara Shale and the Utica Shale)—and there is an observed variation in performance due to phase behavior (the specific influence of phase behavior will be discussed later in this section). The sheer magnitude of wells in a play such as the Eagle Ford Shale provides copious data for comparison, but on a well-by-well (or even

group or “pad” of wells) there remain significant variations in production performance.

Some of this production performance has to do with the technical and economic optimization of the stimulation treatments. Almost all wells currently being deployed in oil and gas shale plays are “multi-fracture horizontal wells”—that is, a horizontal well is drilled and completed, then stimulation treatments are performed from the “toe” to the “heel” of the horizontal well in sequential “fracture stages.” This process is time-consuming, but the efficiency of the stimulation deployment has improved tremendously over the last 5–7 years. In addition, larger and larger stimulation treatments are being performed—on a per well basis, 12–15 million pounds of sand are being used regularly. Obviously such large treatments must be justified economically, but assuming this is the case, we can expect to see continued use of horizontal wells on the order of 5000 to 10,000 ft in

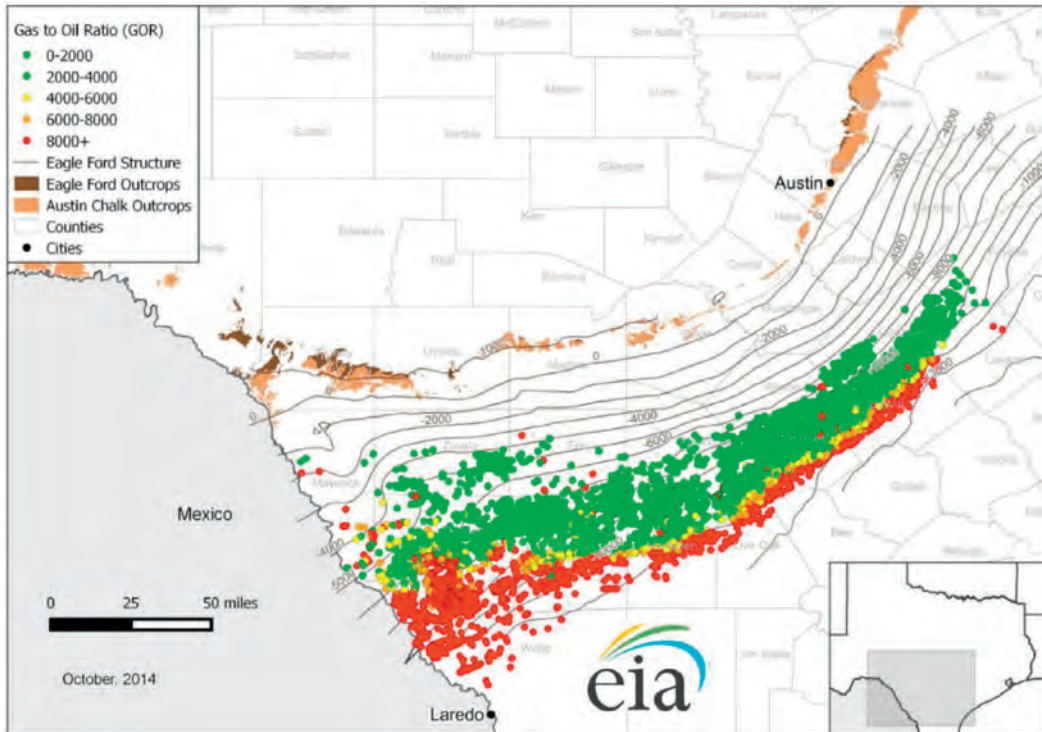

FIGURE 5.13.4 Eagle Ford map—GOR [4].

(horizontal) length, as well as larger and larger volumes of water.

As a final comment on Figure 5.13.4, this graphic clearly illustrates the extensive nature of a specific shale play (i.e., the Eagle Ford Shale), it is very large, encompassing all or part of 15 counties at present. Also, the balance of how to optimally develop such a play remains a critical task—an imbalance in oil and gas prices has existed historically and does so at present as well. Gas wells are generally easier to produce, require less maintenance and artificial lift—but as noted, low gas prices generally mean that wells which produce predominantly gas are less profitable than wells which produce pre-dominantly oil.

For the interested reader, References 5 and 6 provide background on the initial gas shale play development in the United States up to 2009. These references focus on gas shale plays and provide an overview in terms of geology, petrophysical data, production characteristics, water management, and regulatory considerations for the plays reviewed. Reference 7 is a current publication of the American Petroleum Institute (API) and focuses on the most recent information and perspectives of the large-scale deployment of hydraulic fracturing in the United States. This report contains an overview of current shale play developments, as well as current views on drilling, well stimulation, regulatory requirements, water management, emissions control, and the environmental aspects of hydraulic fracturing.

5.13.2 Geology of Unconventional Reservoirs

The large-scale understanding of the geology of unconventional reservoirs (shales) is well-established—including the depositional and maturation histories of these types of reservoirs. Somewhat less understood are the geochemical aspects of shales, in particular the “liquids-rich” shale play (i.e., the Eagle Ford Shale (Texas), the Niobrara Shale (Colorado), the Bakken Shale (North Dakota), the Utica Shale (Ohio), and the Wolfcamp shale and associated members (Texas)). Each of these plays (with the possible exception of the Bakken) has a spectrum of hydrocarbon fluid types, and in some cases (e.g., the Eagle Ford Shale (Texas) and the Niobrara (Colorado)) have very tight gradations from volatile oil to retrograde gas condensates—i.e., the fluid type can change over very small distances, say a few miles or even less where geologic features prevail.

The present challenge for the petroleum industry is the understanding of nano-scale petrophysical behavior for unconventional plays—one will often hear “what is the pore space?” or “how do the fluids move in the reservoir rock?” Since the late 2000s, there has been an enormous effort both scientific and practical on addressing the storage (pore space) and transport (pore connectivity) for unconventional reservoirs. Efforts to characterize the pore space in unconventional (shale) plays tend to focus on the

FIGURE 5.13.5 Secondary electron images of pores in nonorganic matter (Barnett Shale) [8].

micrometer- to nanometer-scale imaging to understand the nature of the rock as well as the organic “kerogen” components.

In Figures 5.13.5–5.13.7, Loucks [8] presents a series of electron microscope images for samples taken from the Barnett Shale. The Barnett Shale was the first major “shale” play development and most studies until about 2010 referenced the Barnett Shale as the primary analog for any new play. After the development of many more shale plays, the Barnett Shale is now thought to be somewhat unique in its reservoir and fluid properties (i.e., the Barnett Shale has more clay and detrital sand in terms of composition, and is primarily a (very) dry gas play (except for a small portion of the Barnett Shale that produces oil)).

In Figure 5.13.6, Loucks [8] shows the pore space in the “inorganic” matter of the Barnett Shale, generally thought to be void spaces that formed around grains or within the crystalline structure of the rock. In Figure 5.13.6, Loucks provides images of the “organic” matter (kerogen) and/or its remnants. In particular, Figure 5.13.6C is one of the most often referenced images as it clearly shows the pore space within a particle of organic matter. Some research-level studies have concluded that the “reservoir” is actually made of nano-reservoirs such as Figure 5.13.6C implies. On a large scale, it is more likely that the representations shown

by Figure 5.13.6A, B, and D represent the “reservoir,” but Figure 5.13.6C remains a reference point of focus for many research studies.

In Figure 5.13.7, Loucks [8] presents images that characterize the “nanopore” nature within the organic matter for Barnett Shale samples. In this image, there are “holes” in the material which are possibly distorted due to the sample preparation—i.e., there is no assurance that isolated pores are in hydraulic communication through the “matrix.” The prevailing rationale is that the nanopores must be in communication because these reservoirs produce fluids, but this could be an overly simplistic view. There must be a communication path, but “nanopore connectivity” remains one of the most debated and intense areas of study.

As will be discussed later, the “morphology” of the pore space has an influence on the thermodynamic “phase behavior” for unconventional reservoir systems—particularly so for the so-called “liquids-rich” hydrocarbon systems. “Liquids-rich” is loosely defined as a volatile oil or retrograde gas condensate fluid which yields substantial quantities of liquid hydrocarbons. In a practical sense, the value proposition for oil (or condensate) is several times higher than that of natural gas (historically and presently). In a thermodynamic sense, there is a known phenomenon whereby

FIGURE 5.13.6 Nanopores associated with organic matter (Barnett Shale) [8].

FIGURE 5.13.7 Secondary electron images showing variations in nanopore morphology in organic matter (Barnett Shale) [8].

FIGURE 5.13.8 Multiple porosity types in the Haynesville include matrix-hosted intercrystalline porosity, intergranular porosity among detrital silt grains, intraparticle porosity within calcareous fecal pellets, and secondary porosity within organic matter [10].

hydrocarbon fluids confirmed in very small volumes tend to have phase behavior characteristics which are dependent on the volume of confinement—which is different than our traditional assumptions where hydrocarbon fluid properties are controlled only by their physical composition, temperature, and pressure—not by confinement volume. As the images provided by Loucks [8] confirm, there is a potential to have hydrocarbon fluids stored in very small volumes, which could affect the very nature of the phase behavior of these fluids.

In Reference 9, Loucks provides a pore-classification for “mudrocks” (i.e., shales). Loucks provides additional images for the Pearsall Shale (Texas) and the Haynesville Shale (Louisiana-Texas)—where both plays produce predominantly (very) dry gas. As comment, the Haynesville Shale has isolated portions in both Louisiana and Texas which produce a “liquids-rich” fluid, but the vast majority of production for the Haynesville Shale is dry gas. The figures and discussion in Reference 9 focuses on similar features as Reference 8, the nature of the nanopores in ultra-low-permeability shales. In particular, Loucks [9] provides a wider variety of scenarios and provides orientation on pores which are formed in organic matter, as a result of dissolution features, and intraparticle features.

Figure 5.13.8 (Spain Reference 10) presents a pore-scale image that contains numerous different possible porosity types in a Haynesville Shale sample. There is an organic particle within a sequence of detrital (very small) silt-grains. There is also evidence of interparticle porosity, as well as porosity within the organic particle. The image in Figure 5.13.8 confirms the enormous complexity of the nanopore system and the multiple different porosity types. As noted earlier, in such systems, it will be particularly difficult to conclusively define a relationship between the storage (porosity) and transport (permeability) components. However; the work of Loucks [1, 9] and Spain [10] confirm that there is significant pore space in unconventional (shale) reservoirs—and while tying this pore space to production remains a challenge, and obviously, commercial-scale production cannot be achieved in such systems without the creation of additional flow-paths as we believe are formed during hydraulic fracturing.

In Figure 5.13.9, Loucks [11] provided a pore classification scheme for mudrocks (shales) using an expanded sequence of pore types—most notably, pores in organic matter and more definitions for intraparticle pores. This scheme should provide more flexibility and better points

FIGURE 5.13.9 Spectrum of pore types and networks in mudrocks [11].

of reference for fluid storage in unconventional reservoir systems.

In Figure 5.13.10, the data of Milliken [12] are shown as a means of providing expected ranges of values for total organic carbon (TOC), porosity, and permeability for a series of different samples from the Barnett Shale, where these values were grouped according to the composition of the grain matrices (e.g., silts, clays, and other minerals). These data suggest that porosity should have a fairly narrow range (perhaps 1.5–3.0%) and that the permeability is very low, on the order of $20 - 40 \times 10^{-6}$ md. In addition, the

Milliken data provide a consistent basis in terms of various mineral constituents (on a per group basis). The data also clearly indicate where there are higher concentrations of clay minerals, and the effect of these clay minerals on the permeability.

As comment, the data in Figure 5.13.10 (Milliken [12]) are taken as valid, but no universal correlation of permeability should be inferred. These data could be used in comparative correlations, but given the strong emphasis on grouping by mineralogical type, the data may not necessarily correlate for systems without similar mineral types.

Sample	Depth (ft)	Silt (vol. %)	TOC (wt. %)	Gas-Filled Porosity (%)	Permeability (md)	R _o (%)	TO ₂ (wt. %)	Al ₂ O ₃ (wt. %)	Quartz (wt. %)	Total Feldspar (wt. %)	Crystalline Illite (wt. %)	Illite + Smectite (wt. %)

*silicate-normalized

FIGURE 5.13.10 Samples sorted into five groups based on selected silicate-normalized elemental and mineralogical data [12].

FIGURE 5.13.11 Host rock compositional variation for selected shale plays [13].

Further evidence of the influence on minerals (clay, quartz, and carbonate) is provided in the ternary diagram shown in Figure 5.13.11 (Gale [13]). The most intriguing feature of this diagram is perhaps the carbonate portion of the diagram, because although the presence of carbonate

may indicate a sealing component, carbonate components are seen as more a more brittle (and weaker) rock to perform hydraulic fracture stimulation. The schematic data in Figure 5.13.11 provide guidance regarding expected pore types and, potentially, the influence of pore types on production.

The work performed by Chalmers [14] parallels the approach by Loucks [9, 10] to characterize the pore system for gas shales. In this case, Chalmers provided an extensive inventory of images for gas shale systems, and analogous to Loucks [9, 10], Chalmers [14] provided guidance on the types pores and the possible nature of storage and flow in these pores. Chalmers concluded that aggregates (pieces) of kerogen, clay, and carbonate have the highest potential for storage, and that the complex pore systems shown in their images confirm the “interconnection between macropores with both coarse to fine mesopores”—implying that there is sufficient connectivity with the pore system for a shale that macroscopic (Darcy flow) is possible. Although not mentioned directly, the use of hydraulic fracture stimulation can (and should) enhance the flow capacity within a nanopore system.

The work performed by Chalmers [14] parallels the approach by Loucks [9, 10] to characterize the pore system for gas shales. In this case, Chalmers provided an extensive inventory of images for gas shale systems, and analogous to Loucks [9, 10], Chalmers [14] provided guidance on the types pores and the possible nature of storage and flow in these pores. Chalmers concluded that aggregates (pieces) of kerogen, clay, and carbonate have the highest potential for storage, and that the complex pore systems shown in their images confirm the “interconnection between macropores with both coarse to fine mesopores”—implying that there is sufficient connectivity with the pore system for a shale that macroscopic (Darcy flow) is possible. Although not mentioned directly, the use of hydraulic fracture stimulation can (and should) enhance the flow capacity within a nanopore system.

In Reference 15, Hammes provides a comprehensive geologic description of the Haynesville Shale (E. Texas and NW. Louisiana). In particular, Hammes [15] provides a map of the various Haynesville depositional sequences—and it is noted that there are clear interfaces of organic-rich muds (shale) and carbonates. Hammes [15] also provides a stratigraphic column of the depositional sequences and cycles, and as noted above, there are clear interfaces of the carbonate and shale sequences during the Upper Jurassic time period in the “Haynesville” depositional sequence.

5.13.3 Petrophysics of Unconventional Reservoirs

The petrophysical aspects of unconventional shale reservoirs are arguably more complex than the geological aspects—and the ability to accurately evaluate storage (porosity) and transport (permeability) in shales is rapidly evolving. Many of the petrophysical evaluation methods (i.e., for core and well logs) originated 30–35 years ago during the initial exploitation of tight gas plays. At present,

the primary focus on petrophysics in gas- and liquid-rich shales is the evaluation of permeability and associated quantities (e.g., diffusion coefficients, capillary pressure, and the influence of multiple phases on the flow behavior in shales).

In Figure 5.13.12, Nelson [16] presents the various scales of diameter, width, or size for various sand sizes, tight gas and shale gas reservoirs, and fluid molecules (hydrocarbons, helium, nitrogen, water, and mercury). There is no vertical scale on Figure 5.13.12 (the vertical portion of the plot is used to present the labels for each case or variable considered). The x-axis of Figure 5.13.12 is logarithmic (in micrometers), ranging from the smallest size (1 Å) to the largest size (1 mm). This plot helps to visualize the enormous difference in scales—in particular, at the small end of the scale the size of pore is only a few times larger than the size of the fluid molecule. The implication is simple, normal rules (and assumptions) for fluid storage and transport will begin to fail at these scales.

Nelson [16] also provides (averaged) sample data results in Figure 5.13.13—specifically, computed pore-throat diameter, porosity, and permeability estimates. These results, being averages, will have some bias, but when permeability is plotted versus porosity on log–log coordinates (see Figure 5.13.14) a strongly power-law trend is observed—which is somewhat in accordance with theory (and certainly in accordance with expectations).

Permeability is next plotted versus porosity on semilog coordinates (see Figure 5.13.15) and the power-law trend obtained from the data in Figure 5.13.14 is superimposed for reference. Figures 5.13.14 and 5.13.15 are not proposed as standards, nor even as definitive correlations, but rather, these plots are used to provide orientation regarding expectations. As mentioned earlier, being averages, the values plotted on Figures 5.13.14 and 5.13.15 will likely exhibit some bias due to averaging (as opposed to normal variance), but the purpose of these plots is to provide a “schematic” understanding of petrophysics in shales, and as such Figures 5.13.14 and 5.13.15 are quite effective in that regard.

In Figure 5.13.16, the results of Heller [17] are presented—the compositions are provided in a fractional bar chart as well as ternary diagram for the “Clay + Kerogen,” “Quartz + Feldspar + Pyrite,” and “Carbonate” components. In the bar chart on Figure 5.13.16, the dominance of a given component(s) is evident—the Barnett Shale samples are clearly dominated by quartz, the Eagle Ford Shale samples by carbonate, and the Marcellus Shale sample is dominated by clay. The ternary diagram in Figure 5.13.16 provides a “spatial” visualization of the different components—and as with the “bar charts,” we note that the Eagle Ford Shale samples are dominated by “Carbonates” and the Barnett and Montney Shale samples are dominated by “Quartz + Feldspar + Pyrite.” As noted

FIGURE 5.13.12 Sizes of molecules and pore throats in siliciclastic rocks on a logarithmic scale [16].

FIGURE 5.13.13 Summary of measurements of pore-throat size and other parameters for siliciclastic rocks (published sources) [16].

in the previous discussion of geology, the composition of the matrix rock can be a critical factor in reservoir performance and recovery.

The table in Figure 5.13.17 (Bust [18]) is presented to provide perspective on the differences between conventional and unconventional reservoirs. The most obvious distinction for reservoir engineers and petrophysicists is formation permeability (i.e., the ability to flow fluid). For gas- and liquid-rich shale plays in the United

States, the formation permeability ranges from 5×10^{-6} to 50×10^{-6} md, which is a factor of almost 1 billion (1×10^9) when comparing ultra-low (unconventional) and high-permeability (conventional) reservoir cases. Of course there are many more factors besides permeability that must be considered. These properties/factors include geology, thermal maturation, heterogeneity, sealed and unsealed natural fractures, water salinity, water saturation, wettability, and organic matter.

FIGURE 5.13.14 Log-log plot of permeability versus porosity (data from Nelson Table 1) [16].

FIGURE 5.13.15 Semilog plot of permeability versus porosity (data from Nelson Table 1) [16].

Although there is considerable uncertainty in most of the variables given by Bust [19], the uncertainty in permeability measurement is cause for concern—not in terms of theory as much as the practical deployment of the permeability estimation techniques for unconventional reservoirs. Specific to the issue of uncertainty in permeability measurements, Cui [19] provides insight on each of accepted permeability estimation techniques for unconventional (shale) reservoirs. Additional research is ongoing in the area of permeability estimation for shales, but in simple language, it is very unlikely that a simple model (such as Darcy flow experiments for convention-type reservoirs) will provide meaningful results for shale reservoir systems. As an example, it may be (and probably is) possible to correlate permeability with capillary pressure attributes for shale reservoir samples, but such correlations may literally be limited to samples for that given section of core.

5.13.4 Pore-Scale Flow in Unconventional Reservoirs

Figure 5.13.18 given by Javadpour [20] presents the schematic for the interrelation of different processes involved in the characterization and modeling of uncon-

ventional reservoir systems. The most important feature of Figure 5.13.18 is the exhaustive number of components considered—each component has the potential to influence production and recovery, and must be addressed in the context of validation of the component and uncertainty in the values used in such model studies.

One of the most frequent points of discussion in the flow of fluids for shale systems is the role of nanoscale flow behavior—in simple terms, whether the fluid behaves as a viscous fluid (like a normal liquid) or if the fluid behaves like a “dilute” gas (where in the most diffuse case, the movement of the gas molecules would be governed by Brownian motion). The “truth” most likely lies somewhere in between.

Figure 5.13.19 is taken from Ziarani [20] and presents a schematic of the presumed three major flow scenarios—bulk diffusion (Darcy’s Law), Knudsen Diffusion (large range of “flow regimes”), and surface diffusion where the fluid molecules are attracted close to the pore wall due to surface energy effects.

In Figure 5.13.20, Florence [22] presents the “Knudsen flow” chart for a specific case to provide guidance on actual flow behavior relative to the definition of Knudsen flow. Particular to Figure 5.13.20, the “continuum flow” region

FIGURE 5.13.16 Mineralogy of shale samples used in the Heller et al. study [17].

Conventional Reservoirs	Unconventional Reservoirs
Extensive single rock type	Multiple electrofacies or petrofacies — thin beds
Homogeneous	Heterogeneous (e.g., variable mineralogy/texture)
Isotropic at micro- and meso-scales	Anisotropic (e.g., ellipsoidal grain shape, laminations)
Compositionally clean	Clay minerals
Clay- and silt-free	Argillaceous and silty
No metallic minerals	Pyrite and others
Uni-modal pore-size distribution	Multi-modal pore size distribution including micro-porosity
Intergranular porosity	Micro-fractures
High-salinity brine	Variable water salinity
Water-wet	Variable wettability
Archie exponents ≈ 2	Archie exponent $\neq 2$
No organic solids	Kerogen

is taken to be equivalent to Darcy's law, "slip flow" is akin to the Klinkenberg effect often observed in the laboratory (the wall slip phenomena). "Transitional flow" and "free molecular flow" are regimes where full consideration of the Knudsen flow definition must be used.

5.13.5 Phase Behavior in Unconventional Reservoirs

The subject of phase behavior in unconventional (shale) reservoirs is perhaps the most active topic of research at present. In the initial development of liquids-rich shale reservoirs, the prevailing assumption was that traditional "bulk fluid" thermodynamics were sufficient for characterizing the "confined" fluids residing in nanopores. For about the last 5 years, there has been a broad and concerted effort to model fluids in confined domains. In chemical engineering, such modeling has been performed for a number of years (back well into the 1980s), but there was very little physical calibration data (especially for hydrocarbon fluids) and most of the modeling was performed on a single component, or perhaps a binary or ternary mixture. Present work focuses on "bubblepoint" suppression for volatile oil cases and "dewpoint" suppression for retrograde gas cases.

The goal of this discussion is to orient the reader that there are presently 2 schools of thought—first, that hydrocarbon fluids can be modeled as "conventional" bulk thermodynamic systems and second that molecular-level modeling must be performed to capture the appropriate thermodynamic behavior. This section discusses the results of recent studies as to how to best to consider the phase behavior for liquids-rich shale systems.

The schematics of Alharthy [23] are shown in Figures 5.13.21 and 5.13.22, where Figure 5.13.21 illustrates the behavior of a retrograde gas system and Figure 5.13.22

FIGURE 5.13.20 Limits of the different flow regimes, as a function of characteristic length, and reciprocal mean free path normalized (1 atm., 300 K). Lines defining various flow regimes are based on flow of air at isothermal conditions [22].

illustrates the behavior of a volatile oil system. These figures are designed to illustrate phase behavior in a “confined” hydrocarbon system where the bubblepoint (or dewpoint) is “suppressed” due to confinement. In short, the confinement results in a lowering of the bubblepoint or dewpoint, which results in lower hydrocarbon liquid yields.

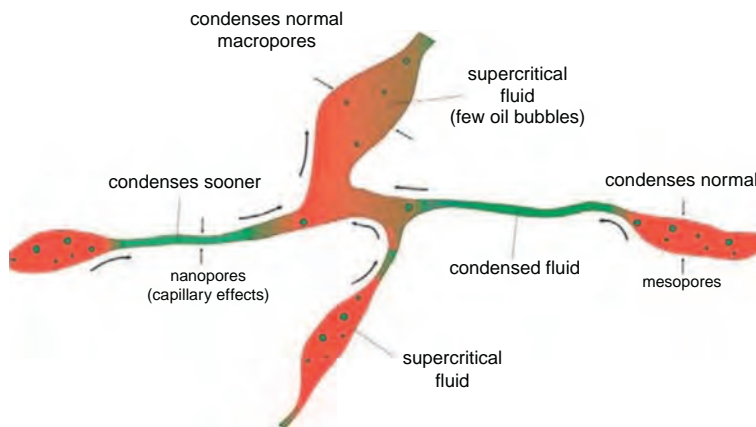

The phenomenon illustrated in Figure 5.13.23 (Zarragoicoechea [24]) illustrates the “shift” in the critical temperature for the given single-component cases (Ar, Xe, CO₂, O₂, N₂, C₂H₄) presented by Zarragoicoechea [24]. The correlation trend presented by Zarragoicoechea [24] has been used to construct bubblepoint and dewpoint suppression cases such as those presented by Sapmanee [26] in Figure 5.13.24.

The phase envelopes presented by Sapmanee [26] in Figure 5.13.24 show that the dewpoint is “suppressed” at reservoir temperature, which as noted earlier means that the liquid yield will be lower. One interpretation of these sorts of phenomena suggests that we are over-predicting liquid yields if only “bulk fluid” thermodynamics are considered. While this is directionally true, this phenomenon may not be as significant as the phase behavior modeling studies suggest.

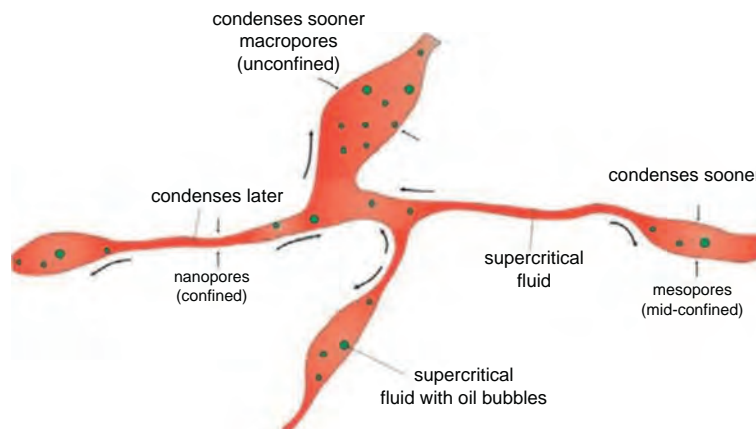

In Figure 5.13.25, the modeling results of Teklu [26] are presented and as the results suggest, there is very little suppression of the bubblepoint pressure for these cases where the pore radius is larger than 10–20 nm. Teklu [26] considers a variety of factors in Figure 5.13.25 (critical temperature and pressure shift as well as the influence of capillary pressure)—however; the results shown in Figure 5.13.25 imply that bulk fluid thermodynamics can be used for any case where the pore radius is larger than 10–20 nm. This observation does not ignore the reality that there are tangible effects of pore size, but this work (and the work of others) tends to suggest that nanopore phase behavior effects can be neglected in most cases.

5.13.6 Reservoir Performance in Unconventional Reservoirs

Any discussion of reservoir performance in unconventional (shale) reservoirs must begin with a statement regarding that, based on the ultra-low permeability of shale systems, there is a very strong likelihood that most wells in unconventional reservoirs will produce *transient flow*

Conceptual pore network model showing similar phase behavior in different pore sizes for a dewpoint system — *without* phase behavior shift.

Conceptual pore network model showing similar phase behavior in different pore sizes for a dewpoint system — *with* phase behavior shift.

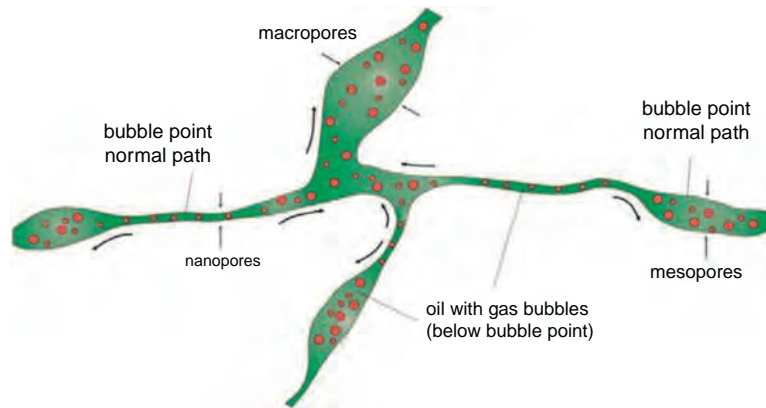

FIGURE 5.13.21 Conceptual pore network model showing similar phase behavior in different pore sizes for a dewpoint system with and without phase behavior shift [23].

for the duration of the productive life of the well. There are exceptions, in particular some of the higher permeability shale plays do present depletion-like effects that very likely represent near-neighbor interference. However, with those exceptions noted, the behavior of wells in unconventional reservoirs having very long-term transient flow behavior is in direct contrast with conventional reservoirs where transient flow last only a few days to a few weeks.

This very long-term transient flow behavior has implications on both recovery and reserves. The actual “drainage area” for a multi-fracture horizontal well in an unconventional reservoir is *essentially* the so-called “Stimulated Reservoir Volume” or SRV—where *the SRV represents the volume of rock that has been effectively stimulated using hydraulic fracturing*. This behavior dictates that assessment

of the SRV is a priority, both for estimated ultimate recovery (or EUR), as well as the nature of the pressure distributions in the reservoir near existing wells. In short, it may not be prudent to try to drill infill wells due to pressure depletion in the near-well regions for the (original) “parent” well. There are numerous examples of degrading the performance of the “parent” well when the “child” (infill) well is turned to production.

Perhaps equally important in this discussion is the fact that the well stimulation *defines* the reserves for wells in unconventional (shale) reservoirs. In short, well performance and recovery are directly proportional to stimulation size and effectiveness. More proppant and more dense fracture clusters have been shown conclusively to yield higher rates and recovery, but of course, there are off-setting economic factors that must be considered.

Conceptual pore network model showing similar phase behavior in different pore sizes for a bubblepoint system— *without* phase behavior shift.

Conceptual pore network model showing similar phase behavior in different pore sizes for a bubblepoint system— *with* phase behavior shift.

FIGURE 5.13.22 Conceptual pore network model showing similar phase behavior in different pore sizes for a bubblepoint system with and without phase behavior shift [23].

Figure 5.13.26 (Al-Kobaisi [27]) presents the various flow configurations expected for a multi-fracture horizontal well (MFHW)—where the primary flow regimes are likely to be (early-time) “linear flow” following well clean-up and (late-time) “compound pseudoradial flow” (which is something of an analog for pseudosteady-state). Unfortunately, in “liquids-rich” shale reservoirs a condition known as “liquid loading” is likely to evolve, particularly in wells that are continuously produced up casing (as opposed to producing up tubing at rates above the critical lifting velocity). Liquid loading provides a signature identical to compound pseudoradial flow—this occurs because the liquid loading holds a backpressure on the formation and causing the pressure response to indicate that there is a one-to-one relationship between pressure and rate, identical to the pseudosteady-state flow signature

(which is approximated in the compound pseudoradial flow regime).

It is important to recognize that the reservoir permeability is so low that virtually any fracture will have a conductivity several orders of magnitude greater than the matrix permeability, hence the linear flow regime should be expected to have several years of influence (it is not uncommon to observe 3–5 years of linear flow, and even for tight gas cases there are instances where linear flow has been observed for 12–15 years).

In Figure 5.13.27 the schematic of the trilinear-flow model (proxy) is presented (Brown [28])—the purpose of this model is to provide a fast and accurate alternative to the full multi-fracture horizontal well model. Brown [28] provides a comprehensive validation of the trilinear flow proxy model, and in fact, more of these “approximate”

FIGURE 5.13.23 Shift on the critical temperature in function of the size of the mesopore [24].

FIGURE 5.13.24 Phase diagrams of confined and unconfined light gas condensate mixture [25].

models continue to emerge. One possible advantage of these models is their use in discriminating the separate contributions of fracture half-length, fracture conductivity, the number of fractures, and the formation permeability. However; there will likely be uniqueness problems with these sorts of models, similar to issues experienced with the full multi-fracture horizontal well models.

In simple terms, the industry could use a workflow that yields a unique description/definition of reservoir and completion parameters (i.e., the permeability, fracture half-length, and fracture conductivity to name the most obvious parameters). The current approach is thought to generate a unique reservoir characterization using rate and pressure data and focuses (almost exclusively) on continuously

FIGURE 5.13.25 Bubblepoint-pressure change at different pore radii and at reservoir temperature for a Bakken oil sample—includes the effects of critical-temperature and -pressure shift, capillary pressure effects, and critical-temperature and -pressure shift plus capillary pressure effects [26].

measured rate and pressure data. The methodology for production analysis is called “rate transient analysis” (or RTA) and these tools are well-established as robust and accurate.

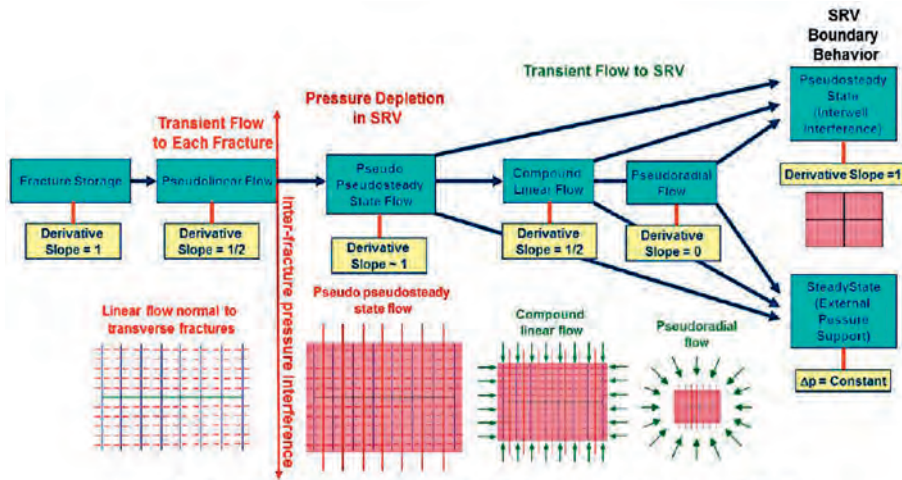

It is worth mentioning that RTA methods are particularly well-suited for the analysis/interpretation of performance data from unconventional (shale) reservoirs. This is because the nature of these ultra-low permeability reservoirs ensures that a significant duration of data are required to produce a conclusive flow regime (i.e., a clear and distinct signature of the reservoir). Unfortunately, for unconventional reservoirs, RTA methods require some foreknowledge of reservoir permeability in order to provide a unique analysis.

There is also a resurgence in interest of deploying pressure transient analysis (or PTA) methods; with the goal being to at least qualitatively validate the underlying reservoir signature. While PTA methods utilize high-frequency/high-resolution pressure data—for shales, PTA testing practices will require relatively long well shut-ins (on the order of 1.5–2 months of data acquisition) which may in some cases represent both a significant loss of revenue (due to production deferral) and a loss in reserves (due to adverse effects on the reservoir and/or completion from a prolonged shut-in).

Figure 5.13.28 (Song [29]) presents a schematic diagram of the expected flow regimes for a multi-fractured horizontal well; where in comparison to Figure 5.13.26 (Al-Kobaisi [27]), Song [29] presents a more traditional “dual porosity” or “naturally-fractured” reservoir concept for the fracture distribution in the reservoir. Most practitioners consider the Al-Kobaisi [27] flow regime concepts shown in Figure 5.13.26 to be more “realistic”—and as with most conceptual models in reservoir engineering, the least complicated concept should typically prevail, at least from an interpretative standpoint.

In Figure 5.13.28, Song [29] also presents an example synthetic case for a multi-fracture horizontal well shown on a “log-log” plot of the rate-normalized pressure drop function and its companion derivative function plotted versus “material balance time” (cumulative production divided by instantaneous flow rate). This plot is the preeminent diagnostic plot for the analysis and interpretation of production data. From this plot, the early-time linear flow behavior is evident (half-slope)—note that this regime occurs when all of the fractures are producing “independently” and the pressure distributions created by these fractures do not interfere with one another. The next major flow regime is the “transition to compound linear flow” or “SRV” flow regime which has an essentially unit slope, imply that the SRV is being “depleted. These two regimes are regularly observed in practice. However; due to the extremely low permeability of the matrix it is possible (more like probable) that the secondary “compound linear flow regime,” much less “radial or pseudo-radial flow” or the terminal depletion trend known as “pseudosteady-state” flow regimes will ever be observed in practice. This is not to say that the flow regimes in the previous sentence do not exist (they can be modeled as shown in Figure 5.13.28), but in practice such flow regimes will take decades, if not centuries to evolve (again due to the ultra-low permeability of a given shale formation).

Figure 5.13.29 (Ik [30]) presents an inventory of common challenges/pitfalls in production data analysis, specific to unconventional reservoirs. This information has significant value as it provides a practical assessment of the severity of the different challenges/pitfalls to be experienced in production data analysis (and other reservoir/production engineering practices). Suffice it to say that the most critical data are the flow rate and pressure data themselves, but many reservoir variables have a significant impact

Schematic of Flow Regimes for a Multi-Fracture Horizontal Well.

"Log-Log Plot" of Production Performance for a Multi-Fracture Horizontal Well.

FIGURE 5.13.28 Flow regimes and production performance behavior a multi-fracture horizontal well [29].

on the analysis/interpretation of production data—e.g., the reservoir thickness is critical parameter for unconventional (shale) reservoirs, as well as the porosity and the phase behavior (oil and gas fluid properties). Well completion factors also rank high, particularly those factors directly related to the stimulation treatment. Lastly, and perhaps not so obvious, production practices can greatly affect the analysis and interpretation of production data—especially operational changes and unreported events. Time-rate (or decline curve) analyses are particularly susceptible to operational changes as the time-rate methods do not incorporate pressure, which would tend to mitigate the influence of operational changes.

To close this section a predictive discussion and a few words of caution are warranted. In terms of reservoir models, most of the full analytical and numerical solutions

for multi-fracture horizontal wells which currently exist are robust and accurate, and should be more than sufficient for reservoir engineering analysis. However, there remains a serious challenge in that such solutions often produce non-unique analysis results; primarily due to the interrelation of permeability, fracture half-length, fracture conductivity, and fracture-face skin effects. There have been numerous effects to develop relations which can extract individual reservoir properties, but these are not likely to be unique either. Perhaps the best approach is to seek guidance from more data types and to consider pressure transient analysis as a means of identifying specific characteristic behavior. Pressure transient data analysis are not likely to provide any more uniqueness than production data analyses, but pressure transient data do typically have higher fidelity and can perhaps give better resolution to the results.

Production Engineering

6.1 PROPERTIES OF HYDROCARBON MIXTURES

Section reviewed by Bill Lyons

This section contains correlation and procedures for the prediction of physical properties of natural gas and oil. Physical constants of single components are given in [Table 6.1.1](#).

6.1.1 Compressibility Factor and Phase Behavior

The compressibility factor Z is a dimensionless factor, independent of the quantity of gas and determined by the character of the gas, the temperature, and the pressure.

$$Z = \frac{PV}{nRT} = \frac{MPV}{mRT} \quad (6.1.1)$$

	Field Units	SI Units
P = absolute pressure	psia	kPa
V = volume	ft ³	m ³
n = moles	m/M	m/M
m = mass	lb	kg
M = molecular mass	lb/lb mole	kg/kmole
T = absolute temperature	°R	K
R = universal gas constant	10.73 [psia·ft ³ / °R·lb mole mole]	8.3145 [kPa m ³ /kmol·K]
ρ = density	slug/ft ³	kg/m ³

A knowledge of the compressibility factor means that the density ρ is also known from the relationship

$$\rho = \frac{PM}{ZRT} \quad (6.1.2)$$

6.1.1.1 Compressibility Factor Using the Principle of Corresponding States (CSP)

The following terms are used, P_r , T_r , and V_r , such that

$$P_r = \frac{P}{P_c}, \quad T_r = \frac{T}{T_c}, \quad V_r = \frac{V}{V_c} \quad (6.1.3)$$

where P_r , T_r , and V_r = reduced parameters of pressure, temperature, and volume

P_c , T_c , and V_c = critical parameters of P , T , and V from [Table 6.1.1](#)

Compressibility factors of many components are available as a function of pressure in most handbooks [1–3]. In application of CSP to a mixture of gases, pseudocritical temperature (T_{pc}) and pressure (P_{pc}) are defined for use in place of the true T_c and P_c to determine the compressibility factor for a mixture.

$$P_{pc} = \sum y_i P_{ci}, \quad T_{pc} = \sum y_i T_{ci} \quad (6.1.4)$$

$$P_{pr} = P/P_{pc}, \quad T_{pr} = T/T_{pc} \quad (6.1.5)$$

where subscript i = component in the gas mixture
 y_i = mole fraction of component “ i ” in the gas mixture

For given values of P_{pr} and T_{pr} , compressibility factor Z can be determined from [Figure 6.1.1](#) [1]. If a gas mixture

NOTES

- a:* Air saturated liquid.
b: Absolute values from weights in vacuum.
c: The apparent values from weight in air are shown for users' convenience and compliance with ASTM-IP Petroleum Measurement Tables. In the United States and Great Britain, all commercial weights are required by law to be weights in air. All other mass data are on an absolute mass (weight in vacuum) basis.
d: At saturation pressure (triple point).
e: Sublimation point.
f: The + sign and number following signify the ASTM octane number corresponding to that of 2,2,4-trimethylpentane with the indicated number of cm³ of TEL added per gal.
g: Determined at 100°C.
h: Saturation pressure and 15°C.
i: Apparent value at 15°C.
j: Average value from octane numbers of more than one sample.
k: Relative density (specific gravity), 48.3°C/15°C (sublimation point; solid C₂H₄/liquid H₂O).

- m:* Densities of liquid at the boiling point.
n: Heat of sublimation.
p: See Note 10.
s: Extrapolated to room temperature from higher temperature.
t: Gross calorific values shown for ideal gas volumes are not direct conversions of each other using only the gas volume per liquid volume value shown herein. The values differ by the heat of vaporization to ideal gas at 288.15 K.
v: Fixed points on the 1968 International Practical Temperature Scale (IPTS-68).
w: Value for normal hydrogen (25% para, 75% ortho). The value for equilibrium mixture of para and ortho is -0.218; however, in most correlations, 0 is used.
x: Densities at the boiling point in kg/m³ for: Ethane, 546.4; propane, 581.0; propene, 608.8; hydrogen sulfide, 960.0; sulfur dioxide, 1462.0; ammonia, 681.6; hydrogen chloride, 1192.
†: Calculated values.
 () Estimated values.
 ‡ Values are estimated using 2nd virial coefficients.

contains significant concentrations of carbon dioxide and hydrogen sulfide, then corrected pseudocritical constants (T'_{pc} , P'_{pc}) are defined as follows:

$$T'_{pc} = T_{pc} - e \tag{6.1.6}$$

$$P'_{pc} = \frac{P_{pc} T'_{pc}}{T_{pc} + y_{H_2S}(1 - y_{H_2S})e} \tag{6.1.7}$$

where

$$e = 120 \left[(y_{CO_2} + y_{H_2S})^{0.9} - (y_{CO_2} + y_{H_2S})^{1.6} \right] + 15 \left(y_{H_2S}^{0.5} - y_{H_2S}^{4.0} \right) \tag{6.1.8}$$

where y_{CO_2} , y_{H_2S} = mole fraction of CO_2 and H_2S in mixture.

6.1.1.2 Direct Calculation of Z Factors

The Hall-Yarborough equation is one of the best:

$$Z = \frac{0.06125 P_{pr} t \exp[-1.2(1-t)^2]}{y} \tag{6.1.9}$$

where P_{pr} = the pseudoreduced pressure
 t = the reciprocal, pseudoreduced temperature T_{pc}/T
 y = the reduced density which can be obtained as the solution of the equation

$$\begin{aligned}
& -0.06125_{\text{pr}}t \exp[-1.2(1-t)^2] + \frac{y+y^2+y^3-y^4}{(1-y)^3} \\
& - (14.76t - 9.76t^2 + 4.58t^3)y^2 \\
& + (90.7t - 242.2t^2 + 42.4t^3)y^{(2.18+2.82t)} = 0 \quad (6.1.10)
\end{aligned}$$

This nonlinear equation can be conveniently solved for y using the simple Newton-Raphson iterative technique.

Good results give cubic equation of state and its modifications. Most significant of the modifications are those of Soave and Peng and Robinson.

The Soave equation (SRK) is [4]:

$$P = \frac{RT}{V-b} - \frac{a}{V(V+b)} \quad (6.1.11)$$

$$Z^3 = Z^2 + (A - B - B^2)Z - AB = 0 \quad (6.1.12)$$

where $b = \sum x_i b_i$ for a mixture

$b_i = 0.08664RT_{ci}/P_{ci}$ for a single component

$a = \sum_i \sum_j x_i x_j (a_i a_j)^{0.5} (1 - k_{ij})$ for a mixture

$a_i = a_{ci} \alpha_i$ for a single component

$a_{ci} = 0.42748(RT_{ci})^2/P_{ci}$

$\alpha_i^{0.5} = 1 + m_i(1 - T_{ri}^{0.5})$

$m_i = 0.48 + 1.574\omega_i - 0.176\omega_i^2$

$A = aP/(RT)^2$, $B = bP/RT$

The Peng-Robinson equation (PR) is

$$P = \frac{RT}{V-b} - \frac{a}{V(V+b) + b(V-b)} \quad (6.1.13)$$

$$\begin{aligned}
Z^3 - (1-B)Z^2 + (A-2B-3B^2)Z \\
- (AB - B^2 - B^3) = 0 \quad (6.1.14)
\end{aligned}$$

where $b = \sum x_i b_i$

$b_i = 0.077796RT_{ci}/P_{ci}$

$a = \sum_i \sum_j x_i x_j (a_i a_j)^{0.5} (1 - k_{ij})$

$a_i = a_{ci} \alpha_i$

$a_{ci} = 0.457237(RT_{ci})^2/P_{ci}$

$\alpha_i^{0.5} = 1 + m_i(1 - T_{ri}^{0.5})$

$m_i = 0.37646 + 1.54226\omega_i - 0.26992\omega_i^2$

A, B as in SRK equation

where $P =$ pressure (absolute units)

$T =$ temperature ($^{\circ}\text{R}$ or K)

$R =$ universal gas constant

$Z =$ compressibility factor

$\omega =$ acentric Pitzer factor (see Table 6.1.1)

$T_{ci}, P_{ci} =$ critical parameters (see Table 6.1.1)

$k_{ij} =$ interaction coefficient ($= 0$ for gas phase mixture)

Both SRK and PR equations are used to predict equilibrium constant K value. See derivation of vapor-liquid equilibrium by equation of state at end of this subsection.

Full description of gas, oil, and water properties are given in Chapter 5, "Reservoir Engineering." Reservoir hydrocarbon fluids are a mixture of hydrocarbons with compositions related to source, history, and present reservoir conditions. Consider the pressure-specific volume relationship for a single-component fluid at constant temperature, below its critical temperature initially hold in the liquid phase at an elevated pressure. This situation is illustrated in Figure 6.1.2[1]. Bubble point and dew point curves in Figure 6.1.2a correspond to the vapor pressure line in Figure 6.1.2b. A locus of bubble points and a locus of dew points that meet at a point C (the critical point) indicate that the properties of liquid and vapor become indistinguishable [6].

Multicomponent systems have different phase behavior than pure component. In the P - T diagram instead of the vapor-pressure line, we have an area limited by saturation line (bubble point+dew point), see Figure 6.1.3[1]. The diagram's shape is more or less the same for two- or three-component systems as for multicomponent systems.

For isothermal production in the reservoir, position A indicates reservoir fluid found as an underposition saturated oil, B indicates reservoir fluid found as a gas condensate, and position C indicates reservoir fluid found as a dry gas. Expansion in the liquid phase to the bubble point at constant temperature is similar to a pure component system. Expansion through the two-phase region does not occur at constant pressure, but is accompanied by a decrease in pressure as the composition of liquid and vapor changes [5,6].

6.1.1.3 Classification of Hydrocarbon Fluids

Hydrocarbon fluids usually are classified as to the phase behavior exhibited by the mixture. Figure 6.1.4 shows the pressure-temperature phase diagram of the four general classifications of fluids: dry gas, gas condensate, volatile oil, and black oil. As it can be seen, the source temperature also plays a role in the determination of fluid type. According to MacDonald [7], each type of fluid has composition as given in Table 6.1.2. Sometimes hydrocarbon mixtures are classified as follows: dry gas, wet gas, gas condensate, and black oil (Figure 6.1.4).

In the case of dry gas, a light hydrocarbon mixture existing entirely in gas phase at reservoir conditions and a decline in reservoir pressure will not result in the formation of any reservoir liquid phase; it is a rather theoretical case. Usually gas reservoirs fall into the next group, wet gas.

Gas condensate or retrograde gas system is the case when the critical temperature of system is such that reservoir temperature is between critical and cricondenthem as shown in Figure 6.1.4c. If the pressure is reduced to the

FIGURE 6.1.2 Phase diagram for a single component.

critical pressure, the liquid phase is increasing, but the liquid phase may reevaporate later on. This phenomena—the condensation of liquid upon decrease in pressure—is termed isothermal retrograde condensation. The liquid phase recovered from a condensate system is recovered from a phase that is vapor at reservoir conditions. This is also partly true of volatile oil systems where the vapor phase in equilibrium with the reservoir liquid phase is particularly rich in liquefiable constituents (C_3 to C_{8+}), and a substantial proportion of stock tank liquid may derive from a reservoir vapor phase. We normally do not expect to see retrograde behavior at reservoir pressures below about 2500 psi (17.2 MPa).

Volatile oil systems are those within the two-phase region under reservoir conditions, the vapor stage corresponding to condensate compositions and conditions. Volatile oil is not an apt description because virtually all reservoir fluids are volatile. What is really meant is that the

reservoir fluid exhibits the properties of an oil existing in the reservoir at a high temperature near its critical temperature. These properties include a high shrinkage immediately below the bubble point. In extreme cases, this shrinkage can be as much as 45% of the hydrocarbon pore space within 10 psi (0.7 bar) below the bubble point. Near-critical oils have formation factor B_o of 2 or higher; the compositions are usually characterized by 12.5 to 20 mole % heptanes or more.

Ordinary oils are characterized by GOR from 0 to approximately 200 ft³/bbl (360 m³/m³) and with B_o less than 2. Oils with high viscosity (about 10 cp), high oil density, and negligible gas/oil ratio are called heavy oils. At surface conditions may form tar sands. Oils with smaller than 10 cp viscosity are known as a black oil or a dissolved gas oil system; no anomalies are in phase behavior. There is no sharp dividing line between each group of reservoir hydrocarbon fluid; however, liquid volume percent versus

FIGURE 6.1.3 Pressure–temperature diagram for reservoir fluids.

pressure diagram [Figure 6.1.5a–ea–e](#) is very useful to understand the subject.

The significant point to be made is that when an oil system exists in intimate contact with an associated gas cap, the bubble point pressure of the oil will be equal to the dew point pressure of the gas cap, and both those values will be equal to the static reservoir pressure at the gas–oil contact, [Figure 6.1.6](#).

6.1.1.4 Reservoir Conditions Phase Behavior

There is one phase flow in reservoir conditions if well flowing pressure P_{wf} is higher than bubble point pressure P_b or dew point pressure P_d and two-phase flow occurs by a wellbore. Reservoir depletion and production consist of two separate processes: flash liberation (vaporization) and differential liberation. A schematic representation of flash vaporization is shown in [Figure 6.1.7](#). At stage 1 reservoir fluid is under reservoir pressure and temperature at known volumes V_t . The pressure in the cell is covered by increasing the space available in the cell for the fluid V_{t2} . This procedure is repeated until a large change in the pressure–volume slope is indicated. The above procedure indicates that flash vaporization is a phase-changing process due to change in pressure and temperature if the mass of reservoir fluid or total composition system remains constant and can be expressed as follows:

$$zF = xL + yV \quad (6.1.15)$$

where

z = mole fraction of component in a reservoir fluid mixture

F = number of moles of sample at initial reservoir pressure and temperature

x = mole fraction of component in liquid (e.g., P_5)

L = number of moles of equilibrium liquid

y = mole fraction component in gas mixture

V = number of moles of equilibrium gas phase

Equilibrium or flash liberation calculations may be made for reservoir fluid that divides into two phases at any temperature and pressure.

Schematic representation of differential liberation in laboratory conditions is shown in [Figure 6.1.8](#). It begins in the same manner as flash vaporization. The sample is placed in a pressure higher than bubble point pressure. The pressure is lowered until such time that free gas is liberated in the cell. Then for predetermined pressure or volume increments, mercury is withdrawn from the cell, gas is released from solution, and the cell is agitated until the liberated gas is in the equilibrium with the oil. All free gas is ejected from the cell at a constant pressure by injection of mercury. The volume of free gas is displaced, and the oil remaining in the cells are thus measured at cell conditions. This procedure is repeated for all the pressure increments until only oil remains in the cell at reservoir temperature and atmospheric pressure.

In contrast to flash vaporization, differential vaporization is undertaken with the decreasing mass participating in the process. [Equation 6.1.15](#) cannot be applied because

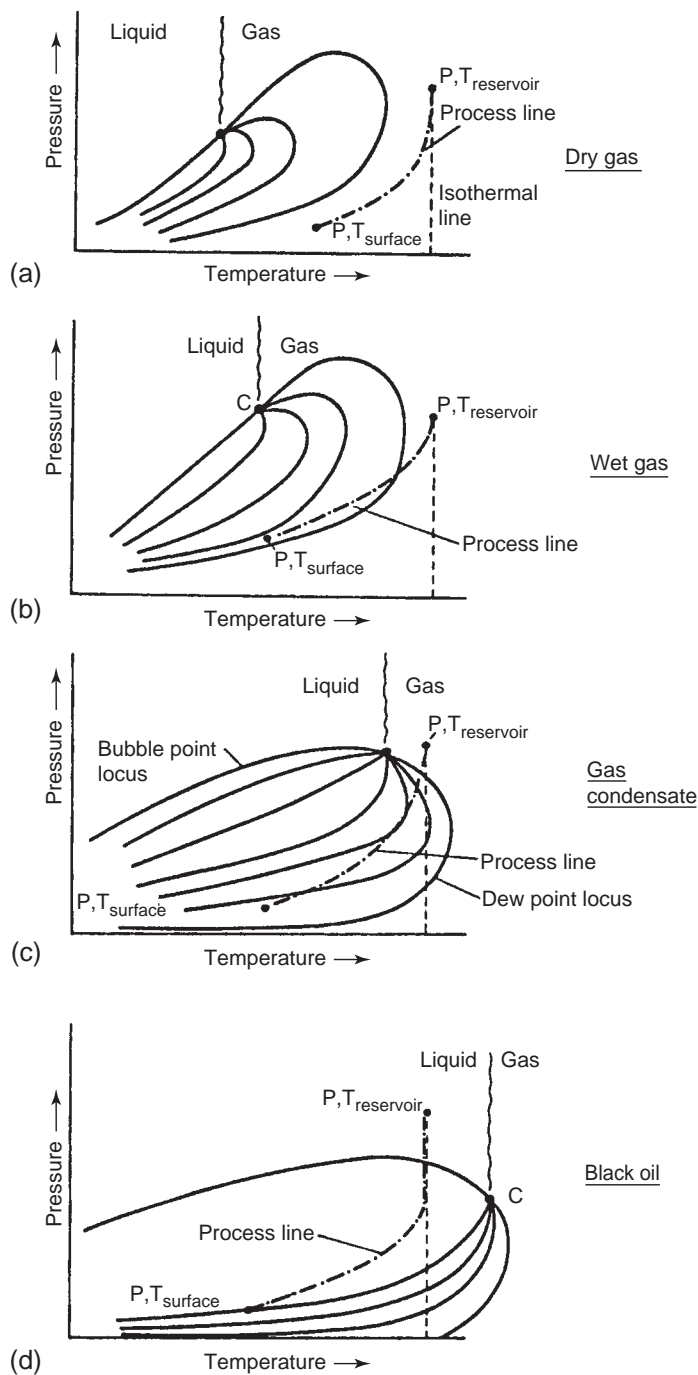

FIGURE 6.1.4 Hydrocarbon mixture classification.

F is not constant anymore at the given set pressure and temperature.

The question arises: Which process occurs in reservoir conditions? Some specialists, e.g., Moses [8], assume that the reservoir process is a combination of differential and flash. Such statements are incorrect. They produce misunderstanding and confusion. The following is meant to clarify and straighten out this problem:

1. In reservoir conditions, differential process always occurs.
2. In production tubing and surface pipeline flow and in the separators, the flash process takes place (subject to some limiting assumption).

Flash process refers to the conditions in which the mass of the considered system does not vary with changes

TABLE 6.1.2 Typical Compositions of Hydrocarbons Fluids [7]

	Dry Gas	Wet Gas	Retrograde Condensate	Volatile Oil or Near Critical Oils	Black Oil	Heavy Oil
C ₁ (mole %)	90		70	5	30

API Liquid Gravity	—		40–60	45–70	30–45	<20
Liquid Specific Gravity	—		0.83–0.74	0.8–0.7	0.88–0.8	>0.94

in pressure and temperature. Flash process in two-phase regions (vaporization or condensation) can be defined in terms of total system composition. The total system composition (z_i) can be measured at any point outside of saturation line, e.g., points A, B, and C (Figure 6.1.3). As a substitution the following treatment can be used; the total system composition in two-phase region flash process remains constant. The flash process may ensue for a composition z_i that separates into two phases for the values of pressures and temperatures inside the saturation curve area. After the temperature and pressure are chosen, all the gas is in equilibrium with all the oil. In other words, a change of pressure or temperature, or both, in a flash process can change the equilibrium conditions according to the Gibbs phase rule. This rule provides the number of independent variables that, in turn, define intensive properties. Flash vaporization may be a batch or continuous process. Treating two-phase flow in tubing as a steady state, neglecting the gas storage effect, and gas slippage result in flash process. In a horizontal flow, and in separators, a similar flash process comes about.

The same kind of equilibrium, but with its fluid mass decreasing differentially, is called a *differential process* (liberation or condensation).

In reservoir conditions the hydrocarbon pore volume (HCPV) remains constant if the expansion of interstitial water and rock compressibility are neglected. For such constant HCPV, it must be made clear that differential process occurs always as differential vaporization of differential condensation. Differential vaporization takes place when the reservoir temperature is less than critical temperature of solution ($T_{res} < T_c$), and also it takes place during retrograde gas reservoir depletion, but only in the region pressure and temperature at which the retrograde liquid is vaporized.

In differential condensation, the oil reservoir pressure is maintained constant or almost constant—for exam-

ple, by gas injection. Differential condensation can also occur just below the dew point in a gas-condensate reservoir.

Above the bubble point and the dew point curves, the virtual (apparent) value of vaporization and/or condensation is zero, but because the mass of fluid in a depleted reservoir is changing as a result of decreasing pressure, the process could be assumed to be differential. One important statement has to be added: there is no qualitative difference between the reservoir fluid in either differential or flash process, if pressure and temperature fall into the area outside of the saturation curves (Figure 6.1.3). A schematic representation of differential vaporization of oil in reservoir conditions is shown in Figure 6.1.9. As indicated in Figure 6.1.9, six hypothetical cases are distinguished. Study Figure 6.1.9 simultaneously with Figure 6.1.3 and Figure 6.1.10.

Consider a first sample, in which there is a fixed mass of oil at given temperature, pressure, and HCPV. When the pressure P_1 drops to P_2 , the volume of oil increases but the HCPV does not change, so the difference in oil-removed volume equals the total oil production when the pressure changes from P_A to P_2 (sample 2).

The third sample is considered at the bubble point; the oil volume change between P_2 and P_b resembles that between P_1 and P_2 . Beginning at P_b , the first gas bubbles are released. Pressure P_4 corresponds to the lowest value of GOR (Figure 6.1.10) and coincides with the highest pressure in a two-phase region, in which only one phase (oil) still flows. Pressure P_4 could be called a *gas flow saturation pressure*. Between P_b and P_4 , compositions x_i , y_i , and z_i are changed. HC mass in pore volume is decreasing, so it is the differential process that is contrary to Moses' [8] belief that this is a flash process.

At point 5, HCPV remains constant as in steps 1 to 4, the oil volume has changed and the system is into a

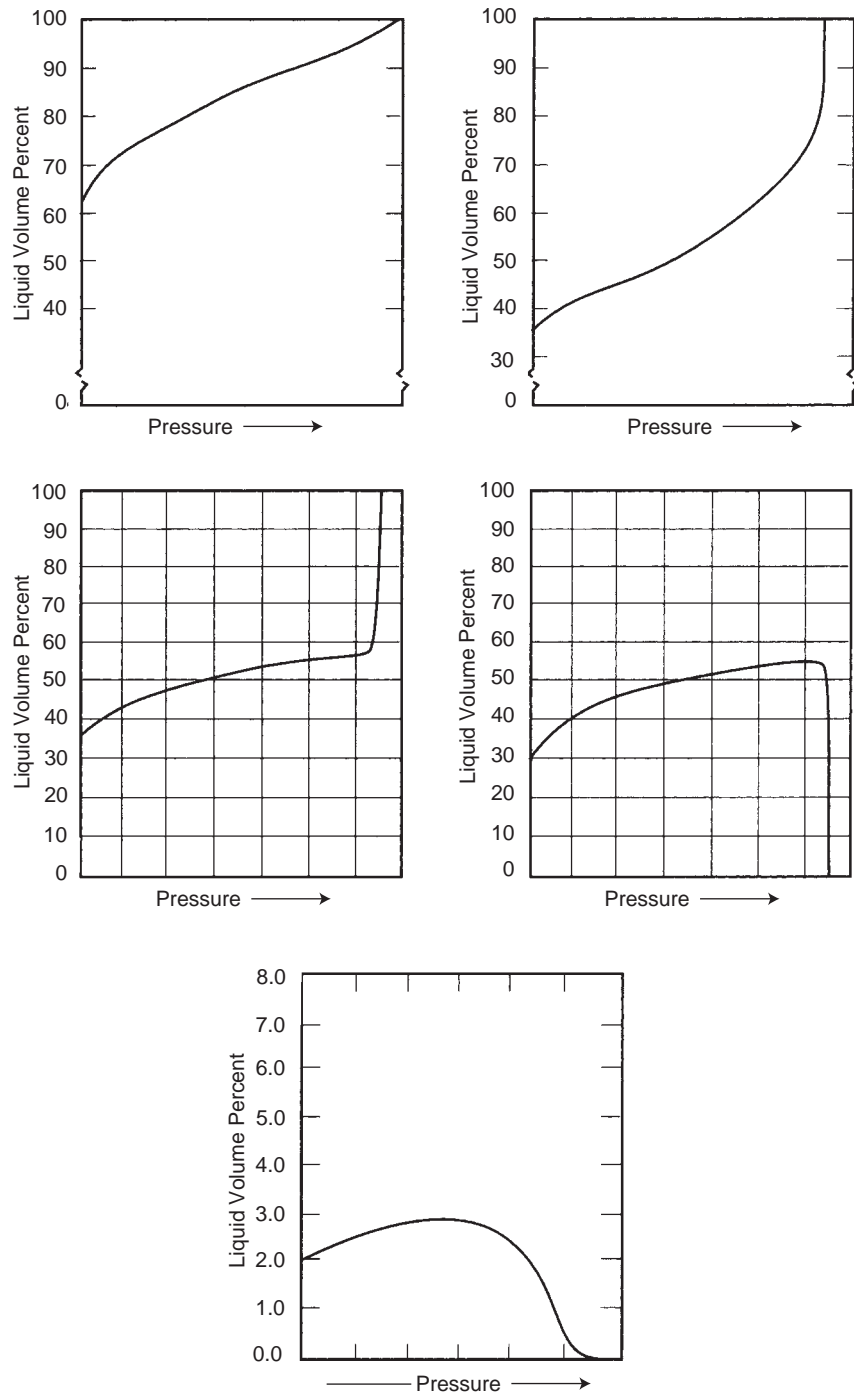

FIGURE 6.1.5a–e Liquid volume percent — pressure diagram for reservoir fluid [6].

two-phase region. An amount of released gas exceeds the gas flow saturation pressure P_4 ; gas begins to run and is partially removed from the HCPV. This is how two-phase flow is generated. Sample 6 characterizes the same process very close to the bottom-hole area. The reservoir fluid mass difference in steps 1 and 6 equals the total production from an HCPV.

In conclusion, it has been shown that the flash process occurs whenever we are dealing with a closed system or a steady-state flow, e.g., a two-phase flow in vertical tubing, in horizontal pipe flow, and in separators. For any open system, such as a reservoir formation, or for an unsteady-state flow, the differential process is properly describing the quasiequilibrium conditions.

FIGURE 6.1.6 Pressure-temperature diagram for gas cap and associated oil [6].

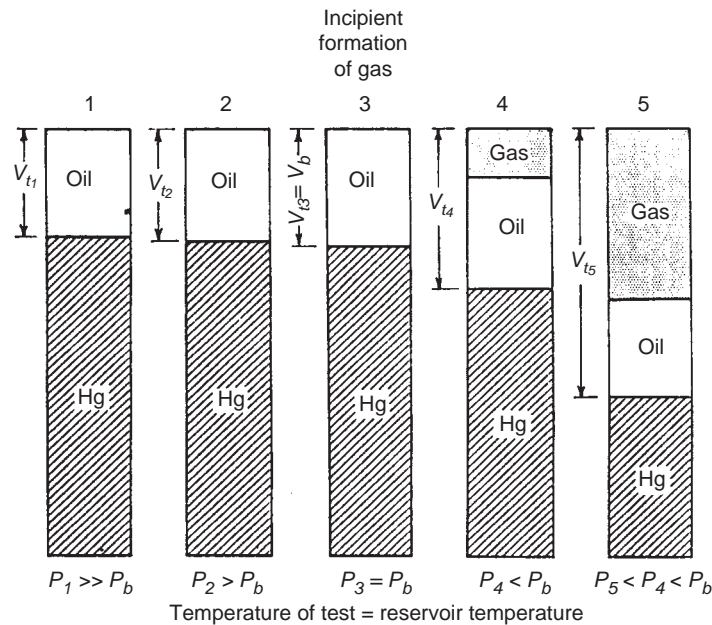

FIGURE 6.1.7 Schematic representation of laboratory P-V equilibrium (flash vaporization) [10].

6.1.2 Sampling Process and Laboratory Measurements

The overall quality of the reservoir fluid study and the subsequent engineering calculations based upon that study can be no better than the quality of the fluid samples originally collected during the field sampling process.

Samples representative of the original reservoir can be obtained only when the reservoir pressure is equal to or higher than the original bubble point or dew point.

The pressure drawdown associated with normal production rates will cause two-phase flow near the wellbore if the fluid in the formation was initially saturated or only slightly undersaturated. Relative permeability effects may

FIGURE 6.1.8 Schematic representation of laboratory differential vaporization [10].

FIGURE 6.1.9 Schematic representation of differential vaporization in reservoir conditions.

then cause the material entering the wellbore to be different from the original overall (total) composition fluid existing at the boundary of drainage area. The problem of drawdown in a saturated reservoir cannot be eliminated; therefore, it is

necessary to limit the pressure drawdown by reducing the flowrate to the lowest possible stable rate while sampling.

There are two basic methods of sample collection: subsurface (bottomhole) and surface (separator). The fluid

Reservoir parameters	Sample #

FIGURE 6.1.10 Schematic representation reservoir pressure (P) and GOR vs. time and mass and composition in reservoir differential vaporization process.

sampling method to be used dictates the remainder of the conditioning process. If the bottomhole samples are to be collected, the period of reduced flowrate will generally last from 1 to 4 days, depending on the formation and fluid characteristics and the drainage area affected. After this reduced flowrate period, the well would be shut in and allowed to reach static pressure. The shut-in period would last about 1 day or up to a week or more, depending on formation characteristics. For the case of the saturated reservoir, the shut-in period has the resultant effect of forcing gas into solution in the oil, thus raising the saturation pressure. In some cases, the desired value of P_b is obtained; however, in most cases this value is only approached and the final difference is a function of well productivity, production rate, and fluid properties. At the conclusion of the shut-in period, the well would be properly conditioned and ready for bottomhole sampling. Subsurface sampling is generally not recommended for gas-condensate reservoirs; the same is true for oil reservoirs producing substantial quantities of water. If separator gas and liquid samples are to be collected, the gas and liquid rates must be monitored continually during the period of stable flow at reduced flowrates. A minimum test of 24 hours is recommended, but more time may

be needed if the pressure drawdown at the formation has been high. Surface sampling, called *separator sampling*, has wider applications than subsurface sampling, and is the only recommended way of sampling a gas-condensate reservoir, but often can be used with good success for oil reservoirs as well. There are three requirements to successful separator sampling.

1. stable production at a low flowrate
2. accurate measurement of gas and oil flowrates
3. collection of representative samples of first-stage gas and first-stage liquid

The above procedure is described in detail in API Standard RP44 [9].

The reservoir process is simulated in the laboratory by flash differential vaporization (Figure 6.1.7 and Figure 6.1.8). Based on both figures, it is possible to prepare the reservoir fluid data for engineering calculations.

In the laboratory, the differential liberation consists of a series — usually 10 to 15 — of flash liberations. An infinite series of flash liberations is the equivalent of a true differential liberation. At each pressure level, gas is evolved and measured. The volume of oil remaining is also measured

at each depletion pressure. This process is continued to atmospheric pressure. The oil remaining at atmospheric pressure is measured and converted to a volume at 60°F (15.6°C). This final volume is referred to as the residual oil. The volume of oil at each of the higher pressures is divided by the volume of residual oil at 60°F (15.6°C).

Example 6.1.1

Surface separator samples were collected from a well on completion of a 2-hr test on June 8, 1984. The gas/liquid ratio measured on this test was 4565 ft.³ of separator gas per barrel of separator liquid and was used as the basis for this recombination. The resultant reservoir fluid exhibited a dew point of 4420 psia at $T_{res} = 285^\circ\text{F}$. The reservoir fluid exists as a gas (an undersaturated gas) at $P_{res} = 12,920$ psia.

A constant volume depletion study is also performed on the reservoir fluid. The produced compositions and volumes from the depletion study are used in conjunction with equilibrium constants to calculate cumulative STO and separator gas recoveries resulting from conventional field separation. Gas plant products in both the primary separator gas and the full well stresses should also be reported.

Sampling Conditions	
Date sampled (on 20/64 choke)	06-08-84 for 1330 hr
Tubing pressure, flowing	9960 psig
Primary separator temperature	95°F

of the well stream based on the GOR in the primary separator. The separator liquid (oil) production was calculated from the measured second-stage production by applying the determined shrinkage factor.

6.1.2.1 Equilibrium Cell Determinations

Following the compositional analyses, portions of the primary separator liquid and gas were physically recombined in their produced ratio in a variable volume, glass-windowed equilibrium cell. Determinations on this mixture were divided into the following main categories.

1. Dew point pressure determination and pressure–volume relations on a constant weight of reservoir fluid at the reservoir temperature: the procedure consisted of establishing equilibrium between gas and liquid phases at a low pressure and measuring volumes of liquid and gas in equilibrium at that pressure. The pressure was raised by the injection of mercury into the cell and phase equilibrium established again at a higher pressure. This procedure was repeated until all of the liquid phase had vaporized, at which point the saturation pressure was observed. The cell pressure was then raised above the dew point pressure in order to determine the supercompressibility characteristics of the single-phase vapor. As a check on all readings and, particularly, to verify the dew point, the cell pressure was incrementally reduced, equilibrium established and volumetric readings made. Reported in Table 6.1.5 are the relative volume relations (Figure 6.1.11) and specific volumes

of the reservoir fluid over a wide range of pressures as well as compressibility factors (Figure 6.1.12), the single-phase vapor above the dew point. Reported in Table 6.1.6 are the dew point pressure (Figure 6.1.13) resulting from recombination's at gas/liquid ratios above and below the ratio measured at the time of sampling.

2. Compositions of the produced wellstream and the amount of retrograde condensation resulting from a stepwise differential depletion. This procedure consisted of a series of constant composition expansions and constant pressure displacements with each displacement being terminated at the original cell volume. The gas

removed during the constant pressure was analyzed. The determined compositions (Figure 6.1.14), computed GPM content (Figure 6.1.15), respective compressibility (deviation) factors, and volume of wellstream produced during depletion (Figure 6.1.16) are presented in Table 6.1.7. The volume of retrograde liquid resulting from the gas depletion is shown in Table 6.1.8 (and Figure 6.1.17), both in terms of barrels of reservoir liquid and percentage of hydrocarbon pore space. Show in Table 6.1.7 are the compositions of the gas and liquid remaining in the reservoir after depletion to abandonment pressure.

6.1.2.2 Equilibrium Flash Calculations

The produced compositions and volumes from a depletion study were used in conjunction with equilibrium constants K (derived from a Wilson modified R-K equation of state) to calculate cumulative stock tank liquid and separator gas recoveries resulting from conventional separation. These data are reported in [Table 6.1.9](#) and [Figure 6.1.18](#). Also, gas plant products in both the primary separator and the full wellstream are attached ([Table 6.1.10](#)).

Example 6.1.2

This is a black oil problem. From differential vaporization ([Table 6.1.11](#)) and separator test data ([Table 6.1.12](#)) discuss the B_o and R_s calculation method.

[Figure 6.1.19](#) and [Figure 6.1.20](#) illustrate laboratory data. These data are reported in a convention other than in Example 6.1.1. The residual oil in the reservoir is never at 60°F (15.6°C), but always at T_{res} . Reporting these data relative to the residual oil at 60°F (15.6°C), gives the relative-oil-volume curve the appearance of an FVF curve, leading to its misuse in reservoir calculations. A better

method of reporting these data is in the form of a shrinkage curve. We may convert the relative-oil-volume data in [Figure 6.1.19](#) and [Table 6.1.11](#) to a shrinkage curve by dividing each relative-oil-volume factor B_{od} by the relative oil volume factor at the bubble point, B_{odb} .

The shrinkage curve now has a value of one at the bubble point and a value of less than one at the subsequent pressures below the bubble point, as in [Figure 6.1.21](#). As pressure is reduced and gas is liberated, the oil shrinks. The shrinkage curve describes the volume of this original barrel of oil in the reservoir as pressure declines. It does not relate to a stock tank or surface barrel.

We now know the behavior of the oil in the reservoir as the pressure declines. We must have a way of bringing this oil to the surface through separators and into a stock tank. This process is a flash process. Most reservoir fluid studies include one or more separator tests to simulate this flash process. [Table 6.1.12](#) is a typical example of a set of separator tests. During this test, the FVF is measured. The FVF is the volume of oil and dissolved gas entering the wellbore at reservoir pressure and temperature divided by the resulting stock-tank oil volume after it passes through a separator.

FIGURE 6.1.11 Pressure–volume relation of reservoir fluid at 285°F (constant mass expansion) [11].

The FVF is B_o ; because separators result in a flash separation, we showed a subscript, B_{of} . In most fluid studies, these separator tests are measured only on the original oil at the bubble point. The FVF at the bubble point is B_{ofb} . To make solution-gas-drive or other material-balance calculations, we need values of B_{of} at lower reservoir pressures. From a technical standpoint, the ideal method for obtaining these data is to place a large sample of reservoir oil in a cell, heat it to reservoir temperature, and pressure-deplete it with a differential process to simulate reservoir depletion. At some pressure a few hundred psi below the bubble point, a portion of the oil is removed from the cell and pumped through a separator to obtain the flash FVF, B_{of} , at the lower reservoir pressure. This should be repeated at several progressively lower reservoir pressures until a complete curve of B_{of} versus reservoir pressure has been obtained. The process is time consuming and consequently adds to the cost of the study. Most studies include only values of B_{ofb} , the FVF at the bubble point. The values of B_{of} at lower pressures must be obtained by other means.

The method calls for multiplying the flash FVF at the bubble point B_{ofb} by the shrinkage factors at various reservoir pressures obtained earlier. The shrinkage factor was calculated by dividing the relative oil volume factors B_{od} by the relative oil volume factor at the bubble point B_{ofb} . If we combine both calculations, we can start with the differential-relative-volume curve and adjust it to separator or flash conditions by

$$B_o = B_{od} \frac{B_{ofb}}{B_{odb}} \quad (6.1.16)$$

This calculation is illustrated in Figure 6.1.22.

To perform material-balance calculations, we must also have the separator and stock-tank gas in solution as a function of reservoir pressure. These values are expressed as standard cubic feet per barrel and usually are designated R_{sf} . The separator test gives us this value at the bubble point, R_{sfb} . As pressure declines in the reservoir, gas is evolved from solution. The amount of gas remaining in solution in

FIGURE 6.1.12 Compressibility factor “Z” of wellstream during depletion at 285°F [11].

TABLE 6.1.6 Observed Saturation Pressures From Stepwise Recombination at 285 °F [11]

Gas-Liquid Ratio (SCF 1st Stg. Gas)	
(BBL. 1st Stg. Liq.)	Saturation Pressure (Psia)
9000	6000 Dew Point
4565 (Produced)	4420 Dew Point
2500	3830 Dew Point

the oil is then somewhat less. The differential vaporization tells us how much gas was evolved from the oil in the reservoir: $(R_{sdb} - R_{sd})$, where R_{sdb} is the amount of gas in solution at the bubble point as measured by differential vaporization at the reservoir temperature and R_{sd} is the gas in solution at subsequent pressures.

The units of R_{sdb} and R_{sd} are standard cubic feet per barrel of residual oil. Because we must have the gas in solution in terms of standard cubic feet per barrel of stock-tank oil,

this term must be converted to a stock-tank basis. If we divide $(R_{sdb} - R_{sd})$ by B_{odb} , we have the gas evolved in terms of standard cubic feet per barrel of bubble point oil. If we then multiply by B_{ofb} , we will have the gas evolved in terms of standard cubic feet per barrel of stock-tank oil. This expression now is $(R_{sdb} - R_{sd})(B_{ofb}/B_{odb})$. The gas remaining in solution then is $R_s = R_{sfb} - (R_{sdb} - R_{sd})(B_{ofb}/B_{odb})$ standard cubic feet per stock-tank barrel. For every pressure studied during the differential liberation, R_s may be calculated from this equation. This calculation is illustrated in Figure 6.1.23.

It is a fairly common practice to use differential vaporization data for material-balance calculations. Values of B_{od} and R_{sd} are almost always higher than the corresponding values from separator tests; consequently, calculations of OIP and recoverable oil will usually be lower than is correct. The differential vaporization data should be converted to separator flash conditions before use in calculations.

6.1.2.3 Vapor-Liquid Equilibrium Calculations

The basic equilibrium calculations are the bubble point, dew point, and flash (or two-phase equilibrium). In the general flash calculation, the temperature and pressure are usually

FIGURE 6.1.13 Effect of gas/liquid ratio upon saturation pressure at 285°F [11].

fixed and L/f is the dependent variable. All equilibrium calculations are based on the definition of the K value, such that

$$K_i = \frac{y_i}{x_i} = \frac{\text{concentration of "i" component in vapor phase}}{\text{concentration of "i" component in liquid phase}} \quad (6.1.16)$$

In bubble point calculations, x_i is known and either T or P is fixed. The vapor phase composition (y_i) and the P or T of the system are unknown.

$$y_i = K_i x_i \quad (6.1.17)$$

Several different values of the dependent variable are assumed. The correct value is the one that yields

$$\sum_{i=1}^n K_i x_i = \sum_{i=1}^n y_i = 1.0 \quad (6.1.18)$$

An additional requirement when using composition dependent K values is

$$|y_i^{m+1} - y_i^m| \leq \epsilon, \quad i = 1 \text{ to } n \quad (6.1.19)$$

where the value of ϵ is arbitrarily small (10^{-4} to 10^{-6}). This requirement is a consequence of using composition dependent K values. If the composition y_i is not correct, the predicted K values will not be correct. As a result, the composition of the vapor phase must be stabilized even though the correct value of the dependent variable has been determined. Iterations through the bubble point calculation must be continued until both Equation 6.1.18 and Equation 6.1.19 are satisfied. A logical diagram illustrating the basic bubble calculation is shown in Figure 6.1.24.

How can we assume initial vapor phase composition? One approach that has been successful is to assume that the mole fraction of the lowest boiling component in the

FIGURE 6.1.14 Hydrocarbon composite of wellstreams produced during pressure depletion [11].

systems is equal to unity with the remaining component mole fractions set to 10^{-6} . Another approach is to get the K value from GPSA [2]. The vapor composition is adjusted after each interaction.

Dew point calculations are the opposite of bubble point calculations: y_i is known and x_i and T or P are to be calculated. The specific equation used in the dew point calculation is

$$x_i = \frac{y_i}{K_i} \tag{6.1.20}$$

As in the bubble point calculation, several different values of the dependent variable are assumed:

$$\sum_{i=1}^n \frac{y_i}{K_i} = \sum_{i=1}^n x_i = 1.0 \tag{6.1.21}$$

subject to the condition that

$$|x_i^{m+1} - x_i^m| \leq \epsilon, \quad i = 1 \text{ to } n \tag{6.1.22}$$

A logical diagram for dew point calculation is shown in Figure 6.1.25. In this case x_i is initially unknown and must be assumed. A procedure is to assume that the mole fraction of the highest boiling component in the system is equal to unity. The remaining component mole fractions are set to 10^{-6} . Liquid phase compositions are adjusted by linear combinations of the assumed and calculated value during each iteration. The convergence of algorithms for T

and P dependent calculations are given in Figure 6.1.26 and Figure 6.1.27.

The purpose of flash calculations is to predict the composition and amount of the coexisting vapor and liquid phases at a fixed temperature and pressure.

According to Equations 6.1.15 and 6.1.16

$$\phi \left(\frac{L}{P} \right)^m = \sum_{i=1}^n \frac{z_i(1 - K_i)}{L/F(1 - K_i) + K_i} = 0.0 \tag{6.1.23a}$$

or

$$\phi \left(\frac{L}{P} \right)^m = 1.0 \tag{6.1.23b}$$

This equation is applicable to a wide range of L/F conditions.

In the basic flash calculation, T, P and the overall composition (z_i) are fixed. The unknown variables are x_i , y_i , and L/F. A convergence algorithm that can be used with Equation 6.1.25 is

$$\left(\frac{L}{F} \right)^{m+1} = \left(\frac{L}{F} \right)^m - \frac{\phi \left(\frac{L}{F} \right)^m}{\phi \left(\frac{L}{F} \right)^{m-1}} \tag{6.1.24a}$$

where

FIGURE 6.1.15 GPM content of hydrocarbons produced during depletion at 285°F [11].

$$\phi \left(\frac{L}{P} \right)^m = - \sum_{i=1}^n \frac{z_i (1 - K_i)^2}{L/F(1 - K_i) + K_i^2} \quad (6.1.24b)$$

This convergence algorithm is very reliable provided the values of $(L/F)^{m+1}$ are constrained to be valid by material balance considerations:

$$0 < (L/F)^{m+1} \leq 1.0 \quad (6.1.25)$$

The classical bubble point/dew point checks

$$\sum K_i z_i > 1.0 \quad \text{and} \quad \sum z_i / K_i > 1.0 \quad (6.1.26)$$

(to assure that the mixture is in two-phase region) cannot be conveniently used in most computer equation-of-state-based flash calculations because the K values for a given system are not known until the final solution

FIGURE 6.1.16 Volume of wellstream produced during depletion [11].

has been reached. Consequently, the flash calculation (and its convergence algorithm) must be capable of performing “flash calculation” on single-phase systems (subcooled liquids, superheated vapors, and dense gas systems) as well as reliably predicting the amount of vapor and liquid present in a two-phase system. When the above flash equation/convergence algorithm is used on single-phase systems, the final predicted value of L/F will usually be outside the interval described by Equation 6.1.25 unless the material balance constraint is enforced. Should a value of $(L/F)^{m+1}$ outside the limits defined by Equation 6.1.25 be detected in an interaction, we recommend that the value of L/F predicted by Equation 6.1.24a be replaced by the appropriate value described by the following equations:

$$\text{if } (L/F)_{m+1} < 0.0, \quad (L/F)^{m+1} = (L/F)^m / 2.0$$

or

$$\text{if } (L/F)^{m+1} > 1.0, \quad (L/F)^{m+1} = [1 + (L/F)^m] / 2.0$$

This procedure eliminates most of the problems associated with flash calculations in single-phase regions and yields excellent results in relatively few iterations inside

the two-phase region. Some problems still occur when attempting flash calculations in the dense gas region.

Initial estimates of the phase composition must be made to initiate the flash calculation. Several procedures are available. It was found that a combination of the bubble point/dew point initial phase estimation procedures works quite well [12]. Set the vapor phase mole fraction of the highest component in the system at 1.0 and the liquid phase mole fraction of the heaviest component in the system at 1.0. All other mole fractions are set to 10^{-6} . This procedure is believed to be superior to the technique of basing the initial assumption of the phase composition on some noncomposition-dependent K value estimation procedure, particularly when a wide range of temperatures, pressures, component types, composition ranges, etc., is to be considered.

The estimated vapor and liquid phase compositions must be compared with the calculated phase compositions. Equations 6.1.19 and 6.1.23 describe this checking procedure. If restraints described by these equations for any component (in either phase) are not satisfied, the calculations must be repeated even though an acceptable value for L/F has been determined. Some feel that this detailed checking

procedure is unnecessary. It probably is unnecessary for most problems involving moderate temperature–pressure–composition conditions. However, at extreme condition of temperature, pressure, and composition (low-temperatures, high pressure, high-acid-gas compositions) failure to perform these composition checks will lead to results that are completely incorrect (poor estimates of the phase compositions and incorrect L/F ratios). Unfortunately, the boundary changes in temperature, pressure, or composition can completely alter the difficulty of a given problem. Consequently, careful application of these checks in all calculations is strongly recommended since one can never be sure that a particular problem will not fall into the area of extreme conditions.

A logic diagram illustrating the basic flash calculation is shown in Figure 6.1.28. All the necessary features described earlier are embodied in this diagram.

Flash calculations at fixed L/F and temperature or pressure are frequently necessary. In these calculations, the dependent variable becomes pressure or temperature, and the flash calculation becomes similar in principle to a bubble point or dew point calculation. The flash calculation equation described earlier, Equation 6.1.23, can be coupled with the temperature or pressure adjusting algorithms described forth bubble point/dew point calculations to perform these calculations. Initial estimates of the vapor- or liquid-phase compositions must be made, and the approach described in the flash at fixed temperature–pressure conditions can be used quite effectively. The logic diagram for this type of calculation can be deduced from earlier diagrams.

6.1.2.4 Predicting the Properties of Hexane Plus (C₆₊) Fractions

Physical properties of light hydrocarbons are given in Table 6.1.1. In naturally occurring gas and oil, C₆₊ is unknown and makes a problem. Since the C₆₊ is a combination of paraffins (P), naphthenes (N), and aromatics (A) of varying

molecular mass (M), these fractions must be defined or characterized in some way. Changing the characterization of C₆₊ fractions present in even small amounts (at 1.0% mole level) can have significant effect on the predicted phase behavior of a hydrocarbon system. The dew point of the gas is heavily dependent upon the heaviest components in the mixture.

The SRK (Equation 6.1.11) and the PR (Equation 6.1.13) require the smallest number of parameters of any of the equations of state. They require the critical temperature, the critical pressure, and the acentric factor. There are many different approaches that can be utilized to predict these parameters for C₆₊ fractions or other mixtures of undefined components.

Some minimum of information must be available on the C₆₊ fraction, usually it is specific gravity (S), average boiling point (T_b), and molecular mass (M) of the fraction.

The following equation is used to estimate the molecular mass (M) of petroleum fractions [12–14]

$$M = 2.0438 \times 10^2 \exp(0.00218T) \exp(-3.07S)T^{0.118}S^{1.88} \quad (6.1.27)$$

where T = mean average boiling point of a petroleum fraction, °R (from ASTM D86 test, Figure 6.1.29)

S = specific gravity, 60°F/60°F

The following equation is to be used to calculate the initial temperature (T_c) of pure hydrocarbons; it is applicable for all families of hydrocarbons:

$$\log T_c = A + B \log S + C \log T_b \quad (6.1.28)$$

T_c(°R); T_b and S given; A, B, and C as below:

Type Compound	A	B	C
Paraffin	1.47115	0.43684	0.56224
Napthene	0.70612	-0.07165	0.81196
Olefin	1.18325	0.27749	0.65563
Acetylene	0.79782	0.30381	0.79987
Diolefin	0.14890	-0.39618	0.99481
Aromatic	1.14144	0.22732	0.66929

For petroleum factions, physical properties can be predicted more accurately if the fraction of paraffins (P), naphthenes (N), and aromatics (A) are known. If θ is a physical property to be predicted and the molecular type fractions are known, a pseudocompound, i.e., a compound having the same boiling point and specific gravity as the fraction, for each molecular type can be defined. These properties can be combined by

$$\theta = P\theta_P + N\theta_N + A\theta_A \quad (6.1.29)$$

FIGURE 6.1.17 Retrograde condensation during depletion at 285°F [11].

where $P + N + A = 1.0$, are the sum of paraffins, naphthenes, and aromatics present in the fraction.

The basic equation for any value of property θ is [15, 16]

$$\theta = aT_b^b S^c \quad (6.1.30)$$

Correlation constants are given in Table 6.1.13.

Next, correlation of critical properties and acentric factor (ω) of hydrocarbons and derivatives is developed in terms of M , T_b , and S . Since molecular mass is readily determined by experiments, it is introduced as a correlating variable to obtain more general results. The specific gravity is the ratio of the density of the liquid at 20°C to that of water at 4°C.

The critical properties and acentric factor of C_1 to C_{20} n-alkanes are correlated with M by the following equation:

$$\theta_A = C_1 + C_2M + C_3M^2 + C_4M^3 + C_5/M \quad (6.1.31)$$

where θ_A represents T_c , L_nP_c , V_c , or ωT_c of a n-alkane. The coefficients C_1 to C_5 are reported in Table 6.1.14 for each property. It was additionally correlated S and T_b of the n-alkanes by Equation 6.1.31, and the coefficients are included in Table 6.1.14. The correlated S_A and T_{bA} of the n-alkanes will be required in the perturbation equations to follow as independent variables.

The average absolute deviations (AAD) of the correlations from the American Petroleum Institute project 44 table

values are 0.15% for T_c , 1.0% for P_c (excluding methane), 0.8% for V_c , 1.2% for ω , 0.11% for T_b , and 0.07% for S . The specific gravity correlation applies only to C_5 – C_{16} , which are the only n-alkanes that are liquids at 20°C.

Properties of the general hydrocarbons and derivatives are correlated as perturbations of those n-alkanes according to the equation

$$\begin{aligned} \theta = & \theta_A + A_1 \Delta S + A_2 \Delta T_b + A_3 (\Delta S)^2 + A_4 (\Delta S)(\Delta T_b) \\ & + A_5 (\Delta T_b)^2 + A_6 (\Delta S)^3 + A_7 (\Delta S)^2 (\Delta T_b) \\ & + A_8 (\Delta S)(\Delta T_b)^2 + A_9 (\Delta T_b)^3 \end{aligned} \quad (6.1.32a)$$

with

$$\Delta S = S - S_A \quad (6.1.32b)$$

$$\Delta T_b = T_b - T_{bA} \quad (6.1.32c)$$

where S_A and T_{bA} are the gravity and boiling point of the hypothetical n-alkane of the M of the substance of interest and are given by Equation 6.1.31.

The coefficients A_i in Equation 6.1.32 are given by

$$A_i = a_i + b_i M \quad (6.1.32d)$$

Table 6.1.15 presents the coefficients a_i and b_i that have been determined by fitting Equation 6.1.32d to the properties of a large number of hydrocarbons and derivatives.

State-of-the-art Equation 6.1.32 gives the best results.

The five general categories of experimental data availability for C_{6+} fractions are:

1. *The specific or API gravity of the C_{6+} fraction.* The molecular mass may have been determined experimentally or estimated from some correlation of specific gravity and molecular mass.
2. *Chromatographic analysis.* The C_{6+} fraction has been analyzed by gas-liquid chromatography. These results may be reported as a series of equivalent n-paraffins up to as high as nC_{30} or as a true boiling point analysis. The specific gravity and/or molecular mass of the fraction may or may not be reported.
3. *ASTM-D158 (or equivalent) analysis.* This analysis is equivalent to a nonrefluxed single-stage batch distillation. Usually the boiling point temperature at seven different points (START, 10%, 30%, 50%, 70%, 90%,

END) will be recorded. The points correspond to the volume fraction of the C₆₊ distilled into the receiver vessel. The specific gravity and molecular mass of the total C₆₊ fraction are normally also measured.

4. A *partial TBP analysis*. A true boiling point (TBP) distillation has been performed on the C₆₊ fraction. The TBP distillation is a batch distillation similar to an ASTM distillation but the distillation apparatus contains several trays (usually 10 or more or the equivalent amount of packing) and a high reflux ratio is used. The TBP gives a sharper separation between the subfractions than an ASTM distillation. Normally, at least five temperatures are reported as a function of liquid volume percent distilled over. Frequently, more than 20 temperatures will be reported. The specific gravity and molecular mass of the total fraction are usually reported.
5. A *complete TBP analysis*. A true boiling point distillation has been performed on the total C₆₊ fraction. The specific gravity and molecular mass have been measured for each of the reported distillate subfractions. Between

5 and 50 temperatures and subfraction properties will be reported.

Table 6.1.15 shows typical information as it may be reported for each of the five categories of C₆₊ characterization. The complete TBP analysis is believed to be the best form of C₆₊ analysis to be used with today's thermodynamic property prediction procedures. Consequently, it is recommended that all noncomplete TBP analyses be converted to this form. This section deals with these conversion techniques. These techniques are based on empirical correlations and, in some cases, experience and judgment. There is also one basic constraint that must be used in these conversion techniques—that is, maintenance of volume-mass-molar relationships in the C₆₊ fraction along with consistency in the composition of the total stream. One cannot capriciously change the molecular mass or specific gravity of the total C₆₊ fraction without simultaneously adjusting the reported composition. All of the procedures reported here strive to maintain consistency of the specific gravity, molecular mass and, when possible, the boiling point (s) of the total C₆₊ fraction.

TABLE 6.1.12 Separator Test [8]

Separator Pressure (psig)	(°F)	GOR, R_{sfb}^*	Stock-Tank Oil Gravity (°API at 60°F)	FVF, B_{ofb}^{**}

**FVF is barrels of saturated oil at 2620 PSIG and 220°F per barrel of stock-tank oil at 60°F.

FIGURE 6.1.19 Adjustment of oil relative volume curve to separator conditions [6].

FIGURE 6.1.20 Adjustment of gas in solution curve to separator conditions [6].

FIGURE 6.1.21 Oil-shrinkage curve [8].

The various procedures for converting noncomplete TBP analyses to complete TBP analyses are illustrated in the following section. A common sample problem is used to illustrate the basic conversion procedure. In addition, the results of several equilibrium calculations are reported for each type of characterization. The gas composition, true boiling point data, gravity, and molecular weight measurements for the C_{7+} fraction are shown in Table 6.1.16. Though the particular system chosen shown C_{7+} as a basis for the heavy and characterization C_{6+} will be used. There are several isomers of hexane, as well as other materials,

that can appear in the C_{6+} subfraction. The molecular mass tabulated for the fractions in Table 6.1.16 makes them appear to be normal paraffins. This, however, is not true and a complete TBP analysis was made on the C_{7+} fraction.

Calculations made based on the different C_{7+} characterizations are compared with experimental values, Table 6.1.17 and Figure 6.1.30. The complete TBP characterization provides the best predictions of the phase behavior and the liquid formation, though there is only a little difference between the full TBP and the partial TBP results. The lumped specific gravity-molecular mass characterization

FIGURE 6.1.22 Adjustment of oil relative volume curve to separator conditions [6].

and the lumped n-paraffin characterization give the poorest predictions. All of the characterizations in Table 6.1.18 are in better agreement with experimental values than one would normally expect.

6.1.3 Vapor-Liquid Equilibrium by Equation of State

Prediction of a vapor-liquid mixture is more complicated than prediction of pure component VLE.

The following condition equations for mixture VLE can be derived from classical thermodynamics:

$$T^V = T^L \quad (6.1.33)$$

$$P^V = P^L \quad (6.1.34)$$

$$f_i^V = f_i^L \quad (6.1.35)$$

The equilibrium constants, or K values, are defined as the ratio of vapor and liquid compositions:

$$K_i = \frac{y_i}{x_i} \quad (6.1.36)$$

The Gibbs free energy is a property of particular importance because it can be related to the equilibrium state and at the same time can be expressed as a function of T and P:

$$dG_i = -SdT + VdP \quad (6.1.37)$$

If Equation 6.1.37 is applied to an ideal gas it becomes

$$dG_i = RT d(\ln P) \quad (6.1.38)$$

If we now define a property such that Equation 6.1.38 will apply for all gases under all conditions of temperature and pressure

$$dG_i = RT d(\ln f_i) \quad (6.1.39)$$

What does “ f_i ” mean?

FIGURE 6.1.23 Adjustment of gas in solutions curve to separator conditions [6].

f_i is called the fugacity of component “i” and has units of pressure. If Equation 6.1.39 is integrated for an ideal gas:

$$f_i = cP \tag{6.1.40}$$

“c” is constant and for an ideal gas is equal to 1.0. For real gases the only condition under which the gas will behave ideally is at zero pressure. This can be expressed as

$$\lim_{P \rightarrow 0} \frac{f_i}{P} = 1.0 \tag{6.1.41}$$

The fugacity of a single component in a mixture is defined in a manner similar to Equation 6.1.36

$$dG = RT d(\ln f_i) \tag{6.1.42}$$

and by analogy to the Equation 6.1.39

$$\lim_{P \rightarrow 0} \frac{f_i}{x_i P} = 1.0 \tag{6.1.43}$$

The fugacity is sometimes referred to as a *corrected pressure*. A more valuable parameter for use in correlative procedures would be a variable with characteristics similar to fugacity, but which ranged over a much smaller range of numbers. It is the fugacity coefficient ϕ_i .

For a pure component

$$\phi_i = \frac{f_i}{P} \tag{6.1.44}$$

For a component in a mixture

$$\phi_i = \frac{f_i}{x_i P} \tag{6.1.45}$$

The fugacity coefficients are readily calculated from P-V-T data for both, pure component and mixture.

P-V-T of a fixed composition system can be developed in pressure explicit forms, i.e.,

$$P = \phi(V, T) \tag{6.1.46}$$

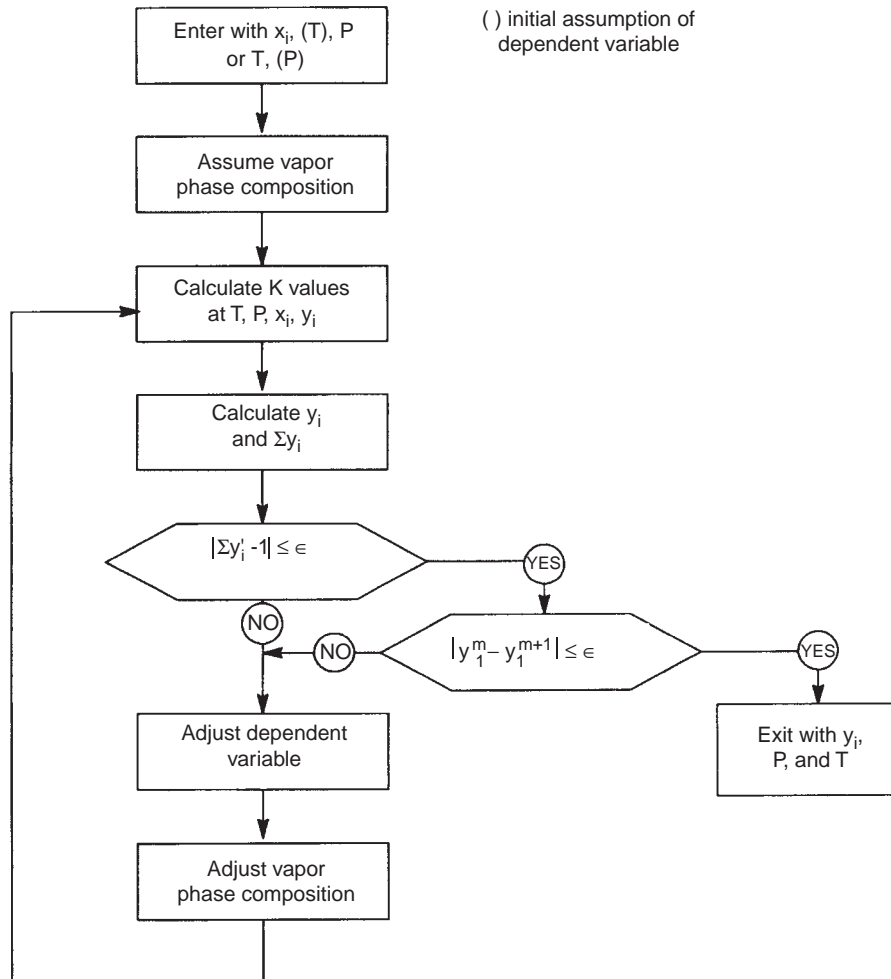

FIGURE 6.1.24 Block diagram for bubble point calculations.

The basic equation of state may be transformed to a compressibility factor Z , but the basic expression given by Equation 6.1.44 still applies. Equilibrium K values are predicted from fugacity, which is related to Gibbs free energy. One of the basic definitions of fugacity gases K values is

$$K = \frac{y_i}{x_i} = \frac{\phi_i^L}{\phi_i^V} = \frac{f_i^L / (P x_i)}{f_i^V / (P y_i)} \quad (6.1.47)$$

The fugacity coefficient ϕ_i is related to the pressure, volume and temperature by

$$\ln \phi_i = -\frac{1}{RT} \int_V^\infty \left[\left(\frac{\partial P}{\partial n_i} \right)_{T, V, n_j} - \frac{RT}{V} \right] dV - \ln Z \quad (6.1.48)$$

Applying the SRK equation

$$\ln \phi_i = -\ln \left(Z - \frac{P b_i}{RT} \right) + (Z - 1) B'_i - \frac{a}{bRT} (A'_i - B'_i) \ln \left(1 + \frac{b_i}{V} \right) \quad (6.1.49)$$

or

$$\ln \phi_i = -\ln(Z - B) + (Z - 1) B'_i - \frac{A}{B} (A'_i - B'_i) \ln \left(1 + \frac{B}{Z} \right) \quad (6.1.50)$$

where

$$B_i = \frac{b_i}{b} \quad (6.1.51)$$

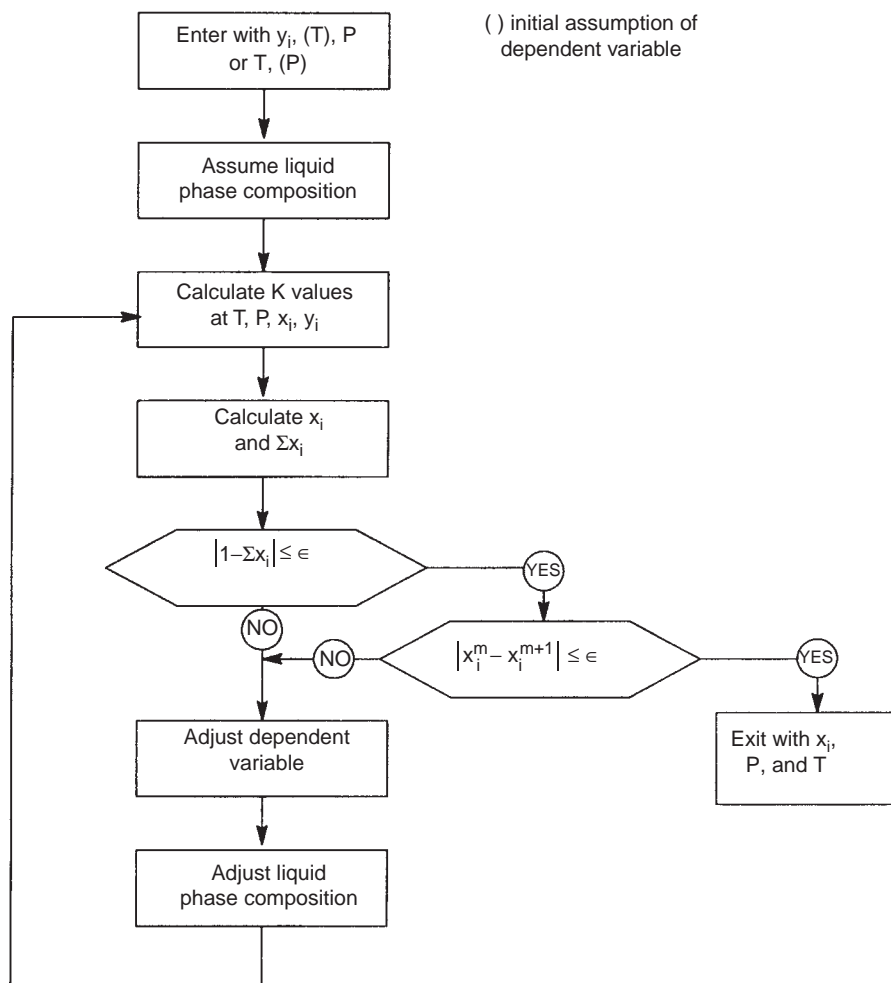

FIGURE 6.1.25 Block diagram for dew point calculations.

$$A'_i = \frac{1}{a} \left[2a_i^{0.5} \sum_j^N x_j a_j^{0.5} (1 - k_{ij}) \right] \quad (6.1.52)$$

Notations are as for Equations 6.1.11 and 6.1.12. For values k_{ij} see Tables 6.1.19 and 6.1.20. The data in Table 6.1.18 was prepared for the Peng-Robinson equation, while the data from Table 6.1.20 was used for the Benedict-Webb-Rubin equation modified by Starling [16].

Applying Peng-Robinson equation

$$\ln \phi_i = -\ln \left(Z - \frac{Pb}{RT} \right) + (Z - 1)B'_i - \frac{a}{2^{1.5}bRT} \times (A'_i - B'_i) \ln \left[\frac{V + (2^{0.5} + 1)b}{V - (2^{0.5} - 1)b} \right] \quad (6.1.53a)$$

or

$$\ln \phi_i = -\ln(Z - B) + (Z - 1)B'_i - \frac{A}{2^{1.5}B} \times (A'_i - B'_i) \ln \left[\frac{Z + (2^{0.5} + 1)B}{Z - (2^{0.5} - 1)B} \right] \quad (6.1.53b)$$

where

$$B_i = \frac{b_i}{b} \quad (6.1.54)$$

$$A'_i = \frac{1}{a} \left[2a_i^{0.5} \sum_j^N x_j a_j^{0.5} (1 - k_{ij}) \right] \quad (6.1.55)$$

Notations are as in Equation 6.1.13 and Equation 6.1.14.

The objectives of any equation-of-state solution method are the reliable and accurate prediction of the volumetric

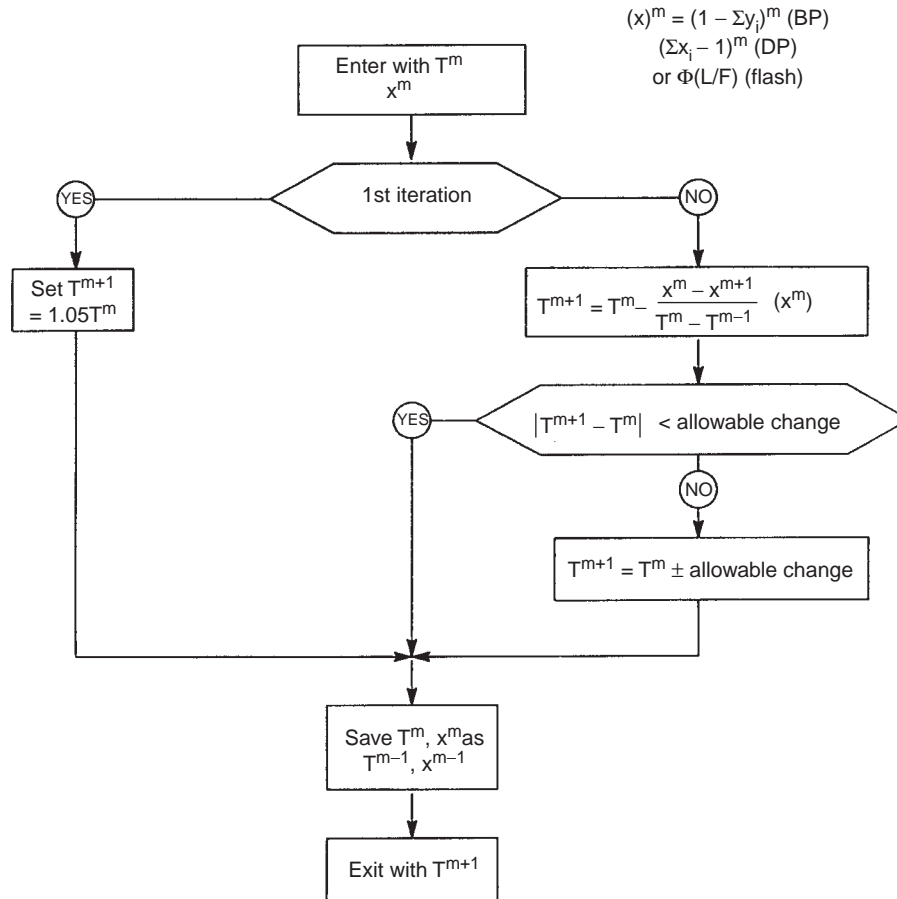

FIGURE 6.1.26 Temperature adjustment diagram for equilibrium calculations.

properties of the fluid mixture under consideration. The overall solution procedure is as follows:

- fix the total composition, temperature and pressure
- calculate constant for the equation of state
- solve equation for the volumetric property (specific volume, density or compressibility factor)

When pressure and temperature fall to a two-phase region, the equation must be solved twice, separately for vapor and liquid. The composition of each phase will be different, so the equation of state constants will have to be evaluated for both the liquid and the vapor phases. Both SRK and PR are cubic equations, so the solution always gives three roots, as shown in Figure 6.1.31 [17]. However, the P_r - V_r relationship at a given T_r is discontinuous at $V_r = b'_1$, $V_r = b'_2$, and $V_r = b'_3$. We are interested in only $V_r > b'_1$, which in case the SRK equation is equal 0.08664 and 0.077796 for the PR equation. For $V_r > b'_1$ and $T_r > 1.0$, there is

only one value of the compressibility factor that will satisfy the equation of state. For $V_r > b'_1$ and $T_r < 1.0$, we will get three values of Z . The largest Z of the vapor Z 's is chosen for the vapor and the smallest amount the liquid Z 's is chosen for the liquid. However, in an earlier stage of the iterative VLE calculations, it is not uncommon to encounter a single root, mainly because of incorrect compositions [17].

A logic diagram for a trial-and-error solution procedure for cubic equations of state is given in Figure 6.1.32. This diagram shows a traditional Newton-Raphson approach with an interval halving limiting procedure superimposed on it [18]. For purposes of the procedure for locating the boundaries of the liquid- and vapor-phase compressibility factors in the two-phase region discussion, assume that the equation of state is given in the form

$$Z^3 + \alpha Z^2 + \beta Z + \gamma = 0 \quad (6.1.56)$$

where γ and β are arbitrary constants.

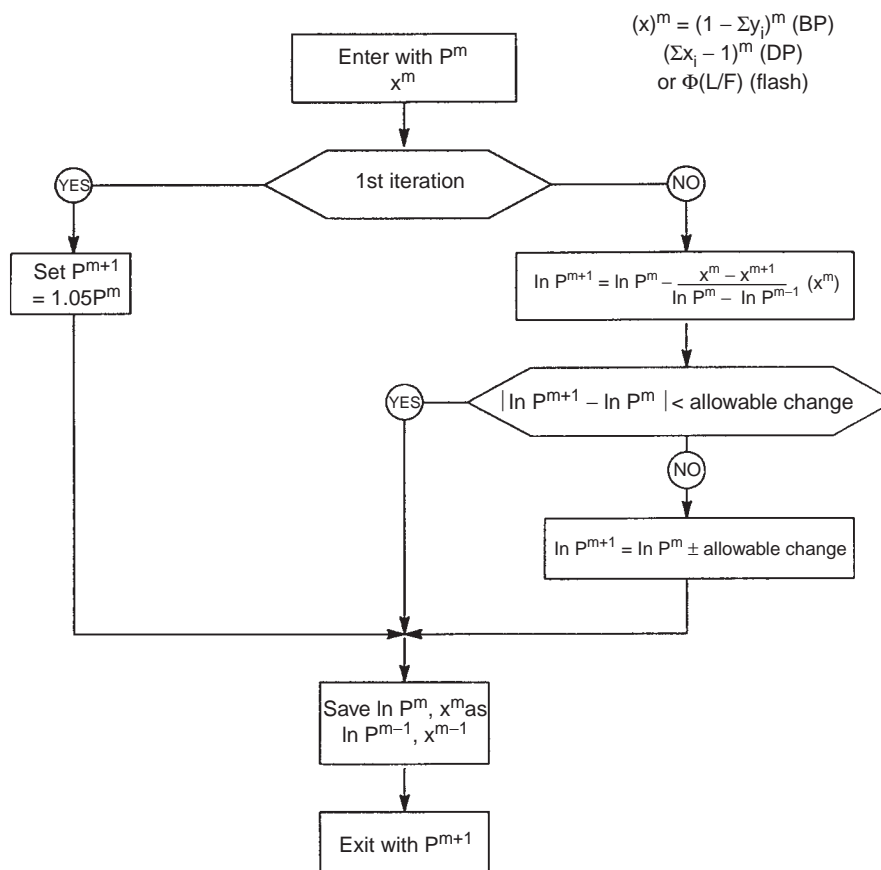

FIGURE 6.1.27 Pressure adjustment diagram for equilibrium calculations.

From Figure 6.1.33a–da–d in the two-phase region the equation of state will have a maximum and a minimum or two points at which the slope of the equation is zero. The value of the compressibility factor at the maximum defines the largest possible value for the liquid-phase compressibility factor. If Equation 6.1.56 is differentiated and set equal to zero the following equation results:

$$Z^2 + \frac{2\alpha Z}{3} + \frac{\beta}{3} = 0 \quad (6.1.57)$$

Solving the above equation for the values of Z at the maximum and minimum gives

$$Z_{1,2} = \frac{-2\frac{\alpha}{3} \pm 4\frac{\alpha^2}{9} - 4\frac{\beta}{3}}{2} \quad (6.1.58)$$

If the algebraic expression under the square root sign is negative or zero, only one real value of the compressibility factor will satisfy the equation of state (Figure 6.1.33a–dc or d). If, however, the value of the expression under the radical is positive, three real roots exist and limits for the vapor and liquid phase compressibility factors can be determined from Equation 6.1.58. The solutions of Equation 6.1.58 represent the value of Z at the maximum and minimum points of Figure 6.1.33a–db. The value of the maximum will represent the largest possible value for the liquid compressibility factor and the value at the minimum represents the smallest possible value of the vapor compressibility factor. These limits can then be used with arbitrary values for the other limit to assure that the root obtained is the valid one. The limits thus set up are adjusted at the end of each iteration to narrow the interval of search.

6.2 FLOW OF FLUIDS

Section reviewed by Bill Lyons

Fluid is defined as a single phase of gas or liquid or both. Each sort of flow results in a pressure drop. Three categories of fluid flow: vertical, inclined, and horizontal are shown in Figure 6.2.1. The engineer involved in petroleum production operations has one principal objective to move the fluid from some location in an underground reservoir to a pipeline that may be used to transport it or storage tank. Possible pressure losses in a complete production system and producing pressure profile are shown in Figures 6.2.2 and 6.2.3, respectively. On the way from reservoir to pipeline or storage tank, fluid is changing its temperature, pressure, and, consequently, composition of each phase. In case of a dry gas reservoir, a change in pressure and temperature does not create two-phase flow; also in case of black oil with a very small GOR, it could be assumed that two-phase flow does not occur.

Based on the law of conservation of energy, the total energy of a fluid at any particular point above datum plane is the sum of the deviation head, the pressure head, and velocity head as follows:

$$H = Z_{el} + \frac{144p}{\gamma} + \frac{v^2}{2g} \quad (6.2.1)$$

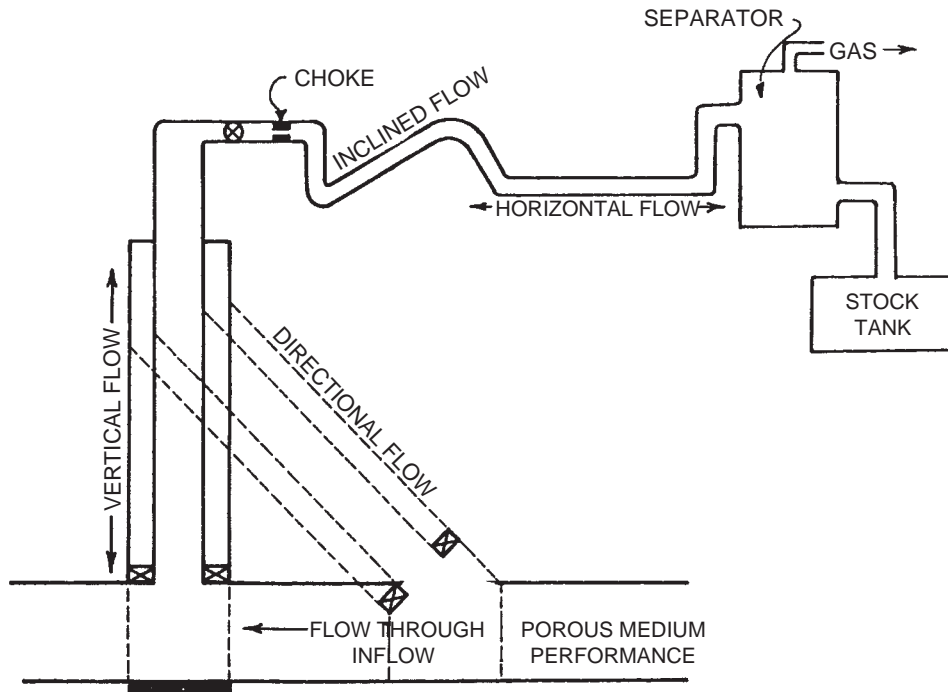

FIGURE 6.2.1 Overall production system [1].

FIGURE 6.2.2 Possible pressure losses in complete system [1].

In reality, whenever fluid is moving there is friction loss (h_L). This loss describes the difference in total energy at two points in the system. Expressing the energy levels at point 1 versus point 2 then becomes

$$Z_{e1} + \frac{144p_1}{\gamma_1} + \frac{v_1^2}{2g} = Z_{e2} + \frac{144p_2}{\gamma_2} + \frac{v_2^2}{2g} + h_L \quad (6.2.2)$$

All practical formulas for fluid flow are derived from the above,

where H = total energy of fluid

Z_{e1} = pipeline vertical elevation rise (ft)

p_1, p_2 = inlet and outlet pressures (psia)

γ_1, γ_2 = inlet and outlet fluid specific weight

v_1, v_2 = inlet and outlet fluid velocity

FIGURE 6.2.3 Production pressure profile [2].

g = acceleration due to gravity
 h_L = loss of static pressure head due to fluid flow

Equation 6.2.2 can be written in differential form as

$$\frac{dp}{\gamma} + \frac{v dv}{g} + dL \sin \theta + dL_w = 0 \quad (6.2.3)$$

where $dL \sin \theta = dZ$, and dL_w refers to friction multiplying the equation by γ/dL to give

$$\frac{dp}{dL} = \frac{\gamma v dv}{g dL} + \gamma \sin \theta + \gamma \left(\frac{dL_w}{dL} \right)_f = 0 \quad (6.2.4)$$

Solving this equation for pressure gradient, and if we consider a pressure drop as being positive in the direction of flow,

$$\frac{dp}{dL} = \gamma \sin \theta + \frac{\gamma v dv}{g dL} + \left(\frac{dp}{dL} \right)_f \quad (6.2.5)$$

where

$$\left(\frac{dp}{dL} \right)_f = \frac{\gamma dL_w}{dL}$$

Equation 6.2.4 contains three terms that contribute to the total pressure gradient, i.e.:

1. pressure gradient due to elevation

$$\gamma \sin \theta = \left(\frac{dp}{dL} \right)_{el}$$

2. pressure gradient due to acceleration

$$\frac{\gamma v dv}{g dL} = \left(\frac{dp}{dL} \right)_{acc}$$

3. pressure gradient due to viscous forces (friction)

$$\frac{\gamma dL_w}{dL} = \left(\frac{dp}{dL} \right)_f$$

$$\frac{dp}{dL} = \left(\frac{dp}{dL} \right)_{el} + \left(\frac{dp}{dL} \right)_{acc} + \left(\frac{dp}{dL} \right)_f \quad (6.2.6)$$

The acceleration element is the smallest one and sometimes is neglected.

The total pressure at the bottom of the tubing is a function of flowrate and comprises three pressure elements:

1. wellhead pressure—back pressure exerted at the surface from choke and wellhead assembly
2. hydrostatic pressure—due to gravity and the elevation change between wellhead and the intake to the tubing
3. friction losses, which include irreversible pressure losses due to viscous drag and slippage

Figure 6.2.4 illustrates this situation for each single-phase and two-phase flow. Possible pressure losses in a complete system are shown in Figure 6.2.2. For a given flowrate, wellhead pressure, and tubing size, there is a particular pressure distribution along the tubing. This pressure-depth profile is called a pressure traverse and is shown in Figure 6.2.5. Gas liberation, gas expansion, and oil shrinkage along the production tubing can be treated as a series of successive incremental states in which saturated oil and gas coexist in equilibrium (flash process). This model is shown in Figure 6.2.6. At (a) the single-phase oil enters the wellbore; (b) marks the first evolution of gas, at the mixture's bubble point; and (c) and (d) show the traverse into the two-phase region. Note that the gas and oil P-T diagrams describing equilibrium phases at points c and d are not the same. This means the composition of equilibrium gas and oil phases changes continuously in the two-phase region. As the two-phase region is entered and gas is liberated, oil and gas phases change in volume and composition, but they are always in a saturated state, the gas at its dew point, and the oil at its bubble point. In Figure 6.2.7 the separation process is shown in forms of the resulting gas and oil.

Engineering analysis of two-phase fluid flow in pipes has focused primarily on the problem of predictive pressure drop, or pressure gradient, from Equation 6.2.6.

FIGURE 6.2.4 Components of pressure losses in tubing [2].

FIGURE 6.2.5 Pressure traverse for single-phase liquid, gas, and multiphase gas–oil mixture [2].

In many cases, it has become possible to treat two-phase pipeline problems with empirical numerical techniques that yield reasonably accurate pressure drops. Most of two-phase pipeline simulation currently is performed using “black oil” simulators. A black oil model’s validity rests on the assumption that the hydrocarbon mixture is composed of two phases, denoted oil and gas, each with fixed composition. A black-oil model usually treats P–V–T properties (solution gas, densities, and viscosities) as single-value function of pressure. More sophisticated models include the temperature effect on fluid properties as well.

The multicomponent or compositional approach is designed for gas condensate and volatile oil systems. These fluids are represented as N-component hydrocarbon mixtures, where N might be equal to components C₁, C₂, C₃, i-C₄, n-C₄, i-C₅, n-C₅, C₆, and C₇₊. Equations of state (SRK, PR, SBWR) are used to determine physical properties. The term “compositional” implies that the overall or in situ fluid composition varies point by point with the distance as is shown in Figure 6.2.6. When a multicomponent gas–liquid mixture flows through a pipe, the composition, pressure, temperature and liquid holdup distributions are related.

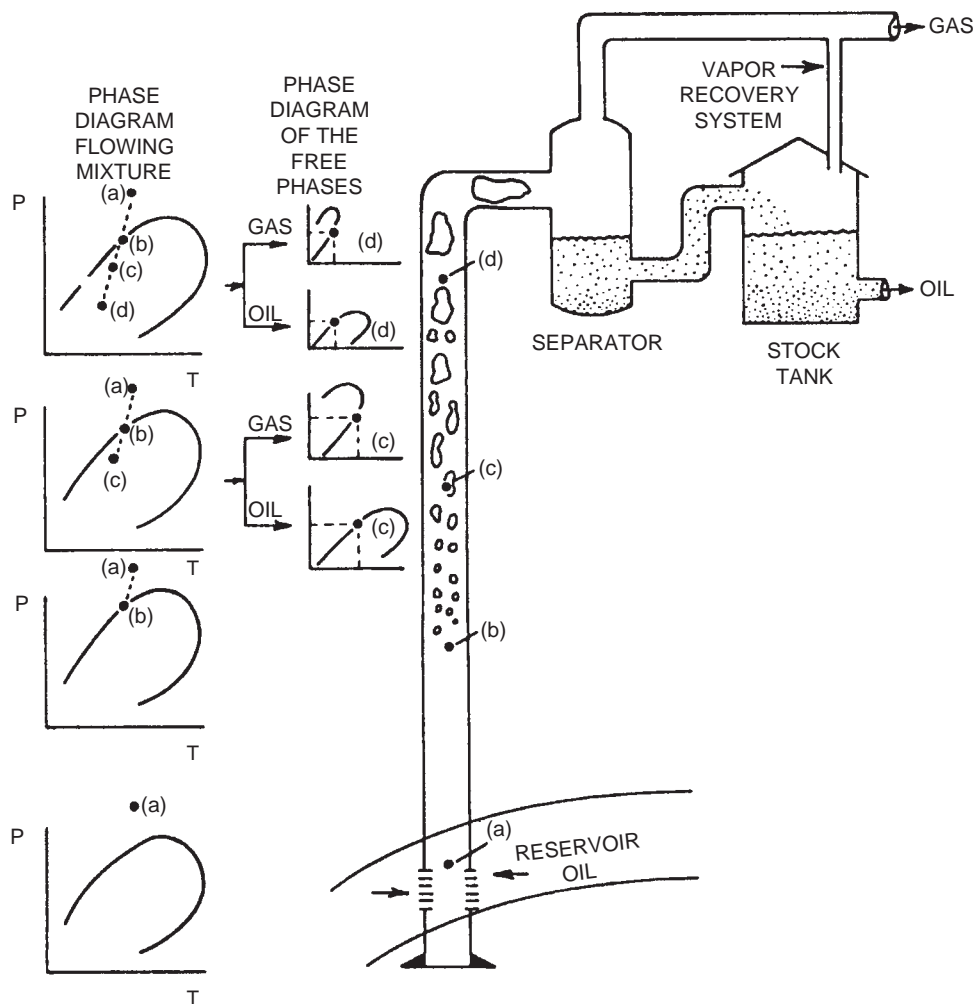

FIGURE 6.2.6 Changes in phase behavior in the production tubing [2].

6.2.1 Basic Parameters of Multiphase Flow [1]

Knowledge of the flow regime determines the selection of the appropriate model for pressure gradient and liquid holdup. The flow regime, pressure gradient, and liquid holdup are calculated for each segment of the pipeline. The information needed to make the calculations includes:

1. pipeline inlet and outlet boundary conditions (liquid and gas flowrates, temperature, and pressure)
2. pipeline geometry, with segments specifications (any riser or well, down-comer, inclined section)
3. fluid properties (assume constant properties, compositional analysis, black oil approaches); this includes gas, oil, and water density; viscosity; and surface tension

It is assumed by flow regime that the distribution of each phase in the pipe is relative to one another. Prediction of flow patterns for horizontal flow is a more difficult task than for vertical flow. Possible flow regimes are shown in Figure

6.2.8. An example of the complexity of two-phase flows in vertical pipe. Numerous authors [1–4] have presented flow-pattern and flow-regime maps in which various areas are indicated on a graph for which there are two independent coordinates. Maps are also dependent on ranges of pipe inclination for vertical upward to vertical downward [1]. Selection of the appropriate flow regime map is based solely on the pipe segment inclination θ from the horizontal, as shown below:

Range of Inclination from the Horizontal	Regime Maps
$\theta = 90^\circ$ to 15°	Upward inclined
$\theta = 15^\circ$ to -10°	Near horizontal
$\theta = -10^\circ$ to -90°	Downward inclined

FIGURE 6.2.7 Pressure–temperature phase diagram used to describe surface separation [2].

6.2.1.1 Flow Regimes

The steps in the determination of the flow regime are as follows:

1. Calculate dimensionless parameters.
2. Refer to flow regime maps laid out in coordinates of these parameters.
3. Determine the flow regime by locating the operating point on the flow regime map.

The discussions in the following sections treat the flow regime maps for vertical upward ($\theta = 90^\circ$); slightly inclined ($\theta = 15^\circ$ to -10°) and vertical downward inclinations.

To proceed with the calculations of the flow regime, it is necessary to calculate the superficial velocities for each flow phase (Figure 6.2.9). The superficial velocities for the gas, oil and water are

$$v_{sg} = q_g / A_p \quad (6.2.7a)$$

$$v_{so} = q_o / A_p \quad (6.2.7b)$$

$$v_{sw} = q_w / A_p \quad (6.2.7c)$$

where A_p = pipe flow area in ft^2
 q = volumetric flowrate at flow conditions in ft^3/s

The superficial velocities of liquid phase (oil and water) are calculated as

$$v_{sL} = v_{so} + v_{sw} \quad (6.2.7d)$$

The mixture velocity that will be used in some of the calculations is the sum of the superficial velocities of the gas and the liquid phases:

$$v_m = v_{sL} + v_{sg} \quad (6.2.7e)$$

The average velocity of each phase is related to the superficial velocity through the liquid holdup:

$$U_L = v_L = v_{sL} / H_L \quad (6.2.7f)$$

$$U_g = v_g = v_{sg} / (1 - H_L) \quad (6.2.7g)$$

For a homogeneous model, both phases are assumed to have equal velocities and each is equal to a two-phase (or mixture) velocity:

$$v_L = v_g = v_m \quad (6.2.7h)$$

H_L in Equations 6.2.7f and 6.2.7g refers to liquid holdup. Liquid holdup is defined as the ratio of the volume of a pipe segment occupied by liquid to the volume of the pipe segment:

$$H_L = \frac{\text{volume of liquid in a pipe segment}}{\text{volume of pipe segment}} \quad (6.2.8a)$$

FIGURE 6.2.8 Gas-liquid flow regimes.

FIGURE 6.2.9 Possible sequence of flow patterns in a vertical tube [3].

In some cases, e.g., for stratified horizontal flow regime, liquid holdup can be calculated as follows:

$$H_L = \frac{A_L}{A_L + A_g} \quad (6.2.8b)$$

where A_L = cross-sectional area occupied by liquid
(oil and water)

A_g = cross-sectional area occupied by gas

6.2.2 Slightly Inclined Pipes

($-10^\circ < \theta < 15^\circ$)

As can be seen from Figure 6.2.8, there are four flow regimes of interest—stratified, slug, annular, and bubbly—and three flow regime transition zones.

6.2.2.1 Step 1. Dimensionless Parameters

1. Martinelli parameter—this is the ratio of the liquid and gas phases as if each flowed alone in the pipe:

$$X = \left[\frac{(dp/dL)_{Ls}}{(dp/dL)_{gs}} \right]^{0.5} = \left(\frac{2f_{hLs}\gamma_L v_{sL}^2/D}{2f_{wgs}\gamma_s v_{sg}^2/D} \right) \quad (6.2.9a)$$

According to standard fluid mechanics book

$$f^* = \begin{cases} 0.046/Re^{0.2} & \text{if } Re = \gamma Dv/\mu > 1500 \\ 16/Re & \text{if } Re < 1500 \end{cases} \quad (6.2.9b)$$

2. Gas Froude number (dimensionless gas flowrate):

$$F_g = v_{sg} \left(\frac{\gamma_g}{(\gamma_L - \gamma_g)gD} \right)^{0.5} \quad (6.2.10)$$

3. Turbulence level

$$T = \left[\frac{(dp/dL)_{Ls}}{g(\gamma_L - \gamma_g) \cos \theta} \right] = \left[\frac{2f_{wLs}\gamma_L v_{sL}^2/D}{g(\gamma_L - \gamma_g) \cos \theta} \right] \quad (6.2.11)$$

4. Dimensionless inclination (slope parameter)

$$Y = \left[\frac{g(\gamma_L - \gamma_g) \sin \theta}{(dp/dL)_{gs}} \right] = \left[\frac{g(\gamma_L - \gamma_g) \sin \theta}{2f_{wgs}\gamma_g v_{sg}^2/D} \right] \quad (6.2.12)$$

6.2.2.2 Step 2. Flow Regime Map

The parameter Y is used to select the flow regime map to be used from Figure 6.2.10a–i. This figure presents nine flow regime maps (a to i) for a wide range of dimensionless inclinations, Y , in the range of interest.

*Calculated separately for “ls” and “gs.”

FIGURE 6.2.10a Flow regime map for slightly inclined pipes (horizontal) [4].

FIGURE 6.2.10c Flow regime map for slightly inclined pipes ($Y = -1000$) [4].

FIGURE 6.2.10d Flow regime map for slightly inclined pipes ($Y = -10,000$) [4].

FIGURE 6.2.10e Flow regime map for slightly inclined pipes ($Y = 10$) [4].

FIGURE 6.2.10g Flow regime map for slightly inclined pipes ($Y = 100$) [4].

FIGURE 6.2.10f Flow regime map for slightly inclined pipes ($Y = 30$) [4].

FIGURE 6.2.10h Flow regime map for slightly inclined pipes ($Y = 1000$) [4].

FIGURE 6.2.10i Flow regime map for slightly inclined pipes ($Y = 10,000$) [4].

6.2.2.3 Step 3. Flow Regime Selection

The flow regime maps are prepared in Froude number–Martinelli parameter–turbulence level (F_g – X – T). Four flow regimes are noted on the maps, doing with the three transition boundaries. Regimes are stratified, slug, annular, and bubbly. The flow conditions for the current pipe segment are located using the X , F_g coordinates. If the located point is in the region labeled “stratified,” then the flow regime is indeed stratified. If the located point is outside of the stratified region, then determine whether the point is to the left or right of the vertical line representing the transition between annular and slug flow regimes. If the point X , F_g is on the right side of the vertical line, X , T coordinates are necessary.

6.2.3 Risers and Wells ($\theta = 90^\circ$)

There are three possible flow regimes, including annular, slug, and bubbly, and two regime transitions.

6.2.3.1 Step 1. Dimensionless Parameters

For this regime map, three dimensionless parameters are calculated. The parameters include dimensionless groups, which represent a balance between buoyancy, inertial,

and surface tension forces. There are called Kutateladze numbers.

$$K_g = \frac{\gamma_g^{0.5} v_{sg}}{[g\sigma_{go}(\gamma_L - \gamma_g)]^{0.25}} \quad (6.2.13)$$

$$K_L = \frac{\gamma_L^{0.5} v_{sL}}{[g\sigma_{go}(\gamma_L - \gamma_g)]^{0.25}} \quad (6.2.14)$$

$$\rho^* = \left(\frac{\rho_L}{\rho_g} \right) \quad (6.2.15)$$

where K_g, K_L = dimensionless gas and liquid flowrates

ρ_g, ρ_L = density of gas and liquid phases in lb_m/ft^3

v_{sg}, v_{sL} = superficial gas and liquid velocities in ft/s

σ_{go} = surface tension between gas–oil phases in lb_f/ft .

ρ^* = dimensionless density ratio

g = acceleration of gravity in ft/s^2

6.2.3.2 Step 2. Flow Regime Map

Once these dimensionless parameters are calculated, then the point with the coordinates (K_g, K_L) is located on the flow regime map in Figure 6.2.11.

6.2.3.3 Step 3. Flow Regime Selection

The boundary for the appropriate density ratio is located for the transition boundary between the slug and bubbly flow regimes. Once the appropriate boundary line is found, then the flow regime is simply bubbly, slug, or annular depending upon the region in which the point falls. This slug to annular transition applies only if the pipe size D is larger than a critical diameter D_{crit} given by

$$D_{crit} = 1.9 \left[\frac{\sigma_{go}(\gamma_L - \gamma_g)}{g\gamma_L} \right]^{0.25} N_L^{(-0.4)} \quad (6.2.16a)$$

where

$$N_L = \frac{\mu_L}{(\gamma_L \sigma_{go})^{0.5} [\sigma_{go}/g(\gamma_L - \gamma_g)]^{0.25}} \quad (6.2.16b)$$

μ_L = liquid phase viscosity in $\text{lb}_m/(\text{ft} \cdot \text{s})$

Usually, the critical pipe size is about 2 in. for conditions of gas and oil pipelines so that Figure 6.2.11 can be used often. The criterion should be checked each time, however. If $D < D_{crit}$, another method has to be used; see Reference 22, Vol. 3.

FIGURE 6.2.11 Flow regime map for vertical upward inclinations ($\theta = 90^\circ$) [4].

6.2.4 Downcomers ($\theta = -90^\circ$)

There are also three possible flow regimes: annular, slug, and bubbly. There are two flow regime transitions to be calculated. Two different maps will be used: one for transition between annular and slug flow regimes, and a second for the transition between the slug and bubbly flow regimes.

6.2.4.1 Annular-Slug Transition

1. Dimensionless parameters X and $|Y|$ from Equations 6.2.9a and 6.2.12, respectively.
2. Flow regime map, see Figure 6.2.12.
3. Flow regime selection. Locate the point with $(X, |Y|)$ coordinates; if the point falls in the region “annular,” then the flow regime is annular. If the point falls in region

“slug” or “bubbly,” then the map from Figure 6.2.13 must be used.

6.2.4.2 Slug-Bubbly Transition

1. Calculate dimensionless parameters K_g , K_L , and ρ^* ; use Equations 6.2.14 and 6.2.15, respectively.
2. The appropriate regime boundary for the specific weight ratio γ^* is selected on the regime map with K_g , K_L coordinates.
3. Flow regime selection. Depending upon which region of the map the data point falls into, flow regime is slug or bubbly.

Similarly as for ($\theta = 90^\circ$), Figure 6.2.13 applies for pipes greater than a certain critical diameter.

FIGURE 6.2.12 Flow regime map for slug-annular transition for vertical downward inclination ($\theta = -90^\circ$) [4].

$$D > D_{\text{crit}} = 19 \left[\frac{(\gamma_L - \gamma_g) \sigma_{go}}{g \gamma_L^2} \right]^{0.5} \quad (6.2.17)$$

The above procedure is valid for $D > 2$ in.

For each flow regime, there is a separate pressure gradient and holdup calculation method.

6.2.5 Stratified Flow Regime

First, the *liquid holdup* H_L and f_i/f_{wg} (friction factor ratio) are calculated. The liquid holdup as a function of X (Equation 6.2.9a), Y (Equation 6.2.12), and (f_i/f_{wg}) is read from Figure 6.2.14a–d. $f_i/f_{wg} = 10$ is recommended to be used as a preliminary estimate. For better accuracy f_i/f_{wg} can be calculated. H_L should be first estimated by the method described above and

$$\frac{f_i}{f_{wg}} = 1.0 \text{ if Equation 6.2.18b} < 1.0 \quad (6.2.18a)$$

$$\frac{f_i}{f_{wg}} = \left[2 + \frac{0.000025 \text{Re}_{Ls}}{D/3.281} \right] (1 - H_L)^{5/2} (1 + 75H_L) \quad (6.2.18b)$$

$$\text{if Equation 6.2.18b} > (1 + 75H_L) \quad (6.2.18c)$$

(D is in inches).

Figure 6.2.15a–h shows Equation 6.2.18 for pipe diameters ranging from 4 to 36 in. The friction factor ratio (f_i/f_{wg})

can be estimated from the plots in Figure 6.2.15a–h or as a result of calculation.

When the friction factor is determined correctly, Figure 6.2.14 should again be used to estimate a new value of the liquid holdup. If the new value of the liquid holdup obtained is different from determined previously, this new value should be used in Equation 6.2.18 or Figure 6.2.15a–h to refine the estimate for f_i/f_{wg} . This is simply an iteration process.

6.2.5.1 Pressure Gradient

Knowing the liquid holdup, H_L , calculations for the pressure gradients due to friction and gravitational effects are straightforward. First, some geometric parameters are calculated:

1. Dimensionless cross-sectional area occupied by gas (A_G) and by liquid (A_L)

$$A_G = 0.25 [\cos^{-1}(2h^* - 1) - (2h^* - 1) \left[1 - (2h^* - 1)^2 \right]^{0.5}] \quad (6.2.19a)$$

$$A_L = 0.25 [\pi - \cos^{-1}(2h^* - 1) + (2h^* - 1) \left[1 - (2h^* - 1)^2 \right]^{0.5}] \quad (6.2.19b)$$

2. Dimensionless wetted perimeter for gas phase (S_G) and for liquid phase (S_L)

$$S_G = \cos^{-1}(2h^* - 1) \quad (6.2.20a)$$

$$S_L = \left[\pi - \cos^{-1}(2h^* - 1) \right] \quad (6.2.20b)$$

3. Dimensionless interfacial length between gas and liquid phases (S_i)

$$S_i = \left[1 - (2h^* - 1) \right]^{0.5} \quad (6.2.21)$$

4. Dimensionless hydraulic diameter for gas phase (D_G) and liquid phase (D_L)

$$D_G = 4A_G / (S_L + S_i) \quad (6.2.22a)$$

$$D_L = 4A_L / S_L \quad (6.2.22b)$$

where h = dimensionless liquid in pipe ($= H_L/D$)

Dimensionless liquid level h can be expressed in terms of H_L as shown in Figures 6.2.16 to 6.2.19, but in terms of h that approach is much easier for the circular pipe cross-section.

Since the liquid holdup is

$$H_L = 4A_L / \pi, \quad (6.2.23)$$

It is necessary to find h first, using the expression in Equations 6.2.19 to 6.2.22. The value of h must be found

FIGURE 6.2.13 Flow regime map for bubble-slug transition for vertical downward inclinations ($\theta = -90^\circ$) [4].

numerically, or alternatively, it can be estimated from Figure 6.2.20. After geometric parameters are calculated (Equations 6.2.19 to 6.2.22), the friction factors for the gas and liquid phase has to be calculated:

$$f_{wg} = \begin{cases} 0.046/Re_g^{0.2} & \text{if } Re_g = \left(\frac{\gamma_g D_G D v_{sg}}{\mu_g (1-H_L)}\right) \geq 1500 \\ 16/Re_g & \text{if } Re_g < 1500 \end{cases} \quad (6.2.24a)$$

$$f_{wL} = \begin{cases} 0.046/Re_L^{0.2} & \text{if } Re_L = \left(\frac{\gamma_g D_L D v_{sL}}{\mu_L H_L}\right) \geq 1500 \\ 16/Re_L & \text{if } Re_L < 1500 \end{cases} \quad (6.2.24b)$$

Then the frictional and gravitational pressure gradients given by Expression 6.2.6 are

$$\left(\frac{dp}{dL}\right)_f = - \left[2f_{wL} \left(\frac{\gamma_L v_{sL}^2}{\pi D}\right) \left(\frac{1}{H_L}\right)^2 (S_L) \right] - \left[2f_{wg} \left(\frac{\gamma_g v_{sg}^2}{\pi D}\right) \left(\frac{1}{1-H_L}\right) (S_G) \right] \quad (6.2.25a)$$

$$\left(\frac{dp}{dL}\right)_{el} = \left(\frac{dp}{dZ}\right) \sin \theta = -g [H_L \gamma_L + (1-H_L) \gamma_g] \sin \theta \quad (6.2.25b)$$

where L = distance in ft.

z = vertical coordinate in ft.

S = pipeline inclination from the horizontal in degree

FIGURE 6.2.14a Liquid holdup in stratified flow regime ($f_i/f_{wg} = 1$) [4].

6.2.5.2 Special Cases for Low and High Liquid Holdup

As $H_L \approx 1.0$ or 0.0 , it becomes difficult to determine the liquid holdup accurately. Small errors in the estimation lead to large errors in the frictional portion of the pressure gradient by Equation 6.2.25a; therefore, in such cases as above, it is recommended that the pressure gradient be calculated by the following methods. If the liquid holdup $H_L > 0.99$, then

$$\left(\frac{dp}{dL}\right)_t = - \left[f_{wL} \left(\frac{\gamma_L v_{sL}}{2D}\right)^2 \left(\frac{1}{H_L}\right)^2 \left(\frac{S_L}{A_L}\right) \right] + \left[\left(\frac{f_i}{f_{wg}}\right) f_{wg} \left(\frac{\gamma_g v_{sg}^2}{2D}\right) \left(\frac{1}{1-H_L}\right)^2 \left(\frac{S_i}{A_L}\right) \right] - g\gamma_L \sin \theta \tag{6.2.26a}$$

If the liquid holdup $H_L < 0.01$, then

$$\left(\frac{dp}{dL}\right)_t = - \left\{ f_{wg} \frac{\gamma_g v_{sg}^2}{2D} \left(\frac{1}{1-H_L}\right)^2 \left[\left(\frac{S_G}{A_G}\right) + \left(\frac{f_i}{f_{wg}}\right) \times \left(\frac{S_i}{A_G}\right) \right] \right\} - g\gamma_g \sin \theta \tag{6.2.26b}$$

where the gravitational pressure gradient is still the same as in Equation 6.2.25b and the frictional pressure gradient can be determined by subtraction from Equation 6.2.26a or 6.2.26b.

6.2.6 Annular Flow Regime

In the annular flow regime, the extent of liquid entrainment must first be estimated, then the liquid holdup and the pressure gradient can be calculated.

FIGURE 6.2.14b Liquid holdup in stratified flow regime ($f_i/f_{wg} = 5$) [4].

6.2.6.1 Liquid Entrainment E_d

Calculation methods in this area have not been validated and may be poor. First, calculation v_e (critical gas velocity on set of entrainment) is made as follows:

$$v_e = 0.00025 \left(\frac{\gamma_L}{\gamma_g} \right)^{0.5} \left(\frac{\sigma_{go}}{\mu_g} \right) \quad (6.2.27)$$

If the value of the $v_{sg} < v_e$, then there is no entrainment $E_d = 0$. If $v_{sg} > v_e$, then the entrainment fraction should be estimated by

$$E_d = 1 - \exp \left[0.23 \left(\frac{v_e - v_{sg}}{v_e} \right) \right] \quad (6.2.28)$$

where E_d = mass fraction or volume fraction of the total liquid flow that is in the form of entrained droplets

Equation 6.2.28 is an empirical correlation without experimental basis. Figure 6.2.21 graphically shows the liquid entrainment fraction for various values of the critical entrainment velocity, v_e .

6.2.6.2 Liquid Holdup H_L

After E_d fraction is calculated, the liquid holdup can be estimated. To determine H_L dimensionless specific weight ratio γ_c^* has to be known:

$$\gamma_c^* = \frac{\gamma_c}{\gamma_g} = \left[E_d \left(\frac{\gamma_L}{\gamma_g} \right) \left(\frac{v_{sL}}{v_{sg}} \right) + 1 \right] \quad (6.2.29)$$

γ_c^* = (density of a gas – droplet mixture in the core of the annular flow) / (density of the gas phase)

FIGURE 6.2.14c Liquid holdup in stratified flow regime ($f_l/f_{wg} = 10$) [4].

with this density ratio, other dimensionless parameters could be defined:

$$X_a = \frac{X}{(\gamma_c^*)^{0.5}} \tag{6.2.30a}$$

$$Y_a = \left(\frac{Y}{\gamma_c^*}\right) \left(\frac{\gamma^* - \gamma_c^*}{\gamma^* - 1}\right) \tag{6.2.30b}$$

where X and Y are the same as the values for the stratified flow regime.

With these parameters, Figure 6.2.22a–d can be used to estimate the liquid holdup in the liquid film H_{Lf} for the annular flow regime.

The total liquid holdup in the annular flow regime is calculated as follows:

$$H_L = H_{Lf} + \left(\frac{E_d v_{sL}}{E_d v_{sL} + v_{sg}}\right) \tag{6.2.31}$$

6.2.6.3 Pressure Gradient

The friction factor for the liquid phase needs to be calculated first.

$$f_{wL} = \begin{cases} 0.046/Re_L^{0.2} & \text{if } Re_L = \left[\frac{\gamma_g D v_{sL} (1 - E_d)}{\mu_L}\right] \geq 1500 \\ 16/Re_L & \text{if } Re_L < 1500 \end{cases} \tag{6.2.32}$$

The fractional and gravitational pressure gradients are

$$\left(\frac{dp}{dL}\right)_f = - \left[2f_{wL} \left(\frac{\gamma_L v_{sL}^2}{D}\right) \left(\frac{1 - E_d}{H_{Lf}}\right)^2 \right] \tag{6.2.33a}$$

FIGURE 6.2.14d Liquid holdup in stratified flow regime ($f_l/f_{wg} = 20$) [4].

and

$$\left(\frac{dp}{dL}\right)_g = g[\gamma_L H_{Lf} + (1 - H_{Lf})\gamma_c] \sin \theta \quad (6.2.33b)$$

Then the total pressure gradient is

$$\left(\frac{dp}{dL}\right)_{total} = -2(1 + 75H_{Lf})(f_{wg}) \left(\frac{\gamma_c v_{sg}^2}{D}\right) \left(\frac{1}{1 - H_{Lf}}\right)^{5/2} - g\gamma_c \sin \theta \quad (6.2.34b)$$

$(dp/dL)_g$ from Equation 6.2.33b could be calculated.

6.2.6.4 Special Case for Low Liquid Holdup

For low values of the liquid holdup, the approach described below is recommended. If $H_{Lf} < 0.002$, then

$$f_{wg} = \begin{cases} 0.046/Re_g^{0.2} & \text{if } Re_g = \left[\frac{\gamma_g D v_{sg}}{\mu_g (1 - H_{Lf})}\right] \geq 1500 \\ 16/Re_g & \text{if } Re_g < 1500 \end{cases} \quad (6.2.34a)$$

6.2.7 Slug Flow Regime

In slug flow, the liquid slugs tend to contain some gas. The fraction of liquid in the liquid slugs can be estimated by

$$E_{Ls} = \frac{1}{1 + \left(\frac{v_m}{28.4}\right)^{1.39}} \quad (6.2.35)$$

FIGURE 6.2.15a Interfacial friction factor ratio for stratified flow regime ($D = 4$ in.) [4].

FIGURE 6.2.19 Dimensionless hydraulic diameters in stratified flow regimes [4].

FIGURE 6.2.20 Dimensionless liquid level stratified flow regimes [4].

FIGURE 6.2.21 Liquid entrainment fraction in annular flow regime [4].

Figure 6.2.23 shows the liquid holdup versus the mixture velocity v_m by this correlation.

6.2.7.1 Slug Velocity

The velocity of the liquid slugs or gas bubbles is determined by

$$v_s = C_o v_m + k \left[\frac{gD(\gamma_L - \gamma_g)}{\gamma_L} \right]^{0.5} \quad (6.2.36)$$

For C_o and k , see Table 6.2.1.

6.2.7.2 Liquid Holdup

The overall liquid holdup is obtained by

$$H_L = 1 - \frac{v_{sg} + (1 - E_{Ls})(v_s - v_m)}{v_s} \quad (6.2.37)$$

6.2.7.3 Pressure Gradient

Two cases will be considered, slightly inclined flow and vertical flow. Pressure for slightly inclined flow is a function of an average liquid velocity v_L , a friction factor f_L , and an average slug density ρ_{Ls} .

$$v_L = v_{sL}/H_L \quad (6.2.38a)$$

$$f_L = \begin{cases} 0.046/Re_L^{0.2} & \text{if } Re_L = \left(\frac{\gamma_L D v_L}{\mu_L} \right) \geq 1500 \\ 16/Re_L & \text{if } Re_L < 1500 \end{cases} \quad (6.2.38b)$$

$$\gamma_{sL} = [E_{Ls}\gamma_L + (1 - E_{Ls})\gamma_g] \quad (6.2.38c)$$

The frictional pressure gradient is then calculated by

$$\left(\frac{dp}{dL} \right)_f = - \left(\frac{2f_L \gamma_{Ls} v_L^2}{D} \right) \quad (6.2.39a)$$

and the gravitational pressure gradient is

$$\left(\frac{dp}{dL} \right)_g = -g [H_L \gamma_L + (1 - H_L) \gamma_g] \sin \theta \quad (6.2.39b)$$

For vertical flow, the fractional pressure gradient is calculated by

$$\left(\frac{dp}{dL} \right)_f = - \left[2f_m \left(\frac{\gamma_{Ls} v_m^2}{D} \right) H_L \right] \quad (6.2.40)$$

where γ_{Ls} , from Equation 6.2.38c, with $E_{Ls} = 0.75$

$$H_L = \frac{v_{sL}}{v_L} = \frac{\text{liquid superficial velocity}}{\text{avg. liquid velocity in slug flow}}$$

FIGURE 6.2.22a Liquid holdup in annular flow regime ($E_d = 0$) (expanded Y scale) [4].

and f_m , from Equation 6.2.38b, using the mixture velocity v_m (replacing v_L) in the Reynolds number.

6.2.7.4 Optional Correction

The approximation to the pressure gradient above neglects the liquid holdup in the liquid film around the gas bubble. This holdup may be significant for long gas bubbles that occur in wells of gas and oil pipelines. Thus Equations 6.2.40 and 6.2.39b will overpredict the pressure gradient. If greater accuracy is desired, a closer estimate (which may tend to underpredict the pressure gradient) is possible.

The thickness δ^* (dimensionless thickness of liquid film in slug bubble) of the liquid film is estimated and the result used to modify the liquid holdup. To get the liquid film thickness, two dimensionless parameters are first calculated;

dimensionless velocity ratio for slug flow in risers N_f and dimensionless velocity ratio for slug flow in risers v^* :

$$N_f = \left[D^3 g (\gamma_1 - \gamma_g) \gamma_L \right]^{0.5} / \mu_L \quad (6.2.41a)$$

$$v^* = v_m \gamma_L^{0.5} / k [gD(\gamma_L - \gamma_g)]^{0.5} \quad (6.2.41b)$$

In Figure 6.2.24, the line of constant v^* is found first; then the line of constant N_f is located. The “turbulent film” line is a limiting case for large values of N_f . The intersection of these two lines determines the film thickness δ^* . The liquid holdup calculated by Equation 6.2.37 is then modified by

$$H'_L = 1 - (1 - H_L) / (1 - 2\delta^*)^2 \quad (6.2.42)$$

FIGURE 6.2.22b Liquid holdup in annular flow regime ($E_d = 0.2$) (expanded Y scale) [4].

This modified value of the liquid holdup is used in Equation 6.2.40 and 6.2.39b to determine the pressure gradient, where the other parameters are calculated as before.

6.2.8 Bubbly Flow Regime

The liquid holdup is found by a drift-flux model

$$H_L = 1 - \left(\frac{v_{sg}}{C_o v_m + k v_\infty} \right) \quad (6.2.43a)$$

where the velocity v_∞ is

$$v_\infty = \left[\frac{g \sigma_{go} (\gamma_L - \gamma_g)}{\gamma_L^2} \right]^{0.25} \quad (6.2.43b)$$

and the parameters C_o and k are determined as below:

Pipe Inclination	C_o	k
$> 0^\circ$	$1.2 - 0.2(\gamma_g/\gamma_L)^{0.5}$	1.4
0°	$1.2 - 0.2(\gamma_g/\gamma_L)^{0.5}$	0
$< 0^\circ$	0.9	0

6.2.8.1 Pressure Gradient

The friction factor for the liquid is first calculated by

$$f_{wLm} = \begin{cases} 0.046/Re_{Lm}^{0.2} & \text{if } Re_{Lm} = \left(\frac{\gamma_L D v_m}{\mu_g} \right) \geq 1500 \\ 16/Re_{Lm} & \text{if } Re_{Lm} < 1500 \end{cases} \quad (6.2.44a)$$

FIGURE 6.2.22c Liquid holdup in annular flow regime ($E_d = 0.4$) (expanded Y scale) [4].

The pressure gradient due to friction in the bubbly flow regime is evaluated from

$$\left(\frac{dp}{dL}\right)_f = \frac{2f_{wLm} v_m (\gamma_g v_{sg} + \gamma_L v_{sL})}{D} \quad (6.2.44b)$$

and the gravitational pressure gradient

$$\left(\frac{dp}{dL}\right)_g = -g [H_L \gamma_L + (1 - H_L) \gamma_g] \sin \theta \quad (6.2.44c)$$

6.2.9 Correction for Acceleration Effects

The methods used in this section so far neglect the contribution of acceleration effects to the pressure gradient.

The acceleration pressure gradient in pipeline flow is due to the changes in the fluid properties through the pipe segment. These changes include expansion of the gas phase, expansion of the liquid phase, and the changes in quality (due to phase behavior).

To account for acceleration effects, the total pressure gradient should be calculated by:

$$\left(\frac{dp}{dL}\right)_t = \frac{\left(\frac{dp}{dL}\right)_f + \left(\frac{dp}{dL}\right)_g}{1 + A} \quad (6.2.45a)$$

where the parameter A is calculated by the method appropriate for each flow regime as follows:

FIGURE 6.2.22d Liquid holdup in annular flow regime ($E_d = 0.6$) (expanded Y scale) [4].

$$A + \left\{ \begin{array}{l} = 0 \quad \text{to neglect acceleration effects} \\ = (\gamma_g v_{sg} + \gamma_L v_{sL})^2 \left[X \left(\frac{dV_g}{dp} \right) + (1 - X) \left(\frac{dV_L}{dp} \right) \right] \\ \quad \text{for bubbly or slug flow regime} \\ = (\gamma_g v_{sg} + \gamma_L v_{sL})^2 \left[\frac{X^2}{(1 - H_L)} \left(\frac{dV_g}{dp} \right) + \frac{(1 - X)^2}{H_L} \left(\frac{dV_L}{dp} \right) \right] \\ \quad \text{for stratified or annular flow regime} \end{array} \right. \quad (6.2.45b)$$

d_g/d_p and d_L/d_p represent the change in specific volume for each phase with a change in pressure as evaluated from the fluid properties. The acceleration portion of the pressure gradient is calculated by

$$(dp/dL)_a = -A(dp/dL)_t \quad (6.2.45c)$$

6.2.10 Limitation

The described-above methods can be applied under the following conditions:

1. flow mass in pipe in constant (steady-state flow)
2. only the gas-liquid phase flow is considered; the liquid phase is treated as an oil

FIGURE 6.2.23 Liquid holdup in liquid slug [4].

3. the temperature is constant and equal to the average temperature

The above procedure presents the multiphase methods in a simplified form to permit quick prediction to be made. The same problems can be solved based on computer methods that are presented in Volumes 2 and 3 of the AGA project [1].

Example 6.2.1

Calculate the pressure gradient for a horizontal pipeline using the flow regime maps. The following data are given:

- $q_g = 40$ MMscf/d
- $q_0 = 40,000$ stb/d
- ID = 9 in.
- API(gravity) = 33°

TABLE 6.2.1 Drift-Flux Parameters for Slug Flow Regime

Pipe Inclination	C_o	k
$80^\circ < \theta \leq 90^\circ$	1.2	0.35
$0^\circ < \theta \leq 80^\circ$	1.3	0.50
$\theta = 0 \leq 1 < 1$	1.3	0
$-80^\circ < \theta < 0^\circ$	1.3	-0.5*
$-90^\circ < \theta < -80^\circ$	0.9	-0.6*

*If the slug velocity becomes small as a result of having the mixture superficial velocity, V_m , very small, then the slug velocity, V_s , should be limited to the mixture velocity.

Also calculate missing fluid properties using proper correlations.

$dp/dL = ?$

1. Stock-tank oil specific weight γ_{sto}

$$\begin{aligned} \gamma_{sto} &= 62.37[141.5/(131.5 + \text{°API})] \\ &= 62.37[141.5/(131.5 + 33)] \\ &= 53.65 \text{ lb/ft.}^3 \end{aligned}$$

2. Gas specific weight at std conditions γ_{gsc}

$$\begin{aligned} \gamma_{gsc} &= 0.0763\gamma_g = 0.0763(0.75) \\ &= 0.05723 \text{ lb/ft.}^3 \end{aligned}$$

3. Pipe flow area

$$A_p = (\pi/4)D^2 = \pi/4(9/12)^2 = 0.4418 \text{ ft.}^2$$

4. Calculate Z , μ_g , μ_o , and GOR at P_{avg} and T_{avg} . From Gas P-V-T Program (see Chapter 5) at $p = 2000$ psia

$$\begin{aligned} T &= 80^\circ\text{F} \\ Z &= 0.685 \\ \mu_g &= 0.0185 \text{ cp} \end{aligned}$$

$$\begin{aligned} P_{avg} &= 2000 \text{ psia} \\ T_{avg} &= 80^\circ\text{F} \\ \text{S.G.} &= 0.75 \text{ at } 14.7 \text{ psia and } T = 60^\circ\text{F} \\ R_p &= 990 \text{ scf/bbl} \end{aligned}$$

FIGURE 6.2.24 Dimensionless film thickness for well in slug flow [4].

From Oil P-V-T program at $p = 2000$ psia

$$\begin{aligned} T &= 80^\circ\text{F} \\ R_p &= 990 \text{ scf/bbl} \\ \mu_0 &= 2.96 \text{ cp} \end{aligned}$$

5. Calculate γ_g at p_{avg} , T_{avg} , and Z_{avg}

$$\begin{aligned} \gamma_g &= \frac{28.97(\gamma) p_{\text{avg}}}{Z_{\text{ave}} R T_{\text{avg}}} = \frac{28.97(0.75)(2000)}{10.685(10.73)(80 + 460)} \\ &= 10.95 \text{ lb/ft.}^3 \end{aligned}$$

6. Calculate vapor superficial velocity, v_{sg} from Equation 6.2.7

$$\begin{aligned} v_{\text{sg}} &= \frac{q_g \rho_{\text{gsc}}}{A_p \rho_g (24) 3600} = \frac{(40 \times 10^6) 0.05724}{0.4418 \times 10.95 \times 24 \times 3600} \\ &= 5.48 \text{ ft./s} \end{aligned}$$

7. Calculate liquid superficial velocity v_{sL}

$$v_{\text{sL}} = \frac{q_L}{A_p} = \frac{40,000(42)}{(7.481)24(3600)0.4418} = 5.88$$

8. Reynolds number and friction factor based on the superficial velocity, from Equation 6.2.9b

a) Liquid

$$\begin{aligned} R_{\text{eL}} &= \frac{\gamma_L D v_{\text{sL}}}{\mu_L g} = \frac{(53.56)(9/12)(5.88)}{(2.86)2.0886 \times 10^{-5}(32.2)} \\ &= 118,851.7 > 1500 \\ f_{\text{wLs}} &= \frac{0.046}{R_{\text{eL}}^{0.2}} = \frac{0.046}{(118,851.7)^{0.2}} = 4.44 \times 10^{-3} \end{aligned}$$

where 2.0886×10^{-5} is a unit conversion factor

b) Gas

$$\begin{aligned} R_{\text{eg}} &= \frac{\gamma_g D v_{\text{sg}}}{\mu_g g} = \frac{(10.95)(9/12)(5.48)}{(0.0187)(2.0886 \times 10^{-5})(32.2)} \\ &= 3,623,080 > 1500 \\ f_{\text{wgs}} &= \frac{0.046}{R_{\text{eg}}^{0.2}} = \frac{0.046}{(3,623,080)^{0.2}} = 2.24 \times 10^{-3} \end{aligned}$$

9. Martinelli parameter X from Equation 6.2.9a

$$\begin{aligned} X &= \left(\frac{2f_{\text{wLs}} \gamma_L v_{\text{sL}}^2 / D}{2f_{\text{wgs}} \gamma_g v_{\text{sg}}^2 / D} \right)^{0.5} \\ &= \left[\frac{4.44 \times 10^{-3} (53.65)(5.88)^2}{2.24 \times 10^{-3} (10.95)(5.48)^2} \right]^{0.5} \\ &= 3.3 \end{aligned}$$

10. Dimensionless inclination Y from Equation 6.2.12

$$Y = \frac{g(\gamma_L - \gamma_g) \sin \theta}{2f_{\text{wgs}} \gamma_g v_{\text{sg}}^2 / D}$$

since $\sin \theta = 0$ (horizontal pipe)

$$Y = 0$$

11. Calculate gas Froude number

$$\begin{aligned} F_g &= v_{\text{sg}} \left[\frac{\gamma_g}{(\gamma_L - \gamma_g) g D} \right]^{0.5} \\ &= 5.48 \left[\frac{10.95}{(53.65 - 10.95)32.2(9/12)} \right]^{0.5} = 0.56 \end{aligned}$$

12. Select flow regime for $X = 3.3$ and $Y = 0$. Figure 6.2.10a indicates slug flow.

13. Liquid holdup in the liquid slug, E_{LS} , from Equation 6.2.7e

$$v_m = v_{\text{sL}} + v_{\text{sg}} = 5.88 + 5.48 = 11.36 \text{ ft./s}$$

from Equation 6.2.35

$$E_{\text{LS}} = \frac{1}{1 + \left(\frac{v_m}{28.4} \right)^{1.39}} = \frac{1}{1 + \left(\frac{11.36}{28.4} \right)^{1.39}} = 0.781$$

14. Slug velocity v_s from Equation 6.2.36

$$v_s = C_0 v_m + K \left[\frac{gD(\gamma_L - \gamma_g)}{\gamma_L} \right]^{0.5}$$

where $C_0 = 1.3$ and $K = 0$ for $\theta = 0^\circ$

$$v_s = 1.3(11.36) + 0 = 14.768 \text{ ft./s}$$

15. Liquid holdup H_L , Equation 6.2.37,

$$\begin{aligned} H_L &= 1 - \frac{v_{\text{sg}} + (1 - E_{\text{LS}})(v_s - v_m)}{v_s} \\ &= 1 - \frac{5.48 + (1 - 0.781)(14.768 - 11.36)}{14.768} \\ &= 0.578 \end{aligned}$$

16. For $\theta = 0^\circ$, calculate average liquid velocity v_L

$$v_L = \frac{v_{\text{sL}}}{H_L} = \frac{5.88}{0.578} = 10.17 \text{ ft./s}$$

17. Calculate R_{eL} and f_{wL} from Equation 6.2.39b

$$\begin{aligned} R_{\text{eL}} &= \frac{\gamma_L D v_L}{\mu_L g} = \frac{53.65(9/12)(10.17)}{12.96(32.2)(2.0886 \times 10^{-5})} \\ &= 205,565 > 1500 \\ f_{\text{wL}} &= \frac{0.046}{R_{\text{eL}}^{0.2}} = \frac{0.046}{(205,564)^{0.2}} = 3.983 \times 10^{-3} \end{aligned}$$

18. Average slug density γ_{Ls} from Equation 6.2.39c

$$\begin{aligned}\gamma_{Ls} &= E_{Ls}\gamma_L + (1 - E_{Ls})\gamma_g \\ &= 0.781(53.65) + (1 - 0.7)(10.95) \\ &= 44.3 \text{ lb/ft.}^3\end{aligned}$$

19. The fractional pressure gradient from Equation 6.2.39a

$$\begin{aligned}\left(\frac{dp}{dL}\right)_f &= -\left(\frac{2f_L\gamma_{Ls}v_L^2}{Dg}\right) \\ &= -\frac{2(3.983 \times 10^{-3})(44.3)(10.17)^2}{(9/12)(32.2)} \\ &= -1.51132 \text{ lb/ft.}^3\end{aligned}$$

20. The total pressure gradient, since $\theta = 0^\circ$

$$\left(\frac{dp}{dL}\right)_{\text{gravitational}} = 0$$

and

$$\left(\frac{dp}{dL}\right)_{\text{total}} = \left(\frac{dp}{dL}\right)_f = 1.51132 \text{ lb/ft.}^3$$

or

$$\left(\frac{dp}{dL}\right)_{\text{total}} = -1.0495 \times 10^{-2} \text{ psi/ft.}$$

6.2.11 Empirical Methods

Many empirical correlations have been developed for predicting two-phase flowing pressure gradients, which differ in the manner used to calculate three components of the total pressure gradient (see Equation 6.2.6). Some of these correlations are described below. The range of applicability of these multiphase flow models is dependent on several factors such as tubing size or diameter, oil gravity, gas-liquid ratio and, two-phase flow with or without water-cut. The effect of each of these factors on estimating the pressure profile in a well is discussed for all empirical methods considered [6,7]. A reasonably good performance of the multiphase flow models, within the context of this section, is considered to have a relative error (between the measured and predicted values of the pressure profile) less than or equal to 20%.

6.2.12 The Duns-Ros Method [20,21]

To better understand the initial concept of the Duns-Ros method, Figure 6.2.25 shows a generalized flow diagram.

The Dun-Ros correlation is developed for vertical flow of gas and liquid mixtures in wells. This correlation is valid for a wide range of oil and gas mixtures with varying water-cuts and flow regimes. Although the correlation is intended for use with “dry” oil/gas mixtures, it can also be applicable to wet mixtures with a suitable correction. For water contents less than 10%, the Duns-Ros correlation (with a correction factor) has been reported to work well in the bubble, slug (plug), and froth regions. Figure 6.2.26 shows that pressure gradient and holdup also depend significantly on superficial gas velocity.

At low gas flowrates, the pipe essentially is full of liquid since the gas bubbles are small. Holdup is approximately equal to unity. At liquid rates less than 1.3 ft/s (0.4 m/s), increased gas rate causes the number and size of the bubbles to increase. Ultimately, they combine into plugs that become unstable and collapse at still higher gas concentrations to form slugs. At gas rates greater than 49 ft/s (15 m/s), with the same liquid rate, mist flow is initiated, and gas is in the continuous phase with liquid drops dispersed in it. When the liquid velocity is over 5.3 ft/s (16 m/s), the flow patterns are not as observable. As gas flow increases, no plug flow is observed; flow is turbulent and frothy until some degree of segregation takes place at higher rates. For this degree of liquid loading, mist flow does not occur until gas velocity reaches at least 164 ft/s (50 m/s).

Figure 6.2.27 graphically outlines the flow regime areas. Duns and Ros mathematically defined these areas as functions of the following dimensionless numbers:

$$N_{vg} = v_{sg}A(\gamma_L/\sigma)^{0.25} \quad \text{gas velocity number} \quad (6.2.46)$$

$$N_{vL} = v_{sL}A(\gamma_L/\sigma)^{0.25} \quad \text{liquid velocity number} \quad (6.2.47)$$

$$N_d = dB(\gamma_L/\sigma)^{0.5} \quad \text{diameter number} \quad (6.2.48)$$

$$N_{L\mu} = N_L = \mu_L C(1/\gamma_L \sigma^3)^{0.25} \quad \text{liquid velocity number} \quad (6.2.49)$$

Any consistent units system may be used, for example,

	English	Metric
ρ_L (liquid density)	slugs/ft. ³	kg/m ³
d (diameter of pipe)	ft	M
σ (liquid surface tension)	dyn/cm	dyn/cm
μ_L (liquid viscosity)	cp	cp

Equations contain a “g” term that was included into the mist conversion factors A, B, and C.

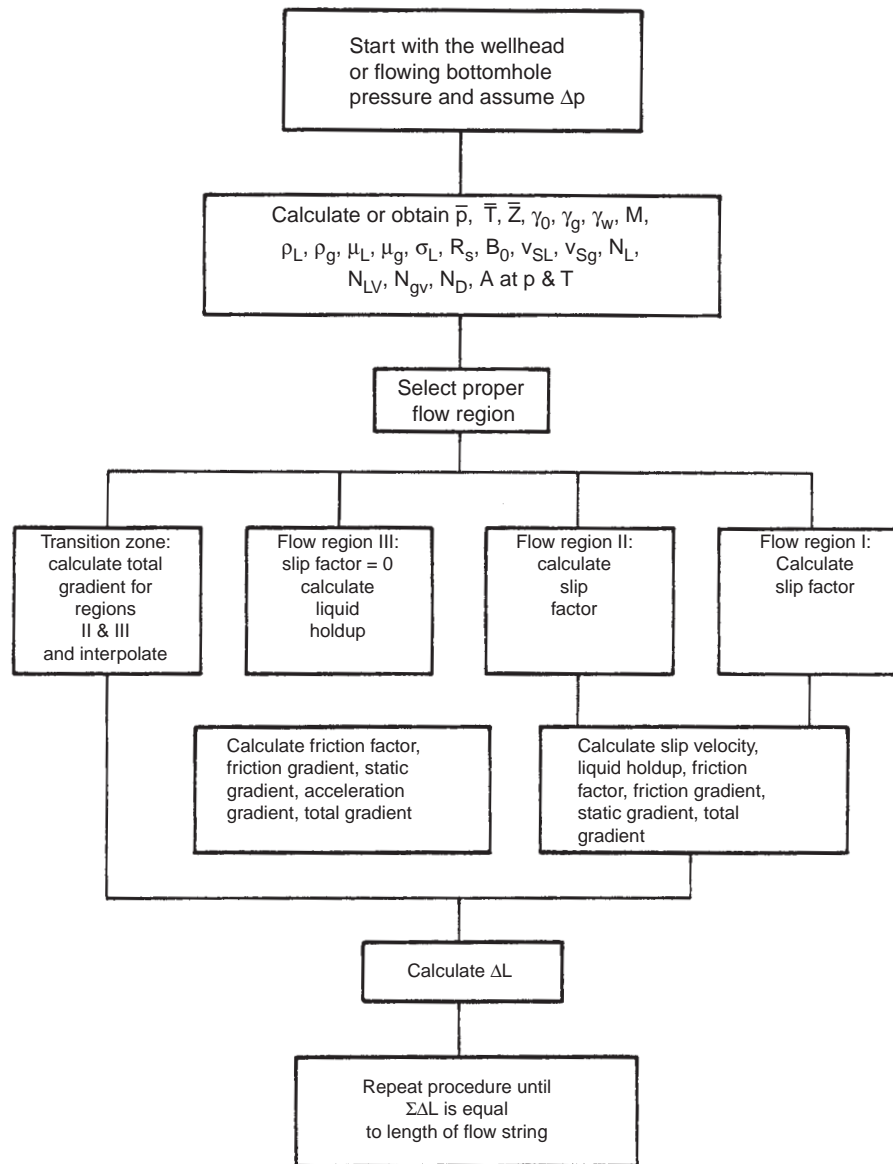

FIGURE 6.2.25 Flow diagram for the Duns-Ros method [1].

	English	Metric
A	1.938	3.193
B	120.9	99.03
C	0.1573	0.3146

At high liquid rates, the pressure gradient varied significantly with the gas rate. The various flow regions were divided into three main regions depending on the amount of gas present.

- Region I. The liquid phase is continuous and bubble flow, plug flow, and part of the froth-flow regime exists.

- Region II. In this region the phases of liquid and gas alternate. The region thus covers slug flow and the remainder of the froth flow regime.
- Region III. The gas is in a continuous phase and the mist-flow regime exists.

The different nature of these three main regions necessitates separate correlations for friction and holdup for each region; therefore in principle, six different correlations are to be expected. The identification of flow region is a function of N_{LV} , N_{gv} , L_1 , L_2 , and N_d . The regions of validity of the correlations are plotted and presented in Figure 6.2.28 as a function of the liquid velocity number N_{LV} and gas-velocity number N_{gv} . Because N_{LV} and N_{gv} are directly related to liquid flowrate and gas flowrate, respectively, it

FIGURE 6.2.26 Example of two-phase flow in vertical pipe [5].

FIGURE 6.2.27 Region of occurrence of different flow regimes [5].

FIGURE 6.2.28 Region of validity of Duns-Ros correlation [5].

FIGURE 6.2.29 L factors versus diameter number, N_d [5].

can be seen from Figure 6.2.28 that a change in one or both of these rates affects the region of flow.

Duns and Ros suggested the following limits for various flow regions:

- Region I: $0 \leq N_{gv} \leq (L_1 + L_2 N_{LV})$
- Region II: $(L_1 + L_2 N_{LV}) < N_{gv}, (50 + 36 N_{LV})$
- Region III: $N_{gv} > (75 + 84 N_{LV}^{0.75})$

L_1 and L_2 are functions of N_d , and their relationships are presented in Figure 6.2.29.

It was also found that the liquid holdup is related to the slip velocity, v_s , as follows:

$$v_s = v_{sg}/(1 - H_L) - v_{sL}/H_L \quad (6.2.50)$$

where v_{sg} , v_{sL} are average gas and average liquid superficial velocities, respectively.

The slip velocity was expressed in dimensionless form as

$$S = v_s(\gamma_L/g\sigma)^{0.25}$$

As soon as S has been determined, v_s , H_L , and, finally, $(dp/dL)_{st}$ can be determined.

Different formulas are used for calculating S in each of the three flow regions. These formulas, which are functions of the four dimensionless numbers, N_{LV} , N_{gv} , N_d , N_L , are found in the example below and make use of Figures 6.2.30 and 6.2.31.

Example 6.2.2

Show stepwise procedure for calculation of the pressure traverse by the Duns-Ros method. Apply this procedure to solve the following problem.

Determine the distance ΔL between two pressure points starting surface conditions if $\Delta p = 500$ psig.

- Given that tubing size $d = 2$ in. = 1.995 in. ID
- wellhead pressure 1455 psig = p_1
- $p_L = p_1 + 500 = 1955$ psig
- $p_{bar} = 14.7$ psia
- $T_1 = 75^\circ F$
- $T_2 = 105^\circ F$
- S.G.g = 0.752
- S.G.o = 54° API
- $q_{oil} = 480$ bpd (std) $q_{water} = 0$ bpd (std)

FIGURE 6.2.30 F_5, F_6, F_7 against viscosity number, N_L [5].

FIGURE 6.2.31 $F_1, F_2, F_3,$ and F_4 versus viscosity number, N_L [5].

$$q_L = q_w + q_o$$

$$\mu_g = 0.020 \text{ cp (constant value)}$$

$$\sigma_0 = 28 \text{ dyn/cm}$$

$$\text{GLR} = \text{GOR} = 3393 \text{ scf/bbl}$$

Choose a commercial steel pipe.

Solutions

- Determine the specific gravity of the oil:

$$SG_0 = \frac{141.5}{131.5 + ^\circ\text{API}} = \frac{141.5}{131.5 + 54} = 0.763$$

- Find the weight associated with 1 bbl of stock-tank liquid:

$$\begin{aligned} m &= SG_0(350) \left(\frac{1}{1 + \text{WOR}} \right) \\ &+ SG_0(350) \left(\frac{\text{WOR}}{1 + \text{WOR}} \right) \\ &+ (0.0764)(\text{GLR})(SG_g) \\ &= 0.763(350) \left(\frac{1}{1 + 0} \right) + 0.763(350) \left(\frac{1}{1 + 0} \right) \\ &+ 0.0764(3393)(0.752) \\ &= 462 \text{ lb/stb of oil} \end{aligned}$$

3. Determine the specific weight of the liquid phase:

$$\begin{aligned}\gamma_L &= 62.4 \left[SG_o \left(\frac{1}{1 + WOR} \right) + SG_w \left(\frac{WOR}{1 + WOR} \right) \right] \\ &= 62.4 \left[0.763 \left(\frac{1}{1 + 0} \right) + SG_w \left(\frac{1}{1 + 0} \right) \right] \\ &= 47.6 \text{ lb/ft.}^3\end{aligned}$$

4. Find the average pressure:

$$\begin{aligned}p_{avg} &= \frac{p_1 + p_2}{2} + p_{bar} = \frac{1455 + 1955}{2} + 14.7 \\ &= 1719.7 \text{ psia}\end{aligned}$$

5. Find the average temperature:

$$T_{avg} = \frac{T_1 + T_2}{2} = \frac{75 + 105}{2} = 90^\circ\text{F} = 550^\circ\text{R}$$

6. Find Z_{avg} for gas phase

$$\begin{aligned}Z_{avg} &= f(T_r, p_r) \\ &= 0.72 \\ T_r &= T/T_{pc} = 550/394 = 1.4 \\ p_r &= 1719.7/660 = 26\end{aligned}$$

7. Find the average specific weight of the gas phase:

$$\begin{aligned}\gamma_g &= SG_g(0.0764) \left(\frac{p}{14.7} \right) \left(\frac{520}{5} \right) \left(\frac{1}{Z} \right) \\ &= SG_g(0.0764)1/B_g \\ &= 0.752(0.0764) \frac{1719.7}{14.7} \frac{520}{550} \frac{1}{0.72} = 8823 \text{ lb/ft.}^3\end{aligned}$$

8. Find R_s at T_{avg} and p_{avg} (see Chapter 5)

$$\begin{aligned}R_s &= SG_g \left(\frac{p}{18} \times \frac{10^{0.0125(^{\circ}\text{API})}}{10^{0.00091(T)}} \right)^{1.2048} \\ T_{avg} &= 90^\circ\text{F}, \quad p_{avg} = 1719.7 \text{ psia} \\ R_s &= 0.752 \left(\frac{1719.7}{28} \times \frac{10^{0.0125(54)}}{10^{0.00091(90)}} \right)^{1.2048} \\ &= 947.3 \text{ scf/stb}\end{aligned}$$

9. Calculate the average viscosity of the oil from correlations (see Chapter 5)

$$\begin{aligned}\mu_{od} &= 10^x - 1.0 \\ X &= T^{-1.163} \exp(6.9824 - 0.04658^{\circ}\text{API}) \\ X &= 90^{-1.163} \exp(6.9824 - 0.04658 \times 54) = 0.4646 \\ \mu_{od} &= 1.915 \text{ cP} \\ \mu_{os} &= A\mu_{od}^B \\ A &= 10.715(R_s + 100)^{-0.515} \\ &= 10.715(947.3 + 100)^{-0.515}\end{aligned}$$

$$A = 0.2983$$

$$B = 5.44(R_s + 150)^{-0.338} = 5.44(947.3 + 150)^{-0.338}$$

$$B = 0.5105$$

$$\mu_{os} = 0.2983 \times 1.915^{0.5105} = 0.416 \text{ cp}$$

10. Determine the average water viscosity. No water is in the example.

11. Calculate the liquid mixture viscosity:

$$\begin{aligned}\mu_L &= \mu_o \left(\frac{1}{1 + WOR} \right) + \mu_w \left(\frac{WOR}{1 + WOR} \right) = \mu_o \\ &= 0.416 \text{ cp}\end{aligned}$$

12. Find the liquid mixture surface tension:

$$\begin{aligned}\sigma_L &= \sigma_o \left(\frac{1}{1 + WOR} \right) + \mu_w \left(\frac{WOR}{1 + WOR} \right) = \sigma_o \\ &= 28 \text{ dyn/cm}\end{aligned}$$

13. Find B_o at p_{avg} and T_{avg} .

$$\begin{aligned}B_o &= 0.972 + 0.00147F^{1.175} \\ F &= R_s \left(\frac{\gamma_g}{\gamma_o} \right)^{0.5} + 1.25\% [T(^{\circ}\text{F})] \\ &= 947.3 \left(\frac{0.752}{0.763} \right)^{0.5} + 1.25(90) = 1052.9 \\ B_o &= 1.495 \text{ bbl/stb}\end{aligned}$$

14. Find the turbine flow area A_p :

$$A_p = \frac{\pi d^2}{4} = \frac{\pi}{4} + \left(\frac{1.995}{12} \right)^2 = 0.0217 \text{ ft.}^2$$

15. Find the liquid viscosity number:

$$N_L = 0.1573 \times (0.5) \left(\frac{1}{(28)^3 47.6} \right)^{0.25} = 2.05 \times 10^{-3}$$

16. Find v_{sL} (assume $B_w = 1.0$):

$$\begin{aligned}v_{sL} &= \frac{5.61q_L}{86400A_p} \left[B_o \left(\frac{1}{1 + WOR} \right) \right. \\ &\quad \left. + B_w \left(\frac{WOR}{1 + WOR} \right) \right] \\ &= \frac{5.61(480)}{86400(0.0217)} \left[1.495(1.0) + 1.0 \left(\frac{0}{1 + 0} \right) \right] \\ &= 2.147 \text{ ft./s.}\end{aligned}$$

17. Find the liquid velocity number:

$$\begin{aligned}N_{LV} &= 1.938 v_{sL} \left(\frac{\gamma_L}{\sigma_L} \right)^{1/4} = 1.938(2.147) \left(\frac{47.6}{28} \right)^{1/4} \\ &= 4.75\end{aligned}$$

18. Find the superficial gas velocity:

$$\begin{aligned}
 v_{sg} &= \frac{q_L \left[\text{GLR} - R_s \left(\frac{1}{1 + \text{WOR}} \right) \right]}{86,400 A_p} \left(\frac{14.7}{p_{avg}} \right) \\
 &\quad \times \left(\frac{T_{avg}}{520} \right) \left(\frac{Z_{avg}}{1} \right) \\
 &= \frac{q_L \left[\text{GLR} - R_s \left(\frac{1}{1 + \text{WOR}} \right) \right] B_g}{86,400 A_p} \\
 &= \frac{480 \left[3393 - 947.3 \left(\frac{1}{1 + 0} \right) \right] 14.7 \times 550(0.72)}{84,400(0.0217) \quad 1719.5 \times 520} \\
 &= 4.08 \text{ ft./s}
 \end{aligned}$$

19. Find the gas velocity number:

$$\begin{aligned}
 N_{gv} &= 1.938 v_{sg} \left(\frac{\gamma_L}{\sigma_L} \right)^{1/4} = 1.938 \times 4.08 \left(\frac{47.6}{28} \right)^{1/4} \\
 &= 9.03
 \end{aligned}$$

20. Find the pipe diameter number:

$$\begin{aligned}
 N_d &= 120.9d \left(\frac{\gamma_L}{\sigma_L} \right)^{0.5} = 120.9 \left(\frac{1.995}{12} \right) \left(\frac{47.6}{28} \right)^{0.5} \\
 &= 26.2
 \end{aligned}$$

21. Select the proper flow regime from Figure 6.2.3:

$$\begin{aligned}
 N_{gv} &= 9.03 \\
 N_{Lv} &= 4.75
 \end{aligned}$$

These numbers fall in Region II; see Figure 6.2.3.

22. Determine the proper slip factor depending upon the region found in step 21.

- a) For Region I: determine the slip factor determination. The slip factor is found by the following formula:

$$S = F_1 + F_2 N_{Lv} + F'_3 \left(\frac{N_{gv}}{1 + N_{Lv}} \right)^2$$

F_1 and F_2 are found in Figure 6.2.31.

$F'_3 = F_3 - F_4/N_d$ where F_3 and F_4 are found in Figure 6.2.31. For annular flow N_d is based on the wetted perimeter; thus, $d = (d_c + d_t)$. Region I extends from zero N_{Lv} and N_{gv} up to $N_{gv} = L_1 + L_2 N_{Lv}$, where L_1 and L_2 can be found in Figure 6.2.29.

- b) For Region II:

$$S = (1 + F_5) \frac{(N_{gv})^{0.982} + F'_6}{(1 + F_7 N_{Lv})^2}$$

F_5 , F_6 and F_7 can be found in Figure 6.2.30 where $F_6 = 0.029 N_d + F_6$. Region II extends from the upper limit of Region I to the transition zone to mist flow given by $N_{gv} = 50 + 36 N_{Lv}$.

- c) For Region III (mist flow):

$$S = 0$$

$$\text{Therefore, } H_L = \frac{1}{1 + v_{sg}/v_{sL}}$$

This is valid for $N_{gv} > 75 + 84 N_{Lv}^{0.75}$. Calculations for Region II from Figure 6.2.5 if $N_L = 2.05 \times 10^{-3}$, then

$$F_5 = 0.218, \quad F_6 = 0.58, \quad F_7 = 0.12$$

$$\begin{aligned}
 F'_6 &= 0.029 N_d + 0.58 = 0.029 \times (2.62) + 0.58 \\
 &= 1.34
 \end{aligned}$$

$$S = (1 + 0.20) \frac{9.03^{0.982} + 1.34}{[1 + (0.12 \times 4.751)]^2} = 4.88$$

23. Determine the slip velocity if in Region I or II:

$$v_s = \frac{S}{1.938(\gamma_L/\sigma_L)^{0.5}}$$

It is Region II; hence

$$v_s = \frac{4.88}{1.938(47.61/28)^{0.5}} = 1.933$$

24. Determine the liquid holdup:

$$\begin{aligned}
 H_L &= \frac{v_s - v_{sg} - v_{sL} + [(v_s - v_{sg} - v_{sL})^2 + 4v_s v_{sL}]^{0.5}}{2v_s} \\
 &= \frac{(1.933 - 4.08 - 2.147)}{2 \times 1.933} \\
 &\quad + \frac{[(1.933 - 4.08 - 2.147)^2 + 4(1.933)(2.147)]^{0.5}}{(2 \times 1.933)} \\
 &= 0.4204 = 0.42
 \end{aligned}$$

This value can be checked

$$v_s = \frac{v_{sg}}{1 - H_L} - \frac{v_{sL}}{H_L} = \frac{4.08}{1 - 0.42} - \frac{2.147}{0.42} = 1.923$$

25. Determine the liquid Reynolds number:

$$N_{RE} = \frac{1488 \gamma_L v_{sL} d}{\mu_L}$$

$$(N_{Re})_L = \frac{1488 \times 47.6 \times 2.147 \times 0.16625}{0.416} = 60,773$$

26. Determine the friction gradient according to the flow region.

a) For Region I and II

$$G_{fr} = 2f_w \frac{N_{Lv}(N_{Lv} + N_{gv})}{N_d}$$

where $f_w = (f_1) \frac{f_2}{f_3}$

f_1 is found in Figure 6.2.32 and f_2 is found in Figure 6.2.33

The abscissa must be determined in Figure 6.2.33 and is $f_1 RN_d^{2/3}$

where $R = \frac{v_{sg}}{v_{sL}}$

$$f_3 = 1 + f_1 (R/50)^{0.5}$$

The friction factor f_w is valid in Regions I and II and covers heading also. It is good from zero N_{Lv} and N_{gv} up to the limit given by $N_{gv} = 50 + 36 N_{Lv}$.

b) For Region III:

In mist flow where $N_{gv} > 75 + 84N_{Lv}^{0.75}$

$$G_{fr} = 2f_w N_\rho \frac{(N_{gv})^2}{N_d}$$

where $N_\rho = \rho_g / \rho_L$

In Region III f_w is taken as f_1 and may be taken from Figure 6.2.32. For $\epsilon > 0.05d$, the value of f_1 is calculated by

$$f_1 = \frac{1}{[4 \log_{10}(0.027\epsilon/d)]^2} + 0.067(\epsilon/d)^{1.73}$$

For $\epsilon > 0.05d$, the value of $d - \epsilon$ should be substituted for d throughout the friction gradient calculation, and also this substitution should be made:

$$v_{sg} = \frac{v_{sg} d^2}{(d - \epsilon)^2}$$

It is Region II; hence, calculate f_1 , f_2 , and f_3 such that

$$f_w = (f_1) \frac{f_2}{f_3}$$

From Figure 6.2.32 read f_1 , but first determine a value for ϵ/d . If the value for ϵ is not known, a good value to use is 0.00015 ft, which is an average value given for commercial steel.

$$\frac{\epsilon}{d} = \frac{0.00015(12)}{1.995} = 9.02 \times 10^{-4}$$

FIGURE 6.2.32 Fanning friction factor f_f versus Reynolds number [5].

FIGURE 6.2.33 Bubble friction correction [5].

For given Reynolds number (60,773) and ϵ/d

$$f_1 = 0.005$$

From Figure 6.2.33

$$\text{where } f_1 \left(\frac{v_{sg}}{v_{sL}} \right) N_d^{2/3} = 0.005 \left(\frac{4.08}{2.147} \right) 26.2^{2/3} = 0.0839$$

$$f_2 = 1.01$$

$$f_3 = 1 + f_1 \left(\frac{4.08}{2.147 \times 50} \right)^{0.5} = 1 + 0.005(0.038)^{0.5} = 1.001$$

$$f_w = 0.005 \left(\frac{1.01}{1.001} \right) = 0.00505$$

calculate friction gradient G_{fr} :

$$G_{fr} = 2(0.00505) \frac{4.75(4.75 + 9.03)}{26.2} = 0.0252$$

27. Determine the static gradient:

$$G_{st} = H_L + (1 - H_L) \frac{\gamma_g}{\gamma_L} = 0.42 + (1 - 0.42) \frac{8.823}{47.6} = 0.5275 \text{ (dimensionless)}$$

28. Determine the total pressure gradient.

a) For Regions I and II:

$$G = G_{st} + G_{fr}$$

b) For Region III (accounting for accelerations):

$$G = \frac{G_{st} + G_{fr}}{1 - (\gamma_L v_{sL} + \gamma_g v_{sg}) / (\gamma v_{sg})} = G_{st} + G_{fr} = 0.5275 + 0.0252 = 0.5527$$

29. Convert to gradient in psi/ft:

$$\begin{aligned} \frac{dp}{dL_{st}} &= \frac{G_{st} \gamma_L}{144}, & \frac{dp}{dL_{(fr)}} &= \frac{G_{fr} \gamma_L}{144}, & \text{or } \frac{dp}{dL_{total}} &= \frac{G \gamma_L}{144} \\ \frac{dp}{dL} &= \frac{0.5527(47.6)}{144} = 0.1827 \text{ psi/ft.} \end{aligned}$$

30. Determine distance ΔL :

$$\Delta L = \frac{(1955 - 1455) \text{ psi}}{0.1827 \text{ psi/ft.}} = 2737 \text{ ft.}$$

If water flows together with oil, it is recommended that the calculations be made using the average oil-water mixture properties.

The pressure profile prediction performance of the Duns-Ros method is outlined below in relation to the several flow variables considered [6]:

- **Tubing Size:** In general, the pressure drop is seen to be over predicted for a range of tubing diameters between 1 and 3 in.
- **Oil Gravity:** Good predictions of the pressure profile are obtained for a broad range of oil gravities (13 to 56 °API).
- **Gas-Liquid Ratio (GLR):** The pressure drop is over predicted for a wide range of GLR. The errors become especially large (>20%) for GLR greater than 5000.
- **Water-Cut:** The Duns-Ros model is not applicable for multiphase flow mixtures of oil, water, and gas. However, the correlation can be used with a suitable correction factor as mentioned earlier.

6.2.13 The Orkiszewski Method [8,9]

This method is recognized for four types of flow pattern, and separate correlations are prepared to establish the slippage velocity and friction for each. This correlation is limited to two-phase pressure drops in a vertical pipe and is an

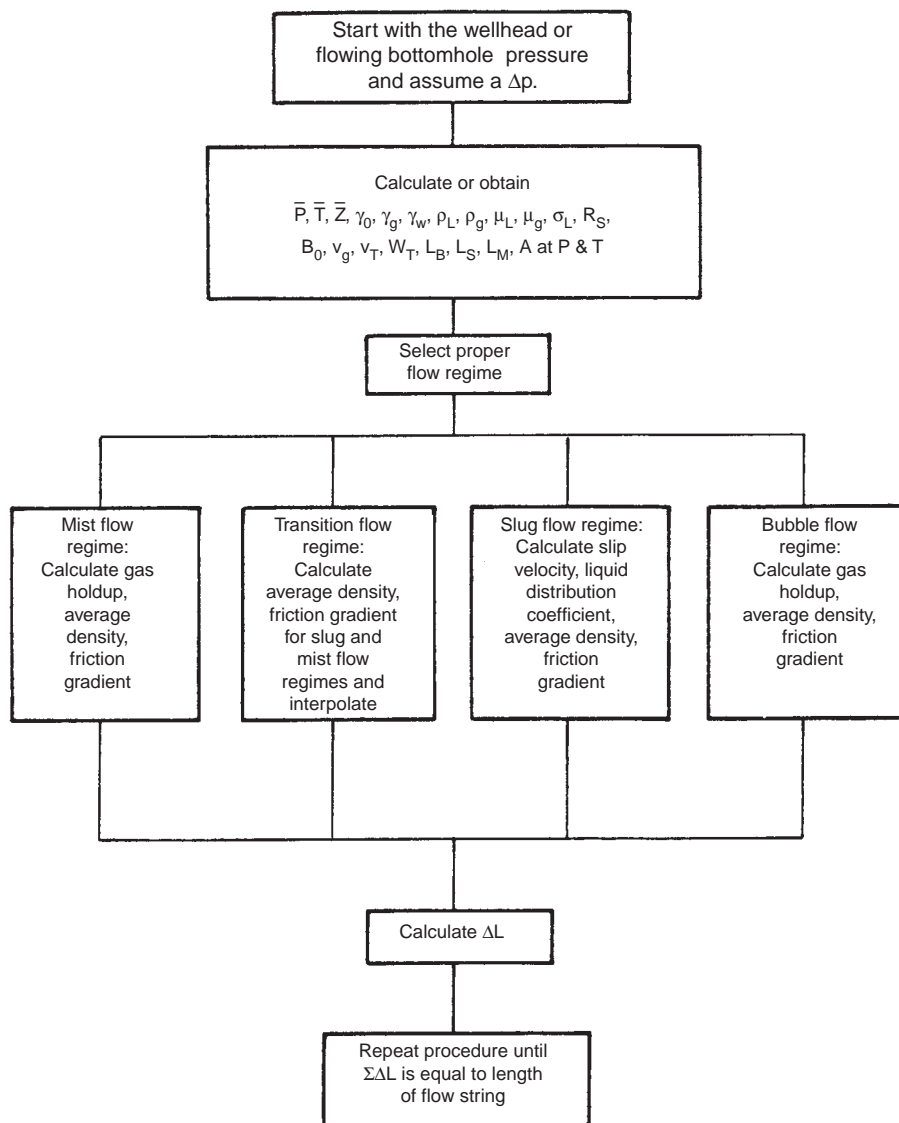

FIGURE 6.2.34 Flow diagram for the Orkiszewski method [1,6].

extension of Griffith and Wallis [10] work. The correlation is valid for different flow regimes such as the bubble, slug, transition, and annular mist and is a composite of several methods as shown below:

Method	Flow Regime
Griffith	Bubble
Griffith & Wallis	Slug (density term)
Orkiszewski	Slug (friction term)
Duns & Ros	Transition
Duns & Ros	Annular Mist

It should be noted that the liquid distribution coefficient (hold-up) is evaluated using the data from the Hagedorn and Brown model (discussed later). The correlation is applicable to high-velocity flow range and gas condensate wells in addition to oil wells and has proven accuracy. To make calculations, a computer is preferable, Figure 6.2.34 shows a generalized flow diagram of this method. After assuming a pressure difference and calculating the various required properties, a flow region is selected. Depending on the flow region, the pressure loss calculations—which, in general, include friction and holdup—are made. The vertical length corresponding to the pressure difference is then determined. The flow regime is found by testing the following limits:

The foregoing new variables are defined as follows:

Regime	Limits of Boundary Lines, L
Bubble	$q_g/(q_g + q_l) < L_B$ or $v_{sg}/v_m < L_B$
Slug	$q_g/(q_g + q_l) > L_B$, $N_{vg} < L_s$
Transition	$L_m > N_{vg} > L_s$
Mist	$N_{vg} > L_m$

Bubble:

$$L_b = 1.071 - (0.2218v_m^2/d) \quad \text{but} \quad \geq 0.13 \quad (6.2.51)$$

Slug:

$$L_s = 50 + 36N_{vg}q_L/q_g \text{ (or } 36N_{vg}v_{sl}/v_{sg}) \quad (6.2.52)$$

Mist:

$$L_m = 75 + 84(N_{vg}q_L/q_g)^{0.75} \left[\text{or } 84(N_{vg}v_{sl}/v_{sg})^{0.75} \right]$$

where v_t = total fluid velocity ($v_{sl} + v_{sg} = v_m$)

q_t = volumetric total flow ($q_L + q_g$)

N_{vg} = dimensionless velocity influence number
 $= v_{sg}(\gamma_L/g\sigma)^{0.25}$

6.2.13.1 Bubble Flow

The γ_m required knowledge of the holdup H_L , such that

$$\gamma_m = \gamma_L H_L + \gamma_g (1 - H_L)$$

In this, the H_L is calculated as follows:

$$H_L = 1 - 0.5 \left[1 + v_m/v_s - (1 + v_m/v_s)^2 - 4v_{sg}/v_s \right]^{0.5} \quad (6.2.53)$$

where v_s = slip velocity = 0.8 ft./s (0.244 m/s)

Therefore, the friction gradient is

$$dp/dL = 2f\gamma_L v_L^2 / (H_L g_c d) \quad (6.2.54)$$

where f = Fanning friction factor obtained from [Figure 6.2.32](#)

$$R_e = dv_{sL}\gamma_L/\mu_L \quad (6.2.55)$$

The elevation gradient is

$$dp/dL = \gamma_m F_e \quad (6.2.56)$$

and the acceleration gradient is negligible. However, Orkiszewski's equation for all these effects is

$$\frac{dp}{dL} = \frac{\gamma_m F_e + 2f\gamma_L v_{sL}^2 / (H_L g_c d)}{1 - m_t q_g / (A_p^2 p_{avg} g_c)} \quad (6.2.57)$$

which is essentially the same as adding the three gradients.

6.2.13.2 Slug Flow

Slug flow specific weight γ_s is difficult to know and difficult to assume. An attempt was made such that

$$\gamma_s = \frac{m_t + \gamma_L v_s A_p}{q_t + v_s A_p} + \delta \gamma_L \quad (6.2.58a)$$

in a slightly different term arrangement using velocities, or

$$\gamma_s = \frac{\gamma_L (v_{sL} + v_s) + \gamma_g v_{sg}}{v_m + v_s} + \delta \gamma_L \quad (6.2.58b)$$

where m_t = total mass/s

A_p = area of pipe

v_s = correlation factor, $C_1 C_2 (gd)^{0.5}$, slip velocity

δ = liquid distribution coefficient (6.2.59)

C_1 and C_2 are functions of a Reynolds number as follows:

$$C_1 \propto (f) dv_s \gamma_L / \mu_L, \text{ or } Re_b \text{ (Figure 6.2.35)}$$

and

$$C_2 \propto (f) Re_b \quad \text{and} \quad Re_n = dv_t \gamma_L / \mu_L \text{ (Figure 6.2.36)}$$

Since v_s is a dependent variable, it must be found by iteration. A value of v_s is assumed, Re_b is calculated, and C_1 and C_2 are determined. If the calculated value of v_s does not agree with the assumed value, try again. [A good initial try, $v_s = 0.5(gd)^{0.5}$.] For details see Example 6.2.3. Now determine δ as follows:

(a) If $v_m < 10$ (continuous phase is water)

$$\delta = [0.013 \log \mu_L / d^{1.38}] - 0.681 + 0.232 \log v_m - 0.428 \log d \quad (6.2.60a)$$

(b) If $v_m > 10$ (continuous phase is oil)

$$\delta = [0.0127 \log(\mu_L + 1) / d^{1.415}] - 0.284 + 0.167 \log v_m + 0.113 \log d \quad (6.2.60b)$$

(c) If $v_m > 10$ (continuous phase is water)

$$\delta = [(0.045 \log \mu_L) / d^{0.799}] - 0.709 - 0.162 \log v_m - 0.888 \log d \quad (6.2.60c)$$

(d) If $v_m > 10$ (continuous phase is oil) (μ_L in cp)

$$\delta = [0.0274 \log(\mu_L + 1) / d^{1.371}] + 0.161 + 0.569 \log d + x \quad (6.2.60d)$$

where

$$x = -\log v_m [(0.01 \log(\mu_L + 1) / d^{1.571}) + 0.397 + 0.63 \log d]$$

These constraints apply to δ :

$$\text{If } v_m < 10, \delta \geq -0.065 v_m$$

$$\text{If } v_m > 10, \delta \geq (-v_x)(1 - \gamma_s/\gamma_L)/(v_m + v_x)$$

FIGURE 6.2.35 C₂ constant versus bubble Reynold’s number [7].

FIGURE 6.2.36 Friction factor [11].

Finally, the friction gradient term is

$$\left(\frac{dp}{dL}\right)_f = \frac{2f_f \gamma_L v_m^2}{gd} \left(\frac{v_{sL} + v_s}{v_m + v_s} + \delta\right) \quad (6.2.61)$$

where f_f is obtained from Figure 6.2.32 using the following:

$$Re = dv_m \gamma_L / \mu_L \quad (6.2.62)$$

Again, the total pressure gradient includes the elevation (static), friction, and acceleration (negligible) components.

6.2.13.3 Transition Flow

Orkiszewski used linear interpolation between slug and mist.

6.2.13.4 Mist-Flow

The Duns-Ros method is used.

Example 6.2.3

Apply Orkiszewski method to solve Example 6.2.2 with the pipe diameter $d = 2$ in.

1. Select the starting point as the 1455 psig pressure.

2. The temperature at each point of pressure is given as 75°F at 1455 psig and 105°F at 1955 psig.
3. Δp is equal to 500 psig
4. It is not necessary to assume depth increment since the temperature at 1955 psia is known.
5. The average temperature of the increment is $(105 + 75)/2 = 90^\circ\text{F}$
6. The following calculations are made in order to complete step 7 to determine flow regime.

a) The average flow conditions are

$$\Delta p = (1455 + 1955)/2 + 14.7 = 1719.5$$

$$T = 90^\circ\text{F} = 550^\circ\text{R}$$

$$Z = 0.72$$

$$R_s = 947.3 \text{ scf/stb}$$

$$B_0 = 1.495 \text{ bbl/stb}$$

b) The corrected volumetric flowrates are

$$\begin{aligned} q_L &= 480 \text{ bpd} = 6.4984 \times 10^{-5} \times 480 \text{ scf/s} \\ &= 6.4984 \times 10^{-5} (q_0 B_0 + q_w B_w) \\ &= 6.4984 \times 10^{-5} \times 480 \times 1.495 \\ &= 0.0466 \text{ ft}^3/\text{s} \end{aligned}$$

$$\begin{aligned} q_g &= 3.27 \times 10^{-7} \times (\text{GLR} - R_s) q_L (T + 460)/p \\ &= 3.27 \times 10^{-7} (0.72)(3397 - 947.3) \\ &\quad \times 480(550)/1719.5 \\ &= 0.08855 \text{ ft}^3/\text{s} \end{aligned}$$

$$q_t = q_g + q_l = 0.08855 + 0.0466 = 0.1352 \text{ ft}^3/\text{s}$$

c) The corrected weight flowrates are

$$\begin{aligned} \dot{w}_L &= 4.05(10^{-3})(q_0 S G_0 + q_w S G_w) + 8.85 \\ &\quad \times (10^{-7}) q_L S G_g (R_s) \\ &= 4.05(10^{-3})(480 \times 0.763 + 0) + 8.85(10^7)480 \\ &\quad \times (0.752)947.3 \\ &= 1.483 + 0.303 = 1.7856 \text{ lb/s} \end{aligned}$$

$$\begin{aligned} \dot{w}_g &= 8.85(10^{-7}) q_L g_g (\text{GLR} - R_s) \\ &= 8.85(10^{-7})480(0.752)(3393 - 947.3) \\ &= 0.7813 \text{ lb/s} \end{aligned}$$

$$\begin{aligned} \dot{w}_t &= \dot{w}_L + \dot{w}_g = 1.7856 + 0.7813 \\ &= 2.567 \text{ lb/s} \end{aligned}$$

d) The corrected specific weights are

$$\gamma_L = \dot{w}_L / q_L = 1.7856 / 0.0466 = 38.32 \text{ lb/ft}^3$$

$$\gamma_g = \dot{w}_g / q_g = 0.7813 / 0.08855 = 8.82 \text{ lb/ft}^3$$

7. Determine the type of flow regime:

a) Test variables

$$A_p = 0.0217 \text{ ft}^2$$

$$v_m = v_t = \frac{q_t}{A_p} = \frac{0.1352}{0.0217} = 6.23 \text{ ft./s}$$

$$\frac{q_g}{q_t} = \frac{0.08855}{0.1352} = 0.655$$

$$N_{vg} = 1.938 v_{sg} \left(\frac{\gamma_L}{\sigma_L} \right)^{0.25}$$

$$v_{sg} = \frac{q_g}{A_p} = \frac{0.08855}{0.0217} = 4.081$$

$$N_{vg} = 1.938(4.081) \left(\frac{38.32}{28} \right)^{0.25} = 8.55$$

b) Boundary limits

$$d = 2/12 = 0.1662 \text{ ft.}$$

From Equation 6.2.51

$$\begin{aligned} L_B &= 1.071 - (0.2218 v_m^2 / d) \\ &= 1.071 - (0.2218 \times 6.23^2 / 0.1662) \\ &= -50.7 \end{aligned}$$

Because L_B has such a low value, we must use $L_B = 0.13$ from Equation 6.2.53 $L_s = 50 + 36 N_{vg} q_L / q_g$.

$$L_s = 50 + 36(8.55)0.0466 / 0.09955 = 212$$

These two values, L_B and L_s , indicate that the regime is slug flow.

8. Determine the average density and the friction loss gradient

a) Slip velocity, v_s

$$\begin{aligned} \text{Re}_n &= d v_m \gamma_L / \mu_L = ((0.1662)(6.23)(38.32)) / \\ &\quad ((0.5 \times 0.000672)) \\ &= 118,080 \end{aligned}$$

Since this value exceeds limits of the graph (Figure 6.2.36) v_s must be calculated using the extrapolation equation.

$$\begin{aligned} v_s &= 0.5(\text{gd})^{0.5} = 0.5(32.2 \times 0.1662)^{0.5} \\ &= 1.155 \text{ (first try)} \end{aligned}$$

$$\begin{aligned} \text{Re}_b &= (1.155)(38.32)(0.1662) / (0.5 \times 0.000672) \\ &= 21,892 \end{aligned}$$

C_1 cannot be read from graph (Figure 6.2.37). To solve this problem, Orkiszewski proposed the following equations:

FIGURE 6.2.37 C_1 constant versus bubble Reynolds number [7].

if $Re_b \leq 3000$

$$v_s = (0.546 + 8.74 \times 10^{-6} \times Re_n)(g_c d)^{0.5}$$

if $Re_b \geq 8000$

$$v_s = (0.35 + 8.74 \times 10^{-6} Re_n)(g_c d)^{0.5}$$

if $3000 < Re_b < 8000$

$$v_s = 0.5F + [F^2 + 13.59 \mu_L / (\gamma_L d^{0.5})]$$

where $F = (0.251 + 8.74 \times 10^{-6} Re_n)(g_c d)^{0.5}$

In this example

$$\begin{aligned} v_s &= 0.35 + 8.74 \times 10^{-6} \times 118,080 \\ &\quad \times (32.2 \times 0.1662)^{0.5} \\ &= 3.19 \text{ ft./s} \end{aligned}$$

b) Liquid distribution coefficient δ and friction factor f Equation 6.2.60 is used to evaluate δ since $v_t < 10$ and there is no water.

$$\begin{aligned} \delta &= 0.0127 \log(0.5 + 1) / 0.1662^{1.415} - 0.284 \\ &\quad + 0.167 \log 6.23 + 0.113 \log(0.1662) \\ &= -0.211 \end{aligned}$$

Checking this value

$$\begin{aligned} -0.211 &\geq -0.065 (6.23) \\ -0.211 &\geq -0.405 \end{aligned}$$

Therefore, δ is okay

$$\epsilon/d = 0.00015 / 0.166 = 0.00009$$

and $Re_b = 21892$

$f_f = 0.0065$ (Fanning factor from Figure 6.2.32)
or $f = 0.025$ (friction factor from Figure 6.2.37)

because $f = 4f_f$, so results are consistent.

c) Evaluation of average flowing specific weight from Equation 6.2.58

$$\begin{aligned} \gamma_s &= \frac{\dot{w}_t + \gamma_L v_s A_p}{q_t + v_s A_p} + \delta \gamma_L \\ &= \frac{2.57 + 38.32 \times 3.19 \times 0.0217}{0.1352 + (3.19)(0.0217)} \\ &\quad + (-0.211)(38.32) \\ &= 17.45 \text{ lb}_m/\text{ft.}^3 \end{aligned}$$

d) Wall friction loss from Equation 6.2.61

$$\left(\frac{dp}{dL}\right)_f = \frac{2f_f \gamma_L v_m^2}{gd} \left(\frac{v_{sL} + v_s}{v_m + v_s} + \delta\right)$$

$v_{sL} = 2.147$ (see Example 6.2.2)

$$\begin{aligned} \left(\frac{dp}{dL}\right)_f &= \frac{2(0.0063)(38.32)(6.23)^2}{(32.2)(0.1662)} \\ &\quad \times \left[\frac{2.174 + 3.19}{6.23 + 3.19} + (-0.211) \right] \end{aligned}$$

$$\left(\frac{dp}{dL}\right)_f = 1.255 \frac{\text{lb}}{\text{ft}^3} = 0.0087 \text{ psi/ft.}$$

$$\left(\frac{dp}{dL}\right)_{\text{total}} = \left(\frac{dp}{dL}\right)_{\text{el}} + \left(\frac{dp}{dL}\right)_f + \left(\frac{dp}{dL}\right)_{\text{accI}}$$

↓
neglected

$$\begin{aligned} \left(\frac{dp}{dL}\right)_{\text{el}} &= \gamma_s \left(\frac{g}{g_c}\right) = 17.45 \frac{32.2}{32.2} \left(\frac{\text{lb}_m \text{ ft.}}{\text{ft}^3 \text{ s}^2} \frac{\text{lb}_f \text{ s}^2}{\text{lb}_m \text{ ft.}}\right) \\ &= 17.45 \frac{\text{lb}}{\text{ft}^3} = 17.45 \left(\frac{\text{lb}_f}{144 \text{ in.}}\right) \frac{1}{\text{ft.}} \end{aligned}$$

$$\left(\frac{dp}{dL}\right)_{\text{el}} = 0.1212 \text{ psi/ft.}$$

$$\left(\frac{dp}{dL}\right)_{\text{total}} = 0.1212 + 0.0087 = \underline{\underline{0.1299 \text{ psi/ft.}}}$$

if $\Delta p = 500$ psi since $\Delta L = 500/0.1299 = 3849$ ft.

The performance of Orkiszewski correlation is briefly outlined below for the flow variables considered [6].

- **Tubing Size:** The correlation performs well between 1- and 2-in. tubing sizes. The pressure loss is over predicted for tubing sizes greater than 2 in.
- **Oil Gravity:** At low oil gravities (13–30 °API), the correlation over predicts the pressure profile. However, predictions are seen to improve as oil °API increases.
- **Gas-Liquid Ratio:** The accuracy of Orkiszewski method is very good for gas–liquid ratio up to 5000. The errors become large (>20%) for GLR above 5000.
- **Water-cut:** The correlation predicts the pressure drop with good accuracy for a wide range of water-cuts.

6.2.14 The Hagedorn-Brown Method [9, 12, 13]

This correlation was developed using data obtained from a 1500-ft. vertical well. Tubing diameters ranging from 1 to 2 in. were considered in the experimental analysis along with five different fluid types, namely water and four types of oil with viscosities ranging between 10 and 110 cp (@ 80°F). The correlation developed is independent of flow patterns.

The equation for calculating pressure gradient is proposed as

$$\frac{\Delta p}{\Delta L} = \gamma_{\text{hb}}(F_e) + \frac{f_f q_L^2 m_o^2}{A d^5 \gamma_m} + \frac{(\gamma_{\text{hb}} \Delta [v_m^2 / 2g])}{\Delta L} \quad (6.2.63)$$

We have one consistent set of units, where

The friction factor used in Equation 6.2.63 is found from Figure 6.2.32. Figure 6.2.38 provides a relative roughness

	English	Metric
p = pressure	lb/ft. ²	kPa
L = length (height)	ft.	m
f _f = Fanning friction factor	—	—
q _L = total liquid flowrate	bbl/day	m ³ /s
m _o = total mass flowing/vol. liquid	slug/bbl	kg/m ³
d = pipe ID	ft.	m
v _m = avg. velocity = v _{sL} + v _{sg}	ft./sec	m/s
g = conversion factor, force from mass	32.2 ft./sec ²	9.81 m/sec ²
A = unit conversion constant	7.41 (10 ¹⁰)	8.63 (10 ⁴)
γ _{HB} = Hagedorn-Brown specific weight		
γ _s = v _L H _L + v _g (1 – H _L) based on pseudoholdup	lb/ft. ³	kg/m ³
γ _m = avg. two-phase specific weight	lb/ft. ³	kg/m ³
v _{sL} = superficial liquid velocity	ft./s	m/s
v _{sg} = superficial gas velocity	ft./s	m/s
γ _L = liquid specific weight	lb/ft. ³	kg/m ³
γ _g = gas specific weight	lb/ft. ³	kg/m ³
H _L = liquid holdup, a fraction		
F _e = force equivalent	1.0	9.81

number. For this method, the Reynolds number for use with Figure 6.2.32 is

$$R_e = \frac{2.2(10^{-2})q_L m_o}{d \mu_m} \quad (6.2.64)$$

where

	English	Metric
q = volumetric flowrate total all fluids	ft ³ /s	m ³ /s
μ _m = averaged viscosity, using an equation of the form of Arrhenius:		
μ _m = μ _L ^{H_L} μ _g ^(1–H_L)		
and		
q _L × ṁ _o = ḡ _t		

The equation would be solved over finite segments of pipe. Δv_m² is the changed velocity at points 1 and 2, the inlet

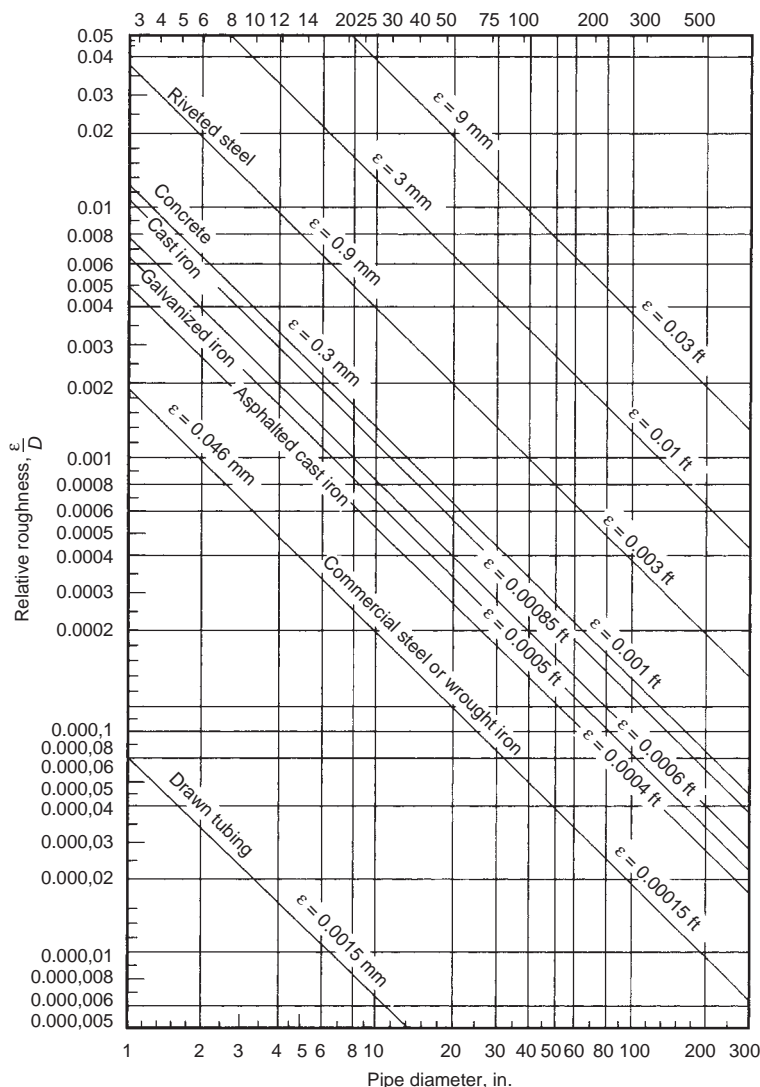

FIGURE 6.2.38 Relative roughness for various kinds of pipe [8,11].

to and outlet from that section. γ_m is the specific weight at the average p and T in the section.

Figure 6.2.39 also contains two empirical correction factors C and ψ . A plot of the data showed that holdup versus viscosity was a series of essentially straight lines. Water was chosen arbitrarily as a base curve ($C = 1.0$). C then is used for other viscosity fluids to make the parallel curves coincident. The viscosity correction curve obtained is shown in Figure 6.2.40.

The factor ψ was included to fit some of the data where it was postulated that a transition would occur before mist-flow begins, with gas velocity as the major variable. As gas velocity approached that required for mist-flow, it breaks through the liquid phase and the turbulence produces a liquid “ring,” which increases slippage. As velocity increases even further, the shear forces on this ring dissipate it until the primary mechanism is mist flow. Figure 6.2.41 shows the correlation for ψ . In most cases ψ will be equal to 1.0.

The basic correlating equation, 6.2.64 can be converted to a form similar to that for either single flow by allowing $H_L \rightarrow 0$ for gas or $H_L \rightarrow 1.0$ for liquids. As gas rate or liquid rate approaches zero, the pressure gradient obtained likewise approaches that for the other single phase. One therefore has a continuous gradient from liquid to two-phase to gas, an important aspect of the model.

Reviewing the foregoing calculation summary, it is necessary to make the calculation for a given diameter pipe and a given flowrate to avoid a trial-and-error solution. One can find R_e and all of the velocity-associated numbers to solve Equation 6.2.64. This would have to be repeated for various pipe size holdup calculations based primarily on data from 1.25-in. (0.031-m) tubing, the correlation in Figure 6.2.39 resulted. Some of the forms in this figure are the output from characterizing numbers and secondary correlations. Four dimensionless characterizing numbers were first proposed by Ros and adapted by others. They are given by Equations 6.2.46 to 6.2.49.

FIGURE 6.2.39 Holdup factor correlation [9,14].

FIGURE 6.2.40 Correlation for viscosity number coefficient [10].

FIGURE 6.2.41 Correlation for secondary factor correction [10].

When the liquid stream contains both oil and water, calculate the properties as follows:

the liquid-specific weight γ_L :

$$\gamma_L = \left[\frac{SG_o(62.4) + R_s SG_g(0.0764)/5.614}{B_o} \right] \left(\frac{1}{1 + WOR} \right) + \left[SG_w(62.4) \left(\frac{WOR}{1 + WOR} \right) \right] \quad (6.2.65)$$

the total weight associated with 1 bbl of stock tank liquid, w :

$$w = SG_o(350) \left(\frac{1}{1 + WOR} \right) + SG_w(350) \left(\frac{WOR}{1 + WOR} \right) + (0.0764)(GLR)SG_g \quad (6.2.66)$$

the weight flowrate \dot{w}_t :

$$\dot{w}_t = \dot{w}(q_w + q_o) \quad (6.2.67)$$

the liquid mixture viscosity μ_L :

$$\mu_L = \mu_o \left(\frac{1}{1 + WOR} \right) + \mu_w \left(\frac{WOR}{1 + WOR} \right) \quad (6.2.68)$$

the liquid mixture surface tension σ :

$$\sigma_L = \sigma_o \left(\frac{1}{1 + WOR} \right) + \sigma_w \left(\frac{WOR}{1 + WOR} \right) \quad (6.2.69)$$

the superficial liquid velocity v_{sL} in ft/s (assuming $B_w = 1.0$):

$$v_{sL} = \frac{5.61 q_L}{86,400 A_p} \left[B_o \left(\frac{1}{1 + WOR} \right) + B_w \left(\frac{WOR}{1 + WOR} \right) \right] \quad (6.2.70)$$

the superficial gas velocity v_{sg} :

$$v_{sg} = \frac{q_L \left[GLR - R_s \left(\frac{1}{1 + WOR} \right) \right]}{86,400 A_p} \left(\frac{14.7}{p} \right) \left(\frac{T}{520} \right) \left(\frac{Z}{1} \right) \quad (6.2.71)$$

Mixture specific weight is calculated by both using the Hagedorn-Brown holdup correlation and assuming no slippage. The higher value is then used.

If bubble flow is the dominant regime, the pressure gradient is used in the same way as in the Orkiszewski approach (step 7).

Example 6.2.4

Solve the problem in Example 2 using the Hagedorn-Brown method:

$$\begin{aligned} p_1 &= 1455 \text{ psig} \\ p_i &= 1955 \text{ psig} \\ d &= 1.995 \text{ in ID } (A_p = 0.0217) \end{aligned}$$

$$\begin{aligned} p_{\text{bar}} &= 14.7 \text{ psia} \\ T_1 &= 75^\circ\text{F} \\ T_2 &= 105^\circ\text{F} \\ SG_g &= 0.752 \\ SG_o &= 54^\circ\text{API} \\ q_o &= 480 \text{ bpd} \\ q_w &= 0 \\ \mu_s &= 0.020 \text{ cp} \\ \sigma_o &= 28 \text{ dyn/cm} \\ GLR &= 3393 \text{ scf/bbl} \end{aligned}$$

Solution

- $p = (1455 + 1955)/2 + 14.7 = 1179.7$
- $T = (75 + 105)/2 = 90^\circ\text{F}$
- $SG_o = 0.763$ from Example 6.2.2
- Total mass flowing from volume liquid - $m_o = 462$ lb/stb of oil from Example 6.2.2
- Solution gas/oil ratio R_s and oil formation volume factor B_o

$$R_s = 947.3 \text{ scf/stb}$$

$$B_o = 1.495 \text{ bbl/stb}$$

- Liquid specific weight γ_L and gas specific weight γ_g from Equation 6.2.65

$$\begin{aligned} \gamma_L &= \frac{(0.763)62.4 + 947.3(0.752)(0.0764)}{(1.495)(5.614)} \\ &= 38.33 \text{ lb/ft.}^3 \\ \gamma_g &= 8.823 \text{ lb/ft.}^3 \end{aligned}$$

- Oil viscosity, μ_{os} and oil surface tension, σ_o

$$\mu_{os} = 0.5 \text{ cp}$$

$$\sigma_o = \sigma_L = 28 \text{ dyn/cm}$$

- $N_L = 0.1573(0.5)(1/(38.33 \times 28^3))^{0.25} = 2.6 \times 10^{-3}$ from Equation 6.2.49
- $CN_L = 0.0022$ (from Figure 6.2.40)
- $v_{sL} = (5.61 \times 480)/(86,400 \times 0.0217)1.495 = 2.147$ ft./s from Equation 6.2.70
- $N_{vL} = 1.938(2.147)(38.33/28)^{0.25} = 4.5$ from Equation 6.2.65
- $v_{sg} = 4.08$ ft./s from Equation 6.2.71
- $N_{gv} = 1.938 \times 4.08(38.33/28)^{0.25} = 8.55$ from Equation 6.2.46
- Check the flow regime; calculate A and B:

$$\begin{aligned} A = L_B &= 1.071 - [0.2218(4.08 + 2.147)^2]/0.1662 \\ &= -50.68 \text{ from Equation 6.2.51} \end{aligned}$$

The minimum limit for L_B is 0.13. To assume 0.13

$$B = v_{sg}/(v_{sL} + v_{sg}) = 4.08/(4.08 + 2.147) = 0.655$$

Since $B - A = 0.616 - 0.13 = 0.486$, the difference is positive; so continue the Hagedorn-Brown procedure. In case $B - A$ is negative, use the Orkiszewski method to find flow regime.

15. $N_d = 120.9(0.1662)(38.33/28)^{0.5} = 23.5$

16. Calculate holdup correlating function ϕ

$$\begin{aligned} \phi &= \frac{N_{Lv}}{N_{gv}^{0.575}} \left(\frac{p}{14.7} \right)^{0.1} \left(\frac{CN_L}{N_d} \right) \\ &= \frac{4.5}{8.55^{0.575}} \left(\frac{1719.7}{14.7} \right)^{0.1} \left(\frac{0.0022}{23.5} \right) = 0.000197 \end{aligned}$$

17. Now from Figure 6.2.39, $H_L/\psi = 0.42$

18. Calculate secondary correlation factor ϕ_s

$$\begin{aligned} \phi_s &= \frac{N_{gv} N_L^{0.38}}{N_d^{2.14}} = \frac{8.55 \times (2.6 \times 10^{-3})^{0.38}}{(23.5)^{2.14}} \\ &= 0.001036 \end{aligned}$$

19. From Figure 6.2.41, $\psi = 1.0$

20. Liquid holdup $H_L = (H_L/\psi)(\psi) = 0.42 \times 1.0 = 0.42$

21. The two-phase Reynolds number $(Re)_{tp}$ is

$$Re_{tp} = \frac{2.2 \times 10^{-2} \times 221,760}{(0.1662)0.5^{0.42}0.02^{0.58}} = 379,760$$

22. Relative roughness $\epsilon/d = 0.00015/0.1662 = 0.0009$

23. Fanning friction factor from Figure 6.2.32

$$f_f = 0.00510$$

24. Calculate the average two-phase specific weight γ_m using two methods:

a) $\gamma_m = \gamma_{HB} = \gamma_L H_L + \gamma_g(1 - H_L)$
 $= 38.33(0.42) + 8.823(0.58) = 21.22 \text{ lb/ft}^3$

b) $\gamma_m = \frac{\dot{w}}{v_m}$

$$= \frac{350SG_0 + 0.0764SG_g(\text{GOR}) + 350SG_w(\text{WOR})}{5.61B_0 + 5.61(\text{WOR}) + (\text{GOR} - R_s)B_g}$$

$$= \frac{350 \times 0.763 + 0.0764(0.752)3393 + 0}{5.61(1.495) + (3393 - 947.3) \times (14.7/1719.7)(550/520)(0.72)}$$

$$= 19.006 \text{ lb/ft}^3$$

Use 21.22 lb/ft³ as a proper value.

25. Calculate

a) $Z_1, B_{01}, R_{s1}, v_{sL2}$ and v_{sg1} at T_2, p_1 (repeat steps 6, 7, 9, 16, 18)

$$T_1 = 75^\circ; p_1 = 1455 \text{ psig}$$

$$\left. \begin{aligned} T_r &= (75 + 460)/394 = 1.358 \\ p_r &= 1455/660 = 2.2 \end{aligned} \right\} Z_1 = 0.71$$

$$\begin{aligned} R_{s1} &= 0.752[(1455/18) \\ &\quad \times 10^{0.0125(54)} / 10^{0.00091(75)}]^{1.2048} \\ &= 804.4 \text{ scf/stb} \end{aligned}$$

$$B_{01} = 0.972 + 0.000147 F^{1.175} = 1.403 \text{ bbl/stb}$$

where $F = 804.4(0.752/0.763)^{0.5} + 1.25(75) = 892.3$

$$v_{sL1} = \left(\frac{5.61 \times 480}{86,400 \times 0.0217} \right) (1.403) = 2.02 \text{ ft./s}$$

$$\begin{aligned} v_{sg1} &= \frac{[480(3393 - 804.4)14.7 \times 535 \times 0.71]}{86,400 \times 0.0217 \times 1,455 \times 520} \\ &= 4.89 \text{ ft./s} \end{aligned}$$

b) $Z_2, B_{02}, R_{s2}, v_{sL2}$, and v_{sg2} at T_2, p_2

$$T_2 = 105^\circ\text{F} \quad p_2 = 1955$$

$$\left. \begin{aligned} T_r &= (105 + 460)/394 = 1.434 \\ p_r &= 1955/660 = 2.962 \end{aligned} \right\} Z_2 = 0.73$$

$$\begin{aligned} R_{s2} &= 0.752[(1955/18) \\ &\quad \times 10^{0.0125(54)} / 10^{0.00091(105)}]^{1.2048} \\ &= 1064.5 \text{ scf/stb} \end{aligned}$$

26. Calculate the two-phase velocity at both P_q and P_2 :

$$V_{m1} = V_{sL1} + V_{sg1} = 2.02 + 4.89 = 6.91$$

$$V_{m2} = V_{sL2} + V_{sg2} = 2.262 + 3.368 = 5.63$$

27. Determine value $\Delta(V_m^2)$

$$\Delta(V_m^2) = (6.91^2 - 5.63^2) = 16.05$$

28. From Equation 6.2.64

$$\Delta L = \frac{\Delta p - \gamma_{HB} \Delta \left(\frac{V_m^2}{2g_c} \right)}{\gamma_{HB}(F_e) + (f_r q_L^2 m_0^2 / Ad^5 \gamma_m)}$$

$$\Delta p = 500 \text{ psi} = 500 \times 144 \text{ lb/ft}^2$$

$$\gamma_{HB} = \gamma_m = 21.22, \quad A = 7.41 \times 10^{10}$$

$$\Delta L = \frac{500(144) - 21.22 \frac{16.05^2}{2 \times 32.2}}{21.22(1) + \frac{[0.0051(480)^2(462)^2]}{[7.41 \times 10^{10}(0.1662)^2 21.22]}}$$

$$= (72,000 - 84.88)/(21.22 + 0.005774)$$

$$= 3388 \text{ ft.}$$

or

$$\frac{\Delta p}{\Delta L} = \frac{500}{3388} = 0.1476 \text{ psi/ft.}$$

The performance of the Hagedorn-Brown method is briefly outlined below [6].

- **Tubing Size:** The pressure losses are accurately predicted for tubing size between 1 and 1.5 in., the range in which the experimental investigation was conducted. A further increase in tubing size causes the pressure drop to be over predicted.
- **Oil Gravity:** The Hagedorn-Brown method is seen to over predict the pressure loss for heavier oils (13–25° API) and under predict the pressure profile for lighter oils (45–56° API)
- **Gas-Liquid Ratio:** The pressure drop is over predicted for gas-liquid ratio greater than 5000.
- **Water-cut:** The accuracy of the pressure profile predictions is generally good for a wide range of water-cuts.

6.2.15 The Beggs-Brill Method [2, 9, 15]

The Beggs and Brill correlation is developed for tubing strings in inclined wells and pipelines for hilly terrain. This correlation resulted from experiments using air and water as test fluids over a wide range of parameters given below:

gas flowrate 0 to 300 Mscfd
 liquid flowrate 0 to 30 gal/min
 average system pressure 35 to 95 psia
 pipe diameter 1 and 1.5 in.
 liquid holdup 0 to 0.870
 pressure gradient 0 to 0.8 psi/ft.
 inclination angle -90° to $+90^\circ$ also horizontal flow patterns

A flow diagram for calculating a pressure traverse in a vertical well is shown in Figure 6.2.42. The depth increment equation for Δ_L is

$$\Delta L = \frac{\Delta p \left(1 - \frac{\gamma_t v_t v_{sg}}{g_p} \right)}{\gamma_t \sin \theta + \frac{f_t G_t v_t}{2gd}} \quad (6.2.72)$$

where γ_t = two-phase specific weight in lb/ft.³

v_t = two-phase superficial velocity

($v_t = v_{sL} + v_{sg}$) in ft./s

f_t = two-phase friction factor

G_t = two-phase weight flux rate (lb/s-ft.²)

A detailed procedure for the calculation of a pressure traverse is following:

1. Calculate the average pressure and average depth between the two points:

$$p = (p_1 + p_2)/2 + 14.7$$

2. Determine the average temperature T at the average depth. This value must be known from a temperature versus depth survey.
3. From P–V–T analysis or appropriate correlations, calculate R_s , B_0 , B_w , μ_0 , μ_w , μ_h , σ_0 , σ_{ws} , and Z at T and p_s .
4. Calculate the specific gravity of the oil SG_0 :

$$SG_0 = \frac{141.5}{131.5 + \text{API}}$$

5. Calculate the liquid and gas densities at the average conditions of pressure and temperatures:

$$\gamma_L = \gamma_0 \left(\frac{1}{1 + \text{WOR}} \right) + \gamma_w \left(\frac{1}{1 + \text{WOR}} \right)$$

$$= \gamma_0 f_0 + \gamma_w f_w$$

$$\gamma_0 = \frac{350 SG_0 + 0.0764 R_s SG_g}{5.615}$$

$$\gamma_w = \frac{250 SG_w}{5.615 B_w}$$

$$\gamma_g = \frac{0.0764 SG_g p(520)}{(14.7)(T + 460)Z}$$

6. Calculate the *in situ* gas and liquid flowrates.

$$q_g = \frac{3.27 \times 10^{-7} Z q_0 (R - R_s)(T + 460)}{p}$$

$$q_L = 6.49 \times 10^{-5} (q_0 B_0 + q_w B_w)$$

7. Calculate the *in situ* superficial gas, liquid and mixture velocities:

$$v_{sL} = q_L / A_p$$

$$v_{sg} = q_g / A_p$$

$$v_t = v_{sL} + v_{sg}$$

8. Calculate the liquid, gas, and total weight flux rates:

$$G_L = \gamma_L v_{sL}$$

$$G_t = G_L + G_g$$

$$G_g = \gamma_s v_{sg}$$

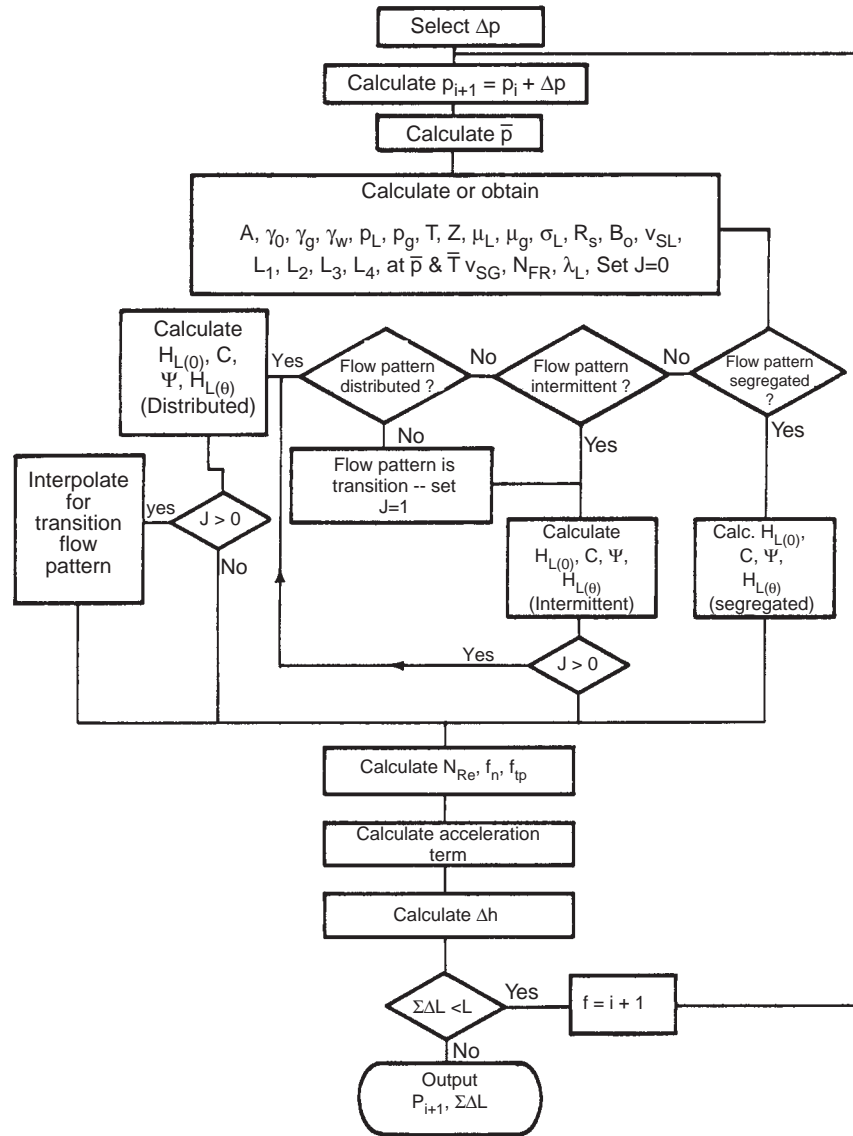

FIGURE 6.2.42 Flow diagram for the Beggs-Brill method [1].

9. Calculate the input liquid content (no-slip holdup):

$$\lambda = \frac{q_L}{q_L + q_g}$$

10. Calculate the Froude number N_{FR} , the liquid viscosity, μ_L , the mixture viscosity μ_m and the liquid surface tension σ_L :

$$N_{FR} = \frac{v_t^2}{gd}$$

$$\mu_L = \mu_0 f_0 + \mu_w f_w$$

$$\mu_t = \mu_L \lambda + \mu_g (1 - \lambda) (6.72 \times 10^{-4})$$

$$\sigma_L = \sigma_0 f_0 + \sigma_w f_w$$

11. Calculate the no-slip Reynolds number and the liquid velocity number:

$$(N_{Re})_{ns} = \frac{G_t d}{\mu_t}$$

$$N_{LV} = 1.938 v_{sL} \left(\frac{\gamma_L}{\sigma_L} \right)^{0.25}$$

12. To determine the flow pattern that would exist if flow were horizontal, calculate the correlating parameters, L_1, L_2, L_3 , and L_4 :

$$L_1 = 316 \lambda^{0.0302}$$

$$L_3 = 0.10 \lambda^{-1.4516}$$

$$L_2 = 0.0009252\lambda^{-2.4684}$$

$$L_4 = 0.5\lambda^{-6.738}$$

13. Determine flow pattern using the following limits:
Segregated:

$$\lambda < 0.01 \quad \text{and} \quad N_{FR} < L_1$$

or

$$\lambda \geq 0.01 \quad \text{and} \quad N_{FR} < L_2$$

Transition:

$$\lambda \geq 0.01 \quad \text{and} \quad L_2 < N_{FR} < L_3$$

Intermittent:

$$0.01 \leq \lambda < 0.4 \quad \text{and} \quad L_3 < N_{FR} < L_1$$

or

$$\lambda \geq 0.4 \quad \text{and} \quad L_3 < N_{FR} \leq L_4$$

Distributed:

$$\lambda < 0.4 \quad \text{and} \quad N_{FR} \geq L_1$$

or

$$\lambda \geq 0.4 \quad \text{and} \quad N_{FR} > L_4$$

14. Calculate the horizontal holdup $H_L(O)$:

$$H_L(O) = \frac{a\lambda^b}{N_{FR}^c}$$

where a, b and c are determined for each flow pattern from the following table:

Flow pattern	a	b	c
Segregated	0.98	0.4846	0.0868
Intermittent	0.845	0.5351	0.0173
Distributed	1.065	0.5824	0.0609

15. Calculate the inclination correction factor coefficient:

$$C = (1 - \lambda) \ln \left(d\lambda^e N_{LV}^f N_{FR}^g \right)$$

where d, e, f, and g are determined for each flow condition from the following table:

Flow Pattern	d	e	f	g
Segregated uphill	0.011	-3.768	3.539	-1.614
Intermittent uphill	2.96	0.305	-0.4473	0.0978
Distributed uphill	No correction		C = 0	
All flow patterns downhill	4.70	-0.3692	0.1244	-0.5056

16. Calculate the liquid inclination correction factor:

$$\psi = 1 + C[\sin(1.8\theta) - 0.333 \sin^3(1.8\theta)] = 1 + 0.3C$$

for vertical well

17. Calculate the liquid holdup and the two-phase density:

$$H_L(\theta) = H_L(0)\psi$$

$$\rho_t = \rho_L H_L + \rho_g(1 - H_L)$$

18. Calculate the friction factor ratio:

$$f_t/f_{ns} = e_s$$

where

$$S = \frac{\ln(y)}{-0.0523 + 3.182 \ln(y) - 0.8725 [\ln(y)]^2 + 0.01853 [\ln(y)]^4}$$

$$y = \lambda/[H_L(\theta)]^2$$

S becomes unbounded at a point in the interval $1 < y < 1.2$; and for y in this interval, the function S is calculated from

$$S = \ln(2.2y - 1.2)$$

19. Calculate the no-slip friction factor:

$$f_{ns} = 1/\{2 \log[N_{Rens}/(4.5223 \log N_{Rens} - 3.8215)]\}^2$$

or

$$f_{ns} = 0.0056 + 0.5/(N_{Rens})^{0.32}$$

20. Calculate the two-phase friction factor:

$$f_t = f_{ns}/(f_t/f_{ns})$$

21. Calculate ΔL . If the estimated and calculated values for ΔL are not sufficiently close, the calculated value is taken as the new estimated value and the procedure is repeated until the values agree. A new pressure increment is then chosen and the process is continued until the sum of the ΔL 's is equal to the well depth.

Example 6.2.5

Solve the problem in Example 6.2.2 using the Beggs-Brill method.

Solution

1. $p = 1719.7$ psia
2. $T = 90^\circ\text{F}$
3. $R_s = 947.3$ scf/stb $B_0 = 1.495$ bbl/stb
 $\mu_{os} = 0.5$ cp, $\sigma_0 = 28$ dyn/cm, $Z = 0.72$
4. $SG_0 = 0.736$, $\gamma_g = 8.823$ lb/ft.³
5. $\gamma_0 = 38.32$ lb/ft.³ (from Example 6.2.3)
6. $q_g = 0.08855$ ft.³/s
 $q_L = 0.0466$ ft.³/s
7. $A_p = 0.0217$ ft.²
 $v_{sL} = q_L/A_p = 2.147$ ft./s, $v_{sg} = 4.081$ ft./s
8. Calculate the liquid, gas, and total weight flux rates:

$$G_L = \gamma_L v_{sL}, \quad G_g = \gamma_g v_{sg}$$

$$G_t = G_L + G_g = 38.32 \times 2.147 + (8.823) \times 4.081$$

$$= 118.3 \text{ lb}/(\text{s}\cdot\text{ft.}^2)$$

9. Calculate the input liquid (no-slip holdup):

$$\lambda = \frac{q_L}{q_L + q_g} = \frac{0.0466}{0.0466 + 0.8855} = 0.3448 = 0.345$$

10. The Froude number, viscosity, and surface tension

$$N_{FR} = \frac{v_t^2}{gd} = \frac{6.23^2}{32.174 \times 0.1662} = 7.26$$

$$\mu_L = \mu_0 f_0 + \mu_w f_w = 0.5(1.0) + \mu_w(0.0) = 0.5$$

$$\mu_t = (6.72 \times 10^{-4}) [0.5 \times 0.345 + 0.02(1 - 0.345)]$$

$$= 1.164 \times 10^{-4}$$

$$= 0.0001164 \text{ lb}_m/(\text{ft.}\cdot\text{s})$$

$$\sigma_L = \sigma_0 f_0 + \sigma_w f_w = 28 \times 1.0 = 28 \text{ dyn/cm}$$

11. Calculate the no-slip Reynolds number and the liquid velocity number:

$$(N_{Re})_{ns} = \frac{G_t d}{\mu_t} = \frac{118.3(0.1662)}{0.000464} = 168,884$$

$$N_{LV} = 1.938 \times 2.147(38.32/28)^{0.25} = 4.5$$

12. Determine the flow pattern that would exist if flow were horizontal:

$$L_1 = 316\lambda^{0.302} = 316 \times (0.345)^{0.302} = 229.14$$

$$L_2 = 0.0009252(0.345)^{-2.4684} = 1.2796 \times 10^{-2}$$

$$L_3 = 0.10\lambda^{-1.4516} = 0.10(0.345)^{-1.4516} = 0.4687$$

$$L_4 = 0.5\lambda^{-6.738} = 0.5(0.345)^{-6.738} = 650.3$$

13. Determine flow pattern:

$$0.4 > \lambda > 0.01 \quad \text{and} \quad L_2 < N_{FR} < L$$

The flow pattern is intermittent.

14. Calculate the horizontal holdup:

$$H_L(O) = 0.845(0.345)^{0.5351}/7.26^{0.0173} = 0.462$$

15. Calculate the inclination correction factor coefficient:

$$C = (1 - 0.345) \ln \left(2.96 \times 0.345^{0.305} \right. \\ \left. \times 4.5^{-0.4473} 7.26^{0.0978} \right)$$

$$= 0.18452$$

16. Calculate the liquid holdup inclination correction factor:

$$\psi = 1 + C [\sin(1.8 \times 90) - 0.333 \sin^3(1.9 \times 90)]$$

$$= 1 + C(0.309 - 0.009826) = 1 + 0.3C$$

$$= 1 + 0.3(0.18452) = 1.055$$

17. Calculate the liquid holdup and the two-phase density:

$$H_L(90) = H_L(O)\psi = 0.462 \times 1.055 = 0.4876$$

$$\gamma_t = \gamma_L H_L + \gamma_g(1 - H_L)$$

$$= 38.32(0.4876) + 8.823(1 - 0.4876)$$

$$= 23.2 \text{ lb}/\text{ft.}^3$$

18. Calculate the friction factor ratio:

$$y = [0.345/(0.4876)^2] = 1.451, \ln 1.451 = 0.3723$$

$$f_t/f_{ns} = \exp [0.3723/(-0.0523 + 3.182 \times 0.3723) \\ - (0.8725 \times 0.3723^2 + 0.1853 \times 0.3723^4)]$$

$$= \exp(0.3723/1.0188) = 3^{0.36796} = 1.4447$$

19. Calculate the no-slip friction factor:

$$f_{ns} = 1/\{2 \log [N_{Rens}/(4.5223 \log N_{Rens} - 3.8215)]\}^2$$

$$= 1/36.84 = 0.0271$$

20. Calculate the two-phase friction factor:

$$f_t = f_{ns}(f_t/f_{ns}) = 0.0271(1.4447) = 0.0391$$

21. Determine the distance ΔL for $\Delta p = 500$ psi from Equation 6.2.72

$$\Delta L = \frac{500 \left[1 - \frac{23.2(6.23)4.081}{32.174 \times 1719.7} \right] 144}{23.2(1.0) + \frac{0.0391(118.3)6.23}{2(32.174)0.1662}}$$

$$= \frac{72,000(0.9893)}{25.894}$$

$$= 2750 \text{ ft}$$

and

$$\frac{\Delta p}{\Delta L} = \frac{500}{2750} = 0.18 \text{ psi/ft.}$$

Example 6.2.6

Solve Example 6.2.1 using the Beggs-Brill method:

$$\begin{aligned} q_g &= 40 \text{ MMscf/d, } p_{\text{avg}} = 2000 \text{ psia} \\ q_0 &= 40,000 \text{ stb/d, } T_{\text{avg}} = 80^\circ\text{F} \\ \text{ID} &= 9 \text{ in. } SG_g = 0.75 \text{ at } p = 14.7 \text{ psia in } T = 60^\circ\text{F} \\ R_p &= 990 \text{ scf/bbl} \end{aligned}$$

Solution

1. $SG_0 = 141.5/131.5 + \text{API} = 0.86$
2. Calculate R_s , B_0 , μ_g , Z_g at p_{avg} and T_{avg} :

$$\begin{aligned} Z_g &= 0.685 \\ \mu_g &= 0.0184 \text{ cp} \\ R_s &= 477 \text{ scf/stb} \\ B_0 &= 1.233 \text{ rb/stb} \\ \mu_0 &= 2.96 \text{ cp} \end{aligned}$$

3. Calculate γ_0 and γ_g at average parameters:

$$\begin{aligned} \gamma_0 &= \frac{350(0.86) + 0.0764(477)(0.75)}{5.614(1.233)} = 47.42 \text{ lb/ft.}^3 \\ \gamma_g &= \frac{0.0764\gamma_g p(520)}{(14.7)(T + 460)Z_g} = \frac{0.0764(0.73)(2000)(520)}{(14.7)(80 + 460)(0.685)} \\ &= 10.96 \text{ lb/ft.}^3 \end{aligned}$$

4. Calculate the in situ gas and liquid flowrates,

$$\begin{aligned} q_g &= \frac{3.27 \times 10^{-7} Z_g q_0 (R - R_s)(T + 460)}{p} \\ &= \frac{3.27 \times 10^{-7} (0.685)(40,000)(990 - 477)}{(80 + 460)} \\ &= \frac{\quad}{2000} \\ &= 1.241 \text{ ft.}^3/\text{s} \\ q_L &= 6.49 \times 10^{-5} (q_0 B_0 + q_w B_w) \\ &= 6.49 \times 10^{-5} [40,000(1.233) + 0] \\ &= 3.201 \text{ ft.}^3/\text{s} \end{aligned}$$

5. Calculate A_p :

$$A_p = \frac{\pi}{4} D^2 = \frac{\pi}{4} \left(\frac{9}{12} \right)^2 = 0.4418 \text{ ft.}^2$$

6. Calculate the in situ superficial gas, liquid, and mixture velocities:

$$\begin{aligned} v_{sL} &= q_L/A_p = 3.201/0.4418 = 7.25 \text{ ft./s} \\ v_{sg} &= q_g/A_p = 1.241/0.4418 = 2.81 \text{ ft./s} \\ v_m &= v_{sL} + v_{sg} = 7.25 + 2.81 = 10.06 \text{ ft./s} \end{aligned}$$

7. Calculate the liquid, gas, and total mass flux rates:

$$\begin{aligned} G_L &= \rho_L v_{sL} = (47.42)(7.25) = 343.6 \text{ lb/(s} \cdot \text{ft.)} \\ G_g &= \rho_g v_{sg} = (10.96)(2.81) = 30.79 \text{ lb/(s} \cdot \text{ft.)} \\ G_m &= G_L + G_g = 343.6 + 30.8 = 374.4 \text{ lb/(s} \cdot \text{ft.)} \end{aligned}$$

8. Calculate the no-slip holdup:

$$\lambda = \frac{q_L}{q_L + q_s} = \frac{3.201}{32 + 1.241} = 0.72$$

9. Calculate the Froude number N_{FR} , the mixture viscosity μ_m , and surface tension σ_L :

$$\begin{aligned} N_{FR} &= \frac{v_m^2}{gd} = \frac{(10.06)^2}{(32.2 \times 9)} = 4.186 \\ \mu_m &= 6.27 \times 10^{-4} [\mu_L \lambda + \mu_g (1 - \lambda)] \\ &= 6.27 \times 10^{-4} [2.96(0.72) + 0.0184(0.28)] \\ &= 1.44 \times 10^{-3} \text{ lb/(ft.} \cdot \text{s)} \\ \sigma_L &= 37.5 - 0.257(\text{API}) = 37.5 - 0.257(33) \\ &= 29.0 \text{ dyn/cm} \end{aligned}$$

10. Calculate the non-slip Reynolds number and the liquid velocity number:

$$\begin{aligned} Re_{NS} &= \frac{G_m d}{\mu_m} = \frac{(374.4)(9)}{(1.44 \times 10^{-3})12} = 195,000 \\ N_{LV} &= 1.938 v_{sL} \left(\frac{\gamma_L}{\sigma_L} \right)^{0.25} \\ &= 1.938(7.25)(47.42/29)^{0.25} \\ &= 15.88 \end{aligned}$$

11. Calculate L_1 , L_2 , L_3 , and L_4 :

$$\begin{aligned} L_1 &= 316\lambda^{0.302} = 316(0.721)^{0.302} = 286 \\ L_2 &= 0.000952\lambda^{-2.4684} = 0.0009252(0.721)^{-2.4684} \\ &= 0.0021 \\ L_3 &= 0.10\lambda^{-1.4516} = 0.10(0.721)^{-1.4516} = 0.161 \\ L_4 &= 0.5\lambda^{-6.738} = 0.5(0.721)^{-6.738} = 4.53 \end{aligned}$$

12. Determine flow pattern:

$$\text{Since } 0.721 \geq 0.4 \text{ and } L_3 < N_{FR} \leq L_4$$

Flow is intermittent.

13. Calculate the horizontal holdup $H_L(O)$:

$$H_L(O) = a\lambda^b / N_{FR}^c = 0.845 \times 0.721^{0.5351} / 7.186^{0.0173} = 0.692$$

14. Calculate ψ and $H_L(O)$ and two-phase specific weight:

$$\text{Since } \theta = 0^\circ, \lambda = 1 + 0 = 1$$

$$H_L(0^\circ) = H_L(O)\lambda = 0.692$$

$$\begin{aligned} \gamma_t &= \gamma_L H_L + \gamma_g(1 - H_L) = 47.42(0.692) \\ &\quad + 10.96(1 - 0.692) \\ &= 36.19 \text{ lb/ft.}^3 \end{aligned}$$

15. Calculate the friction factor ratio:

$$y = \frac{\lambda}{H_L^2} = \frac{0.721}{(0.692)^2} = 1.506$$

$$\ln(y) = 0.4092$$

$$\begin{aligned} S &= \ln(y) / [-0.0523 + 3182 \ln y - 0.8725(\ln y)^2 \\ &\quad + 0.01853(\ln y)^4] \\ &= 0.3706 \end{aligned}$$

$$f_t/f_{ns} = e^S = e^{0.3706} = 1.449$$

16. Calculate the non-slip friction factor f_{ns} :

$$\begin{aligned} f_{ns} &= 1 / \{2 \log[\text{Re}_{ns} / (4.5223 \log \text{Re}_{ns} - 38,215)]\}^2 \\ &= 1 / \{2 \log[195,000 / (4.5223 \log 195,000 \\ &\quad - 3.8215)]\}^2 \\ &= 0.01573 \end{aligned}$$

17. Calculate the two-phase friction factor:

$$f_t = f_{ns}(f_t/f_{ns}) = 0.01573(1.449) = 0.0227$$

18. Calculate the pressure gradient:

$$\begin{aligned} \frac{\Delta L}{\Delta p(144)} &= \frac{1 - \frac{\gamma_t v_m v_{sg}}{gP}}{\gamma_{tp} \sin \theta + \frac{f_t G_m v_m}{2gd}} \\ &= \frac{1 - \frac{(36.19)(10.06)(2.81)}{(32.2)2,000(144)}}{36.19(1)(0) + \frac{0.0227(374.4)(10.06)}{2(32.2)(9/12)}} \\ &= 0.5646 \\ \frac{\Delta L}{p} &= 81.3 \quad \text{or} \quad \frac{\Delta p}{\Delta L} = 1.23 \times 10^{-2} \text{ psi/ft.} \end{aligned}$$

because pressure is decreasing in flow direction to proper value of $\Delta p/\Delta L = -1.23 \times 10^{-2}$ psi/ft.

The performance of the correlation is given below [7].

- *Tubing Size*: For the range in which the experimental investigation was conducted (i.e., tubing sizes between 1 and 1.5 in.), the pressure losses are accurately estimated. Any further increase in tubing size tends to result in an over prediction in the pressure loss.
- *Oil Gravity*: A reasonably good performance is obtained over a broad spectrum of oil gravities.
- *Gas-Liquid Ratio*: In general, an over predicted pressure drop is obtained with increasing GLR. The errors become especially large for gas-liquid ratio above 5000.
- *Water-Cut*: The accuracy of the pressure profile predictions is generally good up to about 10% water-cut.

6.2.16 Mechanistic models

In the past two decades, mechanistic models have been the focus of many investigations to improve the flow behavior predictions in multiphase flow. These models rely more on the theory or mechanisms (or phenomena) in multiphase flow rather than solely on experimental work. Empiricism is still used in a mechanistic approach to predict certain flow mechanisms or provide closure relationships. One of the preliminary works on mechanistic modeling of flow pattern transition and steady, upward, and gas-liquid flow in vertical tubes is presented by Taitel et al. [16]. This flow pattern prediction was later modified by Barnea et al. [17] to account for a whole range of pipe inclinations. These two works have provided the basis for predicting flow patterns by defining transition boundaries between bubble, slug, churn, and annular flows. Although many mechanistic models predict flow behavior for a single flow pattern, only a few comprehensive mechanistic models such as Hasan and Kabir [18, 19] and Ansari et al. [20] have been published in the literature to model all four flow pattern transitions in multiphase flow. Both these mechanistic the models have enjoyed considerable success in multiphase flow predictions and have generally been accepted in the petroleum industry. The Ansari et al. model [20] is relatively more complex, and the reader is referred to the original papers [20, 21] for a complete presentation of the model. Only the details of the Hasan and Kabir model are presented here.

6.2.17 Hasan and Kabir model [18, 19]

Hasan and Kabir developed a mechanistic model to predict multiphase flow pressure gradients and wellbores for the same four flow patterns discussed in the empirical approach.

The bubble/slug transition: The bubble/slug flow transitions across at a void fraction of 0.25 and is expressed in terms of superficial gas velocity.

$$v_{sg} = \frac{\sin \theta}{4 - C_o} (C_o v_{sL} + v_s) \quad (6.2.73)$$

where C_o is the flow parameter written as

$$C_o = \begin{cases} 1.2 & \text{if } d < 4 \text{ in} \\ 2.0 & \text{if } d > 4 \text{ in} \end{cases} \quad (6.2.74)$$

In [equation 6.2.73](#), V_s is the bubble-rise or slip velocity and is given by Harmathy [22] expression as

$$v_s = 1.53 \left[\frac{g\sigma_L(\rho_L - \rho_g)}{\rho_L^2} \right]^{1/4} \quad (6.2.75)$$

The transition to slug flow occurs at superficial gas velocities greater than that given by [equation 6.2.73](#). The slug flow transition is also checked by finding the rise velocity of a Taylor bubble as

$$v_{TB} = 0.35 \sqrt{\frac{g\sigma_L(\rho_L - \rho_g)}{\rho_L^2}} \sqrt{\sin \theta (1 + \cos \theta)^{1.2}} \quad (6.2.76)$$

It should be noted that v_{TB} is dependent on the pipe diameter. In smaller diameter pipes, when Taylor bubble velocity is less than in the slip velocity, the rising smaller bubbles approached the back of the Taylor bubble, coalesce with it, and increase its size thus causing a transition to slug flow.

Dispersed bubble/slug/churn flow transitions: Taitel et al. [16] proposed an equation for the transition to dispersed-bubble flow and is given by

$$v_m^{1.12} = 4.68d^{0.48} \sqrt{\frac{g\sigma_L(\rho_L - \rho_g)}{\rho_L^2}} \left(\frac{\sigma_L}{\rho_L} \right)^{0.6} \left(\frac{\rho_L}{\mu_L} \right)^{0.08} \quad (6.2.77)$$

However, as the gas void fraction exceeds 0.52, bubble coalescence cannot be prevented, and transition to either slug, churn, or annular flow must occur.

Slug/churn transitions is predicted from

$$\rho_g V_{sg}^2 = 0.0067(\rho_L V_{sL}^2)^{1.7} \text{ if } \rho_L V_{sL}^2 < 50 \quad (6.2.78a)$$

$$\text{and } \rho_g V_{sg}^2 = 17.1 \log_{10}(\rho_L V_{sL}^2) - 23.2 \text{ if } \rho_L V_{sL}^2 \geq 50 \quad (6.2.78b)$$

Annular-flow transition: The transition to annular flow is given by

$$v_{sg} = 3.1 \left[\frac{g\sigma_L(\rho_L - \rho_g)}{\rho_g^2} \right]^{1/4} \quad (6.2.79)$$

This criterion is partly based on the gas velocity required to prevent fallback of entrained liquid droplets in the gas stream.

Bubble and dispersed bubble flow: The liquid hold up for the bubble and dispersed bubble flow is given by

$$H_L = 1 - \frac{v_{sg}}{C_o v_m + v_s} \quad (6.2.80)$$

The total pressure gradient is estimated by [Equation 6.2.81](#), and it is used in conjunction with the mixture density, ρ_m , once the hold up is calculated.

$$\left(\frac{dp}{dL} \right)_t = \rho_m g \sin \theta + \frac{2f\rho_m v_m^2}{d} + \rho_m v_m \frac{dv_m}{dL} \quad (6.2.81)$$

$$\text{where } \rho_m = H_L \rho_L + (1 - H_L) \rho_g$$

As usual, the friction factor is determined from the Moody diagram shown in [Figure 6.2.32](#). Mixture Reynolds number for determining the friction factor is given by the [Equation 6.2.82](#).

$$Re_m = \frac{\rho_L v_m d}{\mu_L} \quad (6.2.82)$$

Slug and churn flow: The slip velocity for expressions for slug and churn flow is given by [Equation 6.2.83](#)

$$v_s = 0.35 \sqrt{\frac{gd(\rho_L - \rho_g)}{\rho_L}} \sqrt{\sin \theta (1 + \cos \theta)^{1.2}} \quad (6.2.83)$$

A value of 1.2 and 1.15 are used for C_o in [Equation 6.2.80](#) for slug and churn flow, respectively. The friction pressure gradient is calculated from [Equation 6.2.81](#). Because of the chaotic nature of the flow and difficulty in analyzing the churn flow regime, predictions in this flow regime are less accurate.

Annular flow: The liquid hold up for the central core in annular flow is given by

$$H_{LC} = \frac{E v_{sL}}{E v_{sL} + v_{sg}} \quad (6.2.84)$$

Here $H_{LC} = 1 - f_{gc}$ where f_{gc} is the gas void fraction and E is the liquid entrainment in the central core. The liquid entrainment in the core is calculated by the following expressions

$$\left\{ \begin{array}{l} E = 0.0055 [(v_{sg})_{crit} \times 10^4]^{2.86} \text{ if } (v_{sg})_{crit} \times 10^4 < 4 \\ E = 0.857 \log_{10} [(v_{sg})_{crit} \times 10^4] - 0.20 \text{ if } (v_{sg})_{crit} \\ \quad \times 10^4 > 4 \end{array} \right\} \quad (6.2.85)$$

$(v_{sg})_{crit}$ is given by

$$(v_{sg})_{crit} = \frac{v_{sg} \mu_g}{\sigma_L} \left(\frac{\rho_g}{\rho_L} \right)^{1/2} \quad (6.2.86)$$

The friction pressure gradient is calculated from

$$\left(\frac{dp}{dL}\right)_f = \frac{2f_C \rho_C}{d} \left(\frac{v_{sg}}{f_{gc}}\right)^2 \quad (6.2.87)$$

where

$$f_C = \frac{0.079(1 + 75H_{LC})}{N_{Reg}^{0.25}} \quad (6.2.88)$$

and

$$\rho_C = \frac{v_{sg}\rho_g + v_{sL}\rho_L E}{v_{sg} + v_{sL}E} \quad (6.2.89)$$

Wallis [3] presented a simple equation for gas void fraction in the core given by

$$f_{gc} = (1 + X^{0.8})^{-0.378} \quad (6.2.90)$$

where X is the Lockhart-Martinelli parameter given in terms of the gas mass fraction x_g as

$$X = \left[\frac{(1 - x_g)}{x_g}\right]^{0.9} \left(\frac{\mu_L}{\mu_g}\right)^{0.1} \sqrt{\frac{\rho_L}{\rho_g}} \quad (6.2.91)$$

Example 6.2.7

Solve Example 6.2.2 using the Hasan-Kabir mechanistic model.

The bubble/slug transition is checked using Equation 6.2.73. The slip velocity is first found Equation 6.2.75

$$\begin{aligned} v_s &= 1.53 \left[\frac{g\sigma_L(\rho_L - \rho_g)}{\rho_L^2} \right]^{1/4} \\ v_s &= 1.53 \left[\frac{32.17^2(0.001918)(47.6 - 8.823)}{47.6^2} \right]^{1/4} \\ &= 0.656 \text{ ft/s} \end{aligned}$$

Using $C_o = 1.2$, V_{sg} is calculated from Equation 6.2.73 as

$$\begin{aligned} v_{sg} &= \frac{\sin \theta}{4 - C_o} (C_o v_{sL} + v_s) \\ v_{sg} &= \frac{1}{4 - 1.2} (1.2 \times 2.147 + 0.656) \\ &= 1.1544 \text{ ft/s} \end{aligned}$$

Since $V_{sg} > 0.656$ ft/s, bubble flow does not exist. Now, check dispersed-bubble transition (Equation 6.2.77)

$$\begin{aligned} v_m^{1.12} &= 4.68 \left(\frac{d}{12}\right)^{0.48} \sqrt{\frac{g(\rho_L - \rho_g)}{g_c \sigma_L}} \\ &\times \left(\frac{g_c \sigma_L}{\rho_L}\right)^{0.6} \left(\frac{\rho_L}{g_c \mu_L}\right)^{0.08} \end{aligned}$$

$$\begin{aligned} \left(\frac{dP}{dL}\right)_f &= \frac{2f\rho_L v_m^2 H_L}{d} \\ &= \frac{2 \times 0.004 \times 47.6 \times 6.227^2 \times 0.5025}{0.1662} \\ &= 1.38645 \text{ lb}_f/\text{ft}^3 = 0.009628 \text{ psi/ft} \end{aligned}$$

Thus, the total pressure gradient

$$\begin{aligned} \frac{dP}{dL} &= 0.1965 + 0.009628 = 0.20618 \text{ psi/ft} \\ \Delta L &= \frac{500}{0.20618} = 2425.07 \text{ ft} \end{aligned}$$

In general, the performance of the Hasan-Kabir mechanistic model is good for a wide range of tubing sizes, oil gravity, gas-liquid ratio, and water-cut.

6.2.18 Summary

In this work, attention was paid only to six methods: flow regime maps, the Duns-Ros, Orkiszewski, Hagedorn-Brown, Beggs-Brill, and Hasan-Kabir methods. They are the most often used. A comprehensive discussion of the many other multiphase models published in the literature, including the ones discussed here, can be found in a recently published monograph [23,24]. As alluded to in the preceding discussions, the pressure profile in a pipe is influenced by a number of parameters such as tubing size and geometry, well inclination, and fluid composition and properties (which in turn depend on pressure and temperature). Therefore, the empirical methods presented above should be used with caution, keeping in mind the experimental range of validity for which the correlation have been developed. For example, the Hagedorn-Brown, Orkiszewski, and Duns-Ros correlations have all been developed for vertical wells, and their use in deviated wells may or may not yield accurate results. In addition, the Duns-Ros correlation is not applicable for wells with water-cut and should be avoided for such cases. Similarly, the Beggs-Brill method, primarily developed for inclined wells, is applicable to multiphase flows with or without water cut. In general, mechanistic models such as the Hasan-Kabir have a wide range of applicability because of their limited reliance on empiricism.

Over the years, numerous modifications to the above discussed empirical models have been proposed to improve their multiphase flow predictions and to extend their range of applicability. Some of these modifications are discussed in the monograph by Brill and Mukherjee [23] and are used extensively in many commercial software programs. The monograph also presents a comparative study of the performance of both empirical and mechanistic models with measured field data from a well databank for a variety of cases. Although some methods/models perform better than others for certain cases, no single method performs

accurately for all cases despite development of new mechanistic models. Therefore, it is strongly recommended that the model limitations and validity be kept in mind before a particular model/correlation is selected in the absence of other relevant information such as measured field data.

6.3 NATURAL FLOW PERFORMANCE

Section reviewed by Boyun (Gordon) Guo

The most important parameters that are used to evaluate performance or behavior of petroleum fluids flowing from an upstream point (in reservoir) to a downstream point (at surface) are pressure and flow rate. According to basic fluid flow through reservoir, production rate is a function of flowing pressure at the bottomhole of the well for a specified reservoir pressure and the fluid and reservoir properties. The flowing bottomhole pressure required to lift the fluids up to the surface may be influenced by the size of the tubing string, choke installed at downhole or surface and pressure loss along the pipeline.

In oil and gas fields, the flowing system may be divided into at least four components:

1. reservoir
2. wellbore
3. chokes and valves
4. surface flowline

Each individual component, through which reservoir fluid flow, has its own performance and, of course, affects each other. A good understanding of the flow performances is very important in production engineering. The combined performances are often used as a tool for optimizing well production and sizing equipment. Furthermore, engineering and economic judgments can depend on good information on the well and reasonable prediction of the future performances.

As has been discussed in previous sections, hydrocarbon fluids produced can be either single phase (oil or gas) or two phases. Natural flow performance of oil, gas, and the mixture will therefore be discussed separately. Some illustrative examples are given at the end of each subsection.

6.3.1 Single-Phase Liquid Flow Performance

6.3.1.1 Inflow Performance

Inflow performance represents behavior of a reservoir in producing the oil through the well. For a heterogeneous

reservoir, the inflow performance might differ from one well to another. The performance is commonly defined in terms of a plot of surface production rate (stb/d) versus flowing bottomhole pressure (P_{wf} in psi) on cartesian coordinate. This plot is defined as inflow performance relationship (IPR) curve and is very useful in estimating well capacity, designing tubing string, and scheduling an artificial lift method.

For single-phase liquid flow, radial flow equation can be written as (for oil)

1. semi-steady-state condition

$$q_0 = 0.00708k_0h \frac{(P_r - P_{wf})}{\bar{\mu}_0 \bar{B}_0 \left(\ln \frac{r_e}{r_w} - \frac{3}{4} + s \right)} \quad (6.3.1a)$$

2. steady-state condition

$$q_0 = 0.00708k_0h \frac{(P_r - P_{wf})}{\bar{\mu}_0 \bar{B}_0 \left(\ln \frac{r_e}{r_w} - \frac{1}{2} + s \right)} \quad (6.3.1b)$$

where q_0 = surface measured oil rate in stb/d
 k_0 = permeability to oil in md
 h = effective formation thickness in ft.
 P_r = average reservoir pressure in psia
 P_{wf} = flowing bottomhole pressure in psia
 $\bar{\mu}_0$ = oil viscosity evaluated at $\frac{(P_r + P_{wf})}{2}$
 in cp
 \bar{B}_0 = oil formation volume factor
 evaluated at $\frac{(P_r + P_{wf})}{2}$ in bbl/stb
 r_e = drainage radius in ft.
 r_w = wellbore radius in ft.
 s = skin factor, dimensionless

Assuming all parameters but P_{wf} are constants in the equations above, it is also clear the flowrate q_0 is linearly proportional to flowing pressure P_{wf} . Therefore, for laminar flow the plot q_0 versus P_{wf} on a cartesian coordinate must be linear. This is illustrated in Figure 6.3.1. Strictly speaking, it shows the behavior of single-phase liquid flowing over the range of P_{wf} . In actual cases, however, straightline IPR may be shown by reservoirs producing at P_r and P_{wf} above the bubble point pressure P_b , and by strong water-drive reservoirs.

Productivity index, usually denoted by the symbol J , is commonly expressed in practice for well performance. It is mathematically defined as

$$J = \frac{q_0}{P_r - P_{wf}} \quad (6.3.2)$$

FIGURE 6.3.1 Inflow performance relationship of single-phase oil reservoirs.

where J is in stb/d/psi. The term $(P_r - P_{wf})$ is called *pressure drawdown*. Equation 6.3.1a or 6.3.1b can be rearranged to be used in estimating well productivity index.

By knowing reservoir pressure P_r , it is possible to construct an oil IPR curve from a single flow test on a well. Or, because of the linearity of liquid IPR curves, by conducting a two-point flow test (two different flowrates while measuring the flowing bottomhole pressure) on a well, the static reservoir pressure can be determined.

The equations discussed above are derived from the laminar Darcy's law. In a case where turbulent flow occurs, a modified equation should be used. The occurrence of turbulence at the bottomhole may indicate too few open perforations or too narrow fracture in fractured well or other incorrect completion method applied. All these bring about inefficient production operation because the high drawdown encountered results in insufficient flowrate. The symptom may be analyzed using the correlation of Jones et al. [1]:

$$\frac{\Delta P}{q_0} = C + Dq_0 \quad (6.3.3a)$$

where

$$C = \frac{\mu_0 B_0}{0.00708k_0h} \left(\ln \frac{r_e}{r_w} - \frac{3}{4} + s \right) \quad (6.3.3b)$$

is called the laminar flow coefficient, and

$$D = \frac{9.08 \times 10^{-13} \beta B_0^2 \gamma_0}{4\pi^2 h^2 r_w} \quad (6.3.3c)$$

is the turbulence coefficient, with β = the turbulence factor in ft.^{-1} and γ_0 = oil specific weight in lb/ft.^3 and other terms are the same as in the previous equations. The magnitude of the turbulent factor is in the order of 10^{-6} and 10^{-8} and is usually negligible when compared with

the laminar flow coefficient in most oil wells. But if this is not the case, plot $(\Delta P/q)$ versus q on a cartesian coordinate paper. If the flow is fully laminar, then the plot has a slope of zero. But when turbulence is measurable, the plot has non-zero positive slope, which also means that the productivity decreases as flowrate increases.

For horizontal wells in steady-state condition, the flow equation can be written as [25]

$$q_o = 0.00708k_Hh \frac{(P_r - P_{wf})}{\mu_o B_o \left[\ln \left[\frac{a + \sqrt{a^2 - (L/2)^2}}{L/2} \right] + \frac{h\sqrt{k_H/k_V}}{L} \ln \left[\frac{h\sqrt{k_H/k_V}}{r_w(1 + \sqrt{k_H/k_V})} \right] + s \right]} F_o \quad (6.3.4a)$$

where

$$a = \frac{L}{2} \sqrt{\frac{1}{2} + \sqrt{\frac{1}{4} + \left(\frac{r_{eH}}{L/2}\right)^4}} \quad (6.3.4b)$$

k_H = horizontal permeability to oil in md

k_V = vertical permeability to oil in md

L = length of horizontal wellbore in ft

r_{eH} = radius of drainage area for the horizontal well in ft

F_o = correction factor for wellbore friction, dimensionless.

For horizontal wells in semi-steady-state condition, the flow equation is [26]

$$q_o = 0.00708k_Hh \frac{(P_r - P_{wf})}{\mu_o B_o \left[\ln \left(\frac{\sqrt{AB}}{r_w} \right) + \ln C_H - \frac{3}{4} + S_R \right]} \quad (6.3.5)$$

where A = length of drainage area in the direction perpendicular to the wellbore in ft

B = length of drainage area in the direction of horizontal wellbore in ft

C_H = permeability anisotropy factor, dimensionless

S_R = skin factor, dimensionless.

Pertaining to our problem here dealing with single-phase oil flow in reservoirs, we always assume that gas does not develop over the whole range of flowing pressure at downhole. The consequence is that the following equations are valid for wells that produce only oil (and water).

Recalling the radial flow equation for oil (Equation 6.3.1a,b for instance), we obtain

$$q_{o_{\max}} = \frac{0.00708k_o h P_r}{\bar{\mu}_o \bar{B}_0 \left(\ln \frac{r_e}{r_w} - \frac{3}{4} + s \right)} \quad (6.3.6a)$$

where $q_{o_{\max}}$ is a theoretical possible maximum flowrate when $P_{wf} \approx 0$.

For horizontal wells in steady-state condition, the maximum possible flow rate is expressed as

$$q_{o_{\max}} = \frac{0.00708k_H h P_r}{\mu_o B_o \left[\ln \left[\frac{a + \sqrt{a^2 - (L/2)^2}}{L/2} \right] + \frac{h\sqrt{k_H/k_V}}{L} \ln \left[\frac{h\sqrt{k_H/k_V}}{r_w(1 + \sqrt{k_H/k_V})} \right] + s \right]} F_o \quad (6.3.6b)$$

Assuming no changes in producing interval, skin factor and drainage radius occur during a period of time from present to the future, and also $\bar{\mu}_o$ and \bar{B}_o are nearly constant over the whole range of pressure, the future possible maximum flowrate is:

$$(q_{o_{\max}})_f = (q_{o_{\max}})_p \times \frac{(k_{ro} \times P_r)_f}{(k_{ro} \times P_r)_p} \quad (6.3.7)$$

Because no gas develops in the reservoir, the relative permeability to oil can be a function of water saturation. Figure 6.3.2 suggests the possibility of changes in oil inflow performance curves with time ($t_2 > t_1$).

6.3.1.2 Tubing Performance

A tubing performance may be defined as the behavior of a well in giving up the reservoir fluids to the surface. The performance is commonly showed as a plot of flowrate versus flowing pressure. This plot is called the tubing performance relationship (TPR). For a specified wellhead pressure, the TPR curves vary with diameter of the tubing. Also, for a given tubing size, the curves vary with wellhead pressure. Figure 6.3.3 shows the effect of tubing size and wellhead pressure [2].

For single-phase liquid flow, pressure loss in tubing can be determined using a simple fluid flow equation for vertical pipe, or using some graphical pressure loss correlations where available with $GLR = 0$.

Tubing performance curves are used to determine the producing capacity of a well. By plotting IPR and TPR on the same graph paper, a stabilized maximum production rate of the well can be estimated. Figure 6.3.3 shows the combined plots for determining the flowrate. The larger the diameter of tubing, the higher the flowrate that can be obtained. But there is a critical diameter limiting the rate, even lowering the well capacity. For a specified tubing size, the lower the wellhead pressure, the higher the production rate.

6.3.1.3 Choke Performance

A choke can be installed at the wellhead or downhole to control natural flow or pressure. Chokes are widely used in oil fields. Several reasons in installing chokes are to regulate production rate, to protect surface equipments from

FIGURE 6.3.2 Possibility of changes in wells productivity.

slugging, to avoid sand problem due too high drawdown, or to control flowrate in order to avoid water or gas coning.

There are two types of wellhead choke that are commonly used, positive chokes and adjustable chokes. A positive choke has a fixed size in diameter so that it must be replaced to regulate production rate. An adjustable choke permits gradual changes in the size of the opening.

Placing a choke at the wellhead can mean fixing the wellhead pressure and thus flowing bottomhole pressure and production rate. For a given wellhead pressure, by calculating pressure loss in the tubing, the flowing bottomhole pressure can be determined. If reservoir pressure and productivity index of the well are known, the flowrate can then be determined using Equation 6.3.2.

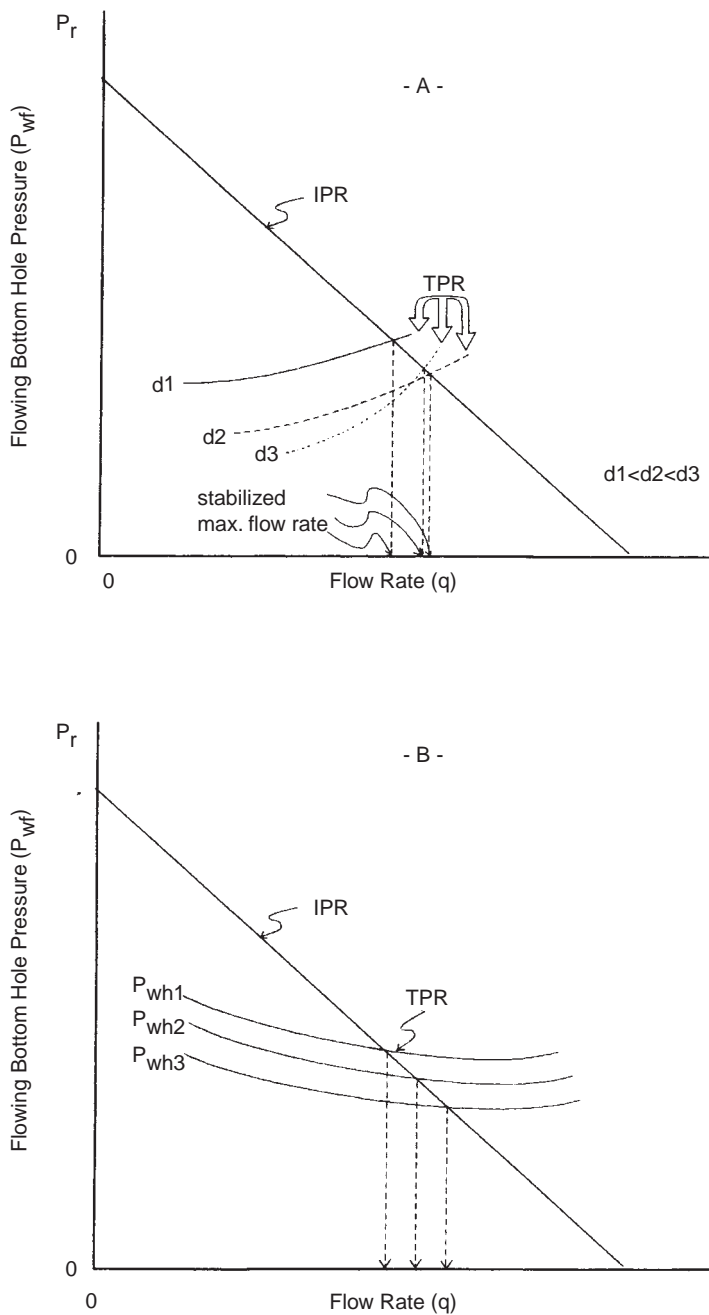

FIGURE 6.3.3 Effects of tubing size and tubing head pressure on a well productivity.

The rate of oil flowing through a choke (orifice or nozzle) depends upon pressure drop in the choke, the inside diameters of pipe and choke, and density of the oil. For incompressible fluids, the Equation 6.3.8 may be used to estimate the flowrate of oil:

$$q_0 = 10,285CA \sqrt{\frac{\Delta P}{\gamma_o}} \quad (6.3.8)$$

where q_0 = oil rate in bbl/day

C = flow coefficient as function of diameter ratio and Reynolds number (see Figure 6.3.4)

A = cross-sectional area of choke in in.^2

ΔP = pressure drop across the choke in psi

γ_o = oil specific weight in lb/ft.^3

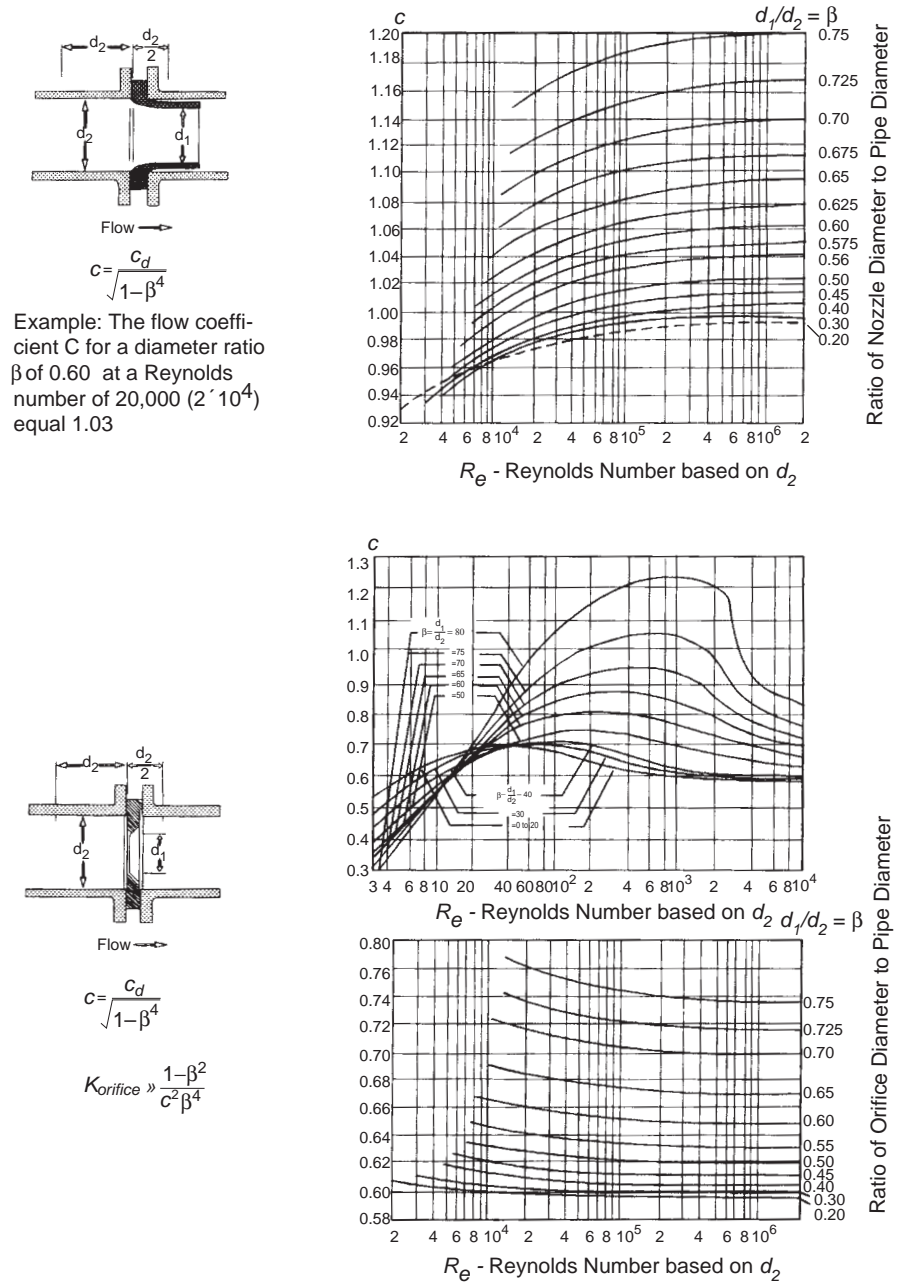

FIGURE 6.3.4 Flow coefficient versus diameter ratio and Reynolds number [2].

In installing a choke, the downstream pressure of the choke is usually 0.55 of the upstream pressure, or even less to ensure no change in flowrate or upstream pressure. This condition is called a sonic flow. A subsonic flow occurs when the upstream pressure or flowrate is affected by a change in downstream pressure.

6.3.1.4 Flowline Performance

After passing through a choke installed at the wellhead, the oil flows through flowline to a separator. If the separator is far from the wellhead and the pressure loss in the flowline

cannot be neglected, pressure-flowrate relationship for flowline can be generated similar to tubing performance curves. Usually the separator pressure is specified. Then by using pressure gradient curves available for horizontal pipes or using a simple horizontal fluid flow equation, the wellhead pressure or downstream pressure of the choke or intake pressure of the flowline can be determined as a function of flowrate. This pressure-flowrate plot is useful in sizing the flowline. Figure 6.3.5 illustrates the relationship between the wellhead pressure and flowrate for some different flowline diameters. This plot is called flowline performance curve.

FIGURE 6.3.5 Flowline performance curves for different flowline diameters.

FIGURE 6.3.6 Combined tubing-flowline performance curves.

By plotting TPR in term of wellhead pressure for various tubing sizes and flowline performance curves on the same graph (Figure 6.3.6), selecting tubing string-flowline combination for a well can be established based on the pipe’s availability, production scheme planned, and economic consideration.

Example 6.3.1

Determination of oil inflow performance.

Suppose two flowrates are conducted on an oil well. The results are as follows:

	Test 1	Test 2
q _o , stb/d	200	400
P _{wf} , psi	2400	1800

Gas/oil ratios are very small. Estimate the reservoir pressure and productivity index of the well, and also determine the maximum flowrate.

Solution

1. Plot the two data points on a Cartesian graph paper (q_o versus P_{wf}), see Figure 6.3.7. Draw a straight line through these two points, the intersection with ordinate is the estimated reservoir pressure which is about 3000 psi.
2. The productivity index is

$$J = \frac{200}{3,000 - 2,400} = 0.333 \text{ stb/d/psi}$$

3. The theoretical maximum flowrate is:

$$q_{\text{max}} = 0.333(3,000 - 0) = 1,000 \text{ stb/d}$$

Example 6.3.2

The well illustrated in Example 6.3.1 has a vertical depth of 4100 ft. Tubing string of 2 3/8 in. has been installed. The flowing pressure at wellhead is 210 psi. What is the stabilized oil rate achieved?

Solution

Using Gilbert’s correlation, we obtain:

q, stb/d	P _{wf} , psi
200	1700
400	1695
600	1690

Plot these values of q and P_{wf} on the same graph paper used for solving problem Example 6.3.1 above (Figure 6.3.7). What we get is the TPR curve intersecting the IPR curve. This intersection represents the stabilized rate achieved, which is 435 stb/d.

Example 6.3.3

The oil well of Example 6.3.1 is producing 25° API oil. If a positive choke with diameter of 14/64 in. is installed at the wellhead, determine the pressure at the downstream of the choke.

Solution

$$\gamma_0 = \frac{141.5}{131.5 + 25} \times 62.4 = 56.42 \text{ lb/ft.}^3$$

Rearranging Equation 6.3.8 and assuming that C ≈ 1.0

$$\Delta P = 56.42 \times \left(\frac{435}{10,285(1.0)(0.03758)} \right)^2 = 72 \text{ psi}$$

$$P_{\text{downstream}} = (210 - 72) \text{ psi} = 138 \text{ psi}$$

FIGURE 6.3.7 Pressure-rate relationship for examples A and B on pages 542 to 544.

6.3.2 Gas Flow Performances

As for oil wells, performance curves characterizing a gas production system are very useful tools used to visualize and graphically predict the effects of declining reservoir pressure, changes in tubular size, increasing water production, or installing gas compressors.

6.3.2.1 Gas Inflow Performance

A mathematical expression commonly used to relate gas flowrate and flowing bottomhole pressure is

$$q = C(P_r^2 - P_{wf}^2)^n \quad (6.3.9)$$

where q = gas flowrate in Mscf/d
 P_r = shut-in reservoir pressure in psia
 P_{wf} = flowing bottomhole pressure in psia
 C = stabilized performance coefficient, constant
 n = numerical exponent, constant

Equation 6.3.9 was first introduced by Rawlins and Schellhardt [3] in 1935 and is known as the back-pressure equation. From gas well test data, plotting q versus $(P_r^2 - P_{wf}^2)$ on a log-log graph will give a straight line passing through the data points, see Figure 6.3.8. This plot was made based on a stabilized four-point test.

The information that can be obtained from this plot is the absolute open flow potential (AOFP) of the well. This is defined as the theoretical maximum flowrate when flowing pressure at the sand face is zero.

Determination of the exponent n and the coefficient C is given here using Figure 6.3.8 as follows:

1. Choose two values of q arbitrarily but separated one cycle from each other.
2. Read corresponding values of $(P_r^2 - P_{wf}^2)$.
3. Calculate

$$n = 1/\text{slope} = \frac{\log q_2 - \log q_1}{\log(P_r^2 - P_{wf}^2)_2 - \log(P_r^2 - P_{wf}^2)_1}$$

FIGURE 6.3.8 Stabilized four-point test and open flow potential of a gas well.

Choosing $q_1 = 1$ gives $(P_r^2 - P_{wf}^2)_1 = 1.5$, and $q_2 = 10$ gives $(P_r^2 - P_{wf}^2)_2 = 20.7$
Then

$$n = \frac{\log 10 - \log 1}{\log 20.7 - \log 1.5} = 0.877$$

4. Rearranging Equation 6.3.9, we obtain:

$$C = \frac{q}{(P_r^2 - P_{wf}^2)^n} = \frac{10,000}{(20.7 \times 10^6)^{0.877}} = 3.84 \times 10^{-3} \text{ Mscf/d/psia}^{2n}$$

The AOFP of the well can then be calculated as:

$$\begin{aligned} \text{AOFP} = q_{\max} &= 3.84 \times 10^{-3} (3887^2 - 0^2)^{0.877} \\ &= 7585 \text{ Mscf/d} \\ &= 7.585 \text{ MMscf/d} \end{aligned}$$

From the graph, the AOFP = 7.6 MMscf/d

The IPR curve can be constructed by using the deliverability equation above. By taking some values of P_{wf} arbitrarily, the corresponding q 's can be calculated. The IPR curve for the example is shown in Figure 6.3.9.

For situations where multipoint tests cannot be run due to economic or other reasons, single-point data can

be used to generate the IPR curve provided that a shut-in bottomhole pressure is known. Mishra and Caudle [4] proposed a simple method for generating a gas IPR curve from just a single-point test data. Employing the basic gas flow in term of pseudo-pressure function, they developed a dimensionless IPR curve to be used as a reference curve. As an alternative, the dimensionless IPR equation to the best-fit curve is introduced

$$\frac{q}{q_{\max}} = \frac{5}{4} \left(1 - 5 \frac{m(P_{wf})}{m(P_r)} - 1 \right) \quad (6.3.10)$$

where q_{\max} = AOFP in Mscf/d

$m(P_{wf})$ = pseudo-pressure function for real gas and defined as

$$\begin{aligned} m(P_{wf}) &= 2 \int_{P_b}^{P_{wf}} \left(\frac{P}{\mu Z} \right) dP \\ m(P_r) &= 2 \int_{P_b}^{P_r} \left(\frac{P}{\mu Z} \right) dP \end{aligned} \quad (6.3.11)$$

where μ = gas viscosity(function of P at isothermal condition) in cp

Z = gas compressibility factor, dimensionless

FIGURE 6.3.9 Inflow performance relationship for a gas reservoir.

The use of pseudo-pressure function is quite complex. A numerical integration technique, however, can be applied to this problem. A detail example in applying this numerical technique can be found in *Fundamentals of Reservoir Engineering* [5].

More recently, Chase and Anthony [6] offered a simpler method that is a modification to the Mishra-Caudle method. The method proposed involves substitution of real pressure P or P^2 for the real gas pseudopressure function $m(P)$. The squared pressure P^2 is used for pressures less than approximately 2100 psia, and the relevant equation is

$$\frac{q}{q_{\max}} = \frac{5}{4} \left(1 - 5 \left(\frac{P_{wf}^2}{P_r^2} - 1 \right) \right) \quad (6.3.12)$$

The real pressures P is suggested for pressures greater than approximately 2900 psia. By having the average reservoir pressure P_r , and a single-point test data P_{wf} and q , it is possible to determine the AOF and to generate the inflow performance curve:

$$\frac{q}{q_{\max}} = \frac{5}{4} \left(1 - 5 \left(\frac{P_{wf}}{P_r} - 1 \right) \right) \quad (6.3.13)$$

For pressures ranging for 2100 to 2900 psia, the original Mishra-Caudle's technique is recommended.

The requirement of the back-pressure method of testing is that the data be obtained under stabilized conditions. That means that the coefficient C of Equation 6.3.9 is

constant with time. This coefficient depends on reservoir characteristics, extent of drainage radius, and produced fluid characteristics.

Wells completed in highly permeable formations stabilize quickly. As demand for gas increased over the years, wells were completed in less permeable formations. In wells of this type, the stabilization period may be very long. Therefore, methods were needed that would permit testing of this type of well without undue waste of time.

In 1955 M. H. Cullender described the isochronal method for determining flow characteristics [7]. The method is based on the assumption that the slope of performance curves of gas wells, exponent n of Equation 6.3.9, is independent of the drainage area. It is established almost immediately after the well is opened. However, the performance coefficient C decreases with time as the radius of drainage recedes from the well. When the radius reaches the boundary of the reservoir or the area of interference of another well, C becomes a constant and the flow is stabilized.

Under the method the well is opened, the flow and pressure data are obtained at specific time intervals without changing the rate of flow. The well is then closed in until the shut-in pressure is reached, approximately the same as at the beginning of the first test. The well is then opened and produced at a different rate, and the pressure and flow data are collected. This procedure is repeated as many times as desired.

FIGURE 6.3.10 Isochronal performance curves of gas well no. 1.

Plotting of these data on log-log paper results in a series of parallel lines, the slope of which gives the coefficient n . This is illustrated in Figure 6.3.10. Relationship of coefficient C and time for a gas well is illustrated in Figure 6.3.11.

From these test and theoretical considerations, different procedures have been developed that permit prediction of the coefficients of performance of gas wells produced from low-permeability formations.

Predicting the wells' deliverability is important to be able to plan some changes required to maintain the production capacity. Here simple but reliable methods are introduced to forecasting future inflow performance gas wells.

Accompanying Equation 6.3.10, Mishra and Caudle presented an empirical equation for predicting gas wells productivity [4]. The equation is:

$$\frac{(q_{\max})_f}{(q_{\max})_p} = \frac{5}{3} \left(1 - 0.4 \frac{m(P_r)_f}{m(P_r)_p} \right) \quad (6.3.14)$$

where subscripts f and p refer to future and present time, respectively. Later, Chase and Anthony [6] also proposed the simplified form of Equation 6.3.14, by substituting real pressure for pseudo-pressure function.

To estimate the AOF of a gas well, one does not have to run well tests as discussed above. An alternative method is to calculate bottomhole pressure, static and flowing, without running a pressure gage down into the well, by knowing pressures at the wellhead. The calculation of

FIGURE 6.3.11 Relationship of coefficient of performance and time of gas well no. 3.

flowing bottomhole pressures will be discussed later. Below, the equations for calculating static bottomhole pressure are given.

One of the most common methods in estimating static bottomhole pressure of a gas well is that of Cullender and Smith, which treats the gas compressibility factor as a function of depth [8]. If we divide the well by equal length, one can calculate the static bottomhole pressure as follows:

1. Having a knowledge of static wellhead pressure, pressure at midpoint of the well is calculated by trial and error:

$$0.0375G_g \frac{H}{2} = (P_{ms} - P_{ws})(I_{ms} - I_{ws}) \quad (6.3.15)$$

where G_g = gas gravity (air = 1.0)
 H = well depth in ft.

$$I_{ms} = (T_{ms} \times Z_{ms})/P_{ms} \quad (6.3.16)$$

where T_{ms} = absolute temperature at midpoint in °R
 P_{ms} = pressure at midpoint (assumed to calculate Z_{ms}) in psia
 Z_{ms} = gas compressibility factor evaluated at T_{ms} and P_{ms}
 P_{ws} = static wellhead pressure in psia

$$I_{ws} = \frac{T_{ws}Z_{ws}}{P_{ws}} \quad (6.3.17)$$

where T_{ws} = absolute temperature at wellhead in °R
 Z_{ws} = gas compressibility factor evaluated at T_{ws} and P_{ws}

The problem here is to calculate P_{ms} . If calculated $P_{ms} \approx P_{ms}$ assumed to determine Z_{ms} , then calculation of bottomhole pressure is the next step. If not, use calculated P_{ms} to determine new Z_{ms} and again use Equations 6.3.16 and 6.3.17 to calculate a new P_{ms} . Repeat this procedure until calculated P_{ms} is close to assumed P_{ms} .

- The same procedure is used, and the equation for static bottomhole pressure P_{bs} is:

$$0.0375G_g \frac{H}{2} = (P_{bs} - P_{ms})(I_{bs} + I_{ms}) \quad (6.3.18)$$

- The very last step is to apply Simpson's rule to calculate P_{bs} :

$$0.0375G_g H = \frac{P_{bs} - P_{ws}}{3} (I_{ws} + 4I_{ms} + I_{bs}) \quad (6.3.19)$$

For wells producing some liquids, the gas gravity G_g in Equations 6.3.15 and 6.3.18 must be replaced by γ_{mix} :

$$G_{mix} = \frac{G_g + 4584G_o/R}{1 + 132800G_o/RM_o} \quad (6.3.20)$$

where G_{mix} = specific gravity of mixture (air = 1.00)
 G_g = dry gas gravity
 G_o = oil gravity
 R = surface producing gas–oil ratio in scf/stb
 M_o = molecular weight of oil in lbm/lb-mole

The G_{mix} is then used to determine the pseudocritical properties for calculation of the compressibility factor.

If water production is quite significant, the following equation may be used [9]:

$$G_{mix} = \frac{G_g + 4584 \left(\frac{G_o}{R} + \frac{1}{R_w} \right)}{1 + 132,800 \left(\frac{G_o}{RM_o} + \frac{1}{18R_w} \right)} \quad (6.3.21)$$

where R_w = producing gas/water ratio in scf/stb

6.3.2.2 Tubing Performance

In a gas well, tubing performance can be defined as the behavior of the well in producing the reservoir gas through the tubing installed. At a specified surface pressure, the flowing bottomhole pressure can be calculated by using an equation for vertical flow of gas. Katz presented the equation that is simple but valid only for dry gas [10]:

$$q_g = 200,000 \left(\frac{sD^5 (P_{wf}^2 - e^s P_{wh}^2)}{G_g \bar{T} Z H f (e^s - 1)} \right)^{0.5} \quad (6.3.22)$$

where q_g = gas flowrate in scf/d
 D = diameter of tubing in in.
 P_{wf} = bottomhole flowing pressure in psia
 P_{wh} = wellhead flowing pressure in psia
 G_g = gas gravity (air = 1.0)
 \bar{T} = average temperature in °R
 \bar{Z} = average gas compressibility factor
 H = vertical depth in ft.
 f = friction factor = $\{2 \log[3.71/(\epsilon/D)]\}^{-2}$
 ϵ = absolute pipe roughness, $\cong 0.0006$ in.

$$s = 0.0375G_g H / \bar{T} Z \quad (6.3.23)$$

The average temperature used in the Equation 6.3.22 is simply the arithmetic average between wellhead temperature and bottomhole temperature. The gas compressibility factor \bar{Z} is evaluated at the average temperature and the arithmetic average between the flowing wellhead and bottomhole pressures. This method is a trial-and-error technique, but one or two iterations is usually sufficiently accurate.

By knowing all parameters in Equation 6.3.22 but q_g and P_{wf} , the TPR can then be constructed. The use of TPR here is the same as discussed previously for oil wells. Figure 6.3.12 shows an idea of the effect of wellhead pressure on a well deliverability. A decrease in P_{wh} , thus an increase in flowrate, can be done by changing a choke/bean diameter to a bigger one.

For a specified wellhead pressure, the flowing bottomhole pressure can be estimated as a function of flowrate and tubing diameter. Equation 6.3.22 can be used to do this.

In many cases, gas wells produce some liquids along with the gas itself. The equation for dry gas should be

FIGURE 6.3.12 Effect of well head pressure on gas well deliverability.

modified to account for the liquid content. One of the modifications presented in the literature was made by Peffer, Miller, and Hill [9]. For steady-state flow and assuming that the effects of kinetic energy are negligible, the energy balance can be arranged and written as:

$$\frac{G_g H}{53.34} = \int_{P_{wh}}^{P_{wf}} \frac{\left(\frac{P}{TZ}\right)}{F^2 + \left(\frac{P}{TZ}\right)^2} dP \quad (6.3.24)$$

where P_{wf} = flowing bottomhole pressure in psia
 P_{wh} = flowing wellhead pressure in psia

$$F^2 = \frac{2666.5fQ^2}{d^5} \quad (6.3.25)$$

d = inside diameter of tubing in in.
 f = friction factor, dimensionless
 Q = flowrate, MMscf/d

Evaluation of friction factor f depends on the stream of fluids in the well. For single-phase (dry gas) and fully developed turbulent flow with an absolute roughness of 0.0006 in., Cullender and Smith [8] suggested the use of:

$$F = \frac{0.10797Q}{d^{2.612}} \quad \text{for } d < 4.277 \text{ in.} \quad (6.3.26)$$

and

$$F = \frac{0.10337Q}{d^{2.582}} \quad \text{for } d > 4.277 \text{ in.} \quad (6.3.27)$$

When some liquids are present in the flowing stream Peffer et al. suggested the use of an apparent roughness of 0.0018 instead of using the absolute roughness of 0.0006. Also, adjustment in specific gravity of the fluids should be made by using Equation 6.3.20 or Equation 6.3.21. Applying these adjustments, the method of Cullender and

Smith [8] may be used for a wide range of gas-condensate well condition.

However, whenever the Reynold's number for a specific can be calculated and pipe specifications are available, the friction factor can then be easily determined to be used for pressure loss calculations. Equation 6.3.28 and Equation 6.3.29 can be used to calculate the Reynold's number and friction factor, respectively.

$$Re = \frac{20011G_g Q}{\mu_g d} \quad (6.3.28)$$

$$\frac{1}{\sqrt{f}} = 2.28 - 4 \log \left(\frac{\epsilon}{d} + \frac{21.28}{Re^{0.9}} \right) \quad (6.3.29)$$

where Re = Reynolds number

G_g = gas gravity (air = 1.00)

Q = gas flowrate in MMscf/d

μ_g = gas viscosity in cp

d = inside diameter of pipe in in.

ϵ = absolute roughness in in.

f = friction factor, dimensionless

For a well divided in equal lengths the upper half of the well has a relation:

$$37.5G_g \frac{H}{2} = (P_{MF} - P_{WH})(I_{MF} + I_{WH}) \quad (6.3.30)$$

where P_{MF} = flowing pressure at midpoint in psia

P_{WH} = flowing wellhead pressure in psia

$I = (P/TZ)/[F^2 + (P/TZ)^2]$

F = shown in Equation 6.3.34

H = well depth in ft.

and the lower half of the well has the relation:

$$37.5G_g H = (P_{WF} - P_{MF})(I_{WF} + I_{MF}) \quad (6.3.31)$$

where P_{WF} = flowing bottomhole pressure in psia.

After trial and error as previously discussed, Simpson's rule applies:

$$37.5G_g H = \frac{P_{WF} - P_{WH}}{3} (I_{WH} + 4I_{MF} + I_{WF}) \quad (6.3.32)$$

6.3.2.3 Choke Performance

Chokes or beans are frequently installed in gas wells. These restrictions can be at the surface or at the subsurface. A surface choke is usually installed for:

1. regulating production rate
2. maintaining sufficient back pressure to avoid sand production
3. protecting surface equipment from pressure surge
4. preventing water coning
5. obeying regulatory bodies

Subsurface restrictions can be a tubing safety valve, a bottomhole choke, or a check valve. A tubing safety

FIGURE 6.3.13 A correlation for gas flow through orifice [12].

valve functions to stop flowstream whenever the surface control equipment is damaged or completely removed. A bottomhole choke is installed if low wellhead pressure is required or freezing of surface control equipment and lines is expected. A check valve is installed to prevent backflow of an injection well. Basically, there are two types of flow conditions: subsonic or sub-critical flow and sonic flow. The criteria to distinguish subsonic from sonic flow has been discussed previously in the section titled “Choke Performance.”

For subsonic flow, the following equation given by Nind can be used to calculate the gas flowrate [11].

$$Q = 1248CAP_u \left\{ \frac{k}{(k-1)G_g T_u} \left[\left(\frac{P_d}{P_u} \right)^{2/k} - \left(\frac{P_d}{P_u} \right)^{\frac{k+1}{k}} \right] \right\}^{0.5} \quad (6.3.33)$$

where Q = gas flow rate in Mcf/d
 C = discharge coefficient, ≈ 0.86
 A = cross-sectional area of choke or restriction in in.²
 P_u = upstream pressure in psia
 P_d = downstream pressure in psia
 G_g = gas gravity (air = 1.00)
 T_u = upstream temperature in °R
 k = specific heat ratio, C_p/C_f

Equation 6.3.33 shows that subsonic flow is affected by upstream and downstream pressure.

In critical or sonic flow, gas flowrate depends only on upstream pressure as shown as:

$$Q = 879CAP_u \left[\frac{k}{G_g T_u} \left(\frac{2}{k+1} \right)^{\frac{k+1}{k-1}} \right]^{0.5} \quad (6.3.34)$$

where Q = flowrate in Mcf/d
 C = discharge coefficient
 A = choke area in in.²
 P_u = upstream pressure in psia
 G_g = gas gravity (air = 1.00)
 T_u = upstream temperature in °R
 k = specific heat ratio

The discharge coefficient C can be determined using Figure 6.3.4 by having a knowledge of diameter ratio β and Reynold’s number. Reynold’s number may be calculated using the following equation:

$$Re = \frac{20.011QG_g}{\mu_g d} \quad (6.3.35)$$

where Q = gas flowrate in Mcf/d
 G_g = gas gravity (air = 1.00)
 μ_g = gas viscosity, evaluated at upstream pressure and temperature in cp
 d = internal diameter of pipe (not choke) in in.

Gas flow through restriction (orifice) may also be estimated using Figure 6.3.13. For conditions that differ

from chart basis, correction factors are required. A gas throughput read from the chart must be multiplied by the proper correction factor,

$$Q = \text{Gas throughput} \times 0.0544 \sqrt{G_g T}, \text{ Mcf/d} \quad (6.3.36)$$

where T is the absolute operating temperature in °R.

6.3.2.4 Flowline Performance

For a single-phase gas flow, pressure-rate relation may be obtained from a known Weymouth equation:

$$Q = 433.49 \frac{T_b}{P_b} \left[\frac{(P_u^2 - P_d^2) d^{16/3}}{G_g \bar{T} \bar{Z} L} \right]^{0.5} E \quad (6.3.37)$$

where Q = gas flowrate in scf/d

T_b = base temperature in °R

P_b = base pressure in psia

P_u = upstream pressure in psia

P_d = downstream pressure in psia

d = inside diameter of pipe in in.

G_g = gas gravity (air = 1.00)

\bar{T} = average flow line temperature in °R

\bar{Z} = average gas compressibility factor

L = pipe length in mi

E = pipe line efficiency, fraction

or the modified Panhandle (Panhandle B) equation (for long lines):

$$Q = 737 \left(\frac{T_b}{P_b} \right)^{1.02} \left(\frac{P_u^2 - P_d^2}{\bar{T} \bar{Z} L G_g^{0.961}} \right)^{0.510} d^{2.530} E \quad (6.3.38)$$

with the terms and units the same as the Weymouth Equation 6.3.37.

The pipeline efficiency E depends on flow stream and pipeline conditions. A gas stream may contain some liquids; the higher the liquid content, the lower the line efficiency. The pipeline may be scaled, or condensate-water may accumulate in low spots in the line. Ikoku [12] presents the information about line efficiency as shown below.

Type of line	Liquid Content	E (gal/MMscf)
Dry-gas field	0.1	0.92
Casing-head gas	7.2	0.77
Gas and condensate	800	0.60

This gives an idea in estimating E for a particular condition.

Example 6.3.4

A gas well was flowed at a rate of 7.20 MMscf/d. The stabilized sandface pressure at the end of the test was 1155 psia, and the current average reservoir pressure was estimated to be 1930 psia. Determine the following parameters using the modified Mishra-Caudle [4] method:

1. AOF at current conditions ($P_r = 1,930$ psia)
2. deliverability at $P_{wf} = 1,000$ psia
3. AOF at a future average pressure $P_{rf} = 1,600$ psia
4. deliverability at a future $P_{wff} = 1,155$ psia

Solution

The readers may refer to the original paper [4]. Here the modified one is given

- (a) For a pressure less than 2100 psia, Equation 6.3.12 is used:

$$\frac{q}{q_{\max}} = \frac{5}{4} \left[1 - 5 \left(\frac{p_{wf}^2}{P_r^2} - 1 \right) \right]$$

$$\text{AOF} = q_{\max} = \frac{7.2 \text{ MMscf/d}}{\frac{5}{4} \left[1 - 5 \left(\frac{1155^2}{1930^2} - 1 \right) \right]} = 8.94 \text{ MMscf/d}$$

- (b) $q = 8.94 \times 10^6 \times \frac{5}{4} \left[1 - 5 \left(\frac{1000^2}{1930^2} - 1 \right) \right]$
 $= 7.73 \text{ MMscf/d}$

- (c) $\frac{(\text{AOF})_f}{(\text{AOF})_p} = \frac{5}{3} \left[1 - 0.4 \frac{P_{rf}^2}{P_r^2} \right]$

$$(\text{AOF})_f = 8.94 \times 10^6 \times \frac{5}{3} \left(1 - 0.4 \frac{1600^2}{1930^2} \right)$$

$$= 6.96 \text{ MMscf/d}$$

- (d) Again use Equation 6.3.12:

$$q_f = (\text{AOF})_f \times \frac{5}{4} \left[1 - 5 \left(\frac{P_{wff}^2}{P_r^2} \right)_f - 1 \right]$$

$$= 6.96 \times 10^6 \times \frac{5}{4} \left[1 - 5 \left(\frac{1155}{1600} \right)^2 - 1 \right]$$

$$= 4.675 \text{ MMscf/d}$$

Example 6.3.5

The following data are obtained from a producing gas well:

Gas gravity = 0.65

Well depth (vertical) = 6000 ft.

Wellhead temperature = 570°R

Formation temperature = 630°R
 Flowing wellhead pressure = 1165 psia
 Flowrate = 10.0 MMscf/d
 Tubing ID = 2.441 in.
 Pseudo-critical temperature = 374°R
 Pseudo-critical pressure = 669 psia
 Absolute roughness = 0.00065

Calculate the following bottomhole pressure using Equation 6.3.22.

Solution

Rearranging Equation 6.3.22, we obtain:

$$P_{wf} = \left(e^S P_{wh}^2 + \frac{q_g^2}{4 \times 10^{10}} \times \frac{G_g \bar{T} Z H f (e^S - 1)}{SD^5} \right)^{0.5}$$

Assume $P_{wf} = 2000$ psia:

$$\bar{P} = \frac{2000 + 1165}{2} = 1582.5 \text{ psia}$$

$$T = \frac{570 + 630}{2} = 600^\circ\text{R}$$

$$\left. \begin{aligned} pP_r &= \frac{1582.5}{669} = 2.365 \\ pT_r &= \frac{600}{374} = 1.064 \end{aligned} \right\} \rightarrow \bar{Z} = 0.848$$

$$S = 0.0375(0.65)(6,000)/(600)(0.848) = 0.287$$

$$f = \left\{ 2 \log \left[371 / \left(\frac{0.00065}{2.441} \right) \right] \right\}^{-2}$$

$$P_{wf} = \left\{ e^{0.287} (1,165)^2 + \frac{(10 \times 10^6)^2}{4 \times 10^{10}} \times \frac{(0.65)(600)(0.848)(6,000)}{(0.287)(2.441)^5} \times [0.0146(e^{0.287} - 1)] \right\}^{0.5}$$

$$= 1,666 \text{ psia} (\ll 2,000 \text{ psia assumed})$$

Assume 2nd $P_{wf} = 1,666$ psia:

$$\bar{P} = \frac{1,666 + 1,165}{2} = 141.5 \text{ psia}$$

$$\left. \begin{aligned} pP_r &= \frac{141.5}{669} = 2.116 \\ pT_r &= 1.604 \end{aligned} \right\} \rightarrow \bar{Z} = 0.857$$

$$S = 0.0375(0.65)(6,000)/(600)(0.857) = 0.284$$

$$P_{wf} = 1666.7 \text{ psia} (\cong 1,666 \text{ psia assumed})$$

Example 6.3.6

Suppose the gas well in Example 6.3.5 is produced through a flowline of 2.5 in. in diameter and 1250 ft long. The

average operating temperature is 100°F. Additional data given are specific heat ratio, $k = 1.3$, and the estimated gas viscosity at the operating condition, $\mu_g = 0.0131$ cp.

Find the positive choke size required for critical condition, and the pressure at downstream of the flowline.

Solution

(1) For a critical flow, Equation 6.3.34 can be used.

$$\begin{aligned} Q &= 879 \times C \times A \times P_u \left[\frac{k}{G_g T_u} \left(\frac{2}{k+1} \right)^{\frac{k+1}{k-1}} \right]^{0.5} \\ &= 879 \times C \times \frac{\pi}{4} d_{ch}^2 \times 1165 \\ &\quad \times \left[\frac{1.3}{0.65 \times 570} \left(\frac{2}{1.3+1} \right)^{\frac{1.3+1}{1.3-1}} \right]^{0.5} \\ &= 27,881 C d_{ch}^2 \text{ (Mscf/d)} \end{aligned}$$

$$R_e = \frac{20 \times 10,100 \times 0.65}{0.013 \times 2.5} = 4.01 \times 10^6$$

Assume a diameter choke, such that $d_{ch} = 0.7$ in. Use Figure 6.3.4 to find coefficient C:

$$\beta = \frac{d_{ch}}{d_{pipe}} = \frac{0.7}{2.5} = 0.28$$

For $R_e = 4.01 \times 10^6$ and $\beta = 0.28$, $C = 0.998$, so

$$Q = 27,881 \times 0.998 \times (0.7)^2 = 13.63 \text{ MMscf/d}$$

If we assume another choke size, let $d_{ch} = 0.6$ in.:

$$\beta = \frac{0.6}{2.5} = 0.24 \rightarrow C = 0.997$$

$$Q = 27,881 \times 0.997 \times (0.6)^2 = 10.0 \text{ MMscf/d}$$

(2) For a critical flow, we may assume $(P_d)_{choke} = 0.5(P_u)_{choke}$. Let's take $T_b = 530^\circ\text{R}$ and $P_b = 15$ psia. Then using Equation 6.3.37 with $E = 0.92$,

$$\begin{aligned} P_d^2 &= P_u^2 - \left(\frac{Q/E}{433.4 T_b/P_b} \right)^2 \times \frac{G_g \bar{T} Z L}{d^{16/3}} \\ &= \left(\frac{1165}{2} \right)^2 - \left(\frac{10^7/0.92}{15,317} \right)^2 \\ &\quad \times \frac{(0.65)(560)(\bar{Z}) \left(\frac{1250}{5280} \right)}{(2.5)^{16/3}} \\ &= 339,306 - 327,422 \bar{Z} \end{aligned}$$

Assume that $P_d = 200$ psia to find \bar{Z} such that:

$$\bar{P} = \frac{200 + (0.5 \times 1165)}{2} = 391.2 \text{ psia}$$

$$\left. \begin{aligned} pP_r &= \frac{391.25}{669} = 0.585 \\ pT_r &= \frac{560}{374} = 1.497 \end{aligned} \right\} \rightarrow \bar{Z} = 0.939$$

$$P_d^2 = 339,306 - 327,422 \times 0.939$$

$$P_d = 178.5 \text{ psia} (\neq P_{d_{\text{assumed}}} = 200 \text{ psia})$$

Assume now that $P_d = 178.5$ psia such that:

$$\bar{P} = \frac{178.5 + (0.5 \times 1165)}{2} = 380.5 \text{ psia}$$

$$\left. \begin{aligned} pP_r &= \frac{380.5}{669} = 0.569 \\ pT_r &= 1.497 \end{aligned} \right\} \rightarrow \sim \bar{Z} = 0.940$$

$$P_d^2 = 339,306 - 327,422 \times 0.940$$

$$P_d = 177.5 \text{ psia} (\cong P_{d_{\text{assumed}}} = 178.5 \text{ psia})$$

6.3.3 Two-Phase Flow Performance

6.3.3.1 Two-Phase Inflow Performance

When a reservoir pressure is below the bubble point pressure, the simple equation of inflow performance (e.g., the productivity index is constant) is no longer valid, because at this condition the oil flowrate will decline much faster at increasing drawdown than would be predicted by Equation 6.3.1a or Equation 6.3.2. An illustrative comparison of the two types of IPR is shown in Figure 6.3.14.

6.3.3.1.1 Vogel's Method

The well-known inflow performance equation for two-phase flow has been proposed by Vogel [13]. The equation is,

$$\frac{q_0}{q_{\text{max}}} = 1 - 0.2 \frac{P_{\text{wf}}}{P_r} - 0.8 \left(\frac{P_{\text{wf}}}{P_r} \right)^2 \quad (6.3.39)$$

FIGURE 6.3.14 Illustrative comparison of liquid and two-phase IPR curves.

which fits a general dimensionless IPR shown in Figure 6.3.15. The reference curve and Equation 6.3.39 is valid for solution-gas drive reservoir with reservoir pressures below the bubble point. The formation skin effect is not taken into account. The method is originally developed with the flowing efficiency $FE = 1.0$. However, for a given well with any FE known, Equation 6.3.39 or the reference curve may be used to generate the IPR curve.

For reservoir pressures above the bubble point but with flowing pressures below the bubble point, the constant J equation and the Vogel equation can be combined to estimate the IPR curves. The equation is

$$q_0 = q_b + (q_{\text{max}} - q_b) \left[1 - 0.2 \frac{P_{\text{wf}}}{P_r} - 0.8 \left(\frac{P_{\text{wf}}}{P_r} \right)^2 \right] \quad (6.3.40)$$

The maximum flowrate q_{max} is calculated using the following equation:

where q_0 = oil flowrate in stb/d

q_{max} = the theoretical maximum flowrate when $P_{\text{wf}} = 0$ in stb/d

q_b = oil flowrate at $P_{\text{wf}} = P_b$ in stb/d

P_b = bubble point pressure in psia

P_{wf} = flowing bottomhole pressure in psia

P_r = average reservoir pressure in psia

$$q_{\text{max}} = q_b + \frac{J \times P_b}{1.8} \quad (6.3.41)$$

The productivity index J is determined based on the following bottomhole pressure of the test:

1. For $(P_{\text{wf}})_{\text{test}} > P_b$, then

$$J = \frac{(q_0)_{\text{test}}}{P_r - (P_{\text{wf}})_{\text{test}}} \quad (6.3.42)$$

2. For $(P_{\text{wf}})_{\text{test}} < P_b$, then

$$J = \frac{(q_0)_{\text{test}}}{P_r - P_b + (P_b \times M/1.8)} \quad (6.3.43)$$

where $M = (1 - 0.2(P_{\text{wf}}/P_b) - 0.8(P_{\text{wf}}/P_r)^2)$

$P_{\text{wf}} = (P_{\text{wf}})_{\text{test}}$

The q_b is calculated using Equation 6.3.2 with $P_{\text{wf}} = P_b$

6.3.3.1.2 Fetkovich Method

Analyzing isochronal and flow-afterflow multipoint back-pressure tests conducted on oil wells, Fetkovich [14] found that back-pressure curves for oil wells followed the same form as for gas wells; that is

$$q_0 = J'_0 (P_r^2 - P_{\text{wf}}^2)^n \quad (6.3.44)$$

FIGURE 6.3.15 A general dimensionless IPR for solution gas drive reservoirs [13].

where J'_0 = back-pressure curve coefficient,
 $\text{stb}/\text{d}/(\text{psia})^{2n}$
 n = back-pressure curve exponent or
 exponent of inflow performance curve

The plot of q_o versus $(P_r^2 - P_{wf}^2)$ on log-log paper is considered as good as was obtained from gas well back-pressure tests. Conducting a multipoint back-pressure test on a well, Equation 6.3.44 can be used to predict the IPR curve for the well.

Figure 6.3.16 shows the comparison of IPR's for liquid, gas and two-phase (gas and liquid). Fetkovich reported that Vogel's equation yields $n = 1.24$ (Figure 6.3.17).

For reservoir pressures above bubble point pressures, the inflow performance curves can be constructed using the following equation:

$$q_o = J'_o(P_b^2 - P_{wf}^2)^n + J(P_r - P_b) \quad (6.3.45)$$

The maximum flowrate of a well can be determined using the following equation:

$$q_{\text{max}} = q_0 \left[1 - \left(\frac{P_{wf}}{P_r} \right)^2 \right]^n \quad (6.3.46)$$

FIGURE 6.3.16 Pressure gradients of flowing liquid and liquid-gas mixture.

6.3.3.1.3 Modified Standing's Method

Vogel's reference curve is originally derived for undamaged or unformulated wells. In other words, the curve is only valid for wells with skin factor $s = 0$. Later, Standing [15] presented a set of companion curves that can be used to predict IPR curves for damaged or stimulated wells. His method is based on the definition of single-phase flow

FIGURE 6.3.17 Inflow performance relationship for various flow equations [14].

efficiency. In fact, solution-gas drive reservoirs producing oil at $P_{wf} < P_b$ and/or $P_r < P_b$ have inflow performance of two-phase flow. The IPR of this type of reservoirs have been shown to have quadratic forms as suggested by Vogel and Fetkovich.

Camacho and Raghavan [16] found that Standing's definition of flow efficiency is incorrect to be used in two-phase flow behavior. It is suggested that the definition of flow efficiency must also reflect the quadratic form of the inflow performance equation. This is expressed by

$$FE = \frac{(1 + VP'_{wf}/P_r)(1 - P'_{wf}/P_r)}{(1 + VP_{wf}/P_r)(1 - P_{wf}/P_r)} \quad (6.3.47)$$

where FE = flowing efficiency

V = quadratic curve factor (V = 0.8 for Vogel and V = 1.0 for Fetkovich)

P'_{wf} = ideal flowing bottomhole pressure (e.g., when skin factor $s = 0$) in psia

P_{wf} = actual flowing bottomhole pressure in psia

P_r = average reservoir pressure in psia

The flowrate when $FE \neq 1.0$ can be calculated using

$$\frac{q_0}{q_{max}^{FE=1.0}} = FE \left[1 + V \left(\frac{P_{wf}}{P_r} \right) \right] \left[1 - \left(\frac{P_{wf}}{P_r} \right) \right] \quad (6.3.48)$$

where $q_{max}^{FE=1.0}$ = maximum flow rate for undamaged/unstimulated well or when FE = 1.0

6.3.3.1.4 Predicting Future IPR

Predicting future well deliverability is frequently needed in most oil fields. Some of the many reasons are:

- (1) to estimate when the choke should be changed or adjusted to maintain the production rate
- (2) to predict well capability and evaluate if the tubing has to be changed
- (3) to do planning for selecting future artificial lift methods
- (4) to do planning for reservoir pressure maintenance or secondary recovery projects

Some prediction methods available in the literature are discussed.

Standing's Method

The method has been developed based on Vogel's equation, the definition of productivity index, and the assumption that the fluid saturation is to be the same everywhere in the reservoir. Three basic equations presented are:

$$J_p^* = \frac{1.8(q_{max})_p}{(P_r)_p} \quad (6.3.49)$$

$$J_f^* = J_p^* \left\{ \frac{[K_{ro}/(\mu_o B_o)]_f}{[K_{ro}/(\mu_o B_o)]_p} \right\} \quad (6.3.50)$$

$$(q_{max})_f = (J_f^* \cdot P_{rf})/1.8 \quad (6.3.51)$$

where

J^* = productivity index at zero drawdown in stb/d/psi

k_{ro} = relative permeability to oil, fraction

μ_o = oil viscosity in cp

B_o = oil formation volume factor in bbl/stb

and subscript p and f refer to present and future conditions, respectively. The relative permeability to oil is at corresponding oil saturation in the reservoir. A method for determining oil saturation and k_{ro} may be found in the reservoir engineering chapter. In the example presented by Standing, Turner's method was used and k_{ro} was evaluated using Corey-type relationship:

$$K_{ro} = \left(\frac{S_o - S_{or}}{1 - S_{wc} - S_{or}} \right)^4 \quad (6.3.52)$$

where

S_{or} = residual oil saturation, fraction

S_{wc} = connate water saturation, fraction

Combined Fetkovich-Vogel Method

Fetkovich suggested that a future well deliverability may be estimated by the relation $J'_f/J'_p = (P_r)_f/(P_r)_p$. Recalling Equation 6.3.44 and taking $n = 1$, we can write

$$\frac{(q_{max})_f}{(q_{max})_p} = \left[\frac{(P_r)_f}{(P_r)_p} \right]^3 \quad (6.3.53a)$$

or

$$(q_{max})_f = (q_{max})_p \times \frac{(P_r)_f^3}{(P_r)_p^3} \quad (6.3.53b)$$

After calculating the maximum flowrate using Equation 6.3.53b, the inflow performance curve into the future can be constructed using Vogel's equation. This method is valid only for undamaged wells.

Unified Method

Recently Kelkar and Cox proposed a new method for predicting future IPR [18]. This method is a result of unification of some methods discussed previously. The relationship suggested can be applied to any of the reference methods. Two sets of data points (each at different average reservoir pressure) are required to predict the future inflow performance curve. The procedure is as follows:

1. Calculate the maximum flowrate (q_{max} or Q_{max}) for both tests conducted using the reference method (Vogel, Fetkovich or Modified Standing).
2. Calculate J^* :

$$J_1^* = \frac{(q_{max})_1}{(P_r)_1} \quad \text{and} \quad J_2^* = \frac{(q_{max})_2}{(P_r)_2} \quad (6.3.54)$$

3. Determine constants A' and B' as

$$A' = \frac{J_1^* - J_2^*}{(P_r)_1^2 - (P_r)_2^2} \quad (6.3.55)$$

$$B' = \frac{\frac{J_1^*}{(P_r)_1^2} - \frac{J_2^*}{(P_r)_2^2}}{\frac{1}{(P_r)_1^2} - \frac{1}{(P_r)_2^2}} \quad (6.3.56)$$

4. Calculate the maximum flowrate of the corresponding future pressure $(P_r)_f$

$$(q_{max})_f = A'(P_r)_f^3 + B'(P_r)_f \quad (6.3.57)$$

5. Construct the future inflow performance curve using the reference inflow performance equation used in Step 1 above for reservoir pressure $(P_r)_f$ and the maximum flowrate calculated in Step 4.

6.3.3.2 Tubing Performance

The problem of simultaneous flow of oil, gas, and water through the vertical tubing of an oil well is complex. The fluid is a compressible mixture, its density increasing with depth. The gradient line has a distinct curvature (see Figure 6.3.16). Along the gradient line of a given well, different flow regimes occur, which may range from a mist flow in the region of low pressures to a single-phase flow at the pressures when all gas is in the solution.

The knowledge of tubing performance of flowing wells is important for efficient operations. Present and future performance of the wells may be evaluated. This may suggest changes in operating practices and equipment to prolong the flowing life of a well. Figures 6.3.18 and 6.3.19 show the idea of the effects of tubing size and a change in IPR on a well performance, respectively.

For a given wellhead pressure, flowing bottomhole pressure varies with production rate. Plotting these two flowing parameters on a Cartesian coordinate will give a curve called *tubing performance relationship* (TPR). By plotting the TPR and IPR of an oil well on a graph paper, the stabilized production capacity of the well is represented by the intersection of the two curves (see Figure 6.3.18).

To construct a TPR curve for a given well, the fluids and well geometry data should be available. Section 6.2 "Flow

FIGURE 6.3.18 Effect of tubing size on oil well deliverability.

FIGURE 6.3.19 Effect of changes in inflow performance on oil well productivity.

of Fluids” provides some good multiphase flow correlations that can be used. In cases where these data and accessibility to computer are limited, a graphical flowing gradients correlation is needed. In fact, many improved graphical correlations covering a broad range of field conditions are available in the literature. The readers may refer to Brown [19] to get a complete set of flowing gradient curves. Sometimes a different company has a different set of curves. Although the best correlation is available, a particular field condition might have specific well characteristics such as salt or asphaltene deposition in the tubing or severe emulsification that may bring about a higher pressure drop than would be estimated from existing graphical correlations. The discrepancy might be used for analyzing the wells. So, it is recommended that a good multiphase flow equation be used instead of a graphical correlation.

For convenience, however, a set of working curves developed by Gilbert [20] is presented for illustrating their use in solving well performance problems. The curves are shown in Figures 6.3.20 through Figure 6.3.29, and available only for small flowrate (50 to 600 stb/d) and tubing sizes of 1.66, 1.90, 2.375, 2.875, and 3.50 in.

The procedure how to use these flowing gradient curves in production engineering problems is given in the example later.

6.3.3.2.1 Use of Vertical Pressure Gradients

In the preceding section of single-phase flow performances, the functions of vertical flow performance curves have been discussed. The following is a more detailed discussion on the applications of pressure gradients in analyses of flowing well performance. Accurate well test data, obtained under stabilized flow conditions, are needed for such analyses.

With flowing tubing known and well test data available, the flowing bottomhole pressure for a given rate of

production can be determined by calculating the flowing pressure gradient to the bottom of the well.

If the static bottomhole pressure is known, the productivity index of the well can be determined from one production rate by determining the flowing bottomhole pressure for the rate of production.

If only surface data are available, the productivity index of the well may be estimated by determining the flowing bottomhole pressures for two or more rates of production.

As stated, the size of the tubing is one of the important parameters affecting the pressure gradients. For low velocity, the slippage of gas by the liquid contributes to the pressure losses. For high velocities, friction becomes the controlling factor. Between these two extremes, there is a range of velocities giving the optimum gradient at the inlet of tubing in the bottom of the well.

If the future range of expected rates and gas/oil ratios can be estimated, selection of the tubing size can be made, which would assure operation within the efficient range of the gradients, with the resulting increase in the flowing life of the well. Such selection can be made by calculating gradients for different tubing sizes for a given set of conditions.

As the gas/oil ratio decreases, the flowing gradients, of course, increase, other conditions being equal. This is clearly illustrated in Figure 6.3.20 for example. As the water content of the produced fluid increases, the overall gas/liquid ratio decreases. If the future behavior of the water content increase can be estimated, future behavior of the well can be evaluated.

To a degree, the wellhead pressure is controllable because it depends, among other things, on the size, length, and geometry of flow lines and on the separator pressure. At the same time, the wellhead pressure has a marked effect on the slope characteristics of the gradient because of the question of density which is involved. For a given reduction of the wellhead pressure, the reduction of the bottomhole flowing pressure may be substantially higher. This is particularly true in case of high-density flow.

The reduction of the bottomhole flowing pressure should result in increase of production. It can be seen from the above that the degree of this increase cannot be estimated from the surface data alone. It can be estimated if information is available also on the flowing gradient and the productivity index of the well.

6.3.3.2.2 Predicting the Flowing Life

The natural flow of an oil well continues as long as there exists a proper balance between two conflicting pressure requirements at the bottom of the well. First, this pressure must be sufficiently high to sustain the vertical lift. Second, it must be sufficiently low to create a pressure differential that permits reservoir fluids to enter the well.

This balance may be destroyed by either one or a combination of two sets of conditions:

FIGURE 6.3.20 Flowing pressure gradients for 2.875-in. tubing with rate of 50 bpd.

1. increase in flowing pressure gradients for any of the reasons mentioned above, increases in the lift pressure requirements above the point needed for maintaining the pressure differential with the available reservoir energy.
2. the declining reservoir energy is not able to maintain this differential for the required vertical lift pressure.

In either case, the natural flow of the well either declines to an uneconomical rate or ceases completely.

The uses of the flowing pressure gradients discussed above may be applied to estimating the length of the flowing life of a well. Additional information needed are the estimate of the static bottomhole pressure of water encroachment, and of gas/oil ratio behavior at different future stages of the cumulative production of the well. Graphic methods have been developed for making such estimates.

FIGURE 6.3.21 Flowing pressure gradients for 2.875-in. tubing with rate of 100 bpd.

6.3.3.3 Choke Performance

The reasons involved in installing chokes in oil and gas fields have been mentioned before. The graphical correlations and empirical or semiempirical equations used for single-phase oil or gas are not valid for two-phase conditions.

The correlations for multiphase flow through chokes have been published, but not one of them gives satisfactory results for all ranges of operating conditions (flow parameters). Theoretically, the correlations are developed with the assumption that the simultaneous flow of liquid and gas is under critical flow conditions so that when an oil well

FIGURE 6.3.22 Flowing pressure gradients for 2.875-in. tubing with rate of 200 bpd.

choke is installed fluctuations in line pressure is gradually increased, there will be no change in either the flowrate or the upstream pressure until the critical-subcritical flow boundary ($P_{\text{downstream}} \cong 0.5 - 0.55 P_{\text{upstream}}$) is reached.

In more oil fields, the most popular correlations are of Gilbert [20] and Poetmann and Beck [21]. Ashford [22] also developed a correlation for multiphase flow through chokes.

6.3.3.1 Gilbert's Correlation

The equation developed to estimate a parameter of fluid flow through the orifice is:

$$P_{\text{wh}} = \frac{435R^{0.546}q}{d^{1.89}} \quad (6.3.58)$$

where P_{wh} = wellhead pressure in psig

FIGURE 6.3.23 Flowing pressure gradients for 2.875-in. tubing with rate of 400 bpd.

- R = gas/liquid ratio in Mscf/stb
- q = gross liquid rate in stb/d
- d = choke (bean) size in 1/64 in.

This equation is derived using regularly reported daily individual well production data from Ten Section Field in California. Gilbert noted that an error of $\frac{1}{128}$ in. in bean

size can give an error of 5 to 20% in pressure estimates. In the type of formula used, it is assumed that actual mixture velocities through the bean exceed the speed of sound, for which condition the downstream, or flow line, pressure has no effect upon the tubing pressure. Thus, the equation applies for tubing head pressure of at least 70% greater than the flow line pressure.

FIGURE 6.3.24 Flowing pressure gradients for 2.875-in. tubing with rate of 600 bpd.

6.3.3.3.2 Poetmann–Beck’s Correlation

F. H. Poetmann and R. L. Beck [21] developed charts for estimating flow of oil and gas through chokes. The charts shown in Figures 6.3.30 through 6.3.32, relate the variables of gas/oil ratio, oil production rate, tubing pressure, and choke size. With three of the variables known, the fourth can

be determined. The charts are valid only under the following conditions:

1. The flow is a simultaneous, two-phase flow of oil and gas. The charts are not valid if water is present.
2. The flow through the choke is at the critical flow conditions; that is, at acoustic velocity. This occurs when

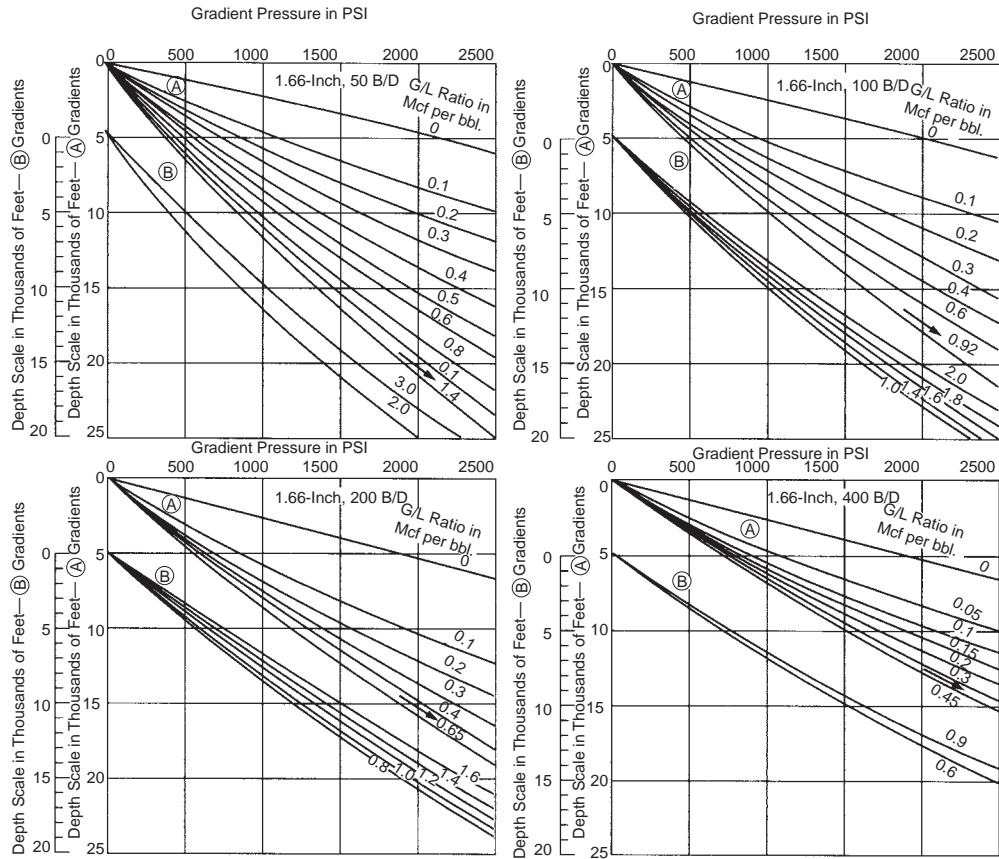

FIGURE 6.3.25 Flowing pressure gradients for 1.66-in. tubing with rate of 50–400 bpd.

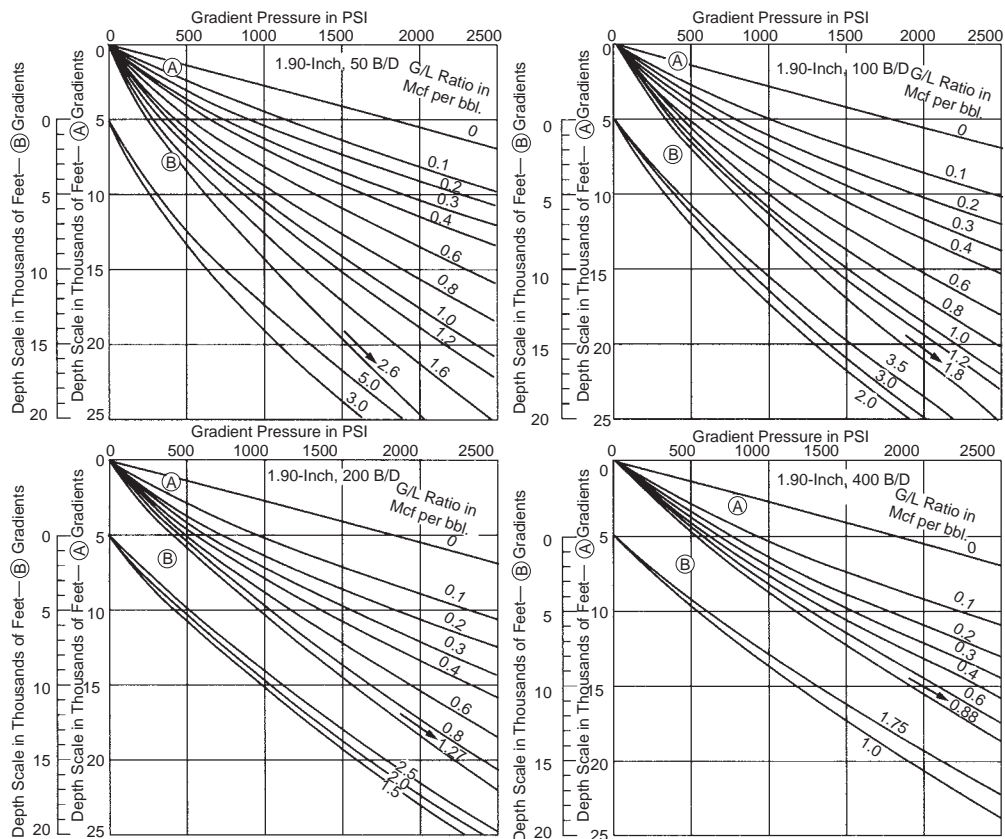

FIGURE 6.3.26 Flowing pressure gradients for 1.90-in. tubing with rate of 50–400 bpd.

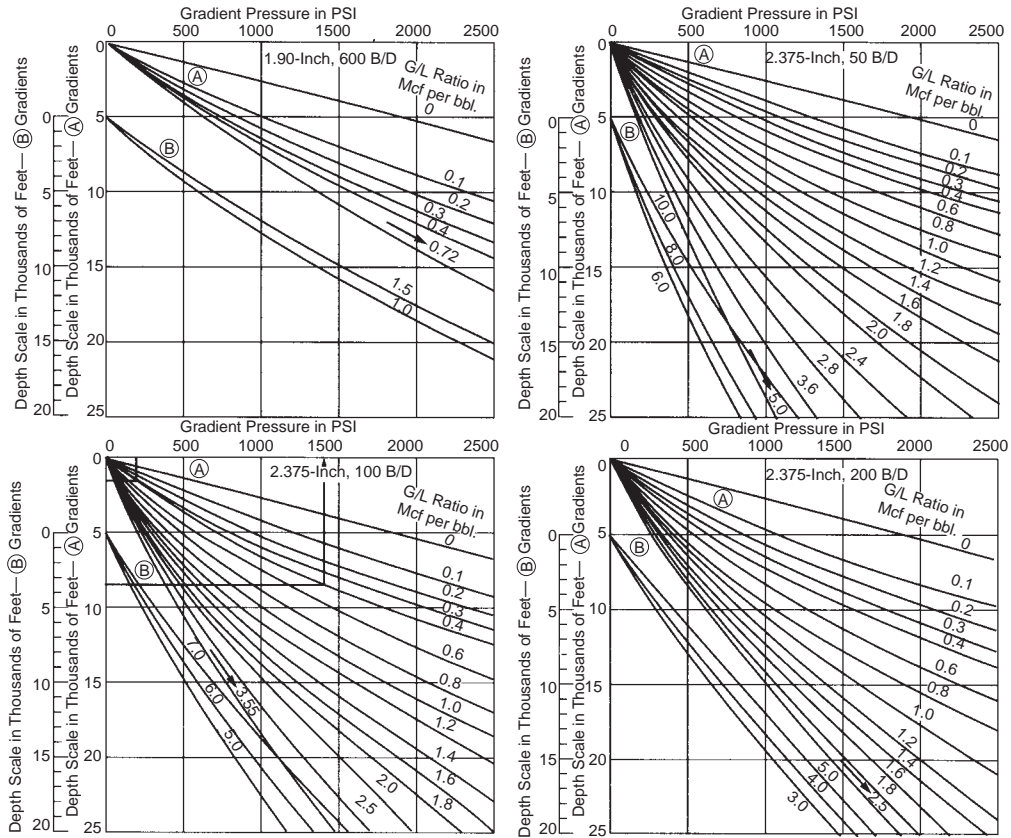

FIGURE 6.3.27 Flowing pressure gradients for 1.90-in. tubing with rate of 600 bpd and 2.375-in. tubing with rate of 50–200 bpd.

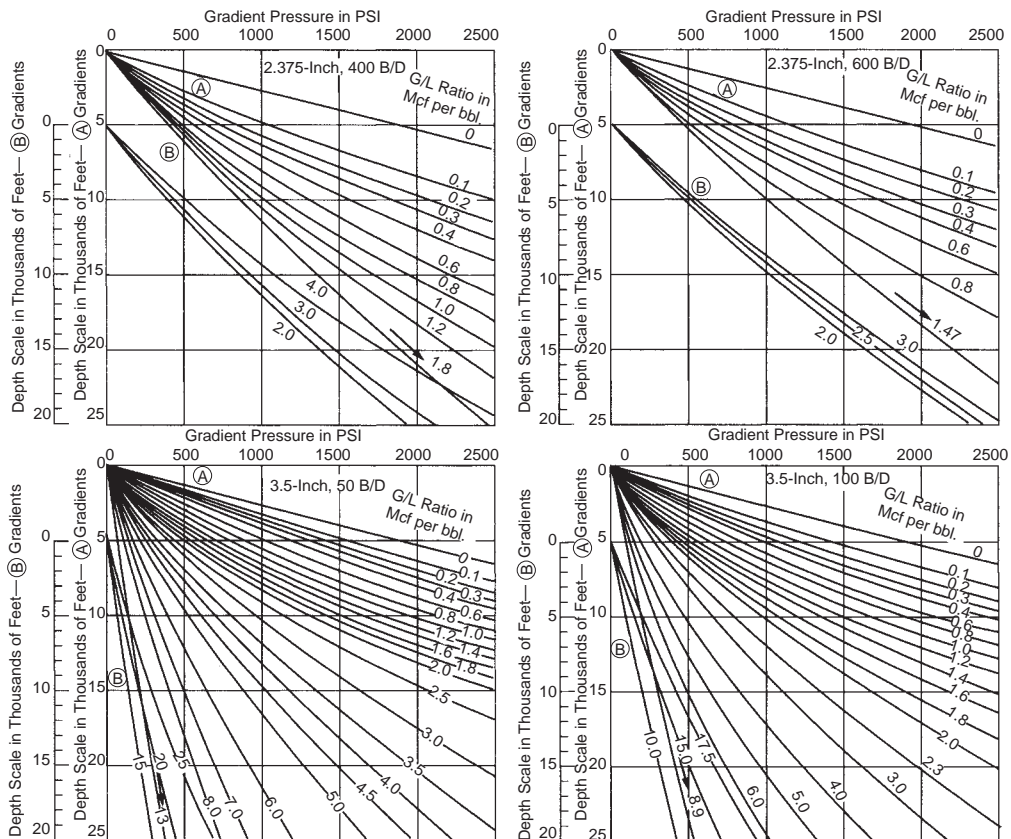

FIGURE 6.3.28 Flowing pressure gradients for 2.375-in. tubing with rate of 400–600 bpd and 3.5-in. tubing with rate of 50–100 bpd.

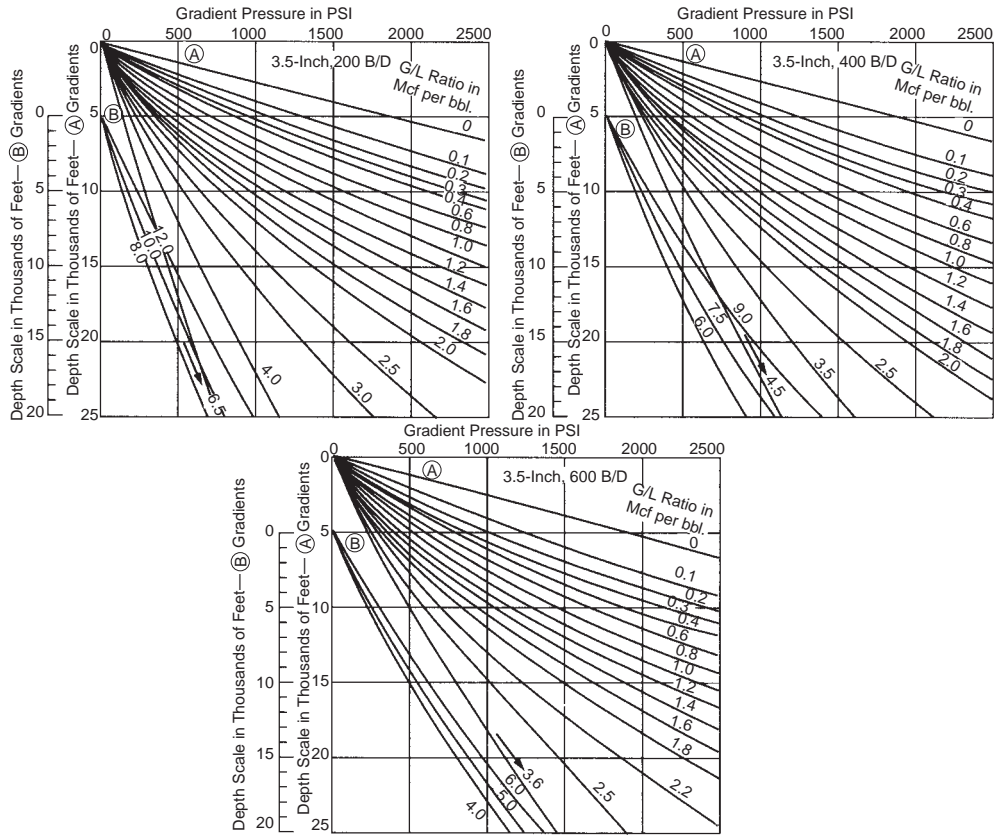

FIGURE 6.3.29 Flowing pressure gradients for 3.5-in. tubing with rate of 200–600 bpd.

FIGURE 6.3.30 A correlation for two-phase flow through chokes with oil gravity of 20° API.

FIGURE 6.3.31 A correlation for two-phase flow through chokes with oil gravity of 30° API.

FIGURE 6.3.32 A correlation for two-phase flow through chokes with oil gravity of 40° API.

the downstream (flow line) pressure is 0.55 or less of the upstream (tubing) pressure. Under such conditions the rate of flow is not affected by downstream pressure.

Actually, this last limitation is of small practical significance since chokes are usually selected to operate at critical flow conditions so that the well's rate of flow is not affected by changes in flowline pressure.

The manner of use of these charts is as follows:

1. The 20°, 30°, and 40° API gravity charts can be used for gravity ranges of 15° to 24°, 25° to 34°, and 35° and up, respectively.
2. When the starting point is the bottom scale, a vertical line is drawn to intersection with tubing pressure curve, then a horizontal line to intersection with the choke size, and then vertical line to the upper scale. Reverse procedure is used when the upper scale is the point of beginning.
3. Performance of a given size choke for a given gas/oil ratio can be plotted. Such a plot would show relationship between different rates and corresponding tubing pressures for a given choke.
4. Free gas in tubing can be estimated by use of charts. For instance, in case of Figure 6.3.32 for 2250 ft.³/bbl gas/oil ratio, 1265 psi tubing pressure and 6/64 in. choke, the rate was found to be 60 bbl/d. For 1265 psi tubing pressure the solution gas is 310 ft.³/bbl. Therefore, the free gas is 2250 – 310 = 1940 ft.³/bbl.

The results obtained by use of these charts compared very favorably with observed data obtained on 108 wells covering a wide range of conditions.

6.3.3.3 Ashford's Correlations

Ashford [22] developed a model for multiphase flow through a choke by applying the polytropic expansion theory. The final form of his equations is:

$$q_0 = 1.53 \frac{Cd^2 P_u}{(B_o + WOR)^{1/2}} \times \frac{[(T_u Z_u (R - R_s) + 151 P_u)]^{1/2}}{T_u Z_u (R - R_s) + 111 P_1} \times \frac{[G_o + 0.000217 G_g R_s + (WOR) G_w]^{1/2}}{G_o + 0.000217 G_g R + (WOR) G_w} \quad (6.3.59)$$

Where q_0 = oil flowrate in stb/d

C = orifice discharge coefficient

d = choke diameter in 1/64 in.

P_u = upstream choke pressure in psia

B_o = oil formation volume factor in bbl/stb

WOR = water/oil ratio

R = producing gas-oil ratio at standard condition in scf/stb

R_s = solution gas-oil ratio at choke conditions in scf/stb

T_u = upstream choke temperature in °R

Z_u = gas compressibility factor evaluated at upstream conditions

G_g = gas gravity (air = 1.00)

G_o = oil gravity (water = 1.00)

G_w = formation water gravity (water = 1.00)

Ashford stated that once C (discharge coefficient) has been fairly well defined for a given production province or operation the Equation 6.3.59 may be used in a conventional manner to evaluate:

1. flowrates arising from changes in choke sizes.
2. wellhead pressures arising from changes in choke sizes.
3. choke sizes necessary to achieve a given wellhead pressure for a known liquid rate.

If C is unknown, a value of 1.0 may be used to obtain a reasonable estimate of choke performance. Later, based on an extensive study, Sachdeva et al., [23] recommended that $C = 0.75$ be used for a choke configuration involving an elbow upstream from the choke and $C = 0.85$ be used for a choke free of upstream disturbances.

6.3.3.4 Flowline Performance

Understanding the behavior of multiphase fluids flow in horizontal or inclined pipe is important because the efficiency of a producing system is accomplished by analyzing all components through which the fluids flow. In the analysis a flowline may be considered as a restriction because higher pressure loss resulted. For instance, for a given set of fluids data 2.5-in. line causes higher pressure loss when compared with 3 and 4-in. line, so one tends to take the larger size to produce more oil. The diameter, however, should not be oversized because additional slugging and heading may occur. Some operators just add a parallel line instead of replacing the current line with a larger size. It should be remembered that production capacity, pipes availability, separator pressure, and other constraints may be involved in judging a final design of producing system.

The knowledge of pressure flowrate relationship is very useful in designing an efficient flowing system. The procedure used to generate a flowline performance for a given

set of fluids data and a given diameter of the pipe is similar with the one for single-phase. No pressure loss correlations for horizontal or inclined pipes are given. The reader can, however, find some good correlations in Section 6.2 titled “Flow of Fluids.”

Example 6.3.7

Consider an oil reservoir producing at an average reservoir pressure below $P_r = 2400$ psia, which is the bubble point pressure. A single-point flow test conducted on a well at stabilized condition resulted in $q = 500$ stb/d and $P_{wf} = 250$ psi. Measured GOR is 400 scf/stb. The well of total depth of 7000 ft. is produced through $2\frac{3}{8}$ -in. tubing. Find (1) the maximum rate possible assuming $P_{wh} = 200$ psi, and (2) the productivity index for the condition corresponding to the maximum possible flowrate.

Solution (assume FE = 1.0)

(1)

- Using Vogel’s equation, calculate q_{max}

$$\frac{500}{q_{max}} = 1 - 0.2 \left(\frac{250}{2,400} \right) - 0.8 \left(\frac{250}{2400} \right)^2$$

$$q_{max} = 515 \text{ stb/d (= oil AOF)}$$

- Choose some values of P_{wf} and determine corresponding q ’s using Vogel’s equation

$$q = 515 \left[1 - 0.2 \left(\frac{P_{wf}}{2400} \right) - 0.8 \left(\frac{P_{wf}}{2400} \right)^2 \right]$$

P_{wf} , psi	q , stb/d
500	476
800	435
1200	361
1500	290
2000	143
2400	0

Plot P_{wf} versus q to get the IPR curve (see Figure 6.3.33).

FIGURE 6.3.33 Pressure rate relationship for Example 6.3.7.

3. Let's select Gilbert's working curves shown in Figures 6.3.26 and 6.3.27 for 2³/₈-in. tubing and choose the curves with rates of 100, 200 and 400 stb/d.
4. Determine the equivalent length depth of P_{wf} = 200 psi. This is done by tracing down a vertical line through pressure point of 200 psi at zero depth until the line of GLR = 400 scf/stb is found and read the depth. This is the equivalent depth. Add this equivalent depth to the actual well depth. Then find the pressure at this total equivalent depth for rate and GLR given. For all three rates chosen, we can obtain

q, stb/d	P _{wf} , psi
100	1410
200	1370
400	1310
(600)	(1400)

5. Plot these values on the same graph made in Step 2 above.
 6. Read the coordinate points (q, P_{wf}) of the intersection between the two curves (IPR and TPR), see Figure 6.3.33. It is obtained that the maximum possible rate is 332 stb/d.
- (2) The productivity index J of two-phase fluids may be defined as:

$$\begin{aligned}
 J &= -dq/dP_{wf} = - \left[-0.2 \frac{q_{max}}{P_r} - 1.6 \frac{q_{max}}{P_r} (P_{wf}) \right] \\
 &= 0.2 \times \frac{515}{(2400)} + 1.6 \times \frac{515}{2400^2} (1325) \\
 &= 0.232 \text{ stb/d/psi}
 \end{aligned}$$

Example 6.3.8

Suppose we have more test data for Example 6.3.7. The additional data given are FE = 0.7. (1) What is the AOF when the skin effect is removed (FE = 1.0)? (2) What is the actual maximum potential (AOF) of the well? (3) Determine the maximum possible rate. (4) Determine the maximum possible rate if no damage occurred.

Solution

1. Using Equation 6.3.48, for V = 0.8,

$$\begin{aligned}
 \frac{500}{q_{max}^{FE=1}} &= 0.7 \left[1 + 0.8 \left(\frac{250}{2400} \right) \right] \left[1 - \left(\frac{250}{2400} \right) \right] \\
 q_{max}^{FE=1} &= 736 \text{ stb/d}
 \end{aligned}$$

2. The maximum potential will occur when P_{wf} = 0,

$$\begin{aligned}
 q_{max}^{FE=1} &= q_{max}^{FE=1} \times 0.7 \left[1 + 0.8 \left(\frac{0}{2400} \right) \right] \left(1 - \frac{0}{2400} \right) \\
 &= 515.2 \text{ stb/d}
 \end{aligned}$$

3. The maximum rate possible is 332 stb/d (already determined in Example 6.3.7).
4. Construct an IPR with FE = 1.0. Vogel's equation is valid now,

$$q_0 = 736 \left[1 - 0.2 \left(\frac{P_{wf}}{2400} \right) - 0.8 \left(\frac{P_{wf}}{2400} \right)^2 \right]$$

P _{wf} , psi	q, stb/d
500	680.0
800	621.5
1200	515.2
1500	414.0
2000	204.4

Plotting P_{wf} versus q, we can determine that q = 477 stb/d (Figure 6.3.33).

Example 6.3.9

An oil well is produced at P_{wf} > P_b. Data given are:

- H = 5000 ft.
- d = 2.375 in.
- P_r = 1500 psi
- J = 0.4 stb/d/psi
- GLR = 0.8 Mscf/stb

Find the production rate of liquid and gas if (a) the bean size is ²²/₆₄ in. or (b) the bean size is ³⁰/₆₄ in. Assume critical flow conditions and use Gilbert's equation.

Solution

Since the well is operated above the reservoir bubble point, we can treat the inflow performance as a linear one:

$$P_{wf} = P_r - \frac{q}{J} = 1500 - \frac{2}{0.4}$$

Chose some values of q (e.g., 100, 200, and 400 stb/d) and use the gradient curves for 2.375-in. tubing. Gilbert's curves are used here for convenience. For a given P_{wf} , P_{wh} is found with a procedure opposite to that for determining P_{wf} for a known P_{wh} (solution to Example 6.3.7, (1), Step 4). Doing so, we can get the following:

q , stb/d	P_{wf} , psi	P_{wh} , psi
100	1250	540
200	1000	400
400	500	40

Plot q versus P_{wh} (shown in Figure 6.3.34). Generate other q versus P_{wh} for the two choke sizes using:

$$P_{wh} = 435R^{0.546}q/S^{1.89}$$

Where (a) $q = (22^{1.89} \times P_{wh}) / (435 \times 0.8^{0.546})$, or (b) $q = (30^{1.89} \times P_{wh}) / (435 \times 0.8^{0.546})$

These are straight line equations through the origin. Draw the choke performance curves (see Figure 6.3.34). From this figure, we can determine that:

FIGURE 6.3.34 Pressure rate relationship for Example 6.3.9.

- installing a $\frac{22}{64}$ -in. choke:

$$q_{\text{liquid}} = 264 \text{ stb/d}$$

$$q_{\text{gas}} = 264 \times 0.8 \text{ M} = 0.211 \text{ MMscf/d}$$

- installing a $\frac{30}{64}$ -in. choke:

$$q_{\text{liquid}} = 319 \text{ stb/d}$$

$$q_{\text{gas}} = 0.255 \text{ MMscf/d}$$

Example 6.3.10

Constructing an IPR curve of an oil well is sometimes difficult in terms of data available. The present reservoir pressure is not available or measured. Some oil companies do not want to lose their production caused by closing the well to measure the static reservoir pressure. A practical means of overcoming this problem is to test the well at two different rates while measuring the flowing bottomhole pressure.

This technique does not require expensive, time-consuming tests. The pressure measurements can be very accurate, using a subsurface gage on flowing wells; they can be obtained with surface-recording downhole gage; or they can simply be obtained with casing pressure and fluid level shots, depending on the well condition.

A typical two-point test datum is taken from a well in the Judy Creek Beaverhill Lake 'A' Pool producing under a solution gas drive [24].

	Test 1	Test 2
q , stb/d	690.6	470
P_{wf} , psi	1152.0	1970
P_b , psi	2290.0	2290

The task is to estimate the static reservoir pressure and to construct IPR for this well.

Solution

$$\left(\frac{q}{q_{\text{max}}}\right)_1 = 1 - 0.2 \left(\frac{1152}{2290}\right) - 0.8 \left(\frac{1152}{2290}\right)^2 = 0.697$$

$$\left(\frac{q}{q_{\text{max}}}\right)_2 = 1 - 0.2 \left(\frac{1970}{2290}\right) - 0.8 \left(\frac{1970}{2290}\right)^2 = 0.236$$

$$q_c = (470 - 690.6) / (0.236 - 0.697) = 478.5 \text{ stb/d}$$

$$= (q_{\text{max}} - q_b)$$

FIGURE 6.3.35 Pressure-rate relationship for Example 6.3.10.

Flowrate at bubble point,

$$q_b = 470 - (0.236)(478.5) = 357 \text{ stb/d}$$

$$J_b = 1.8 \times (478.5/2290) = 0.376$$

$$P_r = 2290 + (357/0.376) = 3239 \text{ psia}$$

The calculated reservoir pressure from the two-point test was 3239 psia, which is consistent with static pressures measured in this area of the 'A' Pool.

Figure 6.3.35 is the constructed IPR. A third test was run to verify this curve, with a rate of 589 stb/d at 1568 psia. This point fell essentially on the curve generated by the original two-test points.

Example 6.3.11

A reservoir with a back-pressure curve slope $(1/n) = 1.12$ has the following two flow tests:

	\bar{P} , psia	q_o , stb/d	P_{wh} , psia
Test 1	2355.9	335.1	1300
Test 2	2254.9	245.8	13

Calculation of future IPR:

- Using Fetkovich's method:

$$q_{max} = \frac{q_0}{\left[1 - \left(\frac{P_{wf}}{P}\right)^2\right]^n}$$

$$q_{max1} = \frac{335.1}{\left[1 - \left(\frac{1300}{2355.4}\right)^2\right]^{0.893}} = 463.5 \text{ stb/d}$$

$$q_{max2} = \frac{245.8}{\left[1 - \left(\frac{1300}{2254.9}\right)^2\right]^{0.893}} = 365.5 \text{ stb/d}$$

- Calculate J^* :

$$J_1^* = \frac{463.5}{2355.4} = 0.197 \text{ stb/d/psi}$$

$$J_2^* = \frac{365.5}{2254.9} = 0.162 \text{ stb/d/psi}$$

- Calculate A' and B' :

$$A' = \frac{0.197 - 0.162}{(2355.4)^2 - (2254.9)^2} = 7.554 \times 10^{-8}$$

$$B' = \frac{\frac{0.197}{(2355.4)^2} - \frac{0.162}{(2254.9)^2}}{\frac{1}{(2355.4)^2} - \frac{1}{(2254.9)^2}} = -0.222$$

- Calculate maximum future rate (for instance, a future reservoir pressure of 1995 psia):

$$q_{max} = 7.554 \times 10^{-8}(1995)^3 + (-0.222)(1,995) = 157 \text{ stb/d}$$

- The future IPR curve can then be predicted using the equation

$$q_o = 157 \left[1 - \left(\frac{P_{wf}}{1995}\right)^2\right]^{0.893}$$

6.4.1 Sucker Rod Pumping

6.4.1.1 Pumping Units

6.4.1.1.1 Pumping System Components

The sucker rod pumping system consists of a pumping unit, a sucker rod string, and a subsurface pump.

The pumping unit is the surface component that supplies the power and reciprocating motion for the operation of the subsurface pump. The sucker rod string connects the pumping unit to the subsurface pump, which is reciprocating, piston type pump. Each of these components of the pumping system will be discussed in detail.

6.4.1.1.2 Pumping Unit Operation

The prime mover is the power source of the pumping unit, which can be an electric motor or an engine that usually runs on well gas. The prime mover drives the gear reducer, which rotates the crankshaft. The crankshaft drives the crank and pitman, which causes the walking beam to oscillate about the saddle bearing and imparts a reciprocating motion to the sucker rods. A sketch of a common pumping unit is shown in [Figure 6.4.1](#).

6.4.1.1.3 Pumping Unit Types and Specifications

Four types of beam pumping units are recognized. The classification is based on where the fulcrum is placed (class I or class III) and how they are counterbalanced (air, crank, or beam). Four types are shown in [Figure 6.4.2](#). In a class I lever system (also called a conventional pumping unit), the fulcrum is near the center of the walking beam and the pitman applies lifting force by pulling downward at the rear of the walking beam. The class I lever system with phased crank counterbalance is the latest in pumping unit designs. In this unit, the fulcrum is near the center of the walking beam similar to a conventional unit; however, the phased crank arms allow the unit to have a larger part of the crank rotation dedicated to the upstroke (186° or longer). This longer upstroke often results in lower torque loads or higher lifting capacities. Examples of this type of unit are the Weatherford American Maximizer II or the Lufkin Reverse Mark. In a class III lever system, the lifting force

CLASS I LEVER SYSTEM - CONVENTIONAL UNIT.

4. Special purpose ultra-high slip typically up to 30% slip; superior starting, electrical, and mechanical characteristics.

Slip is the differences in motor speed between its synchronous (unloaded) and loaded condition divided by the unloaded speed. An induction motor that has a synchronous speed of 1200 rpm and a loaded speed of 1050 rpm has a slip of

$$\frac{1200 - 1050}{1200} \times 100 = 12.5\% \text{ slip}$$

Most oilfield pumping unit electric prime movers are three-phase induction motors. Single-phase motors are restricted to pumping units used for shallow, low-volume wells requiring minimal horsepower.

6.4.1.2.2 Internal Combustion Engines

Internal combustion engines designed to run on natural gas or propane and serve as pumping unit prime movers can be classified based on their speed, strokes per cycle and the number of cylinders. Slow-speed engines are those having a crankshaft rpm of 750 rpm or less. High-speed engines have speeds up to 2000 rpm; these are multi-cylinder engines. A relatively new engine package employs a small horsepower (up to 18 hp); high RPM twin cylinder four-stroke engine, intermediate sheave set (jackshaft), and a simple control for automatically starting and stopping the engine.

6.4.1.2.3 Selecting Prime Mover Size

Several empirical equations are in use for scaling theoretical or hydraulic horsepower rating such as obtained from beam pumping system design procedures (see the section titled

“Selection of Beam Pumping Unit Installation”) to brake or prime mover horsepower. These have been discussed by Brown [3] and Curtis and Showalter [4]. These empirical equations are all essentially of the form

$$HP_{pm} = \frac{q \times D}{PMF} \quad (6.4.1)$$

where HP_{pm} = primer mover in hp

q = oil and water daily production in bbls/d

d = net lift of liquid in ft.

PMF = prime mover factor

This prime mover factor-PMF consists of two components: a units conversion factor that accepts the other terms of equation 6.4.1 in the given units and converts the numerator product to horsepower; and a component that increases the horsepower to account for energy losses such as friction due to the cyclic nature of the prime mover load when applied to a pumping unit. The influence of these extra effects is not easily estimated. Thus an empirical adjustment is made based on experience. Another factor affecting motor size can be the trend towards longer stroke lengths on conventional beam type pumping units. The prime mover must be large enough to start the unit without the assistance of system inertia. Conventional beam pumping units with very long stroke lengths relative to their gearbox size, can exacerbate this initial loading to the point that although a given size motor is large enough to run the unit, it is not large enough to start it.

Sophisticated computer predictive programs mentioned later in this text, can, in many cases, more accurately predict motor loading for a given set of operating parameters.

If the lifted fluid has a specific gravity of 1.0 and is lifted with 100% efficiency, the PMF would be 135,735. The computed horsepower would be the theoretical or hydraulic horsepower. Because of the need for a prime mover rating considerably above the theoretical, various manufacturers use PMFs from 1.8 to 3.0 times smaller than 135,735. Curtis and showalter indicate that for high slip NEMA D motors or slow-speed internal combustion engines, the recommended prime mover horsepower can be obtained from the following equation:

$$HP_{pm} = \frac{q \times D}{56,000} \quad (6.4.2)$$

For high-speed internal combustion engines or normal slip NEMA C motors, the prime mover horsepower suggested is

$$HP_{pm} = \frac{q \times D}{45,000} \quad (6.4.3)$$

Example Problem

Determine the prime mover horsepower for lifting 100 bpd of oil and water production having a composite specific gravity of 1.0. The net lift is 10,000 ft. Assume a slow-speed internal combustion engine or a high slip NEMA D motor will be selected.

Solution

Use Equation 6.4.2, such that

$$HP_{pm} = \frac{\frac{100 \text{ bbl}}{d} (10,000 \text{ ft.})}{54,000} = 17.9 \text{ hp}$$

The actual engine or motor would be selected, with the nearest larger name-plate rating at 20 hp.

6.4.1.3 Sucker Rods

6.4.1.3.1 Types, Sizes and Grades

Sucker rods are solid, high-grade rods, which are run inside the tubing string to connect the pumping unit at the surface to the pump at the bottom of the well. There are two types of sucker rods specified by API 11B; steel sucker rods and fiber reinforced plastic (FRP) sucker rods. Steel sucker rods are 25 or 30 ft. in length and are available in diameters of 5/8, 3/4, 7/8, 1, and 1 1/8 in. FRP sucker rods are 25, 30, or 37.5 ft. in length and are available in diameters of 3/4, 7/8, 1, and 1 1/4 in. Sucker rods having lengths less than 25 ft. are called pony rods. Pony rods are usually manufactured in lengths of 2, 4, 6, 8 and 10 ft. Figure 6.4.3 shows the general shape and dimensions specified by API for steel sucker rod and pony rod ends; and Figure 6.4.4 shows the general dimensions and tolerances for FRP sucker rods and pony rods.

Steel sucker rods are available in three API grades, K, C, and D, which are suitable for most applications. API specifies the chemical composition for each grade. Most

manufacturers also offer a high-strength grade not specified by API. FRP sucker rod ends are available in five API grades, A, B, K, C, and D.

Steel sucker rods are heat-treated, using various methods, in order to achieve the specified yield and tensile strengths. Today's heat-treating methods for sucker rods include normalize, normalize & temper, quench & temper, and case hardening. Although the, normalize & temper method is adequate for many applications, the quench & temper method offers some advantages over other methods which would be important in many applications. These advantages include a higher yield to tensile ratio, finer grain structure, and higher toughness.

Sucker rods are connected with an internally threaded coupling, which is specified by API 11B. Couplings are available in two classes, class T (or through hard) and class SM (or spray metal) and are available in three styles, sucker rod, polished rod, and sub. Sucker rod couplings have the same thread in each end and cannot be used on polished rods. Polished rod couplings have the same thread in each end. Subcouplings have different threads in each end and are used to connect different size rods. Subcouplings have polished rod threads and therefore can be used on sucker rods or polished rods. Table 6.4.2 and Figure 6.4.5 show the general dimensions of sucker rod coupling, polished rod couplings, and sub couplings.

6.4.1.3.2 Selection of API Steel Sucker Rods

The principal consideration in selection of API steel sucker rods are the range of stress, the level of stress that the rods will experience and the degree of corrosiveness of the environment in which they will operate. Rods should be selected to be able to withstand not only the maximum stress that they will experience but also the range of stress. This requires the use of the modified Goodman diagram described in "Allowable Rod Stress and Stress Range."

Chemical inhibition programs can be effective in overcoming corrosion. Refer to Chapter 7 for a discussion of corrosion mitigation procedures. No existing grade of rods will withstand all possible corrosion conditions and some treatment may be needed even for mild corrosion environments.

For nonsour (so-called sweet crudes) one should select the lowest grade rod which meets the stress and stress range conditions.

Where sulfide stress cracking exists, one should use a rod with a hardness less than 23 HRC. Grade C rods meet this requirement. The stress and stress range must be checked to see if the C rods also meet this stress criterion. D grade rods are not recommended for sour crude environments unless an effective corrosion inhibition program is applied.

Grade K rods are available when other grades have not performed satisfactorily.

FIGURE 6.4.3 General dimensions for steel sucker rod pin ends.

Nominal Size of Rod Body +0.015 (+0.38)	Rod Pin Size	Nominal Diameter of Pin P	Outside Diameter of Pin Shoulder +0.005 -0.010 (+0.127 -0.0254)	Width of Wrench Square W _s	Length of Wrench Square W ₁	Maximum Diameter of End Fitting D _E	Maximum Length of End Fitting L	Maximum Diameter of Extension X	Length ¹ of Pin-and-Pin Sucker Rod +2.0(+51)	Length ¹ of Pin-and-Pin Pony Rod +2.0(+51)

Notes :

All dimensions in inches (mm).

¹Minimum length exclusive of fillet.

²The extension is that portion of the rod body or that portion of that end fitting which is immediately adjacent to the smaller end of the elevator taper. If this section of the end fitting is longer than 0.25 inch (6.3mm) the maximum outside diameter shall not be more than 0.200 inch (5.08) larger than the diameter of the rod body. If this section of the end fitting is 0.25 inch (6.3mm)

³The length of sucker rods and pony rods shall be measured from contact face of pin shoulder to contact face of pin shoulder.

⁴Not to exceed 10 inches (254mm) exclusive of extension, if used.

Notes:

See Table 6.

See Section 8 for details of shoulder connection.

FIGURE 6.4.4 General dimensions for frp sucker rod pin ends [63].

6.4.1.3.3 Allowable Rod Stress and Stress Range

A string of sucker rods when in normal operation is subject to alternating high and low stress because of the nature of the pumping cycle. On the upstroke, the rods bear a load that includes their own weight, the weight of the fluid they are lifting, friction and effects of acceleration. On the downstroke, the rods carry some friction load and the load their own weight diminished by effects of deceleration. The ratio of upstroke to downstroke load and hence ratio of upstroke to downstroke stress can be 2 to 1 or often 3 to 1 or more. This cycle of alternating high and low stress occurs at a frequency at least equal to the pumping speed. A unit pumping at 20 strokes per minute goes from high

stress to low stress every 3 s or 10,500,000 cycles per year. This process repeated on the rods over months and years can easily lead to metal fatigue.

In designing API steel sucker rod strings, it is recommended that the modified Goodman diagram shown in Figure 6.4.6 be used as the basis for stress analysis. This method of analysis compensates for the deleterious effects of cyclic stress and helps to prevent premature metal fatigue caused by cyclic stress. The key applicable terms for the diagram and the associated equation are given in the diagram. However, more explanation is given below for the terms of greatest interest. The diagram can be reduced to an equation as follows:

TABLE 6.4.2 Dimensions for Couplings and Subcouplings

Nominal Coupling Size ¹	Outside Diameter (W) +0.005 (+0.13) −0.010 (−0.25)	Length (N _L) +0.062 (+1.57) −0.000 (−0.00)
$\frac{5}{8}$ (15.9) S.H. ²	1.250 (31.8)	4.000 (101.6)
$\frac{5}{8}$ (15.9)	1.500 (38.1)	4.000 (101.6)
$\frac{3}{4}$ (19.1) S.H.	1.500 (38.1)	4.000 (101.6)
$\frac{3}{4}$ (19.1)	1.625 (41.3)	4.000 (101.6)
$\frac{7}{8}$ (22.2) S.H.	1.625 (41.3)	4.000 (101.6)
$\frac{7}{8}$ (22.2)	1.812 (46.0)	4.000 (101.6)
1 (25.4) S.H.	2.000 (50.8)	4.000 (101.6)
1 (25.4)	2.187 (55.6)	4.000 (101.6)
1 $\frac{1}{8}$ (28.6) S.H.	2.375 (60.3)	4.500 (114.3)
1 (25.4) S.H. Sub Coupling	2.000 (50.8)	4.500 (114.3)
1 (25.4) Sub Coupling	2.187 (55.6)	4.500 (114.3)
1 $\frac{1}{8}$ (28.6) Sub Coupling	2.375 (60.3)	5.000 (127.0)

Notes: See Table 6. See Section 8 for details of shoulder connection. All dimensions in in. (mm).

¹ Size of coupling is same as corresponding sucker rod size.

² S.H. is reduced outside diameter coupling known as slim hole.

$$S_A = (T/4 + 0.5625 \times S_{\min}) \times SF \quad (6.4.4)$$

The equation in the form above can be used in either English or metric units. An example is given below. The terms in the equation have the following significance:

S_A = Maximum allowable stress in the rods for a given value of minimum stress, S_{\min} and service factor (see definitions below).

T = Minimum tensile stress for rods of a given API rating. Refer to Table 6-27 for these minimum tensile strength values. (Example: for C rods, $T = 90,000$ psi.)

S_{\min} = Minimum stress to be experienced by the rods in the pump cycle.

SF = Service factor. This is a factor that adjusts, usually downward, the estimated allowable maximum stress to account for corrosive conditions. See Table 6.4.4 for suggested service factors for API grade C and D rods.

FIGURE 6.4.5 Sucker rod couplings, polished rod couplings and subcouplings [6].

Equation 6.4.4 can be written in forms applicable to specific API rod grades as follows:

Grade C rods:

$$S_A = (22,500 + 0.5625 \times S_{\min}) \times SF \quad (6.4.5)$$

Grade D rods:

$$S_A = (28,750 + 0.5625 \times S_{\min}) \times SF \quad (6.4.6)$$

$$S_A, S_{\min} = \text{lb/in.}^2 \text{ or psi}$$

SF is dimensionless.

Example 6.4.1

Given : A 77 Grade D rod string operating in a saltwater-crude oil environment has a minimum polished rod load measured with a dynamometer of 15,000 lbf.

Desired : Maximum allowable stress and load for this rod string.

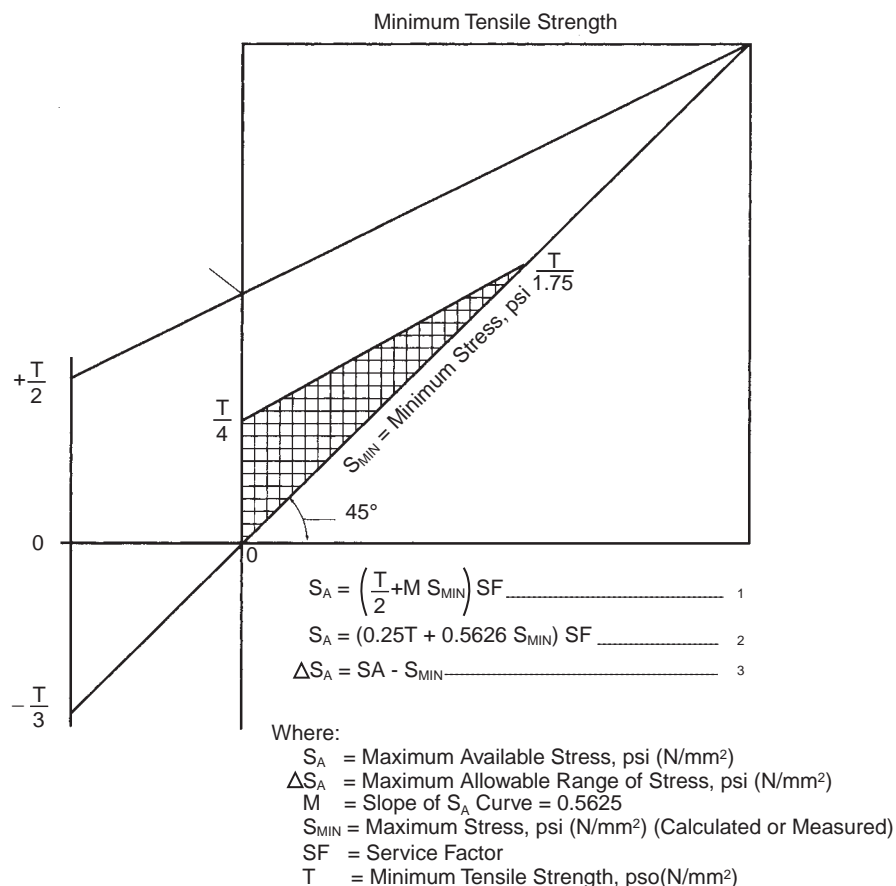

FIGURE 6.4.6 Modified Goodman diagram for allowable stress and range of stress in noncorrosive service [7].

Solution

Step 1: A 77-rod string has a cross-section area of 0.601 in.² (See Table 6.4.2). Use this area to compute rod stress from rod load.

$$S_{min} = \frac{\text{Min. load}}{\text{Rod area}} = \frac{15,000 \text{ lbf}}{0.601 \text{ in.}^2} = 24,960 \text{ psi}$$

Step 2: Determine the service factor. From Table 6.4.4, for a grade D rod, the service factor for saltwater (brine) service is recommended to be 0.90.

Step 3: Use the Goodman diagram equation to compute S_A . Use Equation 6.4.6 for grade D rods.

$$\begin{aligned} S_A &= (28,750 + 0.5625 \times S_{min}) \times SF \\ &= (28,750 + 0.5625 \times 24,960) \times 0.90 \\ &= 38,510 \text{ psi} \end{aligned}$$

Step 4: Compute maximum allowable loads by multiplying S_A by rod area.

TABLE 6.4.3 Chemical and Mechanical Properties of Sucker Rods

API Grade	Chemical Composition
K	AISI 46XX Series Steel
C	AISI 10XX Series Steel
	AISI 15XX Series Steel
D Carbon	AISI 10XX Series Steel
	AISI 15XX Series Steel
D Alloy	AISI 41XX Series Steel
D Special	Special*

*Special alloy shall be any chemical composition that contains a combination of nickel, chromium, and molybdenum that total a minimum of 1.15 percent alloying content.

$$\begin{aligned} \text{Max allowable load} &= S_A \times \text{rod area} \\ 38,510 \text{ psi} \times 0.601 \text{ in.}^2 &= 23,140 \text{ lbf} \end{aligned}$$

Service factors should be considered as guidelines and not as highly precise universal

TABLE 6.4.4 Suggested Service Factors for API Grade C and Grade D Rods in Corrosive Conditions [2]

Service	API C	API D
Noncorrosive	1.00	1.00
Salt water	0.90	0.65
Hydrogen sulfide	0.70	0.50

parameters. Experience from a given area should be used to determine proper service factors for given types of corrosive environments.

6.4.1.4 Reciprocating Rod Pumps

6.4.1.4.1 The Sucker Rod Pump

Sucker rod pumps, also called “plunger” pumps, consist of the following basic components as shown in Figure 6.4.7. A cylinder or barrel, a piston or plunger, a traveling valve that is attached to the plunger, a standing valve that is attached to the bottom of the barrel, and a device for locking the pump in place called an anchor or hold-down.

API Grade	Minimum Yield 0.2% Offset psi (Mpa)	Minimum Tensile psi (Mpa)	Maximum Tensile psi (Mpa)
K	60,000 (414)	90,000 (620)	115,000 (793)
C	60,000 (414)	90,000 (620)	115,000 (793)
D	85,000 (586)	115,000 (793)	140,000 (965)

The pump is placed at the bottom of the well at a depth that allows the pump to remain covered by fluid during the pumping operation. The pumping cycle starts with an upward stroke of the sucker rods, in which the plunger and traveling valve are pulled up through the barrel. The traveling valve closes, the standing valve opens and fluid enters into the barrel to occupy the space displaced by the upward moving plunger. During this motion, the fluid on top of the plunger is forced upward in the tubing towards the surface. On the downward stroke of the plunger, the traveling valve opens and the standing valve closes trapping the fluid above it. The downward motion of the plunger through this trapped fluid forces it to pass through the open traveling valve to the top of the plunger. With each stroke of the pump, more fluid is added to the tubing until the column of fluid reaches the surface and flows into the flow line.

Sucker rod pumps are generally classified as tubing pump and insert or rod pumps. The major difference between the tubing pump and rod pump is that the rod pump can easily be pulled for repairs, while the tubing pump barrel is an integral part of the tubing string which must be pulled for barrel repair or replacement.

FIGURE 6.4.7 Sucker rod pump.

All sucker rod pumps require a device to hold them in place in the well. This device is the anchor or hold-down. There are two standard types of hold-downs, cup type and mechanical type. These hold-downs may be found on top or on bottom of the pump depending on the type of pump and the requirements. Some special pumps have a hold-down in the center of the pump, while others may have a hold-down at the top and at the bottom.

The choice between a tubing pump and a rod pump for a given installation is an important one. A comparison of

TABLE 6.4.5 Comparison of Pump Types and Anchor Types	
<i>Tubing Pumps</i>	
Advantages	Disadvantages
<ul style="list-style-type: none"> ● Largest displacement ● Strongests 	<ul style="list-style-type: none"> ● Must pull tubing to remove pump ● Poor for gassy wells ● Large rod load
<i>Rod Pumps Traveling Barrel, Bottom Anchor</i>	
Advantages	Disadvantages
<ul style="list-style-type: none"> ● Sand kept in motion near barrel ● Good for intermittent pumpers ● Strong plunger-rod connection ● Open cages allow low pressure drop ● Low pressure drop across barrel 	<ul style="list-style-type: none"> ● Less desirable for low static level wells ● Long pull tubes can become bowed
<i>Stationary Barrel, Bottom Anchor</i>	
Advantages	Disadvantages
<ul style="list-style-type: none"> ● Generally suited for deep wells ● Useful for low static level wells ● Useful for gassy wells 	<ul style="list-style-type: none"> ● Hazardous to use in sandy wells ● Not recommended for intermittently produced wells

Advantages	Disadvantages
<ul style="list-style-type: none"> ● Useful for sandy wells ● Useful for some low fluid level gassy wells 	<ul style="list-style-type: none"> ● Thin wall pump barrels can burst in deep wells

the advantages and disadvantages for rod and tubing pumps as well as top and bottom hold-downs is presented in [Table 6.4.5](#). Additional information is available in reference [8].

6.4.1.4.2 Pump Designations

The API presents a standardized notation, shown in [Figure 6.4.8](#), for designating sucker rod pumps.

6.4.1.4.3 Tubing Pumps

Because of their rugged design, the tubing pump is considered the heavy-duty pump of the industry. Tubing pumps have a great production capacity than any API insert pump for the same tubing size. Their inherent design, however, makes them more difficult to install and retrieve than insert pumps and their capacity for large fluid volumes makes them impractical for deep wells. The weight of the large volume fluid column is too much for the strength limits of existing sucker rods.

The barrel of the tubing pump is attached directly to the tubing at or near the lower end of the tubing. A seating nipple is placed below the pump barrel to accept the hold-down and seat the pump. After the pump barrel is in place, the standing valve assembly and plunger assembly is run

into the well. The lower end of the plunger assembly has a standing valve puller to which the standing valve is attached. During the pump installation process, when the standing valve assembly reaches the seating nipple the standing valve is locked in place with the hold-down. The rods are rotated counterclockwise to disconnect the standing valve puller from the standing valve. The plunger is then raised sufficiently to allow minimum clearance on the down-stroke. This spacing must be adjusted after initial pumping begins to account for the fluid load causing additional rod stretch.

6.4.1.4.4 Rod Pumps

A rod pump has the same basic parts as the tubing pump, but the barrel is not an integral part of the tubing as in the tubing pump; therefore, all the components of the pump can be pulled from the tubing using the rod string.

The rod pump is more versatile than the tubing pump. It has a much higher compression ratio when spaced properly, making it a better choice for gassy wells. The rod pump can be used at much greater depths than the tubing pump, but is not capable of pumping the large capacities. Rod pumps can be equipped with top or bottom hold-downs or both for a variety of applications.

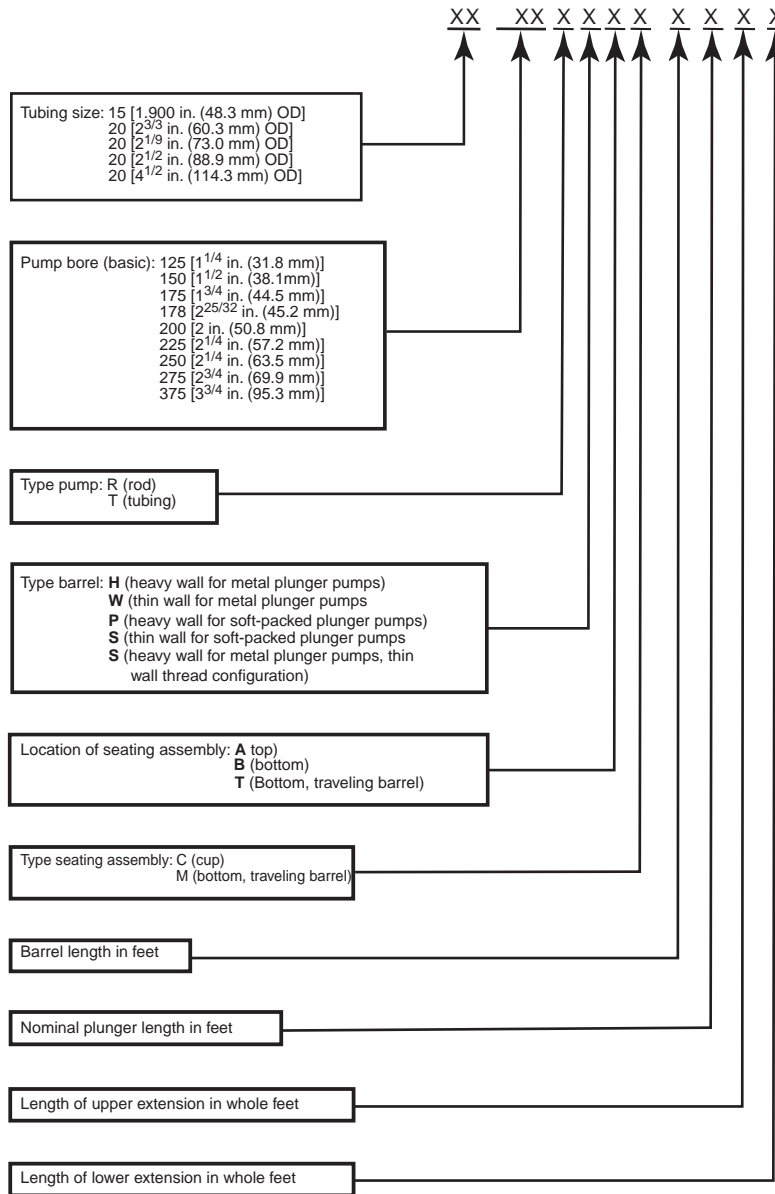

FIGURE 6.4.8 API pump designations [8].

6.4.1.5 Selection of Well Equipment

6.4.1.5.1 Pump Submergence

The energy to fill the pump should be supplied by the formation rather than by a high fluid head in the casing tubing annulus if maximum production is desired. Where feasible, pump intake should be below the perforations or as close above them as possible.

6.4.1.5.2 Gas Separation

Gas evolution within the pump barrel or below the standing valve can cause significant reduction in pump volumetric efficiency. Where gas evolution is a problem, some type of

downhole gas separator (commonly called a *gas anchor*) should be used.

6.4.1.5.3 Sand Control

Where sand production exists, some method of sand control, such as gravel packs, screens, or formation bonding agents, should be used to maximize pump life.

6.4.1.5.4 Common Pump Problems and Solutions

Several frequently occurring operating problems and their solutions are discussed in Reference [8] and are summarized here.

6.4.1.5.4.1 Corrosion

The principal corroding agents in pumping wells are carbon dioxide, hydrogen sulfide, oxygen and brine, either singly or in combination. The failure mechanisms that these agents can create are sulfide stress cracking, corrosion fatigue, erosion corrosion, stress corrosion, galvanic corrosion, pitting and wear abrasion.

When corrosive conditions exist, the metallurgy of the pump and downhole accessories should be chosen to resist the corrosion. Chemical inhibitors can be helpful but will not prevent corrosion in all cases. Such inhibitors protect casing, tubing, and rods better than the pump parts. Thus, corrosion resistance here is best obtained through proper selection of pump materials for construction. Refer to Chapter 7 for more details on corrosion mitigation.

6.4.1.5.4.2 Fluid Pound

A fluid condition exists when insufficient liquid enters the pump barrel on the pump upstroke. Above the liquid, a gas space is created between the traveling valve and the standing valve. During the next downstroke, the traveling valve does not open until the plunger hits the liquid. This impact sends a strong shock wave up the rods to the surface. In some instances the shock can be carried to the gear reducer of the beam pumping unit. When this pounding or shock is repeated with each pump cycle and for significant periods of time, major structural damage can occur in the downhole and surface equipment. This damage can include:

- a. gear tooth failure in pumping units
- b. damage to the pumping unit base structure
- c. rod fatigue and failure
- d. accelerated wear on traveling valve cages, balls and seats
- e. accelerated wear on tubing threaded connections

Fluid pound can be caused by one of two conditions: (1) a “pumpset-off” condition of the well in which the well cannot produce as much fluid as the pump can lift to the surface, and (2) restricted intake to the pump because of mechanical blockage at the pump.

The pumped-off condition can be prevented by slowing down the pump, using a smaller size pump or shorter stroke length, or putting the pump on a percentage timer if the prime mover is electric. Various pump-off controllers are available to sense when a well is nearing a pumped-off condition. The controllers then shut off the pump for a predetermined period.

If the fluid pound is caused by restricted fluid entry, none of the above alternative remedies are appropriate. Only proper pump servicing will remove the restriction.

6.4.1.5.4.3 Gas Pound

Gas pound has a behavior and observed effect somewhat similar to that of fluid pound but has a different cause.

It occurs when no “pumped-off” condition exists. There may or may not be an intake flow restriction. The cause of gas pound is occurrence of excessive gas in the pump barrel on the pump upstroke. It can be caused by inadequate downhole gas separation or gas breakout due to oil flow through flow restrictions in the standing valve or dip tube. A gassy crude can evolve significant gas if it is forced at high velocity through a flow restriction. If the gas pound is caused by excessive free gas and there is ample flow area in the standing valve port and cages, then a better gas anchor is needed. If flow restrictions exist, then more open cages and large-diameter dip tubes should be tried.

6.4.1.5.4.4 Sand Accumulation

Although proper choice of metallurgy for downhole pump barrels, plungers, valves and cages will help in alleviating a sand accumulation problem, sand control methods should be evaluated also.

6.4.1.5.4.5 Scale Formation

Chemical scale deposits can occur in some producing wells, and in extreme cases be so severe as to seriously restrict flow of oil through the pump and tubing. Chemical scale inhibition agents are available that will either eliminate or significantly reduce the effect of scale deposition. Because scale deposition is a cumulative effect, treatment must follow a fixed and uninterrupted treatment regime. Refer to Chapter 7 for a complete discussion of the causes and control procedures for scale deposition.

6.4.1.6 Computation Procedure

Selection of the proper equipment for a new well follows, an orderly sequence based on computation of pumping unit performance. The method suggested here is that recommended by API [9]. Computer programs are available to perform the calculations described here for manual use. The API RP11L calculation procedure is intended for design of conventional geometry (class I) units pumping in non-deviated wells at depths of less than 12,000 ft. The method is based on use of API grade steel sucker rods.

Various commercially available computer programs, such as Rodstar and S-rod, make complete calculations for a wider variety of pumping unit types (class I, class I with Phased crank, and class III units) rod types (steel rods, continuous rod, and fiberglass rods) depth and inclination of the hole. Some of these programs bases their design on dynamic analysis of the elastic behavior of the rods and tubing and can include inertial effects of the surface equipment. With correct input as to well conditions and equipment characteristics, these wave equation programs can make a very precise estimate of loads and stresses in the pumping system and lead to an optimal design.

6.4.1.6.1 Required Information

Before the API RP11L calculation procedure can be started, the following information must be available for the well.

- expected oil and water production, in bbl/d, and their specific gravities
- casing and tubing sizes
- anchoring depth (if any) for tubing
- pump setting depth
- fluid level during production (when pumping)

The design considerations in proper selection of each of these items are discussed separately in the following sections.

6.4.1.6.2 Expected Fluid Production

Expected production depends upon how much the pump in the well can lift and on how much oil the formation can produce. The volume of oil that can theoretically be displaced or moved by the pump is called the *pump displacement* PD and is given by the following equation:

$$PD = A_p \times S_p \times N \times \text{Con} \quad (6.4.7)$$

The volume of oil actually produced at the surface is given by

$$Q = E_v \times PD \quad (6.4.8)$$

where

- PD = theoretical displacement of the pump in bpd
- A_p = cross section area of plunger in in.²
- S_p = effective stroke length of the plunger in in.
- N = pumping speed in strokes/min
- Con = a units conversion constant, 0.1484
- Q = rate of oil and/or water produced at the surface in bpd
- E_v = volumetric efficiency of pump displacement process (a fraction)

To simplify the calculations, the terms A_p and Con are frequently lumped together to give a pump constant, K. Pump displacement is then computed from

$$PD = K \times S_p \times N \quad (6.4.9)$$

Table 6.4.6 gives pump constants K for various sizes of plungers and can be used to compute pump displacement.

Example 6.4.2

Given: A 1½-in. plunger is being used to pump oil at 16 strokes per minute and an effective downhole stroke of 51.5 in. The pump volumetric efficiency is estimated to be 70%.

Desired: Daily surface production of oil, bpd.

TABLE 6.4.6 Pump Factors or Constants [57]

Plunger diam in.	Area of plunger sq. in. (A_p)	Pump Constant (K)
$\frac{5}{8}$	0.307	0.046
$\frac{3}{4}$	0.442	0.066
$\frac{15}{16}$	0.690	0.102
*1	0.785	0.117
*1 $\frac{1}{16}$	0.886	0.132

*2 $\frac{3}{4}$	5.940	0.881
*3 $\frac{3}{4}$	11.045	1.640
*4 $\frac{3}{4}$	17.721	2.630
*API sizes		

Solution

Step 1. Using data from Table 6.4.6 and Equation 6.4.7 we obtain pump displacement:

$$\begin{aligned} PD &= A_p \times S_p \times N \times \text{Con} \\ &= (1.767 \text{ in.}^2) \times (51.5 \text{ in.}) \times (16 \text{ spm}) \\ &\quad \times 0.1484 \\ &= 216 \text{ bpd} \end{aligned}$$

Step 2. Determine surface production from Equation 6.4.8.

$$\begin{aligned} Q &= E_v \times PD \\ &= 0.70 \times 216 \text{ bpd} = 151 \text{ bpd} \end{aligned}$$

An alternate solution using pump constants is

$$\begin{aligned} PD &= K \times S_p \times N \\ &= (0.262)(51.5)(16) = 216 \text{ bpd} \end{aligned}$$

Volumetric efficiency E_v is normally between 70% and 100%. In unusual circumstances where a well is

FIGURE 6.4.9 Inflow performance relationships for solution gas drive reservoirs [10].

partially flowing while pumping, the E_v can be above 100% (flumping wells). Several factors contribute to decrease E_v below 100%. These include slippage past the plunger on the upstroke and gas evolution from the oil as the oil enters the pump barrel and as gas evolves from the oil as it rises up the tubing. This latter effect is accounted for by the oil formation volume factor. An oil with a formation volume factor of 1.15 requires 1.15 barrels of oil at reservoir condition to yield 1.0 barrels at the surface. This factor, alone, without any pump slippage would give an E_v of $(1/1.15) \times 100 = 87\%$.

The pump can displace the computed pump displacement PD only if the formation can produce this much oil. Optimal performance is obtained when the pump production at the surface matches the ability of the formation to produce, or when the pump produces at the statutory limit on production or the limit determined by prudent reservoir operation.

The estimate of the formation's ability to produce should be based on one or more well tests whenever possible. A productivity index or inflow performance relation should be used to determine the volume of fluid which the formation

can produce under various conditions of flowing bottom hole pressure. A method widely used for solution gas drive fields producing oil, gas, and only a small amount of water, or none is based on Vogel's curve [58]. The curve is reproduced here as Figure 6.4.9. This method needs only a single a single point production test, wherein reservoir shut in pressure is measured and total liquid production (oil and water) and flowing bottomhole pressure are measured. The equation for this curve is given below as

$$\frac{q_0}{(q_0)_{\max}} = 1 - 0.2 \frac{(P_{wf})}{(P_r)} - 0.8 \frac{(P_{wf})^2}{(P_r)^2} \quad (6.4.10)$$

where q_0 = total liquid production per unit of time at flowing bottomhole pressure P_{wf}
 $(q_0)_{\max}$ = maximum possible flow per unit of time
 $P_{wf} = 0$
 P_{wf} = flowing bottomhole pressure
 P_r = average reservoir pressure

The equation is used to compute the expected flowrate q_0 at any given flowing bottomhole pressure P_{wf} . Values of

P_r and $(q_0)_{\max}$ are constants that must be determined from the flow test. P_r is measured during the flow test and $(q_0)_{\max}$ is computed using Equation 6.4.10 and the flowrate data.

An example calculation is given below:

Given: A reservoir flow test indicated that the well flowed 100 bpd when the flowing bottomhole pressure was 1500 psia and the reservoir average pressure was 2000 psi.

Desired: Determine the flowrate in bp/d when the flowing bottomhole pressure is 250 psia.

Solution

Step 1: Compute $(q_0)_{\max}$ using Equation 6.4.10, such that

$$\frac{(q_0)}{(q_0)_{\max}} = 1 - 0.2 \frac{(P_{wf})}{(P_r)} - 0.8 \frac{(P_{wf})^2}{(P_r)^2}$$

$$\frac{100}{(q_0)_{\max}} = 1 - 0.2 \frac{(1500)}{(2000)} - 0.8 \frac{(1500)^2}{(2000)^2}$$

$$(q_0)_{\max} = 250 \text{ bbl/d}$$

Step 2. Use P_r and $(q_0)_{\max}$ with desired P_{wf} in Equation 6.4.10 to compute q_0 , such that

$$\frac{q_0}{250} = 1 - 0.2 \frac{(250)}{(2000)} - 0.8 \frac{(250)^2}{(2000)^2}$$

$$q_0 = 241 \text{ bpd}$$

Estimation of water production should be done in company with determination of the oil production.

Where the size of the selected pumping unit is critical or where little data are available, it may be desirable to use a test pumping unit to determine not only flow capacity but also working fluid levels.

6.4.1.6.3 Casing and Tubing Size and Tubing Anchor

Casing size is usually determined long before the decision is made to install a beam pumping unit. Frequently, tubing is also already in place. However, its diameter and weight and weight per foot should be known. If tubing is already in place, it is not cost effective to change out the tubing for a large size as a means of installing a larger pump. Where a pump is needed that is larger than possible with the existing tubing, a casing pump should be investigated.

Tubing anchors have the advantage of keeping the tubing from buckling and oscillating during the pump cycle. Not only does this reduce wear on the tubing, but, as will be seen in the API RP11L calculations, anchors increase the net effective bottomhole stroke over that for unanchored tubing. Anchors can create problems in wells with severe scale, sand, or corrosion conditions as these conditions may so damage the anchor that it cannot be released to allow tubing removal.

6.4.1.6.4 Pump Setting Depth

Whenever possible, the pump should be set at a depth in the well where pump intake pressure is above the bubble point of the oil as it is produced. This would suggest locating the pump one to three tubing joints below the perforations. Sometimes this is not possible because of total well depth, nor desirable because of sand production. Alternatively, the pump should be placed out of and above the turbulence zone near the perforations (three to six joints above the perforations). In any case, the pump should have significant submergence, 50 to 100 ft of fluid, to assist in rapid fluid fillage of the pump barrel. For low productivity wells, this amount of submergence may not be either possible or economically feasible but the consequence will be that wells with lower submergence may experience pump-off and some type of pump-off controller would be needed.

6.4.1.6.5 Expected Pump Fluid Level

This is one of the needed parameters about which there will be much uncertainty in a new installation. If a well test and an inflow performance relationship is available for the well, one can possibly convert flowing bottomhole pressure to flowing liquid height. Such a calculation would be fairly accurate for nearly dead oils or for wells producing mostly water. An alternative, conservative design approach is to assume that the flowing liquid level is at the pump depth. Once a unit is in operation, one of the commercially available acoustical well sounders can be used to measure the working fluid level. This value would be useful in any comparison of the well's current performance with that predicted by the API RP11L procedure.

6.4.1.6.6 Preliminary Design Data

In addition to selecting the data listed in the section titled "Required Information" which items are generally constant for a given pumping installations, the user of the API RP11L calculation procedure must select initial or tentative values for each of the following four parameters:

- a. plunger diameter
- b. pumping speed
- c. stroke length
- d. sucker rod string design

The following paragraphs give guidelines for proper selection of these parameters.

For a given size tubing there is a maximum pump size for each type of pump. Refer to Table 6.4.7. An additional guide to plunger size selection for a given fluid volume and pumping depth is found in Table 6.4.8.

For any given selection of stroke length there is a maximum recommended pumping speed. If this speed is exceeded, the rods are likely to "float" or go into compression on the downstroke. Rods are normally under tension

TABLE 6.4.7 Maximum Pump Size and Type [2]

Pump type	Tubing size, in.			
	1.900	2 $\frac{3}{8}$	2 $\frac{7}{8}$	3 $\frac{1}{2}$
Tubing one-piece, thin-wall barrel (tw)	1 $\frac{1}{2}$	1 $\frac{3}{4}$	2 $\frac{1}{4}$	2 $\frac{3}{4}$
Tubing one-piece, heavy-wall barrel (th)	1 $\frac{1}{2}$	1 $\frac{3}{4}$	2 $\frac{1}{4}$	2 $\frac{3}{4}$
Tubing linear barrel (tl)	—	1 $\frac{3}{4}$	2 $\frac{1}{4}$	2 $\frac{3}{4}$
Rod one-piece, thin-wall barrel (rw)	1 $\frac{1}{2}$	1 $\frac{1}{2}$	2	2 $\frac{1}{2}$
Rod one-piece, heavy wall barrel (rh)	1 $\frac{1}{16}$	1 $\frac{1}{4}$	1 $\frac{3}{4}$	2 $\frac{1}{4}$
Rod liner barrel (rl)	—	1 $\frac{1}{4}$	1 $\frac{3}{4}$	2 $\frac{1}{4}$

on the downstroke as well as the upstroke. If they are put into compression, they will buckle, causing wear on rods and tubing. The range of stress will be large, thus reducing the Goodman diagram maximum allowable stress. The alternating tension and compression will cause severe stress on rod threads and coupling and accelerate rod parting from fatigue and accelerated effects of corrosion. Dynamometer tests (to be discussed later) can detect floating rods. The maximum pumping speed for given stroke lengths is given in Figures 6.4.10, 6.4.11, and 6.4.12. These figures are for three widely used types of pumping units.

Stroke length is a primary variable in determining pump-unit size. Because of the small number of stroke lengths (usually two to four) available for any pumping unit, it is wise to select an available stroke length, then use this length in Equation 6.4.7 to determine an appropriate first estimate of strokes per minute. The selected stroke and speed combination should be checked to see that the rods do not float. Use Figure 6.4.10, 6.4.11, or 6.4.12, whichever is appropriate.

For shallow wells, less than 2000 ft most pumping installations will use sucker rods of the same diameter from the top of the well to the pump. Since the load on the rods is as its greatest at the top of the rod string on the upstroke, for single size rod strings one needs only to check the stress at this point using the Goodman diagram to see if the rods are satisfactory. For deeper wells, one usually uses a larger-diameter rod near the surface and smaller-diameter rods further down the well. Such multiple-size rod strings are called *tapered rods*. A coding system for designating the sizes has been adopted. A 76-rod string consists of $\frac{7}{8}$ -in. rods near the top and $\frac{6}{8}$ - (or $\frac{3}{4}$ -) in. rods near the bottom. An 88-rod string has 1-in. (i.e., eight $\frac{1}{8}$ -s) rods throughout its length. A 75-rod string has $\frac{7}{8}$ -in. rods near the top, $\frac{6}{8}$ - (or $\frac{3}{4}$ -)

in. rods near the middle and $\frac{5}{8}$ -in. rods near the plunger. This is called a three-way tapered rod string. Four-way tapers are also possible. This coding scheme does not specify what percent of each rod size is used in the string.

Two approaches have been used in determining the percent of each rod size. In the first, one starts at the plunger depth and adds rods of the smallest size (for example $\frac{5}{8}$ -in. rods in a 75-rod string design). These are added until the stress at the top of these rods is the maximum allowable according to some criterion such as the Goodman diagram. At that point, one changes to the next large size ($\frac{3}{4}$ -in. rods in the current 75-rod string example). One then continues to add rods until the stress at the top of these rods meets the same maximum stress criterion. At this point, one then changes to the largest size and adds rods until either the top of the hole is reached (a successful design) or until the maximum stress criterion is met but the top of the hole has not been reached. In this latter case, one does not have an acceptable design. One would need either to change to a larger-diameter string such as an 86-rod design or go to a four-way taper (85-rod string in the present instance), adding 1-in. rods to the top of the string.

The above maximum stress method leads to the lightest rod string. It is not as conservative as the next or balanced stress method. In the balanced stress method, the percentages of each size rod in the 75 rod combination, for example, are adjusted until the same stress exists at the top of each size of rods. Usually this stress is less than the maximum allowable stress. The rod string selected by this method is somewhat heavier than the selected by the first method and is generally to be preferred.

The API, using this latter approach, has given rod size and percent length of rods for available rod combinations and plunger diameter. These percentages appear in columns 6 through 11 of Table 6.4.9. For example, a 76-rod string using a 1.50-in. plunger would have 33.8% $\frac{7}{8}$ -in. rods and 66.2% $\frac{3}{4}$ -in. rods. An 85-rod string with 1.75-in. plunger would have 29.6%, 30.4% 29.5% and 10.5% of 1-in., $\frac{7}{8}$ -in., $\frac{3}{4}$ -in. and $\frac{5}{8}$ -in. rods, respectively.

6.4.1.6.7 API RP11L Calculations

The calculation sequence to design a pumping unit installation is best explained through an example calculation. Assume that the following data are available for a pumping well.

1. desired surface production, 150 bpd
2. estimated pumping volumetric efficiency, 85%
3. pump setting depth, 5000 ft
4. fluid level during pumping, 4500 ft
5. tubing is 2 in. nominal, not anchored
6. pumping speed, 16 spm
7. stroke length at surface, 54 in.
8. plunger diameter, 1.50 in.

TABLE 6.4.8 Pump Plunger Sizes Recommended for Optimum Conditions [67]

Net lift of fluid ft.	Fluid production—Barrels per day—80 pct efficiency									
	100	200	300	400	500	600	700	800	900	1000

	1 1/8	1 1/4								
8000	1 1/4									
	1 1/8									

- 9. fluid specific gravity, 0.90
- 10. sucker rod design (API)

Desired calculated results are:

- 1. effective downhole stroke, in.
- 2. pump displacement, bpd
- 3. peak polished rod load, lbf
- 4. minimum polished rod load, lbf
- 5. peak torque, lbf-in
- 6. polished rod horsepower, hp
- 7. counterbalance effect, lbf measured at polished rod

The calculation sequence is shown in Figure 6.4.13. Blank calculation sheets similar to Figure 6.4.13 can be obtained from API. The stepwise sequence for performing the calculations is described below.

- Step 1.** Record on the calculation sheet the factors W_r , E_r , F_0 , from Table 6.4.9 and E_t from Table 6.4.9 for the selected rod design (calculation lines 1–4).
- Step 2.** Using the data recorded in Step 1 and the given data, compute the nondimensional parameters

F_0/Sk_r , N/N_0 , N/N_0 , and the term $1/k_t$ (calculation lines 5–11).

- Step 3.** Compute the effective stroke length S_p and the pump displacement PD (calculation lines 12–14). For line 12, one needs to get S_p/S from Figure 6.4.14 using the previously computed values for F_0/Sk_r and N/N_0 .

- Step 4.** Compare the computed pump displacement with that desired. The calculated value of PD is 175 bbl/d. Use Equation 6.4.8 to compute Q and compare it to the desired Q:

$$Q = EV \times PD$$

$$= (0.85) \times 175 \text{ bpd} = 149 \text{ bpd}$$

This is close enough to the desired production to proceed to the next step of the calculations.

Calculation line 14 is a crucial intermediate checkpoint. If the production is close to the desired production, then one should proceed with calculation lines 15 through 27. However, if production is considerably different from that desired, one

FIGURE 6.4.10 Maximum practical pumping speed, conventional unit [2].

FIGURE 6.4.11 Maximum practical pumping speed, air balanced unit [2].

should make different selections for some of the eight parameters that are listed on the calculation sheet as known or assumed data. Parameters that allow greatest change in pump displacement are stroke length and plunger diameter. Stroke lengths should be selected that are available from the manufacturers' catalogues, stroke and speed combination should not allow rods to float, and the plunger diameter should be one possible for the given tubing size. When relatively small adjustments are needed, one usually changes pumping speed first, then changes stroke length if necessary.

In making calculations for lines 5 through 11, one should try to select input data that will keep

F_0/Sk_r less than about 0.35 and N/N_0 less than about 0.5 for optimal pumping performance.

- Step 5.** Compute nondimensional terms for calculation lines 15 through 17.
- Step 6.** Using the previously computed values for F_0/Sk_r , N/N_0' , and N/N_0 record from Figures 6.4.15 through 6.4.18 the values needed in lines 18 through 22. Note the special correction procedure needed for T_a from Figure 6.4.19 when Wrf/Sk is different from 0.30.
- Step 7.** Compute the five operating characteristics of the pumping unit. This step is the final one in the calculation sequence if the operating characteristics are acceptable. However, because the overall task is to

FIGURE 6.4.12 Maximum practical pumping speed, Mark II unit [2].

design not just a feasible pumping unit but rather to seek an optimal design, it may be necessary to select other alternative values for the assumed data and then repeat the calculation. It is the repetitive nature of the calculation that makes it attractive for a computer solution.

6.4.1.6.8 Testing the Design

The five operating characteristics of the pumping unit (lines 23 through 28) are used to specify more completely the selected unit. The operating characteristics will allow one to:

1. determine whether the rods are overstressed
2. specify feasible specifications for pumping unit such as:
 - a. Peak torque

- b. Structural capacity
- c. Stroke length
- d. Prime mover horsepower

An explanation and definition of each of these five operating characteristics of calculation lines 23 through 27 is given below. This followed by a description of how to use these operating characteristics to choose feasible specifications for the pumping unit operating characteristics. The operating characteristics of lines 23 through 27 have the following significance.

PPRL = peak polished rod load in pounds. This is the maximum load on the polished rod during the upstroke.

MPRL = minimum polished rod load in pounds. This is the maximum load on the polished rod during the downstroke.

*Rod No. shown in first column refers to the largest and smallest rod size in eighths of an inch. For example, Rod No. 76 is a two-way taper of $\frac{7}{8}$ and $\frac{6}{8}$ rods. Rod No. 85 is a four-way taper of $\frac{3}{8}$, $\frac{7}{8}$, $\frac{6}{8}$, and $\frac{5}{8}$ rods. Rod No. 109 is a two-way taper of $1\frac{1}{4}$ and $1\frac{1}{8}$ rods. Rod No. 77 is a straight string of $\frac{7}{8}$ rods, etc.

Fluid Level, H = 4500 ft.	Pumping Speed, N = 16 SPM	Plunger Diameter, D = 1.50 in.
Pump Depth, L = 5000 ft.	Length of Stroke, S = 54 in.	Spec. Grav. of Fluid, G = 0.9
Tubing Size 2 in. Is it anchored? Yes, <u>No</u>	Sucker Rode 33.8% - $\frac{7}{8}$ " & 66.2% - $\frac{3}{4}$ "	

Record Factors.

- | | |
|--------------------------------|-------------------------------|
| 1. $W_r = 1.833$ | 3. $F_e = 1.082$ |
| 2. $E_r = .804 \times 10^{-6}$ | 4. $E_t = 307 \times 10^{-6}$ |

Calculate Non-Dimensional Variables:

- | | |
|--|--|
| 5. $F_e = .340 \times G \times D^2 \times H = .340 \times 0.9 \times 2.25 \times 4500 = 3098$ lbs. | 9. $N/N_e = NL + 245,000 = 16 \times 5000 + 245,000 = .326$ |
| 6. $1/k_r = E_r \times L = 0.804 \times 10^{-6} \times 5000 = 4.020 \times 10^{-3}$ in/lb. | 10. $N/N'_e = N/N_e \div F_e = .326 \div 1.082 = .301$ |
| 7. $Sk_r = S \div 1/k_r = 54 \div 4.020 \times 10^{-3} = 13,433$ lbs. | 11. $1/k_r = E_t \times L = .307 \times 10^{-6} \times 5000 = 1.535 \times 10^{-3}$ in/lb. |
| 8. $F_e/Sk_r = 3098 \div 13,433 = .231$ | |

Solve for S_p and PD:

12. $S_p/S = .86$
 13. $S_p = [(S_p/S) \times S] - [F_e \times 1/k_t] = [.86 \times 54] - [3098 \times 1.535 \times 10^{-3}] = 41.7$ in.
 14. $PD = 0.1166 \times S_p \times N \times D^2 = 0.1166 \times 41.7 \times 16 \times 2.25 = 175$ barrels per day

If the calculated pump displacement fails to satisfy known or anticipated requirements, appropriate adjustments must be made in the assumed data and steps 1 through 14 repeated. When the calculated pump displacement is acceptable, proceed with the Sign Calculation.

Determine Non-Dimensional Parameters P:

- | | |
|--|---|
| 15. $W = W_r \times L = 1.833 \times 5000 = 9165$ lbs. | 17. $W_{rt}/Sk_r = 8110 \div 13,433 = .604$ |
| 16. $W_{rt} = W[1 - (.128G)] = 9165[1 - (.128 \times .9)] = 8110$ lbs. | |

Record Non-Dimensional Factors:

- | | | |
|-----------------------|-----------------------|------------------|
| 18. $F_1/Sk_r = .465$ | 20. $2T/S^2k_r = .37$ | |
| 19. $F_2/Sk_r = .213$ | 21. $F_3/Sk_r = .29$ | 22. $T_a = .997$ |

Solve for Operating Characteristics:

23. $PPRL = W_{rt} + [(F_1/Sk_r) \times Sk_r] = 8110 + [.465 \times 13,433] = 14,356$ lbs.
 24. $MPRL = W_{rt} - [(F_2/Sk_r) \times Sk_r] = 8110 - [.22 \times 13,433] = 5249$ lbs.
 25. $PT = (2T/S^2k_r) \times Sk_r \times S/2T_a = .37 \times 13,433 \times 27 \times .997 = 133,793$ lb inches
 26. $PRHP = (F_3/Sk_r) \times Sk_r \times S \times N \times 2.53 \times 10^{-5} = .29 \times 13,433 \times 54 \times 16 \times 2.53 \times 10^{-6} = 8.5$
 27. $CBE = 1.06(W_{rt} + 1/2F_e) = 1.06 \times (8110 + 1549) = 10,239$ lbs.

FIGURE 6.4.13 Example design calculations — conventional sucker rod pumping system [57].

PT = peak torque in inch-pounds. This is the maximum torque generated on the gear reducer during the pumping cycle.

PRHP = theoretical horsepower needed by the pumping unit.

CBE = Counterbalance effect. This is the pounds of counterbalance effect measured at the polished rod needed to properly counterbalance the unit. It is *not* equal to the pounds of counterbalance weights needed. See discussion below.

Rod Stress

One should use the PPRL and MPRL in a stress analysis of the rod string to determine whether the rods are overstressed. For this, the Goodman diagram is used. The procedure is explained using the above calculation example.

Step 1. Convert the rod loads (PPRL and MPRL) to stress by dividing by the rod cross section area.

Since PPRL and MPRL are computed at the polished rod, one uses the cross-section area of

the largest rod ($\frac{7}{8}$ -in. diameter in this case). The cross-section areas of the rods are listed in Table 6.4.3. For $\frac{7}{8}$ -in. rods, the cross-section area is 0.601 in.². The stress's are

$$\frac{PPRL}{\text{Rod area}} = \frac{14,356 \text{ lb}}{0.601 \text{ in.}^2} = 23,887 \text{ lb/in.}^2$$

$$\frac{MPRL}{\text{Rod area}} = \frac{5249 \text{ lb}}{0.601 \text{ in.}^2} = 8734 \text{ lb/in.}^2$$

Step 2. Select the rod grade and tensile strength. Refer to Table 6.4.3. Let us assume that the rods are grade C. These have a minimum tensile strength of 90,000 lbf/in.² Minimum rather than maximum tensile strength is used to give a more conservative design and to reduce the possibility of rod failure.

Step 3. Apply the modified Goodman diagram equation. Refer to "Allowable Rod Stress and Stress Range" for a discussion of this equation. Thus

$$S_A = (T/4 + 0.5625 \times S_{\min}) \times SF$$

FIGURE 6.4.14 Plunger stroke factor [9].

where T = minimum tensile strength in psi

S_{\min} = minimum tensile stress
experience by the rod

S_F = service factor

S_A = allowable maximum stress in
rod in psi

Here $T = 90,000$ psi for a grade C rod

$S_{\min} = 8734$ psi from Step 2.

Let us assume a service factor of 1.0, i.e.,
normal noncorrosive conditions (no H_2S , CO_2 or
brine)

Step 4. Compute S_A :

$$\begin{aligned} S_A &= (T/4 + 0.5625 \times S_{\min}) \times S_F \\ &= (90,000/4 + 0.5625 \times 8734) \times 1.0 \\ &= 27,412 \text{ psi} \end{aligned}$$

Step 5. Compare allowable maximum stress S_A with the design maximum.

The API R11L design gives a maximum stress of 23,887 psi. The modified Goodman diagram allowable stress is 27,412 psi. Thus this rod string will not be overstressed. The design stress is $(23,887/27,412) \times 100 = 87\%$ of the maximum stress. The actual design stress should not be more than 95% of the Goodman diagram allowable stress. If this percent value is much less than 50%, a lighter rod string could be used. The comparison of actual to allowable stress in this step is critically dependent upon the value chosen for the service factor. In this example, a service of 0.80 would mean that the allowable stress was

FIGURE 6.4.15 Peak polished rod load factor [9].

$$S_A = (90,000/4 + 0.5625) \times 0.80 = 21923 \text{ psi}$$

which gives a percentage of the allowable stress of

$$\frac{23,887 \text{ psi}}{21,923 \text{ psi}} \times 100 = 109\%$$

and so the rods would be overstressed.

Peak Torque

The calculated peak torque for this example design is 133,793 lb-in. The unit selected must have a gear reducer torque rating larger than this computed value. Refer to Table 6.4.1 for available ratings. Any unit having a rating of 160,000 lb-in. or larger would serve. Normally one would choose a 160,000-lb-in. unit rather than a 228,000 or 320,000-lb-in. unit. Normal notation is to refer to a 160,000-lb-in. unit as a 160 unit.

Structural Capacity

Structural capacity is based on the peak polished rod load (PPRL). In each torque rating class, several structural capacities are available. One chooses a structural capacity rating larger than the PPRL. A 17,300-lb structural capacity unit would be selected here.

Stroke Length

Although a stroke length of 54 in. was initially chosen, one now needs to see if the selected pumping unit with 160,000 lb-in. of torque and 17,300 lbf structural capacity is available in a 54-in. stroke. The API unit closest to that desired is 160-173-64. The 64 refers to the *largest* stroke available in this size. One would need to check manufacturers' catalogues to see what smaller strokes are possible for a 160-173-64 unit. If, for instance, a 53-in. stroke were available as a second stroke length setting, one would need to increase the pumping speed slightly to overcome the reduction in stroke length.

Prime Mover Horsepower

The computed polished rod horsepower rating PRHP is a theoretical horsepower value and is less than the rated capacity of any prime mover that should be selected. The value also does not indicate whether one should use an electrical motor or an internal combustion engine. Refer to "Selecting Prime Mover Site" for a discussion of prime mover selection criteria. If a slow-speed internal combustion engine or a high slip NEMA D electric motor were selected, the prime mover horsepower would be computed by Equation 6.4.2

FIGURE 6.4.16 Minimum polished rod load factor [9].

$$\begin{aligned}
 HP_{pm} &= \frac{q \times D}{PMF} \\
 &= \frac{(150 \text{ bpd}) \times (4500 \text{ ft})}{56,000} = 12.0
 \end{aligned}$$

Note that the actual lifting depth, 4500 ft, and the surface flow rate 150 bpd were used. The efficiency given as 85% is incorporated into the value selected for PMF. One would choose the next size larger available nameplate rating for the engine or motor to serve as prime mover.

6.4.1.7 Analyzing Existing Pumping Units

Several different procedures are available to test an existing pumping installation. Because causes of malfunction are

many and because the observed consequences of many malfunctions can be the same, the process of identifying one or more problems that can exist can be complex. In most instances, the most rapid and accurate analysis will occur where the largest amount of precise data are available. The benefit of the extra data comes in less work over expense and less lost production due to downtime.

6.4.1.7.1 Dynamometers

An extremely valuable tool for analysis of well performance is the well dynamometer. Several manufacturers provide these devices that measure polished rod load versus polished rod position. The new electronic dynamometers also allow rod position and rod load to be recorded versus time. If an electric prime mover is used, some new dynamometer

FIGURE 6.4.17 Peak torque factor [9].

systems also provide a graph of motor current versus rod position and versus time. This later graph is a simple and rapid way to determine proper counterbalance. The load measuring part of the dynamometer is attached to the polished rod so that the load can be sensed and sent to a recorder. A companion part of the dynamometer attached to the walking beam senses the polished rod position and sends it to the same recorder. The graph produced is called a *dynagraph* or more commonly a *dynamometer* or *dynagraph card*. A typical card is shown in Figure 6.4.20.

Force \times distance equals work. The dynamometer measures force on the polished rod and distance the polished rod

moves. The dynamometer thus records work done during one pump cycle. Because power is the rate of doing work, and because the time to create one pumping cycle, creating one dynagraph card is known, the rate of doing work, namely the horsepower at the polished rod can be estimated from the dynamometer card.

The rods, fluid, and tubing (if unanchored) constitute an elastic system whose motion under the action of the reciprocating pump can be very complex. The dynamometer records the changing load versus position at one point in the system, i.e., the polished rod. To understand the behavior of the system at points other than at the point of measurement

FIGURE 6.4.18 Polished rod horse power factor [9].

is very difficult in many installations. Older references to the pumping system as following simple harmonic motion represent a gross oversimplification for moderate to deep wells. For such wells, the only reasonably precise estimation of downhole behavior based on dynamometer cards can be obtained through computer programs based on solutions to the wave equation such as described by Gibbs [11]. However, for troubleshooting of wells, several types of problems can easily be identified through qualitative analysis of the appearance of the dynamometer card. Other problems can be identified through simple computations using dynamometer card data. In any program of troubleshooting of wells with a dynamometer, it is always helpful to have a dynamometer card for the well when it is operating normally. The card when taken during a troubleshooting test should be run under identical conditions of pumping speed,

stroke length and dynamometer constant settings as when the well was running normally. In the following paragraphs, some of the more common and easily identified problems will be described where these problems can be identified through card shape.

Fluid Pound

Refer to the section titled “Fluid Pound” for a discussion of the causes and cure for fluid pound. Its presence is indicated by a relatively steep drop in the load somewhere along the downstroke portion of the dynagraph. The farther that this drop occurs to the left, the farther the plunger has moved down the pump barrel before it hits liquid. A typical example of fluid pound appears in Figure 6.4.21. A more severe example of fluid pound is given in Figure 6.4.22.

FIGURE 6.4.19 Adjustment for peak torque factor [9].

Gas Pound

This effect is similar to that of fluid pound and cannot always be positively distinguished from fluid pound based solely on card shape. Gas pound shows a more gradual load decrease on the downstroke relative to fluid pound. An example of gas pound is shown in Figure 6.4.23.

Well Pumping Off

Under normal conditions, exactly the same dynamograph is traced on each pump cycle. However, when a condition

of fluid pound exists and the drop off a load occurs later and later in the downstroke cycle, then a well pumped off condition exists. The well cannot produce as much as the pump is attempting to lift to the surface so the pump barrel fills less with each successive cycle. This condition is shown in Figure 6.4.24.

Additional Qualitative Dynamometer Tests

Analysis of problems wells is enhanced if a few extra simple tests are made while the dynamometer is in place. These

FIGURE 6.4.20 Dynamometer card [9].

FIGURE 6.4.21 Example of fluid pound [12].

FIGURE 6.4.22 Severe case of fluid pound [2].

tests include (1) traveling valve check, (2) standing valve check and (3) counterbalance effect measurement. Each is described below and typical diagnostic examples are shown.

For the traveling valve check, leave the dynamometer in place recording a stable card. Stop the pumping unit about half way through the upstroke and pull the polished

rod position indicator cord sharply four or five times at 1-s intervals. A nonleaking traveling valve will show a single horizontal line on the card. A leaking valve will appear as in Figure 6.4.25. The constant line across the middle of the diagram labeled "Traveling Valve" is the line that would appear for a nonleaking valve. However, when the valve

FIGURE 6.4.23 Example of gas pound [2].

FIGURE 6.4.24 Example of well pumping off [2].

FIGURE 6.4.25 Traveling valve with severe leak [2].

FIGURE 6.4.26 Standing valve with severe leak [2].

leaks, fluid above the valve moves downward through the leak and exerts a pressure on the standing valve and reduce the load on the traveling valve and plunger. In the case of a severe leak, the entire fluid load will bear on the standing valve and the dynamometer will indicate only the buoyant weight of the rods.

The standing valve check is done in a manner similar to that for the traveling valve but on the downstroke rather than the upstroke. At approximately half way through the downstroke, stop the unit and the pull the polished rod position indicator cord sharply four or five times at 1-s intervals. If the traveling valve holds and the standing check valve leaks, the dynamometer card will appear as in Figure 6-136. When the standing leaks, the fluid in the

barrel, instead of going up through the traveling valve, will go downward through the leaky standing valve. This fluid motion will cause fluid to move downward through the traveling valve causing it to close. The dynamometer will then sense an increase in load on the rods. This is the cause for the rise shown on the example card in Figure 6.4.26.

The counterbalance effect measurement will indicate whether a pumping unit is properly counterbalanced. Proper counterbalancing is important to reduce power consumption and to ensure long life to the prime mover and pumping unit gear reducer. To measure the effect in pounds that the counterweights have at the polished rod, install the dynamometer as when preparing a dynagraph, then when a stable card has been obtained, stop the unit where the max-

Also, an engineer designing gas lift installations needs a working concept of valve mechanics. This topic is also covered in a later section. As with computer software for gradient curves, there is available computer software for assisting the designer with determining gas lift mandrel depths, gas lift valve calculations or set pressures, and analyzing gas lift valve performance under dynamic flowing conditions.

After a working knowledge of these topics is covered, an example design of both tubing-operated and casing-operated valves will be presented. These are offered as simple examples under certain assumptions. They can be elaborated upon and changed under certain conditions. In other words, there are many sound engineering variations leading to working designs. A trained representative of a reputable gas lift service company should be consulted for further design techniques.

6.4.2.1 Inflow Performance

Inflow performances of a reservoir can be defined as the functional relationship between the flowing bottomhole pressure and the resulting flowrate. Several models are available, such as straight line (productivity index, or PI), Vogel's method, the Fetkovich method, and others [13].

First, the straight line, or PI, is given as the ratio of the total barrels of fluid produced to the pressure drawdown across the reservoir (drawdown is defined as the average reservoir pressure minus flowing bottomhole pressure), or

$$PI = \frac{q(\text{bpd})}{\delta P(\text{psi})}$$

This value can be obtained by direct measurement on a particular well by physically measuring the flowing and shut-in bottomhole pressure while also noting the surface flowrate. This number is valid only while the oil/water ratio for the well remains fairly constant. The effect of changing oil/water ratios can be seen below. If measured values are not available, one can estimate the PI with the approximate relationship obtained from the Darcy equation. This is done by utilizing a typical relative permeability relationship and correlations for viscosity and formation volume factors:

$$PI = HK_a \left(\frac{K_{ro}}{\mu_o B_o} + \frac{K_{rw}}{\mu_w B_w} \right)$$

where K_a = absolute permeability of the rock in darcies

K_{ro} = relative permeability to oil

K_{rw} = relative permeability to water

B = formation volume factor

μ = viscosity

H = reservoir thickness in ft.

A second method is that developed by Vogel, originally obtained for volumetric reservoirs at bubble point pressure where resulting gas saturations around the vicinity of the wellbore cause a decrease in the relative permeability. The relationship derived is given as

$$\frac{q}{q_0} = 1 - 0.2 \left(\frac{P_w}{P_b} \right) - 0.8 \left(\frac{P_w}{P_b} \right)^2$$

where q = flowrate in bpd

q_0 = flowrate at maximum drawdown in bpd

P_w = flowing bottomhole pressure of interest in psig

P_b = bubble point and reservoir pressure in psig

With this method, a measured value of flowing bottomhole pressure, average reservoir pressure and the associated flowrate is required to define q_0 . Once the equation is thus normalized, it can then be used to predict the well's performance at any drawdown.

A third method occasionally used is that of Fetkovich, where flowrate is given by

$$q = C(P_r - P_w)^n$$

where C and n are constants and must be determined by conducting two separate flow tests. The parameter P_r is the average reservoir pressure.

Example 6.4.3

A well flowing 50% water (viscosity = 0.5 cp and FVF = 1) and 50% oil (viscosity = 4 cp and FVF = 1.5) from a 20-ft.-thick reservoir. Core analysis indicates the absolute permeability to be 300 md. Estimate the PI of this well.

Answer

Assuming typical relative permeability relationships, we estimate the relative permeability of the reservoir to oil to be 0.25 and to water of 0.25. This yields a $PI = 3.25$ bfpd/psi. Note that when this well produced all oil, the PI would be estimated at 1 bpd/psi.

If this well is tested at a flowrate of 200 bopd and 200 bwpd, with a shut-in bottomhole pressure of 4500 psig, and a flowing bottomhole pressure of 4350 psig, what is the calculated PI? What is the expected production rate for a drawdown of 1000 psi by the PI method?

Answer

$PI = 2.67$ bfpd/psi, implying a rate of 2670 bfpd for a 1000-psi drawdown.

If a well is tested at 400 bopd for a drawdown of 150 psi, what does the Vogel method predict for a 1000-psi drawdown? The reservoir pressure (also the bubble point pressure) is 4500 psi.

Answer

$q_0 = 6767$ bopd, and yields a flowrate of 2439 bopd for a 1000 psi-drawdown.

A second test on this well shows a production rate of 1000 bopd for a 500-psi drawdown. What flowrate does the Fetkovich method predict for the 1000-psi drawdown?

Answer

$C = 0.006$ and $n = 0.79$; flowrate = 1704 bfpd at the 1000-psi drawdown.

Neither of these calculation techniques can be considered preferable; each depends on the engineer's experience and the actual reservoir conditions.

6.4.2.2 Gradient Curves

The first concept needed in gas lift design is that of gradient curves. For the case of single fluid flow in pipes, one can calculate the total pressure difference between two points with well-defined mathematical equations, requiring only a friction factor empirical relationship for the case of turbulent flow. Even in the case of non-Newtonian fluids, appropriate assumptions have been made enabling the calculation of pressure difference with a single equation for pipe or annular flow. In the case of multiphase flow involving gas-liquid mixtures, a single equation is not possible. Pressure variation along the length of the pipe causes gas volume changes. In the case of oil-gas flow, the oil may liberate solution gas into the flow stream. Consequently, a change of the *in situ* gas-liquid fraction implies a constantly changing hydrostatic component of pressure, a constantly changing friction factor and, possibly, an acceleration component of pressure change.

The only method of calculating pressure differences for multiphase flow is to resort to computer numerical evaluation utilizing incrementing type algorithms. Starting conditions in the first increment are used to estimate conditions in the next increment and so on until the total pressure difference is calculated. Calculation techniques are available in the literature such as Poettmann and Carpenter, Hagedorn and Brown, Orkiszewski, Beggs and Brill, Duns and Ros, and many others [14]. The reader is encouraged to use appropriate computer programs with which to obtain gradient curves for design work. The appropriate choice of calculation technique is dependent on such factors as the geographical area the wells are located, etc. The author will refer to the gradient curves given by K. Brown in *The Technology of Artificial Lift Methods* [13].

Gradient curves for multiphase flow in vertical pipes are used in one of three ways: (1) to predict the pressure at the bottom of a measured interval if the pressure at the top of the interval, the gas/liquid ratio, and the liquid flowrate are known; (2) to predict the pressure at the top of a measured interval if the pressure at the bottom of the interval, the gas/

liquid ratio, and the liquid flowrate are known; or (3) to predict the gas/liquid ratio required if the pressures at both ends of a measured interval and the liquid flowrate are known.

First, one must realize that the vertical axis on typical gradient curves (see [Figure 6.4.29](#)) does not represent absolute depth but rather a relative vertical length. The user must determine the appropriate section of a gradient curve to use for his or her particular problem. For (1) above, one first identifies the appropriate gradient curve and then locates the pressure of interest at the top of the interval, noting the vertical ordinate for that point. The interval length of interest is then added to this vertical ordinate. This identifies the appropriate interval of interest. The pressure at the interval bottom is the predicted pressure. In the case of (2) above, this process is reversed. For (3) above, we imagine two vertical lines drawn at the end pressures. These lines intersect the entire family of gradient curves, but only one curve (perhaps an interpolated one) has the prescribed vertical interval. This process is a trial-and-error one until the correct curve is identified. Of course, a computer program with which to calculate gradient curves would be somewhat easier to use.

Example 6.4.4

Three example problems will be worked below for a well with 2-in. tubing (1.995" ID) flowing all oil at a rate of 600 bpd and a GLR of 400 scf/bbl. It is assumed that the gas and oil properties given by Brown [13; 3a, page 194] are appropriate (see [Figure 6.4.29](#)).

1. If the well is flowing with a surface pressure of 400 psig, what is the pressure at a depth of 5000 ft.? At 10,000 ft.? The answers are 1520 psig; 3280 psig.
2. If the same well is flowing with a bottomhole pressure of 4000 psig at a depth of 8000 ft., what is the pressure at the surface? At 4000 ft.? The answers are 1240 psig; 2520 psig.
3. The same well is flowing with an unknown gas/liquid ratio. The surface pressure is 600 psig and a known pressure of 1600 psig at a depth of 5000 ft. What is the flowing gas/liquid ratio? The answer is a pressure difference of 1000 psi over the 5000-ft interval implies approximately 600 scf/bbl.

6.4.2.3 Valve Mechanics

Gas lift valves, by necessity, are constructed as shown in [Figure 6.4.30](#) and [6.4.31](#), where all components must be built into a small cylindrical-shaped tube. The diameter and length will vary according to size restrictions imposed by tubing size, mandrel size, etc. Gas Lift Valves are available in two different configurations:

- Wireline retrievable valves—installed in sidepocket mandrels and will not require pulling the tubing string or

FIGURE 6.4.29 Example of vertical flowing pressure gradient for multiphase flow.

completion string for repair or recalibration on gas lift valves (example shown in Figure 6.4.32).

- Tubing retrievable valves—installed on conventional mandrels and can only be repaired or recalibrated by removing the tubing or completion string (example shown in Figure 6.4.33).

A typical valve must have a closing force (provided by a spring, gas pressured chamber, or both of these), an opening force (provided by a metal bellows upon which either tubing or casing pressure acts) and a flow-controlling orifice.

If tubing pressure is exerted against the bellows in the open position, this valve is referred to as a fluid-operated or production pressure—operated (PPO) gas lift valve. If casing pressure is applied on the bellows in the open position, then we have a casing-operated or injection pressure—operated (IPO) gas lift valve.

Gas lift valves operate similarly to pressure regulators. Note that a casing-operated valve acts to maintain a set casing pressure. If casing pressure increases, the valve opens further, attempting to relieve the additional pressure. Conversely, a pressure decrease causes the valve to pinch

FIGURE 6.4.30 Simplified drawings of IPO and PPO valves.

down in an attempt to decrease gas flow and thereby maintain casing pressure.

On the other hand, a tubing-operated valve attempts to maintain a set tubing pressure. An increase in tubing pressure opens the valve to allow additional gas into the tubing in an attempt to lighten the fluid column above. If tubing pressure decreases, then the valve pinches down in an attempt to increase the tubing fluid gradient by reducing the gas flow into the tubing. There are several variations on this arrangement such as balanced valves, etc., but these will not be covered here.

The force balance equations (see Craft, Holden, and Graves [1]) give the following relationships for a casing-operated valve that is open and on the verge of closing:

$$P_{vc} = P_{bT} + S_t(1 - A_v/A_b)$$

where A_v = area of the valve port

A_b = effective area of the bellows

S_t = spring constant in psig

P_{bT} = bellows pressure temperature T in psig

P_{vc} = casing pressure opposite the valve at closing in psig.

In the case of a valve fully closed and on the verge of opening, we have the equation

$$P_{v0} = \frac{P_{bT}}{(1 - A_v/A_b)} + S_t - \left[\frac{A_v/A_b}{(1 - A_v/A_b)} \right] P_t$$

where P_t = tubing pressure opposite the valve in psig

P_{v0} = casing pressure opposite the valve at opening in psig

Note that P_{v0} and P_{vc} are not equal due to the fact that the casing pressure is applied to the valve stem during flow

and tubing pressure is applied to the valve stem during closed conditions. This difference is called the *valve spread* and is utilized in the gas lift unloading process to ensure that valves above the lifting valve are closed. Hence, a casing-operated valve will have a gas passage somewhat as shown below in Figures 6.4.34. For exact valve performance characteristics, one would have to consult the valve manufacturer or utilize the computer software program, Valve Performance Clearinghouse (VPC) 2002 (current version for year 2003). The VPC Program is a proprietary software program available only to VPC members. This gas lift valve performance correlation program is based on tested valve performance and incorporates valve parameters such as loadrate, maximum effective travel, flow coefficients, dynamic test data. Other gas lift valve performance correlations available are Thornhill-Craver (use for orifice valves only), Winkler-Eads, Bertovic (developed for PPO valves only), API Simplified, TUALP (Tulsa University Artificial Lift Project), and VPC/TUALP. Typical flow performance curves, as predicted by VPC correlation, for 1" OD IPO and 1" OD PPO valves are illustrated in Figure 6.4.35 and in Figure 6.4.36 respectively. In Figure 6.4.37, the predicted flow performance for same IPO valve is compared with different correlations. This shows the reason for not using a square-edged orifice table or correlation (Thornhill-Craver) to select the correct port size in a gas lift valve.

In the case of a tubing-operated valve, the situation is somewhat different in that a valve spread is meaningless. One would calculate a valve tubing closing pressure at a tubing pressure greater than the valve tubing opening pressure. This is impossible; thus the actual closing pressure for a tubing operated valve is determined experimentally in a test rack at the shop; however, the valve closing equation above for a casing operated valve is very close if we substitute tubing pressure for P_{vc} .

FIGURE 6.4.31 Cutaway view of 1" IPO model R-1 and 1" PPO model RF-1 (courtesy of Weatherford-Production Systems).

Since the bellows volume can be considered constant, the bellows pressure at any temperature is related to that at shop conditions of 60°F by the equation

$$\frac{P_{bT}}{Z_T(460 + T)} = \frac{P_{b60}}{Z_{60}(460 + 60)}$$

The gas deviation factor for nitrogen is given by Sage and Lacy [15] or Craft, Holden and Graves [1]. However, Z

FIGURE 6.4.32 Example of sidepocket [wireline retrievable gas lift valve] mandrel (valve installs into mandrel pocket—valve not shown). Courtesy of weatherford-PS.

factors for nitrogen are very close to 1.0 and only deviate from that value by up to 5%.

Example 6.4.5

A casing-operated valve is to be run at a depth of 2000 ft., where the operating temperature is expected to be 95°F. The valve has an A_v/A_b ratio of 0.1, and a spring effect of 200 psig. What nitrogen pressure at depth is required in the bellows if the closing pressuring desired at depth is 900 psig? What nitrogen pressure must be placed in the valve at 60°F?

Answer

$P_{bT} = 720$ psig; $P_{b60} = 683$ psig using a Z factor of 1.006 for nitrogen at 95°F.

FIGURE 6.4.33 Example of conventional gas lift valve mandrel (valve screws on the lower lug adapter—valve not shown). *Courtesy of Weatherford-PS.*

One must also calculate the pressure increase for static gas columns due to its own density. A good approximation for methane is

$$\delta P = 0.25(P_{wh}/100)(D/100)$$

For example, if the available casing surface pressure P_{wh} is 1000 psig, then the casing pressure will increase 25 psi/1000 ft. of depth. This can be rewritten as

$$P_a = P_{wh}(1 + D/4.0 \times 10^4)$$

where P_B is the pressure at the bottom of an interval D in feet, and P_{wh} is the surface pressure, in psia. Typical gas lift situations have a large annular casing cross-section and the gas flow to the valve can be thought of as a static column. For greater accuracy, we have

$$P_B = P_{wh} \exp(0.01875\sigma D/Z_{avg} T_{avg})$$

where

- σ = gas specific gravity (air = 1.0)
- Z_{avg} = average Z factor over the interval
- T_{avg} = average temperature of the gas column in °R

For gas flow in small pipes, frictional pressure losses may be critical. Buthod and Whitely [7] have developed the following equation

$$P_B^2 = B(P_{wh}^2 - A) + A$$

where

- $B = \exp(0.0376\sigma D/Z_{avg} T_{avg})$
- $A = 1.51 \times 10^{-5} (q T_{avg} Z_{avg})^2 / d^{5.23}$
- d = equivalent flow channel diameter in in.
- q = gas flow rate in Mcf/d

For example, 300 Mcf/d of gas flow down a 1-in. ID tubing ($\sigma = 0.65$, $T_{avg} = 560^\circ R$, and $Z_{avg} = 1$), with a surface pressure of 1000 psig, will have a pressure at a 2000-ft depth of 1025 psig as compared to the expected 1050 psig for a static gas column.

6.4.2.4 Unloading the Well

A phenomenon one must address in gas lift design is that of unloading the casing annulus. Unloading simply means removing all the casing (packer) fluid left in the well between the tubing and casing at the time of completion and replacing it with gas down to the point of injection. First, if

FIGURE 6.4.34 Gas passage characteristics for casing and tubing operated valves.

FIGURE 6.4.35 VPC correlation — flow performance on IPO model R-1 (courtesy of Weatherford-PS).

FIGURE 6.4.36 VPC correlation — flow performance on PPO model RF-1 (courtesy of Weatherford-PS).

drilling mud or other abrasive fluid is in the casing annulus, it must be replaced with clean water by using a circulating pump. In the case of tubing retrievable valves, this task is easily accomplished at the time the pulling rig is on location. For wireline retrievable valves, a mandrel below the expected point of gas injection should be opened, and clean water circulated until the packer fluid is completely replaced. The accepted practice for circulating fluid through the pocket and pocket seal bores in a sidepocket gas lift

mandrel is to use a circulating valve or dump kill/shear orifice valve as illustrated in Figure 6.4.38. By using these special service valves, the pressure integrity of the sidepocket mandrel is maintained.

It is very likely that the desired point of gas injection will be deeper than can be unloaded with a single valve. Imagine a U-tube that is filled with liquid on both sides and has a gas pressure applied to one side. The fluid will move from one side to the other, spilling over at the top, and continuing

FIGURE 6.4.37 Comparison of Correlations — IPO model R-1 under same conditions (courtesy of Weatherford-PS).

FIGURE 6.4.38 Cutaway view of dump kill valve, model RDDK-1 (courtesy of Weatherford-Production Systems.)

until the pressure at the bottom on both sides become equal. If the U-tube is too long, this process will stop whenever the pressures equalize. For example, if the desired depth of injection is at 5000 ft. and the casing fluid is formation water of density given by 0.465 psi/ft., a gas pressure at the valve of 2325 psig would be required to unload the well with a single valve. Since this gas pressure is excessive, the conclusion is that one simply cannot unload the well with a single valve.

By this logic, several unloading valves will be needed. There are two methods for locating the unloading valves and the operating valve. The first method, Single Operating Depth, will be discussed in the following paragraphs with details. The second method, “Bracketing Envelope” Operating Depth, will be covered with general comparisons to the first method. In both methods, the location of the first unloading valve depth is determined by the same steps.

6.4.2.4.1 Single Operating Depth Method

The depth of the first valve can be determined by the equation

$$P_{ts} + \sigma_w D_1 = P_{cs} + \sigma_g D_1$$

- where P_{ts} = surface tubing pressure in psig
- P_{cs} = surface casing pressure in psig
- σ_w = water density in psi/ft
- σ_g = average gas density in psi/ft
- D_1 = depth to first valve in ft.

This equation can be solved either algebraically or graphically (see Figure 6.4.39) by plotting the left and right sides independently, finding the intersection. This is done by plotting pressure on the X-axis and depth on the negative Y-axis (standard plot for gas lift design). For example, if the well is being unloaded to a separator whose pressure is 50 psi, with a packer fluid of 0.5 psi/ft, and the available casing pressure is 1000 psig, then the first valve can be run as deep as 2000 ft. Of course, a more shallow depth would ensure

FIGURE 6.4.39 Locating the unloading valve depths.

successful unloading to the first valve, but would cause the deepest possible point of lift.

Once this first valve has been uncovered, it can be used to reduce the hydrostatic pressure in the tubing above that point by gas injection. Reduction of the hydrostatic pressure simply means that a second valve can be run below and the casing gas pressure will push the packer fluid down, through the second valve so it can be lifted to the surface by the first valve. Again, the depth to the second valve is determined by a pressure balance condition given by

$$P_{ts} + \sigma_{\min} D_1 + \sigma_w (D_2 - D_1) = P_{CS} + \sigma_g D_2$$

where σ_{\min} = the average minimum two-phase gradient that can be developed by the first valve in psi/ft.

The value of P_{CS} to be used here may differ from that used to locate the first valve. For example, a design for casing-operated valves will require that the casing pressure be reduced. Therefore, the value to be used is the surface casing pressure available for that valve. In the example above for the first valve, assume the average minimum gradient to be 0.15 psi/ft. and the surface casing pressure available for the second valve is 975 psig. The deepest depth to which the second valve can be run is therefore 3421 ft.

This process would continue to locate subsequent valve depths until the casing pressure (right side of the equation) can no longer produce the minimum gradient. Note that the distance between valves is decreasing. Typically, whenever

a minimum incremental distance (on the order of 400 ft. or less) or the expected lift depth is reached, several valves will be positioned, if possible, at this distance apart. This accounts for any errors made in the design and increases the probability that one of these valves will be the optimum lift depth.

At this point, another definition is needed, that of the deepest point of injection. This depth is defined by the equation

$$\text{FBHP} - \sigma_{\text{ave}} (D_T - D_{iv}) = P_{CS \text{ lift}} + D_{iv} \sigma_g$$

where FBHP = flowing bottomhole pressure in psig

σ_{ave} = average flowing gradient in the tubing from the perforations to the lift valve in psi/ft.

D_T = total depth of the well to the perforations in ft.

D_{iv} = depth to the injection valve in ft.

$P_{CS \text{ lift}}$ = surface casing pressure operating the lift valve in psig

The average flowing gradient in the tubing can be estimated to be the average density of the flowing liquids. This assumes that essentially no gas is liberated from solution until the liquid is above the lift valve. If, on the other hand, gas is liberated, then a straight line approximation is no longer valid, and a gradient curve should be used to approximate the second term on the left side of the equation above. Graphically, we can solve the above expression as shown in Figure 6.4.40.

FIGURE 6.4.40 Locating the injection valve depth by single operating depth method.

6.4.2.4.2 “Bracketing Envelope” Operating Depth Method

The purpose of gas lift is injecting high-pressure gas into a well with the result of reducing the bottom hole pressure and increasing the fluid recovery. The deepest gas injection depth as possible will optimize the fluid recovery and minimize the volume of injection gas requirements. Traditionally, the gas lift design engineer solved for a single gas injection depth, as illustrated in Figure 6.4.40. From experience, this method would limit the potential production from the well, because the gas lift valves were not spaced deep enough or were spaced too far apart due to inaccurate information (such as errors in flow correlations, well performance [PI or IPR], changing reservoir conditions, changing surface operating parameters).

Weatherford’s (McMurry-Macco) gas lift design engineers developed a better approach for spacing mandrels within an operating area. This method can account for errors in the original design information. The “bracketing envelope” method controls the differential between the injection pressure and the flowing tubing pressure in the operating area. This differential pressure is termed as the “operating differential”, and the well’s deliverability can be modeled based upon PI by available software programs (specifically Well Evaluation Model–WEM). As shown in Figure 6.4.41, with the operating differential (P_c - P_t) decreasing, the production rate from the well increases. This becomes more significant the higher the PI. Gas lift valve spacing is directly proportional to the operating differential selected. The smaller operating differential, the closer the valve spacing. Therefore, the operating differential (P_c - P_t) may be controlled through the valve spacing. This fact makes it necessary to attempt to define the unloading area and

the operating area. A wider spacing may be utilized in the unloading area reserving more valves for the operating area. Once the operating area has been identified the concept of the bracketing envelope can be utilized to maintain the proper operating differential and to offset any errors introduced through the inherent inaccuracies of the multiphase flow correlations used to profile tubing pressures or other design parameters.

A bracketing area tolerance must be selected. This tolerance should be based on the reliability of the information available. A small error tolerance may be used with good data. Questionable or unknown data justifies using a larger error tolerance. This will result in a more conservative design. Experience has indicated a potential 10% to 20% error associated with the use of the curves. Computer generated curves are more accurate than the published curves but inaccuracies still exist. The bracketing area is defined in the following manner (10% was selected for this example):

1. Multiply the wellhead pressure by the bracketing error percent

$$P_t = 120 \text{ Psi}$$

$$120 \times 10\% = 12 \text{ Psi}$$

Subtract and add this amount to the wellhead pressure and mark at the zero depth on the graphical design sheet, reference Figure 6.4.41.

$$P_1 = 120 + 12 = 132 \text{ psi}$$

$$P_2 = 120 - 12 = 108 \text{ psi}$$

2. Find the tubing pressure at the indicated point of injection or POI. This depth is determined by same method

FIGURE 6.4.41 Example of operating differential or gas lift valve spacing depths versus potential well production capacity.

used for selecting the deepest point of injection, as illustrated in Figure 6.4.40. When using the bracketing envelope method, this depth locates the center of the operating area or envelope. For this current example, the tubing pressure at 3850 ft is 700 psi. Multiply this pressure by the bracketing area percent that was selected.

$$700 \text{ psi} \times 10\% = 70 \text{ psi}$$

Subtract and add this amount to the tubing pressure at the point of injection.

$$P3 = 700 + 70 = 770 \text{ psi}$$

$$P4 = 700 - 70 = 630 \text{ psi}$$

Mark these two pressures at the point of injection.

3. Connect a line from P1 (132 psi) to P3 (770 psi). At the intersection of this line and the operating differential pressure line, P5, is the approximate depth at which the bracketing spacing should begin or the top of the bracketing envelop. For this example, the top of the bracketing envelope is 3300 ft.
4. Connect a line from P2 to P4 until it intersects the differential pressure line. At the intersection is the depth for the bottom of the bracketing envelope.

Since the operating differential was selected at 150 psi (from our WEM modeling), all mandrels from the top of the bracket at 3300 ft. to the bottom of the bracket at 4600 ft. will be spaced 323 ft. apart.

$$\begin{aligned} \text{Bracketing spacing} &= \text{Operating Differential (psi)} / \\ &\quad \text{Kill fluid gradient (psi/ft.)} \\ &= 150 \text{ psi} / 0.465 \text{ psi/ft.} \\ &= 323 \text{ ft.} \end{aligned}$$

For convenience, 350 ft. spacing would be used. The graphical solution for defining the bracketing envelope and bracketing spacing is illustrated in Figure 6.4.35.

Now, the logic of the unloading process must be explained. First, the casing operated valve design will be examined. An adjustable gas flow valve at the surface at the entrance to the casing annulus is required to have the valves function properly. Note that once lift is achieved, opening the surface casing valve will cause an increase in the casing pressure and will thereby cause the lift valve to open (allowing more gas into the tubing) since a casing-operated valve attempts to maintain a preset value of pressure. Conversely, pinching down on the surface valve causes the lift valve to reduce the gas passage. This is true unless the valve is fully opened and flow through the orifice is critical.

In the unloading process, gas pressure is applied to the casing annulus, causing water to be pushed through the valves until the first valve is uncovered and begins passing gas. To maintain a constant casing pressure, the surface valve is set to a gas flowrate that is essentially equal to the gas passage rate of the first valve that is now uncovered. Remember, packer fluid is being pushed through lower valves into the tubing and is being lifted to the surface by the first valve. Once the second valve is uncovered, gas is passed into the tubing by both valves. However, since the surface valve is set to a rate equal to one valve, the casing pressure will drop. The second valve closes when the casing pressure drops to the set closing pressure of the first valve. The casing pressure will then remain at this new, lower value as long as the surface valve has a flowrate equal to that of the second valve. By manipulating the surface valve, a pumper must at this time ensure that the casing pressure remains at this new value, below the opening pressure of the first valve.

This process is repeated when the third valve is uncovered, and the casing pressure is again lowered, consequently closing the second valve. This continues until all the unloading valves have been closed and the lifting valve is the only valve injecting gas into the tubing. Note that if the well supplies formation fluid at such a rate that the next lower valve cannot be uncovered, the well is flowing, which is the desired result. If conditions become favorable in the future, the next valve may be uncovered and the well will begin lifting from the lower valve.

The use of casing-operated valves implies that one has temporarily available gas at a higher than lift pressure for the unloading process, or the well will be lifted with less than available casing pressure, thereby lowering efficiency. However, due to the operating characteristics of casing valves, the pumper, by manipulating the surface valve, has some surface control of the lifting valve. This design could not be used in the case of a dual lift, that is, when there are two tubing strings in a single wellbore.

Tubing-operated valves are sometimes referred to as automatic valves since the unloading process proceeds without pumper assistance. These valves respond primarily to tubing pressure and one causes the valves to respond to tubing pressure only by maintaining a constant casing pressure. The design process is done graphically, and requires first that the injection valve depth be identified, and then that the expected lifting gradient be determined. Since the flowing gradient–injection valve intersection determines a pressure and depth, and the flowing surface tubing pressure is known, the lifting gradient can be obtained from a family of gradient curves as described above in the *gradient curve* section or by a computer program.

The depth to the first valve is obtained as described above. The valve closing pressure is now dictated to be a value as close to, yet greater than, the lifting gradient; that is,

to the right of the lifting gradient on a graphical design. This condition is required such that when this lifting gradient is achieved by the lifting valve, all valves above will be closed. The process starts with gas pressure applied to the casing annulus, causing the water to be pushed through the valves and up the tubing to the surface. When the first valve is uncovered, it will lighten the fluid column above because a temporary lifting gradient from the first valve is created when water enters the tubing from lower valves. This temporary gradient will become lighter and approach the final lifting gradient but not reach it due to the valve closing tubing pressure. Consequently, the depth to the second valve is found by the condition where

$$P_{ts} + P_{TG} + P_{safety} + \sigma_w(D_2 - D_1) = P_{CS} + \sigma_g D_2$$

where P_{TG} = total pressure difference of temporary gradient in psi

P_{safety} = small margin to ensure flow through valve in psi

Once the depth to the second valve is determined, its valve closing pressure is also chosen at a tubing pressure that is larger than the lifting gradient at that depth. Again, a temporary gradient is found from the surface unloading pressure to the second valve, and the above process is repeated for the next valve depth. This process continues until a transfer can be made to the injection valve found earlier.

Fluid-operated valves are typically used whenever minimal pumper surveillance is desired. Also, in the case of dual completions, the most popular choice is fluid-operated valves. However, another valve option would be “balanced gas lift valves”. These type valves can be controlled with either casing annulus pressure or tubing pressure. Therefore, the gas lift designer can use either fluid-operated or balanced gas lift valves, which allow maximum utilization of the available casing pressure to the operating depth. The efficiency of the gas lift design increases by lowering the injection depth. However, a string of fluid-operated or balanced valves usually require more unloading valves than a string of casing-operated valves.

Tubing-operated valves are typically used whenever minimal pumper surveillance is desired. Also, in the case of dual completions, tubing-operated valves are the only choice. Tubing-operated valves allow maximum utilization of the available casing pressure, thereby increasing efficiency. However, a string of tubing-operated valves usually require more unloading valves than a string of casing operated valves.

6.4.2.4.3 Tubing Operated Valves Example

Now that all the tools have been developed, a comprehensive example using tubing operated valves (see [Figure 6.4.42](#) and [6.4.43](#)) will be presented. The well is 10,000 ft.

FIGURE 6.4.42 PFO Bracketing.

deep ($2\frac{7}{8}$ -in. tubing) with a shut-in bottomhole pressure of 4000 psig and a measured PI of 1.33 bfpd/psi. The well flows 20% oil (30° API) and 80% water (specific gravity of 1.07). The surface pressure during lift is expected to be 50 psig, and the available gas pressure is 1000 psi (approximately 0.025 psi/ft. increase due to density). The bottomhole temperature is 200°F and the expected flowing temperature is 100°F. The design flowrate is 800 bfpd.

The flowing bottomhole pressure is 3400 psi. The expected gradient below the injection valve is 0.45 psi/ft. This information indicates the lowest possible point of gas injection to be at 4950 ft., where casing pressure is equal to the flowing tubing gradient. Consequently, the design point of injection is chosen at approximately 4700 ft. where a differential of 100 psi is available between the tubing gradient and casing pressure. This differential allows for the

pressure loss for gas flow through the valve and a safety margin for design error.

The packer fluid is assumed to be 0.5 psi/ft. density. An actual value can be used if it is known. However, since lease water is typically used, a high estimate is used as a design factor. This implies that the first valve can be run as deep as 2000 ft. In the case of mandrels already run in the well, any depth above 2000 ft. would work. The second valve depth is determined by first finding the design GLR curve from the lowest valve. By trial and error, the GLR curve connecting the surface tubing pressure of 50 psi and the design point of injection-flowing gradient intersection of 1020 psi at 4700 ft. is found to be approximately 210 scf/bfpd. This GLR curve indicates pressure of 350 psi at 2000 ft. Consequently, the closing pressure of the first valve must be greater than 350 psi. The actual number is

FIGURE 6.4.43 IPO Bracketing.

dependent on engineering judgment and the manufacturer of the valve used. In this example, we choose 425 psig, or 75 psi greater than the GLR curve.

A column of water will exist between the first and second valve, and a temporary GLR curve will exist between the first valve and the surface. The temporary gradient must be at least as heavy as 425 psig at the first valve since this is the closing pressure of the first valve. For a design factor, we will choose 475 psi, which we will call the transfer point. Adding a water column of 0.5 psi/ft. to this 475 psi, we see that this tubing pressure is equal to the casing

pressure at a depth of 3200 ft. Note that once the second valve begins admitting gas into the tubing, the gradient will become lighter and begin closing the first valve. During the time when the gradient from valve two is somewhat heavy, the first valve will be open and assist in reducing the gradient. Also, if no fluid is in the casing, such as with a well shut-in after it has been unloaded, the deepest valve that can open and allow gas into the tubing will do so. This would then start a process similar to unloading in that the opened valve lightens the gradient, allowing a deeper valve to begin passing gas and thus close the valve above. By definition,

this condition must exist somewhere in the well; we simply cannot gas lift the well if the liquid column is below or unable to open the lowest valve.

The lifting gradient has a pressure of 600 psig at the second valve at 3200 ft. A typical closing pressure of 650 psi is chosen for the second valve, and the liquid column transfer point from the third valve is chosen at 700 psi. This gives a depth of 4000 ft for the third valve. The gradient pressure at the third valve is 815 psig, giving a closing pressure of 860 psig and a transfer point of 900 psig. The fourth valve is therefore located at 4440 ft. with a gradient pressure of 860 psig. The valve closing pressure is taken as 950 psig and the transfer point as 985 psig.

This unloading process continues uncovering the next lowest valve and closing the valve above until a reservoir drawdown is achieved and formation fluid is lifted. In the example, formation fluid will be lifted by the third valve during the unloading process, but will be in small volumes since it will be on the order of perhaps 400 bfpd according to our PI information. If the PI used is correct and the lower valves are sized to input the correct gas flowrate, the well will continue to increase the drawdown until the last valve is lifting the well. If we can expect the well to produce 50 Mcfpd from the formation, then an injection rate of approximately 118 Mcfpd is required to bring the GLR up to 210 scf/bf. The valve chosen must be capable of varying gas flowrates from the 118 Mcfpd to 168 Mcfpd by throttling to accommodate those situations where the formation gas does not materialize, such as in the case of heading, etc. Its closing pressure will be less than 1000 psi, the value of the final lifting gradient at the valve depth.

Note that if our PI information were incorrect, a GLR gradient would indeed establish itself. For example, if the actual PI is higher, then the well will lift from a more shallow valve, perhaps the third or fourth. This would be a heavier gradient than the 210 GLR designed, but would establish itself at a greater liquid flowrate determined by the available gas and GLR actually established. If, on the other hand, the actual PI is less than expected, the well will unload to the deepest valve and establish a flow rate of less liquid with the available gas passage rate at a steeper lifting gradient. From experience, this variance, the predicated PI and the actual PI in the well completion, is one reason the gas lift design engineer would prefer the “bracketing envelope” design method. The designer must be aware of both of these possibilities since a greater than expected liquid flowrate can be damaging to the formation (gravel pack, etc.) as can a greater than expected drawdown across the formation.

A malfunctioning gas lift design would require testing to determine the difficulty. For example, a casing fluid level determination as used in pumping wells can be useful in cases when the unloading process is not successful. Also, a flowing pressure survey (pressures taken while the well

is lifting at various points in the tubing) can determine the actual point of gas injection. Pressure charts on the tubing and casing can sometimes pinpoint lift problems. Furthermore, a temporary increase, if available, of the casing pressure will help ensure a successful unloading of the well. After unloading, the casing pressure can be reduced to the designed value.

6.4.2.4.4 Casing Operated Valves Example

The same well described in the tubing-operated valves example will now be designed for gas lift with casing-operated valves. Several design techniques are available for casing-operated valves and one of these will be presented here. Further, an important assumption must be made concerning the casing pressure available. In this example, it is assumed that the 1000-psi lift gas is the maximum available pressure, that is, casing pressure cannot be increased, even temporarily. This assumption implies that the available casing pressure must be able to open all valves, even when there is no packer fluid in the casing annulus. This is the case whenever the well is shut-in (no packer fluid in the casing annulus) and the unloading valves are used to again start the well flow.

Some repetitive calculations are required in order to close the upper valves. The number of repetitive calculations will be reduced as the designer gains more experience in design methods and well characteristics within the field. Another option available to the designer is the application of a “spacing safety factor” during his graphical design. This spacing safety factor ranges from 25 to 50 psi, as illustrated in Figure 6.4.44. First, casing pressure traverses are drawn on the pressure versus depth (see Figure 6.4.45). Lines spaced 50 psi apart are drawn for reference. The static tubing pressure and flowing tubing pressure lines from the perforations are also placed on the graph.

The depth to the first valve is found in the same way as the tubing operated valves at 2000 ft. Because of the condition mentioned above, the opening pressure of the first valve is chosen to be 1050 psig, or the casing pressure at depth. If the valves chosen have an A_v/A_b of 0.067, the closing pressure of the valve at depth is 980 psig. This is an observed surface casing pressure of approximately 930 psig. Also, if the valve has a 200-psi spring effect, the required bellows pressure at depth is 793 psig, or a test rack pressure of 702 psig nitrogen pressure must be loaded into the bellows at 60°F. This surface casing pressure of 930 psig becomes the operating pressure of the second valve.

The depth to the second valve is chosen as the depth at which the U-tube pressures are equal: that of the casing (corresponding to a surface casing pressure of 930 psig) and the tubing. The tubing pressure is again a water gradient between the first and second valves and a GLR gradient from the first valve to the surface. A convenient gradient to use is the design lifting gradient from the deepest valve.

FIGURE 6.4.44 Example design fluid-operated values and single operating depth method.

FIGURE 6.4.45 Example design using casing-operated (IPO) values and single operating depth method.

Since the depth is not known at this point, it must be decided. By knowing the valves below the first are to be closed by a decrease of 30 psi surface casing pressure, we determine that four valves are needed. This implies that the final surface casing lifting pressure is 870 psig and the design depth of injection is approximately 4400 ft. Using the Hagedorn-Brown correlation, the design GLR curve is found to be approximately 230 scf/bbl.

The logic of using this GLR curve as the gradient above the valves is that during unloading, the valves can certainly achieve this condition since this is the design lift condition. Consequently, using a transfer point of 400 psig and a 0.5 psig/ft water density, the second valve should be run at 3250 ft. where the casing pressure at depth is 1025 psig. The closing pressure of the second valve, therefore, is taken to be 995 psig (surface casing pressure of 920). This casing

pressure becomes the operating pressure for the third valve, which has a value of 1010 psi at the third valve at a depth of 4000 ft. This valve depth is found by using a transfer point of 635 psig at the second valve. The closing pressure of the third valve is therefore 980 psig (a surface casing pressure of 870 psig). Since this is the last valve to close, the operating pressure for the lift valve is a surface casing pressure of 870 psig.

The closing pressure of the valve at 4400 ft. must be chosen such that the gas rate through the valve achieves the design GLR curve of 230 scf/bbl. If the formation can furnish 50 Mcfpd, then the valve must supply an additional 134 Mcfpd. This setting would depend on the type of valve and manufacturer used.

With an expected surface flowing temperature of 100°F and a Bht of 200°F, the design temperatures at the valves are 120, 132.5, 140, and 144°F. The bellows pressures needed in the second and third valves are therefore 808 and 793 psig. The surface rack nitrogen pressure needed for proper operation is 700 and 678 psig. By the choke equation [60], the orifice required in the lifting valve should be taken as $\frac{8}{64}$ -in., ensuring that excessive flowrates are prevented since this represents a maximum flowrate of 150 Mcf/d. A better solution for the designer would be using the dynamic flow characteristics of the particular gas lift valve and model the flowrate performance with available software programs, as discussed in “Valve Mechanics.”

6.4.3 Hydraulic Pumping

6.4.3.1 Definition

A hydraulic pumping system such as is being marketed today takes liquid from a power fluid reservoir on the surface, puts it through a reciprocating multiplex piston pump or surface electrical submersible pump to increase its pressure, and then injects the pressurized liquid down hole through a tubing string. At the bottom of the injection tubing string, the pressurized liquid is directed into the nozzle of a jet pump or the hydraulic engine of a piston pump, both of which have been set below the producing fluid level.

6.4.3.1.1 Types of Operating Systems

There are two basic operational types of hydraulic pump systems: the open power fluid system and the closed power fluid system. In an open power fluid (OPF) system the operating power fluid mixes with the produced fluid while down hole and both fluids are returned to the surface in a commingled state. In a close power fluid (CPF) system the production and operating power fluids are never allowed to intermix throughout the entire system. The closed power fluid system is used with piston pumps only.

6.4.3.1.2 OPF System

In an OPF system only two down-hole fluid conduits are required: one, to contain the pressurized power fluid and direct it to the pump, and another (normally the annulus) to contain both the spent power fluid and produced fluid and to return them to the surface (Figure 6.4.46). Since this is the simpler and more economical of the two systems, it is by far the most common system used.

Besides the simplicity and economical advantage of the OPF system, the intermingling of the power fluid and the produced fluid has some other inherent advantages.

First, the circulated power fluid is ideal for carrying chemical additives. Corrosion, scale, and paraffin inhibitors can be added to extend the lift of the subsurface equipment. Also, if there are emulsions downhole in the produced fluids, emulsion breakers can be added to the power fluid stream.

Second, the commingled power fluid has a diluting effect. Where highly corrosive production fluids are being lifted, the clean power fluid reduces the concentration of the corrosive elements by about 50%. Where extremely viscous oil is produced, the injected power fluid has a diluting effect and can often reduce the viscosity enough to make lifting the heavy crude more practical.

Third, in production fluids with a high paraffin content, the OPF system allows the circulation of heated fluids or dissolving agents through the power fluid lines to remove waxy build ups which may hinder or halt production.

6.4.3.1.3 CPF System (Piston Pumps Only)

In a closed power fluid system (Figure 6.4.47), an extra tubular string is required both down hole and on the surface. One string is for carrying the production to the tank battery and the other to return the spent power fluid to the power fluid tank for repressurization and recirculation.

This requirement for an additional tubing string, plus the associated complication of the bottomhole design, makes the closed power fluid system more expensive than the open system. For this reason, the CPF system is less popular and less used than the open power fluid configuration.

Since the produced fluids and power fluids are always separated, the closed system finds some advantage where the produced fluids are extremely abrasive or corrosive and where inhibitors are not used. A closed system allows the use of less exotic materials in the engine end of the pump and may extend the lift of both the pump and the surface power fluid facility.

A closed system may also find some slight preference on marine platforms and in industrial or residential installations where available space is scarce and at a premium. Because the power fluid conditioning and reservoir tank only needs to be large enough to provide an adequate volume of power fluid to feed the multiplex pump, the size

FIGURE 6.4.46 Open power fluid system.

of the power fluid tank is relatively small and almost all of the produced fluid can be put directly into the flow line.

In most down-hole pumps designed for use in a closed power fluid system, the pump end is lubricated by the power fluid. However, approximately 10% of the power fluid is lost into the production fluid so this amount of make-up fluid must be fed back into the power fluid system from the production line.

It must also be realized that even in a closed system, the power fluid can not remain clean. First, all of the pipes, fitting, pumps, tanks, etc. are not completely free of contaminated materials. Second, when a liquid containing any solid material is leaked through a close fit clearance (such as slippage past the engine piston) the solid material will tend to be held back.

6.4.3.2 Types of Subsurface Pump Systems

There are three basic subsurface pump systems: the free-type, the fixed-type, and the wireline-type.

The free-type does not require a pulling unit to run or retrieve the pump. The pump is placed inside the power fluid tubing string and is "free" to be circulated by the power fluid to bottom and back out again (Figure 6.4.48).

In a fixed-type system the subsurface pump is attached to the power fluid tubing and is run in the hole as an integral part of the tubing string. The pump must be run or pulled with a pulling unit (Figure 6.4.49).

In a wireline-type system (for jet pumps only), the subsurface pump is installed in a sliding sleeve, straddling a gas-lift mandrel, or straddling a chemical-injection mandrel. The pump is run into the well or pulled from the well on

FIGURE 6.4.47 Closed power fluid system.

a wireline. The pump can be operated in standard flow or reverse flow.

6.4.3.2.1 Free-Pump Systems

There are two main types of free-pumping installation designs: the casing-free design and the parallel-free design.

6.4.3.2.2 Casing-Free Installations

The casing free design is the least complicated and least expensive free pump design. It consists of a single tubing string, a bottom-hole assembly, and a packer. During operation, power fluid is circulated down the tubing string where it operates the subsurface hydraulic pump and mixes with the produced liquids and gas. This mixture of spent power

fluid and produced fluids is then returned to the surface via the casing annulus.

Figure 6.4.50 shows a casing-free design for an open power fluid system. In this design all of the produced gas must pass through the pump. This effects the liquid displacement efficiency of a piston pump in direct relation to the amount of gas being produced. Jet pump performance can actually improve due to the presence of gas. Because of the simplicity and cost benefits of the casing-free open power fluid system, there are more hydraulic pumps installed of this design than any other type installation.

Figure 6.4.51 shows some variations of the casing-free design.

The casing free OPF with gas vent can be used where displacement efficiency is severely affected by a high GOR. In this design, an auxiliary parallel string is run into a dual

FIGURE 6.4.48 Installation/removal of free style pump.

packer below the pump in order to vent gas to the surface. The production plus spent power fluid, returns by the casing annulus.

Another variation in installation design is shown in Figure 6.4.52. This shows a safety valve installed below the hydraulic pump. The safety valve is kept open by power fluid pressure. If a disaster strikes at the surface, power fluid pressure will be released and the spring-loaded safety valve will shut in the well at the packer.

6.4.3.2.3 Parallel Free Installations

The parallel free design for an open power fluid system incorporates two strings of tubing and a bottom-hole assembly, but no packer (Figure 6.4.53). The bottomhole assembly is attached to the main string and has a landing bowl which receives the spear that is on the bottom of the parallel string.

During production operations, the pressurized power fluid is pumped down the main tubing string where it operates the pump. It then mixes with the produced fluid and this mixture returns up the parallel string to the surface. This subsurface design permits gas to be vented up the casing annulus.

The drawback to this design is the extra tubing string required. Usually the parallel string is smaller and must

carry both the production and spent power fluid. This situation can create higher return friction losses and result in a need for more horsepower. The maximum size of both strings is dictated by the casing diameter. This also restricts the size of the pump, which can be run and the volume of fluid, which can be lifted.

Figure 6.4.54 shows two designs used with closed power fluid installations. Three parallel tubing strings are required in both of these designs: a power fluid string, a power fluid return string and a production string.

In parallel-free type installations, the main string should always be anchored to minimize tubing stretch as an unanchored string could actually unseat the parallel string(s) and disable it (them) from functioning as a return conduit(s).

6.4.3.2.4 Fixed-Pump Systems

Fixed-pump installations are like sucker rod tubing-pump installations, electric submersible pump installations, or conventional gas lift installations in that the bottomhole pump is attached to and run to bottom on the tubing string. These are considered to be “permanent-type” installations because a pulling unit is required to change out the pump.

There may be several reasons for selecting a fixed-pump but the main reasons would be to lift large volumes. Since the physical size of these pumps is not limited by tubing

FIGURE 6.4.49 Fixed insert open power fluid installations.

FIGURE 6.4.50 Casing free, open power fluid installation.

inside diameter, larger pumps can be used which are able to produce larger volumes than those produced by a free style pump.

6.4.3.2.5 Fixed-Insert Installations

In a fixed-insert installation (or fixed-concentric installation) a large tubing string is run to bottom. The pump is then run on a string of macaroni tubing inside the main tubing string and seated in a seating shoe (Figure 6.4.49). In this design, the macaroni string carries the pressurized power fluid to the pump. The exhausted power fluid plus the produced fluids are carried up the tubing-tubing annulus. This allows gas to be vented up the casing annulus to the surface.

A variation of the fixed-insert design would involve a packer set below the pump and bottomhole assembly. This will cause all of the produced gas to go through the hydraulic pump but isolates the perforated zone below the pump from the rest of the well. This design would be advantageous when bad casing up the hole is a problem, or when another zone above the packer is being produced.

6.4.3.2.6 Fixed-Casing Installations

In fixed-casing installations, the pump is run on the tubing string with a packer below the pump (Figure 6.4.55). The tubing string carries the pressurized power fluid down to the pump. The spent power fluid and the production are returned through the casing annulus.

FIGURE 6.4.51 Variations of casing free installations.

This type of installation is generally used where high production rates require that large pumps are run but any produced gas must pass through the hydraulic pump.

6.4.3.2.7 Bottomhole Assemblies

Bottomhole assemblies (BHAs) are housings where hydraulic pumps are located while they are operating. They have an internal seal sleeve that matches with a seal on the outside diameter of the pump when the pump is landed.

The casing-type BHA and the parallel BHA both provide the same sealing/operating functions, however, only a single tubing string is run with a packer for the casing type. In a stab-in parallel installation, the main tubing string is run by itself. The macaroni string is run separately and stabbed

into the shoe assembly. The screw-in type requires more time to install and the use of parallel tubing string clamps.

Figure 6.4.56 shows some BHAs for single displacement casing free pumps.

6.4.3.2.8 Retrievable Tubing Standing Valve

A retrievable tubing standing valve is also required when using a free-type pump (Figure 6.4.57). This standing valve lands in the lower end of the bottomhole assembly and the pump sits on top of it during operation. The purpose of the standing valve is to prevent the power fluid from traveling out the bottom of the tubing string when installing or retrieving the subsurface pump.

It is designed to be retired with a wireline tool for servicing if necessary.

FIGURE 6.4.52 Casing free installation with subsurface safety valve.

FIGURE 6.4.53 Parallel free, open power fluid installation.

6.4.3.2.9 Cleaning the System

In a free-type installation, the system can be cleaned by circulating fluid after installing the tubing standing valve and before installing the pump.

In a fixed type installation, however, this is not possible so a circulating valve, starting filter assembly and check valve are normally used. The circulating valve, when run, is placed in the circulating position. This permits fluid to be circulated down the tubing string, but it is prevented from going to the pump. When the circulating time is finished, a ball is dropped down the tubing string and lands in the circulating valve. Pressure causes a sleeve in the valve to shift which shuts off the circulation ports and permits the power fluid to flow through a starting filter and on to the hydraulic pump.

6.4.3.3 Power Water Versus Power Oil

Arguments can be made for and against the use of either water or oil as a power fluid.

6.4.3.3.1 Power Oil

Power oil has a natural lubricity that water does not. This is especially important when operating piston pumps due to their close tolerance clearances. Also, oil has some compressibility as opposed to water. This means that neither the surface piston pump nor the subsurface pump is exposed to as much "fluid hammer" with oil as with water, and the service life of the equipment is usually longer on oil.

FIGURE 6.4.54 Parallel free, closed power fluid installation.

FIGURE 6.4.55 Fixed casing, open power fluid installations.

Significant drawbacks to power oil are the potential fire hazard, which is not present with the use of power water, and pollution damage in the event of a line break.

Another issue is in the potential revenue the operator has tied up in his power oil system, particularly in a central surface system with a power oil tank. For example, if the system has a 750-barrel power oil tank, this represents 750 barrels of marketable oil the operator cannot sell.

6.4.3.3.2 Power Water

During recent years an increased number of hydraulic systems have changed from using power oil to using power

water. Many of them were changed to power water because of ecological reasons, code restrictions, town site locations, or increased watercuts or because the produced crude oil had a high viscosity.

A high-viscosity power fluid can mean excessive friction losses in the system. This in turn increases the operating pressure and, consequently the horsepower requirements for lifting the well. Therefore, in some instances it would be prohibitive to use the produced crude as a power fluid.

Water, because of its low viscosity, can be used in these instances. There are hydraulic installations where produced water is heated and used as a power fluid (and as a diluent or thinner) for the 8° gravity, crude being pumped.

FIGURE 6.4.56 Free style bottomhole assemblies.

Water, having low lubrication qualities, sometimes requires a chemical additive for lubrication when using hydraulic piston pumps. Frequently, the chemicals used will include oxygen inhibitors and agents to combat corrosion. These are easily added at the multiplex suction via a chemical pump. Improvements in lubricants, surface, and subsurface equipment, designed in recent years, has greatly enhanced the use of power water.

Aside from the usual chemical treatment for corrosion and scale depositions, salt crystals will occasionally be a problem in power water. This problem can usually be solved by having a fresh water blanket on the bottom of the power fluid tank, or by injecting fresh water into the power fluid.

FIGURE 6.4.57 Retrievable tubing standing valve and accessories.

Surface multiplex pump modifications for converting from oil service to water service are limited mainly to the fluid end of the pump and its plungers/lines. For example, a power oil fluid end can be made of ductile iron or forged steel but a fluid end for power water will be of aluminum/bronze to resist the corrosion effects of water. It is now common to use the aluminum/bronze fluid end for both power oil and power water. Metal-to-metal pistons and liners can be used for power oil service, but metal pistons against soft packing are needed for water service. As with the fluid end metallurgy, it is now common to use the soft packing for both water and oil service.

6.4.3.4 Inflow Performance for Artificial Lift

6.4.3.4.1 Inflow Performance

The relationship between production rate and producing bottomhole pressure is called *inflow performance*, which is the ability of a well to give up fluids.

In any artificial lift method, including hydraulic and jet pumping, the pumping system must be designed to provide the extra energy necessary to lift the production to the surface at the desired (or achievable) rate. Thus, the producing bottomhole pressure for an established production rate is one of the primary pieces of input data required in the design of the installation.

Knowing how much fluid can be produced at one particular bottomhole pressure, however, does not tell the whole story. It also needs to be known in order to have a complete IPR is:

- How much was the bottomhole pressure lowered to achieve the current production rate (draw down)
- How much more (or less) will it need to be lowered in order to produce at a different rate

For a given well, at a given time, there is only one producing bottomhole pressure associated with a specified production rate. To predict accurately the performance of any pump in a well, it is necessary to know the producing bottomhole pressure at the desired production rate as determined by the well's inflow performance. The two most commonly used methods for this making this prediction are Productivity Index (PI) and Inflow Performance Relationship curve. Several different methods are used to estimate the flowing bottomhole pressure for a given production rate including the straight line method (PI), J.V. Vogel's method [17] and others [18].

6.4.3.4.2 Productivity Index

PI is defined as the production rate in barrels per day (bbl/d), which can be achieved for each psi that the bottomhole pressure is reduced. It has long been used for estimating well production capacity.

H.H. Evinger and M. Muskat first introduced the concept of the PI relationship, shown in the following equation, in 1942 [19]. However, as was suggested by Evinger and Muskat, the producing rate does not always change with producing bottom-hole pressure along a straight line as the PI equation suggests.

The equation that is typically used for PI is:

$$\text{PI} = \frac{\left[\frac{\text{Change in Oil Production}}{\text{Change in pressure}} \right] + \left[\frac{\text{Change in Water Production}}{\text{Change in pressure}} \right]}{\text{Change in Total Production Rate (bbl/d)}} \quad (6.4.11)$$

$$= \frac{\text{Change in Total Production Rate (bbl/d)}}{(\text{SBHP} - \text{PBHP})(\text{psi})}$$

$$= \frac{\text{Production Rate}}{\text{Drawn Down}} = \text{bbl/d/psi}$$

Provided the data is available, an improved equation derived from Darcy's radial flow equation [18] is:

$$\text{PI} = \text{HK}_A \left(\frac{\text{K}_{\text{RO}}}{\mu_o \text{B}_o} + \frac{\text{K}_{\text{RW}}}{\mu_w \text{B}_w} \right) \quad (6.4.11a)$$

where K_A = absolute permeability of the rock in darcies

K_{RO} = relative permeability to oil

K_{RW} = relative permeability to water

B = formation volume factor

μ = viscosity

H = reservoir thickness

The above values are normally obtained through measuring shut-in bottomhole pressure and a flowing bottomhole pressure with its associated flow rate (provided the flowing data is not close to the static case). As can be seen, both oil and water phases are represented in the above equation. A more accurate estimation of PI is possibly by using data for the individual phases as opposed to considering the flow as a single phase.

A given PI is valid only for the conditions for which its measurements were made, i.e. percentages of water and oil. As those values change, the accuracy of the PI value is reduced and a new value should be calculated or new measurement made.

6.4.3.4.3 Inflow Performance Relationships

In 1968, J. V. Vogel [17] offered a solution to the problem of determining an inflow performance curve for a solution gas drive well where the producing bottomhole pressure is below the bubble point pressure.

Vogel's work resulted in the construction of a reference curve which could be used as a general solution for predicting production rates and bottomhole pressures. This curve is known as the "General IPR Curve by Vogel," [Figure 6.4.58](#).

$$\frac{Q_{\text{actual}}}{Q_{\text{max}}} = 1 - 0.2 \left(\frac{P_w}{P_b} \right) - 0.8 \left(\frac{P_w}{P_b} \right)^2 \quad (6.4.12)$$

where Q_{actual} = flow rate (bpd)

Q_{max} = flow rate at maximum draw down (bpd)

PBHP = flowing bottomhole pressure (psi)

SBHP = static bottomhole pressure (psi)

This is a general or "unity" reference curve, which is easy to use for predicting producing rates and pressures below bubble point pressure. It can be used when data from only one production test are available provided it is not close to the static case.

FIGURE 6.4.58 General IPR curve by Vogel.

Standing [20] proposed the following equation for estimating the bubble point pressure of the oil:

$$P_b = 18 \left(\frac{GOR_s}{SPGR_{gas}} \right) \left[\frac{10^{0.00091 \text{ BHT}}}{10^{0.0125 \text{ API}}} \right]^{0.83} \quad (6.4.13)$$

where GOR_s = Dissolved gas–oil ratio

$SPGR_{gas}$ = Specific gravity of gas

BHT = Bottom hole temperature in °F

API = API degree of oil

Following is a sample IPR calculation for a well (Figure 6.4.58).

Given: SBHP = 1878
 PBHP = 1543
 Production Rate (Q) = 154 Barrels/d
 Desired Production Rate = 414 Barrels/d

Find: PIP at 414 Barrels/d

- 1) Determine PBHP/SBHP $1543/1878 = 0.82$
- 2) From Figure 2-1, find $Q/Q_{max} = 0.30$
- 3) Calculate $Q_{max} = 154/0.30$
- 4) Find $Q/Q_{max} = 414/513 = 0.80$
- 5) From Figure 2-1 obtain PBHP/SBHP = 0.38
- 6) Calculate PBHP at desired production rate = $0.38 \times 1878 = 713$
- 7) 713 PSI is pump intake pressure at 414 Barrels/d

In 1970, M. B. Standing [21] proposed a companion chart to go along with Vogel's which accounted for damaged or improved wells. To determine and predict rates and pressures in damaged or improved (reworked) wells, more than one set of test data is required.

6.4.3.5 Jet Pumps

A Jet Pump is a venturi-type device where high-pressure fluid is caused to accelerate to a high velocity and thereby create a low-pressure area into which reservoir fluids will flow. The jet pump has no moving parts. A typical downhole jet pump is shown in Figure 6.4.59. A closer look at the effective mechanism is shown in Figure 6.4.60. These pumps require a high-pressure fluid pump on the surface, and this fluid is circulated down the well, typically the tubing. However there are reverse flows available and are used in most offshore applications. The flows through the jet causing a low-pressure area, and the power fluid produced fluid mixture are brought to the surface by a second conduit, usually the casing annulus. Once installed, the jet pump can be repaired or replaced by simply reversing the circulation and circulating the pump up the tubing to the surface. The repairs can be made a well site then the pumps can pump back into position in the bottom hole assembly.

FIGURE 6.4.59 Sketch of a hydraulic jet pump installation.

Jet pumps can produce high volumes and handle free gas very well. However, jet pumps are not as efficient as positive displacement pumps. Which means jet pumps require higher surface horsepower. A thorough coverage of the application of jet pumps is given by, Petrie et al [22].

This type of pump is very useful in certain situations, for example, where high production rates are desired or needed, and, locations where other forms of lift cannot be used, such as populated areas, offshore platforms or remote locations. Deviated wells or wells that produce sand or where gas lift is not an option.

Since fluid density, gas and viscosity effects are variables needed in the calculations to simulate a jet pump performance the calculations are complex and require iterative solutions. Here, the computer enters the picture. Weatherford Artificial Lift Systems has the latest in software design and can furnish characteristic plots of the form show in Figure 6.4.61. This plot is for a particular pump size and well since the PI of that well is needed as well as tubing length and diameter, fluid type, and fluid properties. However, once this plot has been generated, and engineer can predict the power fluid and surface pressure requirements for a desired production rate. Because the pump size is known, the intake pressure generated is predicted as well. Because PI must be known to design any lifting mechanism, the well's performance will follow the PI line overlaid on the graph. Note that the cavitation zone is also shown, which the pump can operate but throat becomes a choke or damage occurs to the throat portion of the pump.

6.4.3.5.1 Jet Pump Performance Equations

The following calculations, performed in order, will provide the information necessary to analyze the performance of a jet pump for any well application. (The user may wish to use more sophisticated calculation techniques in place of some of the equations listed below.)

1. Specify jet pump configuration.
Determine nozzle area (A_N) and area ratio (R)
2. Specify production rate and associated pump intake pressure.

$$Q_{PROD} \text{ and } P_{IP}$$

3. Initialize down-hole power fluid pressure.

$$P_{PWR} = 5000 + GRAD_{PWR} \times DEPTH \quad (6.4.14)$$

FIGURE 6.4.60 Working principle of a hydraulic jet pump.

$$CZ = 0.0694 - 17.6 BZ \quad (6.4.29)$$

$$DZ = \frac{0.022 \times \text{PIP}}{14.65} - 3.5 \quad (6.4.30)$$

$$EZ = 214 \times BZ \quad (6.4.31)$$

$$Z = CZ \times (DZ)^2 + EZ + 0.15 \quad (6.4.32)$$

13. Compute gas formation volume factor (B_g)

$$B_g = \frac{0.0283 \times Z \times (\text{BHT} + 460)}{\text{PIP}} \quad (6.4.33)$$

14. Compute two-phase formation volume factor (B_T)

For $\text{GOR}_S \geq \text{GOR}$:

$$B_T = B_O \quad (6.4.34)$$

For $\text{GOR}_S < \text{GOR}$:

$$B_T = B_O + \frac{B_g \times (\text{GOR} - \text{GOR}_S)}{5.6146} \quad (6.4.35)$$

15. Compute Volumetric Efficiency (EFF_V) using percentage of water in production (WC)

$$\text{EFF}_V = \frac{1}{\text{WC} + (1 - \text{WC}) \times B_T} \quad (6.4.36)$$

16. Compute nozzle constant (K_Q).

$$K_Q = 1264 \times A_N \sqrt{\frac{0.433}{\text{GRAD}_{\text{PWR}}}} \quad (6.4.37)$$

17. Compute power fluid volume (Q_{PWR}).

$$Q_{\text{PWR}} = K_Q \sqrt{P_{\text{PWR}} - \text{PIP}} \quad (6.4.38)$$

18. Compute momentum ratio (M)

$$M = \frac{\text{GRAD}_{\text{PROD}} \times Q_{\text{PROD}}}{\text{GRAD}_{\text{PWR}} \times Q_{\text{PWR}} \times \text{EFF}_V} \quad (6.4.39)$$

19. Check for solution convergence.

If change in M is less than 0.001, go to step 30.

20. Compute return fluid volume (Q_{RTN}).

$$Q_{\text{RTN}} = Q_{\text{PROD}} + Q_{\text{PWR}} \quad (6.4.40)$$

21. Compute return fluid gradient (GRAD_{RTN}).

$$\text{GRAD}_{\text{RTN}} = \frac{\text{GRAD}_{\text{PWR}} \times Q_{\text{PWR}} + \text{GRAD}_{\text{PROD}} \times Q_{\text{PROD}}}{Q_{\text{RTN}}} \quad (6.4.41)$$

22. Compute water fraction of return (WC_{RTN}).

For power oil:

$$\text{WC}_{\text{RTN}} = \frac{\text{WC} \times Q_{\text{PROD}}}{Q_{\text{RTN}}} \quad (6.4.42)$$

For power water:

$$\text{WC}_{\text{RTN}} = \frac{Q_{\text{PWR}} + \text{WC} \times Q_{\text{PROD}}}{Q_{\text{RTN}}} \quad (6.4.43)$$

23. Compute return fluid viscosity (μ_{RTN}).

$$\mu_{\text{RTN}} = \mu_{\text{WTR}} \times \text{WC}_{\text{RTN}} + \mu_{\text{OIL}} (1 - \text{WC}_{\text{RTN}}) \quad (6.4.44)$$

24. Compute pressure loss due to friction (PL_{FN})

Turbulent Flow Only

Reynold's Number (Re) and Pressure Loss due to friction (PL):

$$\text{Re} = \frac{213 \times Q \times G(D_1 - D_2)}{\mu(D_1^2 - D_2^2)^2} \quad (6.4.45)$$

$$\text{PL} = \frac{2.644 \times 10^{-5} \times Q^2 \times L \times G \times f}{(D_1 - D_2)(D_1^2 - D_2^2)^2 \left(\frac{D_1}{D_1 - D_2}\right)^{0.1}} \quad (6.4.46)$$

Where:

$$f = \text{friction factor} = \frac{0.236}{\text{Re}^{0.21}}$$

G = Gradient (psi/ft.)

L = Length (feet)

Q = FlowRate (BBL/d)

μ = Viscosity (c.p.)

D_1 = Casing I.D. (Annular Flow)

D_1 = Tubing I.D. (Tubing Flow)

D_2 = Tubing O.D. (Annular Flow)

$D_2 = 0$ (Tubing Flow)

$$\text{PL} = \frac{202 \times 10^{-8} \times L}{(D_1 - D_2)(D_1^2 - D_2^2) \left(\frac{D_1}{D_1 - D_2}\right)^{0.1}} \left[\frac{D_1^2 - D_2^2}{D_1 - D_2}\right]^{0.21} \times \left[\frac{\mu}{G}\right]^{0.21} G \times Q^{1.79} \quad (6.4.47)$$

25. Compute pressure loss in return fluid (PL_{RTN})

A flowing gradient correlation is preferred for this calculation if the $\text{GLR} > 10$.

However, if one is not available or $\text{GLR} = 10$, then see pressure loss equation under step 24.

26. Compute pump discharge pressure (P_{DIS}).

$$P_{\text{DIS}} = P_{\text{WELLHEAD}} + \text{GRAD}_{\text{RTN}} \times \text{DEPTH} + \text{PL}_{\text{RTN}} \quad (6.4.48)$$

If a flowing gradient is used, then replace right side of equation with results from correlation.

27. Compute pressure ratio (N).

$$N = \frac{2R + (1 - 2R) \frac{M^2 R^2}{(1 - R)^2} - (1 + k_{34}) R^2 (1 + M)^2}{1 + k_1 - \text{numerator}} \quad (6.4.49)$$

Where:

$$k_1 = 0.03$$

$$k_{34} = 0.2$$

28. Compute down-hole power fluid pressure (P_{PWR}).

$$P_{PWR} = \frac{P_{DIS} - PIP}{N} + P_{DIS} \quad (6.4.50)$$

29. Go to step 17.

30. Compute cavitation limit (M_{LIM}).

$$M_{LIM} = \frac{1 - R}{R} \sqrt{\frac{PIP - 1}{1.3(P_{PWR} - PIP)}} \quad (6.4.51)$$

31. Check for cavitation.

- a. If $M > M_{LIM}$, pump is cavitating, stop.
- b. If $M < M_{LIM}$, go to step 30.

32. Compute pressure loss down tubing (PL_{FN}).
See pressure loss equations in step 24.

33. Compute multiplex pressure (P_{TPLX})

$$P_{TPLX} = P_{PWR} - GRAD_{PWR} \times DEPTH + PL_{FN} \quad (6.4.52)$$

34. Compute hydraulic horsepower (HHP).

$$HHP = 0.000017 \times P_{TPLX} \times Q_{PWR} \quad (6.4.53)$$

As one can see, the process to size a jet pump properly becomes is complex, but the computer programs that are now available have made performing these calculations much faster and easier. Weatherford Artificial Lift Systems, which now has the Oilmaster, Guiberson, and Kobe product lines can furnish this software and service.

6.4.4 Hydraulic Piston Pumps

6.4.4.1 General

The subsurface production pump is the heart of a hydraulic pumping system. This pump is driven by a reciprocating hydraulic engine piston, which is connected to the production pump piston (Figure 6.4.62). While the stroke length of the pump is fixed, various pump bore sizes are available for different volume and depth requirements. A wide operating speed range adds further flexibility to meet production rate requirements.

The basic components of all hydraulic pumps include an engine piston and cylinder, an engine reversing valve (which controls piston motion by directing the power fluid

Model 220 Pump

FIGURE 6.4.62 Model 220 pump.

to the appropriate areas), and the pump piston and barrel. Conventional valves (usually balls and seats) control the production fluid intake and discharge. The arrangement of these components in the pump is based on the specific designs of the individual pumps.

The two most common pump end designs are:

- The “single-acting” production pump end, which displaces produced fluid only during the upstroke or only during the downstroke, and
- The “double-acting” production pump end, which displaces produced fluid on both the upstroke and downstroke.

The engine end may be designed to displace equal volumes of power fluid on each up and down stroke (i.e., a double displacement pump), or to displace a greater power fluid volume during one or the other of the two strokes (i.e., a single displacement pump).

Generally, the power fluid used to drive these pumps is clean crude oil or clean water drawn from the top of a settling tank or from a well site unit such as the Unidraulic®. In most installations, the spent power fluid is mixed with the produced well fluids at the pump and both come to the surface together.

The power required to return the spent power fluid to the surface is essentially what is required to overcome mechanical and fluid friction, and the difference in piston areas as seen by the power fluid and return fluid. The reason is that the static pressure head of the incoming power fluid at the pump tends to balance the static pressure head of the returning power fluid column.

As stated above, hydraulic subsurface piston pumps are composed of two basic sections — a hydraulic engine and a piston pump. They are directly connected with a middle rod. Therefore, as the engine piston moves upward, the pump piston also moves upward causing the barrel chamber under the pump piston to fill with production fluid. When the hydraulic engine makes a down stroke, the pump piston also makes a down stroke displacing the production fluid in the pump barrel.

The arrangement of the pump end is the same as with a sucker rod pump in that there is a barrel, a piston, a piston traveling valve and a standing valve. However, since there is no mechanical linkage to the surface because the sucker rod string is replaced by a column of high pressure power fluid, many of the limitations imposed by sucker rod pumping are eliminated. These include:

- rod stretch
- the difficulty in adjusting the stroke length of the pump in order to eliminate or at least gas locking problems
- load limitations imposed by depth
- excessive rod/tubing friction and wear caused by crooked holes and deviated wells

6.4.4.2 Single Displacement Pump

The pump in [Figure 6.4.57](#) is a single displacement pump, and its operation is as follows. Additional pump models are available that utilize different designs but the concept holds true for all of them.

The hydraulic engine end of the Oilmaster 220® series is basically composed of an engine barrel, an engine piston, and a reversing valve mechanism. The reversing valve and pilot valve assembly are mounted in stationary positions above the engine piston. The bottom of the engine piston is exposed to the power fluid on both the up and down

strokes. During the down stroke, the reversing valve is in the down position and the pilot valve is in the up position. A dashpot on the bottom of the pump piston halts the downward motion of the downstroke of the engine/pump piston traveling assembly. During the downstroke, the reversing valve is held in place by the flow of the power fluid around it. At the end of the downstroke, the fluid flow is halted and the pressure forces on the reversing valve cause it to shift to the up position. At this time, the pilot valve is hydraulically shifted to the down position and opens a pathway, which exposes the top of the reversing valve to discharge pressure. With the reversing valve in the up position, a pathway is opened which exposes the top of the engine piston to discharge pressure. The resulting pressure imbalance creates a net force up on the engine piston. At the end of the upstroke, the pilot valve is pushed up, which reopens the pathway for the top of the reversing valve to be exposed power fluid again. This moves the reversing valve down, which then allows the top of the engine piston to be exposed to power fluid. Because there is no middle rod on top of the engine piston, more area on top is exposed to the power fluid than on the bottom and this results in a net force downward.

As stated above, the arrangement of the pump end is the same as with a sucker rod pump in that there is a barrel, a piston, a piston traveling valve, and a standing valve. As was also noted above, the sucker rod string is replaced with a column of high-pressure power fluid, which supplies the energy needed to move the engine piston. As the engine piston moves upward, the pump piston also moves upward, causing the barrel chamber under the pump piston to fill with production fluid. When the engine piston moves downward, the pump piston also makes a down stroke, displacing the production fluid in the pump barrel from below the pump piston to above it.

6.4.4.3 Double Displacement Pump

The pump in [Figures 6.4.63](#) and [6.4.64](#) is a double displacement pump and its operation is as follows. As is the case with the single displacement pumps, additional pump models are available that utilize different designs but the concept holds true for all of them.

When the pump starts the upstroke, the reversing valve is positioned at the top of the valve body. Power fluid enters the pump through a port in the center of the valve body. The reversing valve directs the power fluid into the barrel above the reversing valve housing and under the upper piston. Because the pressure below the upper piston is greater than the pressure above it, the result is an upward movement of the piston.

The fluid above the upper piston, which is production that entered the upper barrel during the downstroke, enters the valve section of the pump between the inlet valve

FIGURE 6.4.63 PL-II double displacement pump, upstroke

and discharge valve. The inlet valve is closed and the discharge valve is opened, allowing the production to exit the pump and bottomhole assembly in route to the surface.

The lower piston is also moving up, causing the spent power fluid above that piston to enter the lower end of the valve body. This spent power fluid passes by the reversing valve as it leaves the pump and returns to the surface.

Below the lower piston, the pressure is reduced inside the lower barrel and between the lower valves by the upward movement. This reduced pressure opens the inlet valve, and the higher pressure on the return side closes the discharge valve. This allows production to enter the lower barrel so it can subsequently be discharged on the downstroke.

The middle rod of the pump moves through the center of the reversing valve. As the pump reaches the end of the

FIGURE 6.4.64 PL-II double displacement pump, downstroke.

upstroke, a reduced O.D. section of the middle rod enters the I.D. of the reversing valve. This undercut creates a path that allows the top of the reversing valve to be exposed to the power fluid. With a higher pressure above, the reversing valve is made to shift to the bottom of the reversing valve body. This shift causes the power fluid to be directed to the lower half of the pump and the downstroke begins.

On the downstroke, production in the lower barrel is discharged. Production also enters the pump below the lower production inlet valve and is directed to the upper valve section through side tubes in the bottomhole assembly. This fluid then enters the upper barrel, above the piston, to be subsequently discharged on the next upstroke.

The upper piston is also moving down, causing the spent power fluid below it to enter the upper end of the valve body.

This spent power fluid passes by the reversing valve as it leaves the pump and returns to the surface.

Another upstroke begins as the pump reaches the end of the downstroke. Again, a reduced O.D. section of the middle rod enters the I.D. of the reversing valve. This undercut creates a path that allows the bottom of the reversing valve to be exposed to the power fluid. With a higher pressure below, the reversing valve is made to shift to the top of the reversing valve body. This shift causes the power fluid to be directed to the upper half of the pump and the upstroke begins.

Because the power fluid is cleaned and chemically treated at the surface, it provides good chemical protection to virtually all of the pump.

6.4.4.4 Piston Velocity

A common cause of failure among all piston pumps is excessive piston velocity on the displacement stroke. This usually occurs when a pumped-off or fluid pound situation occurs.

The pump in Figure 6.4.62 uses the velocity of the power fluid going around the reversing valve to control the downstroke velocity. When this velocity is excessive, the reversing valve moves to reduce the flow-by area and this action reduces the downward speed (velocity) of the engine piston. The downward speed of pump piston matches the downward speed of the engine piston.

The pump in Figures 6.4.63 and 6.4.64 controls piston velocity through a series of sensing holes in the reversing valve. These holes sense whenever the flow of power fluid through the reversing valve/reversing valve body is excessive and directs the reversing valve to restrict the flow.

6.4.4.5 Fluid Separation

Obviously, there must be some means of keeping high-pressure power fluid and low-pressure return fluid separated both inside and outside of the pump.

Internally, a close-fitting metal-to-metal seal around the middle rod accomplishes separation. This seal prevents the power fluid inside the pump from bypassing the pump engine and mixing with the produced fluids. A leak or loss of this seal results in reduced pump speed and engine efficiency.

Externally, separation is accomplished by elastomeric seals on the outside diameter of the pump and one or more seal collars, which are part of the bottomhole assembly. This seal prevents the power fluid outside of the pump from bypassing the pump engine and mixing with the produced fluids. A leak or loss of this seal also results in reduced pump speed and engine efficiency.

6.4.4.6 Piston Size

The engine piston diameter for a given size of hydraulic pump will always be the same. The pump piston, however, can be reduced by several sizes from the size of the engine piston. For example, a 2½-in. hydraulic pump (the maximum size which can be used in 2½-in. tubing) will always have a 2-in. diameter hydraulic engine piston. The pump piston, however, can have a diameter of 2, 1¾, 1⅝, 1½, 1¼, or 1⅓ in. The displacement rate chart (Table 6.4.10) shows the maximum pump end displacement rates for different pump piston sizes of the single displacement Powerlift® I pumps. The displacement rate chart (Table 6.4.11) shows the maximum pump end displacement rates for different pump piston sizes of the double displacement Powerlift® II pumps.

Varying the piston size primarily permits two things:

- Sizing the pump end to the actual well requirements
- Sizing the pump to have the lowest operating pressure possible.

(The smaller the pump piston size in relation to the size of the engine piston, the lower the pressure required to operate the hydraulic unit.)

6.4.4.7 Selecting A Pump

6.4.4.7.1 Pump/Engine Ratio

The pump/engine ratio (P/E) is an important factor to consider in selecting a pump because of its relationship to the surface pump that is providing the high-pressure power fluid. The P/E is determined by dividing the engine piston area (A_E) less the middle rod area (A_{MR}) into the pump piston area (A_P),

$$P/E = \frac{A_P}{A_E - A_{MR}} \quad (6.4.54)$$

A higher P/E requires a lower power fluid volume and higher multiplex pump pressure. A lower P/E requires a higher power fluid volume and lower multiplex pump pressure.

Ensure that pump selection calculations are done carefully. If the P/E is too low, the increase in power fluid volume will cause increased friction loss in the system, resulting in higher multiplex pump pressure.

6.4.4.7.2 Hydraulic Piston Pump Calculations

The following calculations, performed in order, will provide the information necessary to determine the proper piston pump for any well application. (The user may wish to use more sophisticated calculation techniques in place of some of the equations listed below.)

1. Compute oil-specific gravity (SPGR_{OIL})

$$\text{SPGR}_{\text{OIL}} = \frac{141.5}{131.5 + \text{API}} \quad (6.4.55)$$

2. Compute oil gradient (GRAD_{OIL})

$$\text{GRAD}_{\text{OIL}} = 0.433 \times \text{SPGR}_{\text{OIL}} \quad (6.4.56)$$

3. Compute solution GOR (GOR_s) using pump intake pressure, bottomhole temperature and °API of the oil

$$\text{GOR}_s = \text{SPGR}_{\text{GAS}} \left[\left(\frac{\text{PIP}}{18} \right) \left(\frac{10^{0.0125 \text{ API}}}{10^{0.00091 \text{ BHT}}} \right) \right]^{1.2048} \quad (6.4.57)$$

4. Compute value of F for use in computing oil formation volume factor (B_o)

For $\text{GOR}_s \leq \text{GOR}$:

$$F = \text{GOR}_s \left(\frac{\text{SPGR}_{\text{GAS}}}{\text{SPGR}_{\text{OIL}}} \right)^{0.5} + 1.25 \text{ BHT} \quad (6.4.58)$$

For $\text{GOR}_s > \text{GOR}$:

$$F = \text{GOR} \left(\frac{\text{SPGR}_{\text{GAS}}}{\text{SPGR}_{\text{OIL}}} \right)^{0.5} + 1.25 \text{ BHT} \quad (6.4.59)$$

5. Compute oil formation volume factor (B_o)

$$B_o = 0.972 + 0.000147 F^{1.175}$$

6. Compute gas compressibility factor (Z)

$$\text{BZ} = \frac{\text{BHT} + 460}{203,320} \quad (6.4.60)$$

$$\text{CZ} = 0.0694 - 17.6 \text{ BZ} \quad (6.4.61)$$

$$\text{DZ} = \frac{0.022 \times \text{PIP}}{14.65} - 3.5 \quad (6.4.62)$$

$$\text{EZ} = 214 \times \text{BZ} \quad (6.4.63)$$

$$Z = \text{CZ} \times (\text{DZ})^2 + \text{EZ} + 0.15 \quad (6.4.64)$$

7. Compute gas formation volume factor (B_g)

$$B_g = \frac{0.0283 \times Z \times (\text{BHT} + 460)}{\text{PIP}} \quad (6.4.65)$$

8. Compute two-phase formation volume factor (B_T)

For $\text{GOR}_s \geq \text{GOR}$:

$$B_T = B_o \quad (6.4.66)$$

For $\text{GOR}_s < \text{GOR}$:

$$B_T = B_O + \frac{B_g \times (GOR - GOR_s)}{5.6146} \quad (6.4.67)$$

9. Compute volumetric efficiency (EFF)

$$EFF_V = \frac{1}{CW + (1 - CW) \times B_T} \frac{STBF}{BBL} \quad (6.4.68)$$

10. Compute required pump end displacement (DISP)

$$DISP = \frac{Q_{PROD}}{(EFF_V) \times (EFF_{PUMP\ END})} \quad (6.4.69)$$

11. Select pump size

Pump end displacement (DISP) should be less than 75% of the pump displacement at maximum strokes per minute.

12. Calculate strokes per minute (SPM)

$$SPM = \frac{DISP}{(PUMP\ END\ DISP/STROKE/MINUTE)} \quad (6.4.70)$$

13. Calculate power fluid volume (Q_{PWR})

$$Q_{PWR} = \frac{SPM \times (ENGINE\ END\ DISP/STROKE/MINUTE)}{EFF_{ENGINE}} \quad (6.4.71)$$

14. Compute return fluid volume (Q_{RTN})

$$Q_{RTN} = Q_{POWER\ FLUID} + Q_{PRODUCTION} \quad (6.4.72)$$

15. Compute oil viscosity (μ_{OIL}) using average wellbore temperature

$$T = LN \left(\frac{BHT + WHT}{2} + 460 \right) \quad (6.4.73)$$

$$C = 3.55(6.328 - T) + 11.53 SPGR_{OIL} - 9.254 \quad (6.4.74)$$

$$E = e^C \quad (6.4.75)$$

$$\mu_{OIL} = (e^E - 0.6) SPGR_{OIL} \quad (6.4.76)$$

16. Compute water viscosity (μ_{WTR}) using average wellbore temperature

$$T_{AVG} = \frac{BHT + WHT}{2} \quad (6.4.77)$$

$$T = 1.003 - 0.01479 T_{AVG} + 0.00001928 T_{AVG}^2 \quad (6.4.78)$$

$$\mu_{WTR} = e^T \quad (6.4.79)$$

17. Compute pressure loss in power fluid (PL_{PWR})
Reynold's number

$$RN = \frac{213QG(D_1 - D_2)}{\mu(D_1^2 - D_2^2)} \quad (6.4.80)$$

Turbulent flow pressure loss

$$PL = \frac{2.644 \times 10^{-5} Q^2 LGf}{(D_1 - D_2)(D_1^2 - D_2^2)^2 \left(\frac{D_1}{D_1 - D_2} \right)^{0.1}} \quad (6.4.81)$$

where:

$$f = \text{friction factor} = \frac{0.236}{RN^{0.21}}$$

G = Gradient (psi/ft.)

L = Length (ft.)

Q = FlowRate (bbl/d)

μ = Viscosity (c.p.)

D₂ = Tubing O.D. (annular flow)

D₂ = 0 (tubing flow)

D₁ = Casing I.D. (annular flow)

D₁ = Tubing I.D. (tubing flow)

$$PL = \frac{202 \times 10^{-8} \times L}{(D_1 - D_2)(D_1^2 - D_2^2)^2 \left(\frac{D_1}{D_1 - D_2} \right)^{0.1}} \times \left[\frac{D_1^2 - D_2^2}{D_1 - D_2} \right]^{0.21} \left[\frac{\mu}{G} \right]^{0.21} G \times Q^{1.79} \quad (6.4.82)$$

18. Compute return water fraction (WC_{RTN})

$$\text{For power water :} \quad WC_{RTN} = \frac{PRODUCED\ WATER + Q_{PWR}}{Q_{RTN}} \quad (6.4.83)$$

$$\text{For power oil :} \quad WC_{RTN} = \frac{PRODUCED\ WATER}{Q_{RTN}} \quad (6.4.84)$$

19. Compute gradient of return fluid (GRAD_{RTN})

$$GRAD_{RTN} = WC_{RTN} \times GRAD_{WATER} + (1 - WC_{RTN}) GRAD_{OIL} \quad (6.4.85)$$

20. Determine viscosity of return fluid (μ_{RTN})

$$\text{For } WC_{RTN} > 0.6 : \mu_{RTN} = \mu_{WATER} \quad (6.4.86)$$

21. Compute pressure loss in return fluid (PL_{RTN})

A flowing gradient correlation is preferred for this calculation if the GLR > 10. However, if one is not available or GLR = 10, then see pressure loss equations under Step 17.

22. Compute pump discharge pressure (P_{DIS})

$$P_{DIS} = \text{PRESSURE}_{WELL\ HEAD} + \text{GRAD}_{RTN} \times \text{DEPTH} + \text{PL}_{RTN} \quad (6.4.87)$$

If a flowing gradient correlation is used, then replace right side of equation with results from correlation.

- 23a. Compute pressure loss in pump in Figure 6.4.20 and its BHA (PL_{PUMP})

$$\text{PL}_{PUMP} = 973 \left(\frac{\text{SPM}}{\text{SPM}_{MAX}} \right)^{1.355} \quad (6.4.88)$$

- 23b. Compute Pressure Loss in Pump in Figure 6.4.20 and its BHA (PL_{PUMP})

$$\begin{aligned} \text{PL}_{PUMP} = & 204.86 \left(\frac{\text{SPM}}{\text{SPM}_{MAX}} \right)^5 \\ & + 204.56 \left(\frac{\text{SPM}}{\text{SPM}_{MAX}} \right)^4 \\ & + 368.18 \left(\frac{\text{SPM}}{\text{SPM}_{MAX}} \right)^3 \\ & + 336.02 \left(\frac{\text{SPM}}{\text{SPM}_{MAX}} \right)^2 \\ & + 652.24 \left(\frac{\text{SPM}}{\text{SPM}_{MAX}} \right) + 0.344 \end{aligned} \quad (6.4.89)$$

24. Compute multiplex pressure (P_{TPLX})

$$\begin{aligned} P_{TPLX} = & P_{DIS} \times \left(\frac{P}{E} + 1 \right) - \text{PIP} \times \frac{P}{E} + \text{PL}_{POWER} \\ & + \text{PL}_{PUMP} - (\text{DEPTH} \times \text{GRAD}_{POWER}) \end{aligned} \quad (6.4.90)$$

25. Compute hydraulic horsepower (HHP)

$$\text{HHP} = 0.000017 \times P_{TPLX} \times Q_{POWER} \quad (6.4.91)$$

6.4.4.8 Surface Power Fluid Conditioning Systems

The purpose of a surface power fluid conditioning system is to provide a constant and adequate supply of suitable power fluid to operate the subsurface pumps. The success and economical operation of any hydraulic pumping fluid installation is, to a large extent, dependent on the effectiveness of the surface conditioning system in supplying clean power fluid for surface power and down-hole pump system.

The presence of gas, solids, or abrasive materials in the power fluid will seriously affect the operation and wear life of the subsurface pump as well as the surface power unit. Therefore, the primary objective in conditioning crude oil or water for use as power fluid is to make it as free of

gas and solids as is practical. In addition to removing gas and solid material, chemical treatment of the power fluid at the surface will also increase the wear life of the pumping equipment.

There are two types of power fluid conditioning systems for hydraulic pump installations: the central power fluid conditioning system and the well-site, self-contained power fluid conditioning system (Unidraulic®).

6.4.4.8.1 Central Power Fluid Conditioning System

A central power fluid conditioning facility (Figure 6.4.65) is one in which the power fluid for one or more wells is treated to remove gas and solids at a large centralized facility.

Figure 6.4.66 shows a typical power fluid treating system which has been proven through years of design experience. This power fluid treating system design assumes that the normal lease separators and heater treaters have delivered “stock tank” oil to the treating facility which is essentially free of gas.

The power fluid-settling tank in this system is usually a 24-ft.-high, three-ring, bolted steel tank. A tank of this height generally will provide an adequate head for gravity flow of fluid from the tank to the intake of the charge pump. The diameter of the power fluid tank is dictated by the amount of power fluid required.

The basic purpose of the power fluid settling tank is to allow separation of solids from the power fluid, which the lease separator has not removed in the continuous flow system. The clean fluid is supplied to the surface pump, where it is pressurized and then used to operate the down-hole pump.

In a tank of static fluid, all foreign material in the fluid, which is heavier than the fluid would fall or settle out to the bottom. Some of the particles, such as fine sand would fall more slowly than the heavier solids. These factors, plus viscosity-related resistance factors influence the rate of separation. In time, however, all solids and heavier liquids would settle out leaving a layer of clean fluid.

In an actual power fluid system it is not practical, nor is it necessary, to furnish tank space to allow settling under perfectly still conditions. Sufficient settling can be accomplished when the upward flow through the settling tank is maintained at a velocity just slower than the velocity at which the contaminating material will fall. It has been found through tests and experience that an upward velocity of 1 ft./hr is low enough to provide gravity separation of entrained particles in most crude oils.

6.4.4.8.2 Weatherford Unidraulic® Unit

The Weatherford Unidraulic® Fluid Conditioning Unit is a unitized surface equipment package for hydraulic pumping applications. The unit provides complete fluid conditioning

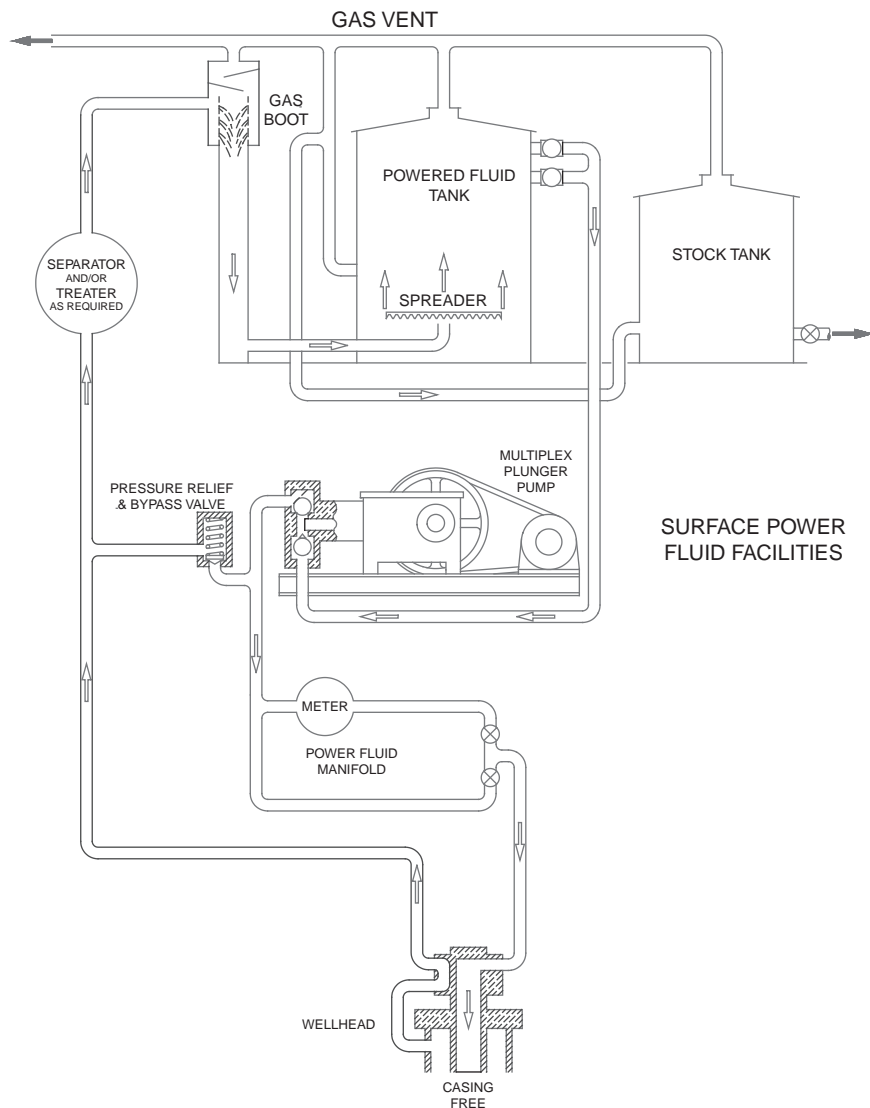

FIGURE 6.4.65 Central power fluid conditioning facility.

as well as a surface pump to provide pressurized power fluid to the downhole pump [Figure 6.4.67](#).

The Unidraulic[®] is designed for continuous operation and will perform satisfactorily when properly set, adjusted and maintained. Periodic inspections and repairs will be required. The end-user of the equipment must determine the intervals of inspections.

Vertical Accumulator

This is an ASME-coded vessel that is available in multiple sizes and working pressure ratings. Some of the sizes/ratings are 30 in. in diameter and 72 in. high with a 200 psi working pressure rating, 36 in. in diameter and 36 in. high with a 200 psi working pressure rating and 36 in. in diameter and 96 in. high with a 650 psi working pressure rating.

Produced fluid and spent power fluid flow from the wellhead to the accumulator. After entering the accumulator, the fluids pass over a series of baffles in order to separate the free gases from the liquids as well as to remove the majority of trapped gases. The gases plus liquids are then directed to the cyclone desander(s). This vessel also serves as a surge chamber to buffer high pressure kicks from the well so that those surge forces are kept from the cyclone desander(s) and the horizontal fluid conditioning vessel. This vessel also has a safety relief valve that is preset to open at the maximum working pressure.

Fluid Conditioning Vessel

This is also an ASME coded vessel that is available in multiple sizes and working pressure ratings. Some of the sizes/ratings are 42 in. in diameter and 141 in. long with

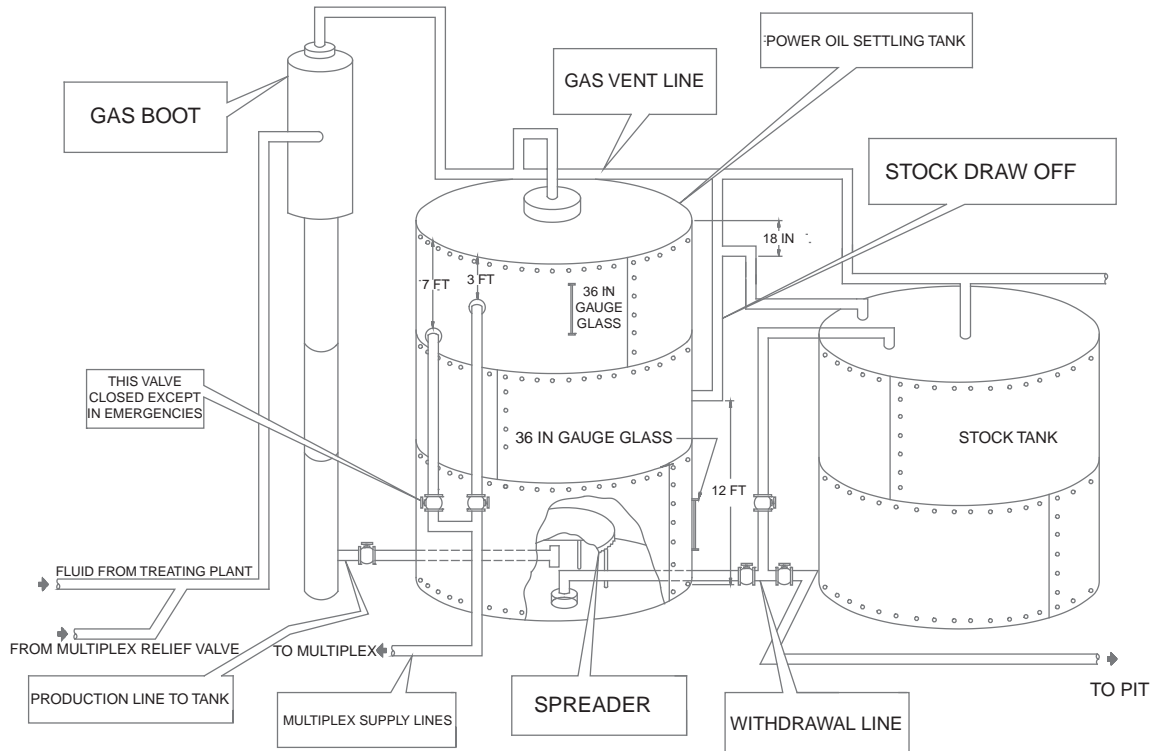

FIGURE 6.4.66 Typical power fluid treating system.

a 130 psi working pressure rating, 60 in. in diameter and 240 in. long with a 150 psi working pressure rating and 60 in. in diameter and 240 in. long with a 500 psi working pressure rating.

After the fluids leave the desander(s), they enter the vessel, where they pass over a series of baffles. There free gas is separated from the fluid flow and sent to the production line. The remaining fluid, which consists of oil and water, then passes over additional baffles that cause the two liquids to separate from each other. Another baffle is located such that any sediment in the vessel is prevented from entering the power fluid outlets and going to the triplex. By appropriately adjusting the outlets, either oil or water can be sent to the triplex for use as the power fluid, and the vessel made to fill with the desired power fluid (either oil or water). An auxiliary pump is available to charge the intake of the triplex pump if it is needed, but the pressure in the vessel, which is usually flowline pressure, is almost always sufficient to meet that requirement. If the flowline pressure is too low, then a back-pressure valve can be installed between the horizontal vessel and the flowline in order to increase the pressure in the horizontal vessel. This vessel also has a safety relief valve that is preset to open at the maximum working pressure.

By design, the retention time of the power fluid in the conditioning vessel is not sufficient for any appreciable

setting of solids particles from the fluids, so most solids separation must be done by the cyclone desander. This is what makes proper installation, sizing, monitoring, and operation of the cyclone desander so important to the entire system operation.

The purpose of the tanks is to supply the multiplex pump with sufficient fluid. If the liquid level in the horizontal vessel is allowed to drop to a point that the pump draws gas, the pump will cavitate and cause damage. Therefore, as protection for the pump, an oversupply of fluid must be directed to the vessel. The fluid not required by the multiplex pump is automatically discharged to the flow line.

This over supply of fluid is also important in maintaining a proper oil/water interface. If the supply is insufficient, the interface level will move up to the pump suction connection on the vessel. The interface often carries iron sulphite, which can cause pump damage.

6.4.4.8.3 Power Fluid Pump

Fluid from the conditioning vessel is supplied to the surface power fluid pump (normally a multiplex pump), which provides pressurized liquid to operate the subsurface hydraulic pump. An electric motor, diesel, or gas engine powers the power fluid pump.

FIGURE 6.4.67 A typical hydraulic jet pumping system.

6.4.4.8.4 Control Panel

The control panel is normally a standard oil-field type Murphy panel with indicators and limit controls for safety, start up, operation, and shut down.

6.4.4.8.5 Cyclone Desander

The cyclone desander is considered to be the very heart of the Unidraulic[®] Unit. Without excellent solids separation, the result will be unnecessarily short pump runs and excessive multiplex maintenance. It must be sized to affect maximum solid particle separation and furnish essentially clean fluid for the surface power fluid pump and the downhole hydraulic pump.

A cyclone desander, microstrainer, filter, centrifuge, or similar device is used to remove solids such as sand, silt, dirt, or drilling mud, from the produced fluid or from any fluid that is subsequently used to operate a hydraulic pump. The desander should function to provide a fluid clean enough to prevent excessive wear in the surface multiplex pump and the subsurface (downhole) hydraulic pump.

Surface pumps, subsurface piston pumps, and hydraulic engines used to drive the piston pumps are the components of an hydraulic pumping system most susceptible to wear because they contain close fitting metallic parts moving next to or rubbing against each other. Jet pumps are also subject to wear when operated with contaminated fluids.

Most subsurface piston pumps and hydraulic engines have a piston/cylinder radial clearance of 0.001 in. Other parts of the pumps have metal-to-metal seals which have clearances of less than 0.001 in. Solid contaminants in the fluid cause wear leading to excessive clearance of mating parts. This, in turn, leads to inefficient operation of the components and eventual replacement.

Table 6.4.12 may be used as a guide for estimating sizes of particulate matter which might enter the cyclone desander cleansing unit for the majority of oil wells which are candidates for hydraulic pumping.

6.4.4.8.6 Removal of Suspended Solids

The volume of suspended solids such as sand, drilling mud, and scale in one barrel of produced fluid may be 100 lb or more when a pump is first installed in a well. More typical is a well with particles in the 10- to 500-micron size range and a total content of suspended solids of 100 lb or less per 1000 barrels entering the cyclone desander inlet.

With reasonable operating efficiency, the cyclone desander should allow no more than 5% of the total suspended solids to pass on to the clean fluid reservoir. Of these solids, none should be larger than 25 microns (.001 diameter). No more than 20% of the total suspended solids entering the desander should be larger than 10 microns (.0004 diameter) and the remaining 80% should be 10 microns or less.

TABLE 6.4.12 Approximate Size Equivalents

Inches	Microns	Screen Mesh	Common Materials
.00004	1		Clay, Colloids
.0002	5		Bentonite, Talcum Powder, Fine Silt, Barites, Red Blood Corpuscles, Fine Cement Dust, Cocoa
.0004	10	1470	
.0018	44	325	Pollen, Milled Flour, Coarse Silt, Fine Human Hair
.002	53	270	
.003	74	200	
.004	105	140	API Sand, Coarse Human Hair, Table Salt
.006	149	100	
.012	297	50	Coarse Sand
.20	500	18	
.040	1000	18	
.125	3125		Foreign Matter

Ideally, the cyclone desander should function to prevent suspended solids not larger than one micron (.00004-in. diameter) from entering the clean fluid reservoir. Realistically, 10 microns is closer to the maximum size, which should be adopted as standard.

When fluid volume exceeds 2000 barrels per day, two cyclone desanders operating in parallel may be required.

6.4.4.8.7 Pressure Drop

Particle separation in a cyclone desander is related to the pressure drop from the inlet to the outlet of the cyclone desander.

Generally the greater the pressure drop across the cyclone desander (up to 50 psi) the cleaner the fluid. However, a pressure drop greater than 50 psi will carry the higher solids upward giving a solids concentration which is too high even if the particle size is in the acceptable size range.

The recommended pressure drop across the cyclone desander is 35 to 50 psi with the optimum being 40 to 45 psi. If the pressure drop across the cyclone desander gets below 35 psi, excessively large particles will be passed to the conditioning vessel. The volume of fluid passing through it and the cyclone desander's internal parts—the

vortex and feed nipple, primarily determines the pressure drop. In operation, it is easier to change the vortex and/or feed nipple of the cyclone desander to maintain the desired pressure drop rather than to change the volume of fluid passing through the cyclone desander.

6.4.5 Introduction Electrical Submersible Pumps

The electrical submersible pump (ESP) is considered the high volume and depth choice among lift systems. ESP systems require very little surface space and can be installed in highly deviated wells for both onshore and offshore applications. Adaptable to a variety of wellbore configurations, ESP systems can be used in wells with 4½-in. casing and larger, and are excellent candidates for vertical wells with doglegs (crooked holes). Typically, these systems do best in high volume wells where gas, solids, and excessive pressures are not present in great volumes. ESP systems are highly efficient beginning at 1000 BPD, although can be operated as low as 200 BPD, require very little maintenance and are resistant to corrosive downhole environments.

6.4.5.1 ESP Application Considerations

The ESP system have the ability to operate in a large range of applications up to 13,000' + TVD and flow rates up to 60,000 BPD. Typical operating ranges can be found in (Figure 6.4.68). ESPs are designed individually and specifically for each application. Careful attention must be paid each design choosing the proper equipment for any given well. Operating and ESP system outside of its defined range can result in less than desirable performance including possibly shorten the run-life of the system. Additional design information is presented in "ESP Product Design."

6.4.5.2 ESP Product Identification

ESP systems are divided into subsurface and surface components. Both are required for any installation. Beginning downhole, each component is defined below. A typical ESP installation schematic is found in (Figure 6.4.69).

6.4.5.2.1 Submersible Electric Motors

The ESP system's prime mover is the submersible motor. The motor is a two-pole, three-phase, squirrel-cage induction type. Motors run at a nominal speed of 3500 rpm in

Pump recommended operating range for Manufacturer A.

Model	Housing OD (inches)	BEP @ 60Hz (Bls/day)	Maximum HP (HP)	Recommended Operating Range @ 60 Hz (Bls/day)	
				Minimum	Maximum
400-365	4.00	365	94	200	500
400-450	4.00	450	94	200	650
400-675	4.00	675	94	400	1000
400-850	4.00	850	94	600	1300

FIGURE 6.4.68 ESP system design

FIGURE 6.4.69 Typical ESP installation.

60-Hz operation (2917 rpm in 50-Hz). Motors are filled with a highly refined mineral oil that provides dielectric strength, bearing lubrication, and thermal conductivity.

The standard motor thrust bearing is a fixed-pad type. Its purpose is to support the thrust load of the motor rotors. Other types are used in high-temperature applications (above 250°F). Heat generated by motor operation is transferred to the well fluid as it flows past the motor housing. A minimum fluid velocity of 1 ft./sec is recommended to provide adequate cooling. Because the motor relies on the flow of well fluid for cooling, a standard ESP should never

be set at or below perforations or producing zone unless the motor is shrouded.

Motors are manufactured in four different diameters (series) as 3.75, 4.56, 5.40, and 7.38 inches. Thus, motors can be used in casing sizes as small as 4.50 inches. 60 Hz horsepower capabilities range from a low of 7.5 HP in 3.75-inch series to a high of 1200 HP in the 7.38-inch series. Motor construction may be a single section or several “tandem” sections bolted together to reach a specific horsepower. Motors are selected on the basis of the maximum OD that can be run easily in a given casing size and specific horsepower required.

6.4.5.2.2 Seal Section

The seal section’s primary purpose is to isolate the motor oil from the well fluid while bottomhole pressure (BHP) and the motor’s internal pressure are balanced. There are two types of seal section design — the positive seal and the labyrinth path. The positive seal design relies on an elastic, fluid-barrier bag to allow for the thermal expansion of motor fluid in operation, while still isolating the well fluid from the motor oil. The labyrinth path design uses the specific gravity of the well fluid and motor oil to prevent the well fluid from entering the motor. This is accomplished by allowing the well fluid and motor oil to communicate through tube paths connecting segregated chambers.

The seal section performs four basic functions:

1. Connects the pump to the motor by connecting both the housing and drive shafts
2. Houses a thrust bearing to absorb pump shaft axial thrust
3. Isolates motor oil from well fluid while allowing wellbore-motor pressure equalization
4. Allows thermal expansion of motor oil resulting from operating heat rise and thermal contraction of the motor oil after shutdown

6.4.5.2.3 Pump Intake/Gas Separator

There are three types of pump intakes: the standard intake, the static gas separator, and the rotary gas separator.

The amount of free gas by volume at pump intake conditions should be no more than 10% to 15% by volume. The standard intake has several fairly large ports, allowing fluids to flow into the lower section of the pump and enter the bottom stage in the pump. Some models are equipped with a screen to keep large debris out of the pump.

The static gas separator is a reverse-flow intake. This type separator will, in most cases, separate up to 20% (by volume) free gas. The fluid moves up along the outside diameter of the gas separator and then must reverse its flow as it enters the perforated holes of the separator. The fluid changes direction and must go back down to the pickup impeller. A portion of the gas breaks out and travels up into

the annulus. The remaining fluid goes through the pickup impeller, changing directions and moves up into the lower portion of the pump, to first stage of the pump.

The rotary gas separator will separate free gas with an efficiency of up to 90% under some conditions. The rotary gas separator should be used where the free gas available at the intake exceeds 20% (VLR of 0.20), unless there is abrasive material in the fluid. Then the use of rotary separator must be carefully considered. Even though the rotary gas separator is very efficient, there can still be cases where the pump will gas lock. If the pump intake pressure gets so low that slug flow develops, then there will be moments of time when nothing but gas is present at the intake. Only during this interval will gas enter the pump.

6.4.5.2.4 Multistage Centrifugal Pump

The ESP pump is a multistage centrifugal pump type. A stage consists of an impeller and a diffuser. The impeller is keyed to the shaft and rotates at the rpm of the motor. Centrifugal force causes the fluid to move from the center (or eye) of the impeller outward. These forces impart kinetic or velocity energy to the fluid.

The diffuser is stationary, and its function is to direct the fluids to flow efficiently from one impeller to another and to convert a portion of the velocity (kinetic) energy into pressure (potential) energy.

The stages (an impeller–diffuser combination) are placed onto a keyed shaft and then loaded into a steel housing (pipe or tube). When the threaded head and base are screwed into the housing, they compress against the outside edge of the diffuser. It is this compression that holds the diffusers stationary. If for any reason this compression is lost, then the diffusers would be free to rotate. This rotation would cause the pump to lose almost all of its ability to produce any head (or lift).

The impellers incorporate a fully enclosed curved vane design, the maximum efficiency of which is a function of impeller design and type, which generally increases when the volumetric capacity of that design. The operating efficiency is a function of the percent of design capacity at which the impeller is operated.

The fluid enters the impeller at the eye. The vanes in the impeller create channels through which the fluid is directed. The size of the impeller (or the volume between the upper and lower shroud) determines the volume per unit time (or fluid rate) that can be produced.

There are two types of impellers used in oil well submersible pumps. These are the radial flow and the mixed flow. The radial stages generally range from 200 to 2500 BFPD. The radial stage is a flat stage and is the most efficient design for these lower flow rates. The mixed-flow stage ranges from approximately 1700 up to 40,000 BFPD.

Through the use of the corrosion-resistant materials, cast Ni-resist (high nickel-iron) or molded nonmetallic

polyphenylene-sulfide (ryton) impellers and diffusers with K-monel shafting, pump wear, and corrosion can be minimized. Most stages are Ni-resist. However, unless otherwise specified, the housings, heads, and bases of the pumps, protectors, and motors will be carbon steel. In corrosive applications the equipment should be corrosion coated, or special ferritic steel housing should be specified. These multistage pumps may be assembled as a floater or fixed-impeller compression pump design, depending on how the axial thrust of the pump is handled.

6.4.5.2.5 Surface and Subsurface Measurement Instrumentation Equipment

Switchboard

The switchboard is basically a motor control device. Voltage capability ranges from 600 to 4800 volts, on standard switchboards. All enclosures are NEMA 3R, which is suitable for virtually all, outdoor applications. The switchboards range in complexity from a simple motor starter/disconnect switch to an extremely sophisticated monitoring/control device.

There are two major construction types: electromechanical and solid state. *Electromechanical construction switchboards* provide overcurrent/overload protection through three magnetic inverse time-delay contact relays with push-button, manual reset. Undercurrent protection is provided by silicone-controlled rectifier (SCR) relays. These features provide protection against downhole equipment damage caused by conditions such as pump-off, gas lock, tubing leaks, and shut-off operations. The *solid-state switchboards* incorporate the motor controller (as the Vortex and Eliminator). The purpose of the motor controller is to protect the downhole unit by sensing abnormal power service and shutting down the power supply if current exceeds or drops below preset limits. This is accomplished by monitoring each phase of the input power cable to the downhole motor. A valuable switchboard option is the recording ammeter. Its function is to record, on a circular strip chart, the input amperage to the downhole motor. The ammeter chart record shows whether the downhole unit is performing as designed or whether abnormal operating conditions exist. Abnormal conditions can occur when a well's inflow performance is not matched correctly with pump capability or when electric power is of poor quality. Abnormal conditions that are indicated on the ammeter chart record are primary line voltage fluctuations, low amps, high amps, and erratic amps.

Variable Speed Drives

The variable-speed drive (VSD) is a highly sophisticated switchboard-motor controller. A VSD performs three distinct functions. It varies the capacity of the ESP by varying the motor speed, protects downhole components from power transients, and provides "soft-start" capability. Each

of these functions is discussed in more detail below. A VSD changes the capacity of the ESP by varying the motor speed. By changing the voltage frequency supplied to the motor and thus motor rpm, the capacity of the pump is also changed in a linear relationship. Thus, well production can be optimized by balancing flow performance with pump performance. This applies to both long-range reservoir changes and short-term transients such as those associated with high-GOR wells. This may eliminate the need to change the capacity of a pump to match changing well conditions, or it may mean longer run life by preventing cycling problems. This capability is also useful in determining the productivity of new wells by documenting pressure and production values over a range of drawdown rates. The change in voltage frequency can be made manually or automatically. The VSD can operate automatically in a “closed loop” mode with a programmable controller and pressure-sensing instrument.
